▶ Dopamine System

Dopamine System

Nataliia Katolikova and Raul R. Gainetdinov
Institute of Translational Biomedicine, Saint-Petersburg State University, Saint-Petersburg, Russia

Synonyms

Basal ganglia; Dopamine; Dopaminergic receptors; GPCR; L-DOPA; Parkinson's disease; Substantia nigra; Ventral tegmental area (VTA)

Definition

Dopamine (dopaminergic) system plays an important role in central neural system, taking part in regulating motor control, executive functions, motivation, reinforcement, reward, sleep, feeding, attention, cognitive functions, olfaction, vision, hormonal regulation, and outside of central neural system in sympathetic regulation and penile erection. Dopamine as well influences immune, gastrointestinal, and cardiovascular systems and renal function.

Basic Characteristics

Dopaminergic Pathways

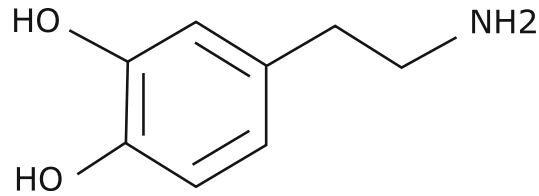
Dopaminergic neurons are a heterogenic group of cells, most of which are localized in mesencephalon and diencephalon, and a small amount is located in bulbus olfactorius. In mesencephalon cells are localized in three groups – in substantia nigra pars compacta (SN), in the ventral tegmental area (VTA), and in the retrorubral field (RRF). The axons of these neurons form four major dopaminergic pathways: nigrostriatal, mesocortical, mesolimbic (often collectively termed the mesocorticolimbic), and tuberoinfundibular pathways. The nigrostriatal pathway connects SN and dorsal striatum (caudate nucleus and putamen), and this pathway is involved in regulation of movement. Mesocortical pathway connects VTA and prefrontal cortex, and it is involved in cognitive and emotional control. The mesolimbic pathway connects VTA and ventral striatum (nucleus accumbens and olfactory tubercle), and it is involved in mediating reinforcements and reward. The tuberoinfundibular pathway is formed mostly by axons of neurons localized in arcuate nucleus in hypothalamus that end in median eminence. This pathway inhibits the secretion of prolactin from anterior pituitary gland.

Dopamine

Dopamine (DA) ($C_8H_{11}NO_2$, 3-hydroxytyramine, 4-(2-aminoethyl)benzene-1,2-diol (IUPAC)) is a catecholaminergic monoamine neurotransmitter. Chemically DA is catecholamine, in which the hydrogen at position 4 is substituted by a 2-aminoethyl group (Fig. 1).

Dopamine Synthesis

The DA synthesis consists of two reactions: (1) conversion of L-Tyrosine to L-3,4-dihydroxyphenylalanine (L-DOPA) and (2) conversion of L-DOPA to dopamine. Tyrosine is a nonessential amino acid that can be synthesized in the human body from the amino acid phenylalanine. This process goes primarily in the liver catalyzed by an enzyme phenylalanine hydroxylase. Then L-Tyrosine from the blood enters the brain by a low affinity amino acid transport system, and it enters the neurons by high and low affinity amino acid transporters. L-Tyrosine is converted to L-DOPA by tyrosine hydroxylase

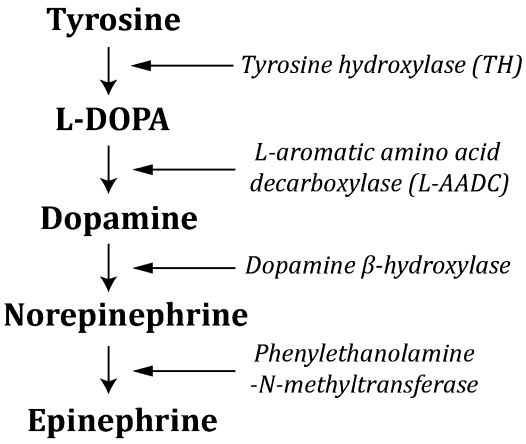


Dopamine System, Fig. 1 Dopamine structure

(TH). TH is the rate-limiting enzyme of catecholamine biosynthesis. The activity of TH is regulated by feedback inhibition of the catecholamine neurotransmitter, which binds to amino-terminal regulatory domain (R-domain) of TH, by phosphorylation by multiple kinases at four different serine residues and dephosphorylation by two phosphatases, by protein-protein interactions with enzymes in the same pathway or from the tetrahydrobiopterin pathway, by interaction with structural proteins considered to be chaperones that mediate the neuron's oxidative state, and by the protein that transfers dopamine into secretory vesicles (Daubner et al. 2011).

TH uses a cofactor tetrahydrobiopterin to convert tyrosine to L-DOPA by the addition of a hydroxyl group to the third carbon of the aromatic ring. Then the L-aromatic amino acid decarboxylase (L-AADC) removes the carboxylic acid group from the backbone of the L-DOPA and converts L-DOPA into dopamine (Fig. 2).

Dopamine is an active neurotransmitter in the brain, but at the same time, it is a precursor for norepinephrine (NE) and epinephrine in respective neurons. In the norepinephric neurons, dopamine is converted to NE by the enzyme dopamine β-hydroxylase, which can be converted further to epinephrine by the enzyme phenylethanolamine N-methyltransferase in epinephric neurons. This reaction takes part mainly within the adrenal medulla, but detectable levels of this enzyme are found in association with epinephrine neurons in the brain.



Dopamine System, Fig. 2 Catecholaminergic synthesis

After the synthesis dopamine is actively transported from the cytoplasm into the vesicles by vesicular monoamine transporter 2 (VMAT2). VMAT2 functions as a stoichiometric antiporter, transporting two H^+ ions out of a vesicle to transport one monoamine molecule into a vesicle (German et al. 2015). The activity of VMAT2 depends on posttranslational modification, protein interactions, presynaptic localization, H^+-ATPase activity, and pH in the cell (German et al. 2015). Vesicles are trafficked to the plasma membrane, neurotransmitter is released into the synapse, and then vesicles are reformed through internalization.

Dopaminergic Receptors

The physiological actions of dopamine are mediated by dopaminergic receptors (DR). DRs are G-protein-coupled receptors (GPCRs). GPCRs are a large family of receptors also called seven-transmembrane domain-containing receptors because they have seven transmembrane domains. There are five types of dopaminergic receptors, and on the basis of structural, pharmacological, and biochemical properties, they are combined in two groups: D1-like (D1, D5) and D2-like (D2, D3, D4) receptors.

There are certain differences between two groups. The genes of receptors of D1-class do not contain introns in their structure. D2-class has several introns, with six introns in D2 receptor gene, five in the gene that encodes D3 receptor, and three in D4 receptor gene. That is why all of the D2-class receptors have different splice variants. For example, D2 receptor has two splice variants, D2S (414 amino acids) and D2L (443 amino acids), and these splice variants have different features and pharmacological properties. D2S are mostly presynaptic receptors and are mostly involved in autoregulation, when D2L are presented mostly postsynaptically.

The D1-class of the receptors activates $G\alpha_{s/olf}$ family of G-proteins and stimulates cAMP production. The receptors of D2-class are coupled to $G\alpha_{i/o}$ that inactivates the cAMP.

D1 dopamine receptors are expressed at a high level of density in the nigrostriatal, mesolimbic,

and mesocortical areas, such as the caudate-putamen (striatum), nucleus accumbens, substantia nigra, olfactory bulb, amygdala, and frontal cortex, as well as at lower levels in the hippocampus, cerebellum, thalamic areas, and hypothalamic areas. D5 dopamine receptors are expressed at low levels in multiple brain regions, including pyramidal neurons of the prefrontal cortex, the premotor cortex, the cingulated cortex, the entorhinal cortex, the substantia nigra, the hypothalamus, the hippocampus, and the dentate gyrus. A very low level of expression has also been observed in the MSNs of the caudate nucleus and nucleus accumbens.

The highest levels of D2 dopamine receptors are found in the striatum, nucleus accumbens, and olfactory tubercle. D2 receptors are also expressed at significant levels in the substantia nigra, ventral tegmental area, hypothalamus, cortical areas, septum, amygdala, and hippocampus. The D3 dopamine receptor has a more limited pattern of distribution, the highest level of expression being observed in the limbic areas, such as in the shell of the nucleus accumbens, the olfactory tubercle, and the islands of Calleja. At significantly lower levels, the D3 dopamine receptor is also detectable in the striatum, the substantia nigra pars compacta, the ventral tegmental area, the hippocampus, the septal area, and in various cortical areas. The D4 dopamine receptor has the lowest level of expression in the brain, with documented expression in the frontal cortex, amygdala, hippocampus, hypothalamus, globus pallidus, substantia nigra pars reticulata, and thalamus.

D1, D2, and D4 dopamine receptors have also been observed in the retina, and prominent levels of expression of D2 dopamine receptors have been detected in the pituitary gland. In the periphery, all subtypes of dopamine receptors have been observed in the kidney, adrenal glands, sympathetic ganglia, gastrointestinal tract, blood vessels, and heart (Beaulieu and Gainetdinov 2011).

The role of dopamine and the contribution of activation of different types of DRs to various physiological processes are very wide, but among the main ones, the participation in the regulation of locomotion activity is controlled by D1, D2, and D3; significant parts of reward and reinforcement mechanisms are also controlled by dopamine with participation of D1 and D2 receptors mainly and of D3 receptors less; D1 and D2 dopamine receptors seem to be critical for learning and memory mechanisms, such as working memory, that are mediated primarily by the prefrontal cortex (Beaulieu and Gainetdinov 2011); D2 dopamine receptors play a critical role in the psychotic reactions observed in schizophrenia and bipolar disorder.

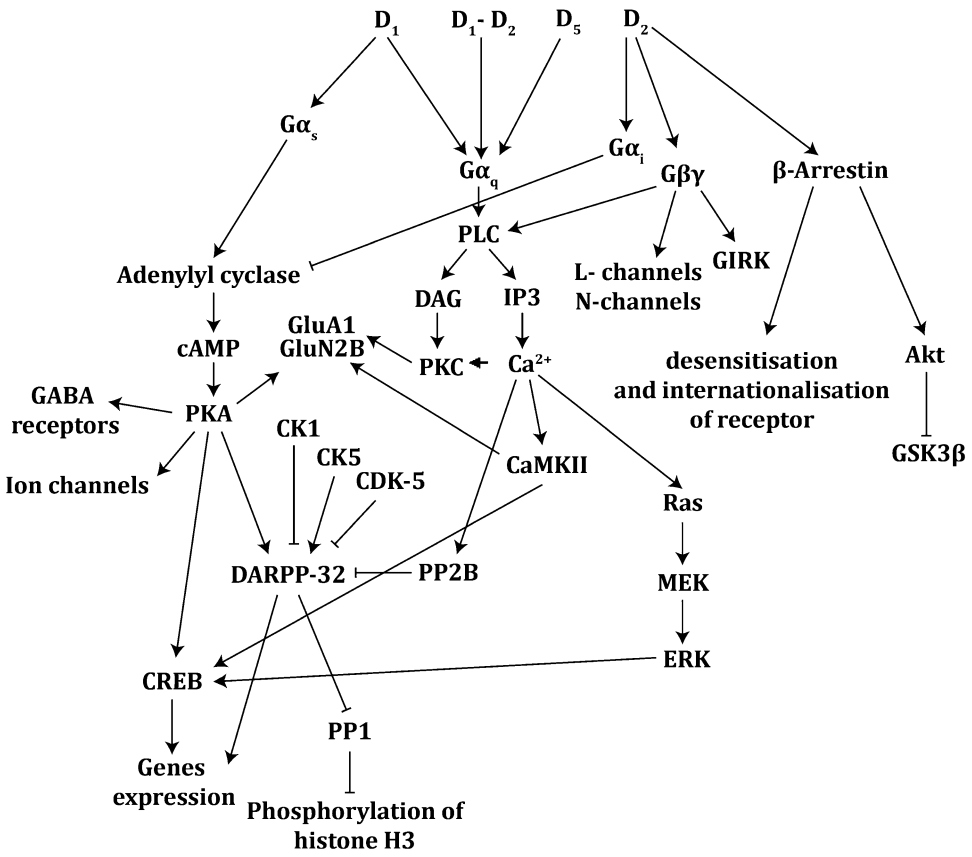
Dopaminergic receptors can form heterodimers, which lead them to the appearance of new pharmacological properties and have an effect on various signaling pathways. The following heterodimers were already described, with different types of dopaminergic receptors, D1–D2 heterodimers, D1–D3 heterodimers, and D2–D4 heterodimers, and with other types of receptors: D2-TAAR1 heterodimers, D1-NMDA heterodimers, D1-adenosine A2 heterodimers, D2-ghrelin heterodimers, D4-β1 adrenoceptor, and D4-α_{1b} adrenoceptor heterodimers (Beaulieu and Gainetdinov 2011).

Dopaminergic Signaling

Dopamine interaction with its receptors activates different signaling cascades mainly involving the G-proteins, but at the same time, it activates G-protein-independent signaling (Fig. 3).

G-proteins belong to a group of proteins which are enzymes called GTPases, because they hydrolyze guanosine triphosphate (GTP) to guanosine diphosphate (GDP). There are two classes of G-proteins, monomeric GTPase and heterotrimeric G-protein complex, consisting of three subunits: α, β, and γ. GPCR are couples with heterotrimeric G-proteins. Without a ligand agonist, the α-subunit is bound to GDP, and β and γ subunits form an inactive trimeric protein complex. Agonist binding to receptor results in GDP release and binding of GTP to the complex, which leads to dissociation of the α-subunit. This dissociation forms free α-subunit (Gα) and the β/γ-complex (Gβγ), both of which can transduce the signal and activate the effector systems.

Depending on type of α-subunit, G-proteins are classified into four families: $G\alpha_{s/olf}$, $G\alpha_{i/o}$,



Dopamine System, Fig. 3 Dopaminergic signaling

$G\alpha_q$, and $G\alpha_{12}$ (Kamato et al. 2015). Dopaminergic receptors are connected with different types of G-proteins. D1-like receptors are coupled with $G_{s/olf}$ proteins, activation of which leads to an activation of adenylyl cyclase and increase in the intracellular content of cAMP. High level of intracellular cAMP stimulates activity of protein kinase A (PKA). PKA have several targets such as cAMP response element (CREB), glutamate receptors (GluA1 and GluN2B), GABA receptors, ion channels (e.g., calcium and potassium), and dopamine- and cAMP-regulated phosphoprotein 32-kDa (DARPP-32) (Klein et al. 2019).

CREB is a cellular transcription factor involved in regulation of transcription of several genes, including BDNF, tyrosine hydroxylase, c-Fos, and some others. Phosphorylation and activation of CREB lead to an increase of gene expression. The activity of CREB also can be regulated by CaMKII and by ERK (Calabresi et al. 2014), which will be discussed later. It was shown that altered CREB signaling is involved in cognitive and neurodegenerative disorders (Saura and Valero 2011).

DARPP-32 is a multifunctional protein mainly expressed in medium spiny neurons in striatum (MSN). PKA phosphorylates DARPP-32 at Thr34. This enhances the gene expression. Also the phosphorylation of DARPP-32 at Thr34 promotes inhibitory effect of DARPP-32 on protein phosphatase-1 (PP1), which is responsible for histone dephosphorylation (mainly H3) (Klein et al. 2019). The phosphorylation of DARPP-32 at other sites can influence the phosphorylation of it at Thr34. It can be reduced by phosphorylation of DARPP-32 at Ser137 by casein kinase 1 (CK1) and enhanced by phosphorylation of DARPP-32 at Ser97/102 by casein kinase 2 (CK2). The phosphorylation of DARPP-32 at Thr75 is made by

cyclin-dependent kinase 5 (CDK-5), and it prevents the inhibition of PP1 by DARPP-32 and converts the DARPP-32 to an inhibitor of PKA (Beaulieu and Gainetdinov 2011), but this phosphorylation by CDK5 can be prevented by PKC (Sahin et al. 2008). Dephosphorylation of DARPP-32 at Thr34 can also be promoted by protein phosphatase 2B (PP2B), activated by increased level of intracellular Ca^{2+} (the causes of increasing concentration of intracellular Ca^{2+} will be discussed later). DARPP-32 can also interact with different hormones and neurotransmitters (Greengard 2001).

The activation of D1 receptors also leads to phosphorylation of ribosomal protein S6 (rpS6) at $Ser^{235/236}$ and $Ser^{240/244}$ which results in activation of CAP-dependent mRNA translation, and additional activation of PKA leads not only to phosphorylation of DARPP-32 but also to activation of mTOR complex 1 (Hutchinson et al. 2011).

In contrast to D1-like receptors, D2-like receptors are coupled to $G_{i/o}$ proteins, which have opposite effect on adenylyl cyclase, reducing its activity, which leads to a decrease in intracellular levels of cAMP, PKA activity, and phosphorylation of DARPP-32 at Thr34.

D2-like signaling also includes $G_{\beta\gamma}$ activation of phospholipase C (PLC) leading to increase cytoplasmic calcium with downstream signaling events. $G_{\beta\gamma}$ involved in regulation of activity of L- and N-type calcium channels, and G-protein coupled inwardly rectifying potassium channels (GIRKs). It was shown that these channels involved in phosphorylation of two subunits of glutamate receptors (GluA1 and GluN2B) followed by activation of signal cascades.

Another direction of D2-like dopamine signaling is signal cascade mediated through β-arrestin 2 (βArr2). Arrestins are a family of multifunctional molecular adapter proteins. Originally, it has been convincingly established that β-arrestins are involved in desensitization and internationalization of GPCRs (Ferguson 2001). However, later studies revealed that βArr2 and βArr1 can act also as molecular scaffolds for signaling molecules such as kinases and phosphatases (Beaulieu et al. 2015). In fact, βArr-dependent phosphorylation of Akt results in Thr^{308} and Ser^{473} by PDK and PDK2/rictor-mTOR, respectively (Beaulieu et al. 2015). Akt phosphorylate further several substrates including GSK3α at Ser^{21} and GSK3β at Ser^{9}, which results in their inhibition. Thus, βArr can form complexes with protein phosphatase 2A (PP2A) and Akt kinase, resulting in Akt inhibition and in subsequent GSK3β activation.

Dopamine receptors (D1, D5, or D1–D2 heterodimers) can couple also with $G\alpha_q$ protein, which leads to activation of phospholipase C_β (PLC). As it was mentioned before, PLC can also be activated by βγ subunit of G-protein. Phospholipase C_β hydrolyzes phosphatidylinositol 4,5-biphosphate into diacylglycerol (DAG) and inositol triphosphate (IP3). DAG activates number of isoforms of protein kinase C (PKC). IP3 diffuses to endoplasmic reticulum and binds to IP3 receptors on ligand-gated calcium channels, which increase calcium efflux to cell surface from the endoplasmic reticulum and from extracellular space (Kamato et al. 2015). The increased level of Ca^{2+} can activate calcium-dependent PKC variants and upregulate calcium-regulated enzymes, such as PP2B and calcium-/calmodulin-dependent kinase II (CaMKII). CaMKII can phosphorylate CREB and activate the gene expression (Calabresi et al. 2014). Also PKC and CaMKII can modulate the cross talk to cAMP signaling, by effecting glutamate receptors GluA1 and GluN2B as it is done by PKA (Beaulieu et al. 2015). At the same time, increased level of intracellular Ca^{2+} activates the MAPK signaling cascade including ERK (Cahill et al. 2014). EKR activation targets the intracellular protein CREB and also activates it (Calabresi et al. 2014).

Dopaminergic receptors can interact with other receptors like NMDA, sodium channels, GABA receptors, and Na^+/K^+ ATPase (Klein et al. 2019) and with receptor of tyrosine kinases (RTK). It was shown that RTK can be transactivated by different dopaminergic receptors: platelet-derived growth factor β receptor (PDGFβR) by D4; insulin-like growth factor receptor (IGFR) by D2; BDNF receptor by D1, D2, and D1–D2 heterodimers; and TrkB by D1. RTK transactivation by GPCR results in rapid activation of several

signaling cascades, including PI3K/Akt, Ras/MAPK, and PLC.

Disorders Associated with Dopaminergic System

Changes in the dopaminergic system play a role in a number of diseases, among which are Parkinson's disease (PD), schizophrenia (SZ) (Abi-Dargham et al. 2009), bipolar disorder (Cousins et al. 2009; Ashok et al. 2017), Huntington's disease (Chen et al. 2013), attention deficit hyperactivity disorder (ADHD) (Blum et al. 2008; Montarolo et al. 2019), Tourette's syndrome, addiction, depression, restless leg syndrome, pituitary tumors, hyperprolactinaemia, hypertension, gastroparesis, nausea, and erectile dysfunction (Beaulieu and Gainetdinov 2011).

Dopaminergic Drugs

Dopamine Precursors

L-DOPA

Dopamine Receptor Agonists

Apomorphine, bromocriptine, cabergoline, dihydrexidine, pramipexole, ropinirole, fenoldopam, piribedil, lisuride, pergolide, rotigotine

Dopamine Receptor Antagonists

Typical antipsychotics: haloperidol, chlorpromazine, fluphenazine, loxapine, molindone, perphenazine, pimozide, thioridazine, thiothixene, trifluoperazine

Atypical antipsychotics: clozapine, olanzapine, amisulpride, quetiapine, risperidone, sulpiride, ziprasidone

Antiemetics: domperidone, alizapride, metoclopramide, prochlorperazine

Reuptake Inhibitors

Methylphenidate, bupropion, amineptine, nomifensine, cocaine, methylenedioxypyrovalerone, phencyclidine

Transporter Blockers

Inhibitors of VMAT2: reserpine, tetrabenazine, deserpidine

Releasing Agents

Phenethylamine, amphetamine, lisdexamfetamine, methamphetamine, methylenedioxymethamphetamine, phenmetrazine, pemoline, 4-methylaminorex (4-MAR), benzylpiperazine

Inhibitors of Degradation (MAO Inhibitors)

Nonselective: phenelzine, tranylcypromine, isocarboxazid

MAO-A selective: moclobemide

MAO-B selective: selegiline, rasagiline, pargyline

Inhibitors of Different Parts of Dopamine Signaling

Catechol O-methyl transferase (COMT) inhibitors: entacapone, tolcapone

Dopamine β-hydroxylase inhibitors: disulfiram

Phenylalanine hydroxylase inhibitors: 3,4-dihydroxystyrene

Tyrosine hydroxylase inhibitors: α-methyl-para-tyrosine (AMPT)

Aromatic L-amino acid decarboxylase (L-AADC) or DOPA decarboxylase inhibitors: benserazide, carbidopa

Drug-drug interactions; Pharmacokinetic and/or pharmacodynamic consequence of multiple drug therapy; Pharmacokinetic and/or pharmacodynamic interactions

Background

Clinical Significance of Drug-Drug Interactions

Evidently there is an increasing risk of multimorbidity with age. As a consequence, the number of prescriptions and the number of possible related side effects rise in elderly patients. In addition, there is an increased risk of adverse events or of drug failure due to drug-drug interactions leading to changed drug concentrations or synergistic or antagonistic pharmacodynamic effects. Early studies on inappropriate drugs in the elderly stated that in average five or more drugs are taken simultaneously by patients being 65 years or older (Fialova et al. (2005); (Gallagher et al. 2008)). Drug-drug interactions were

identified as cause of adverse events leading to admission to medical wards or for prolonged hospital stays (Lazarou et al. 1998; Smith et al. 2008; Thomsen et al. 2007). These observations have been confirmed by a number of further studies. In an Austrian study, adverse drug effects were regarded as the reason in 10% for inpatient admission among 543 elderly patients (median age: 82 years), who were taking 7.5 ± 3.8 drugs at the time of their admission (Schuler et al. 2008). Moreover, the authors regarded 36% of the prescribed drugs as unnecessary and 30% as even inappropriate for elderly people according to the PRISCUS list (Holt et al. 2010). Adverse drug effects may occur also during inpatient treatment. A British study in 3695 patients showed that almost 15% of the patients suffered from adverse drug effects during their stay in hospital, causing a prolonged hospital stay in 25% out of these patients, one definition of severe adverse events. Data analysis revealed that the number of simultaneously prescribed drugs was the only significant predictor. In most frequent cases, the medication dose was incorrectly or not adjusted or renal impairment was not considered (Davies et al. 2009). Today it is estimated that drug interactions could account for 1% of hospitalizations in the general population and 2–5% of hospital admissions in the elderly (Letinier et al. 2019). However, the impact of DDI on overall health burden is difficult to assess as the clinical consequence may vary widely.

Basic Mechanisms

Pharmacodynamic Interactions

Pharmacodynamic interactions occur when two or more drugs interact directly at their site of action affecting the efficacy in the same direction (additively, synergistically) or leading to amelioration through antagonistic effects. In clinical medicine, additive or synergistic effects are often desired if a monotherapy is not indicated or efficient. For example, according to the recent guidelines of hypertension, at least two antihypertensives with different mode of action should be described to improve the speed, efficiency, and predictability of blood pressure control (Williams et al. 2018).

Similarly, potentiating strengthening (synergistic) effects are desired to treat infections or also severe pain. Although synergistic effects may be beneficial, the risk of adverse events may increase as well. This is exemplified in the treatment of heart failure with mineral corticoid antagonists such as spironolactone and ACE inhibitors, bearing the potential risk of hyperkalemia (Juurlink et al. 2004); careful monitoring however allows the application of this combination even in patients with mild to moderate kidney disease (Edwards et al. 2012). Similarly, bleeding risk is potentially elevated applying dual antiplatelet therapy with clopidogrel and aspirin while treating patients with coronary artery disease who underwent stent implantation (Sorensen et al. 2012; Lopes et al. 2019).

Severe adverse events such as QT interval prolongation are known to be (albeit rare) the result of combinations of drugs, intended to strengthen the treatment of infections such as the combination of fluoroquinolones and macrolides like erythromycin (Saxena et al. 2013). Now in the SARS-CoV2 pandemic, the use of hydroxychloroquine together with azithromycin was suggested to treat patients with acute Covid-19 symptoms. However, despite unproven efficacy of this regimen, both drugs bear the risk to augment QT interval prolongation with the risk of torsade de pointes (Chorin et al. 2020).

Pharmacodynamic Interactions as Cause of Bleeding Events

Bleeding events were identified as the most frequent cause of adverse events leading to a fatal outcome in a Swedish registry (Wester et al. 2008).

In particular gastrointestinal bleeding events could occur while patients with atrial fibrillation and coronary artery disease are in antithrombotic treatment, in particular with acute coronary syndrome or percutaneous coronary intervention (PCI). A recent meta-analysis study demonstrated that a regimen of NOACs plus an adenosine P2Y12 inhibitor was associated with less bleeding compared with a regimen of vitamin K antagonists plus P2Y12 inhibitor and aspirin (Lopes et al. 2019). However, also specific serotonin reuptake inhibitors (SSRIs) such as citalopram bear a twofold risk

of gastrointestinal bleeding events that is further elevated by concomitant administration of aspirin or another NSAIDs (Andrade et al. 2010). The serotonin uptake transporter SLC6A4 is expressed on the surface of platelet as well. Inhibition by SSRI leads to a reduction of intra-platelet serotonin concentrations with consecutive deterioration of platelet function resulting in a 3.0 (2.1–4.4) bleeding risk when SSRIs are administered together with aspirin compared to aspirin alone. Other antidepressants are not known to cause such an interaction. In addition, the SSRI-mediated loss of platelet function is augmented by anticoagulants (Schalekamp et al. 2008). Administration of proton pump inhibitors may reduce bleeding risk in those patients.

In contrast, some NSAIDs may deteriorate platelet inhibition of aspirin potentially increasing the cardiac risk in CAD patients through competition at the serine residue at position 529 of COX-1 hindering the irreversible acetylation by aspirin (Catella-Lawson et al. 2001). Clinical long-term investigations confirmed this in vitro observation (Hudson et al. 2005). Later investigations showed that more NSAIDs like naproxen, metamizole, and others may negatively interact with aspirin antiplatelet effect (Saxena et al. 2013).

Many more pharmacodynamic interactions may occur, exceeding the length of this review. In essence, there is no simple systematic to predict pharmacodynamic interactions like it is the case for pharmacokinetic interaction (see below). Hence it is still a challenge to estimate the consequences of combinations. Approaches for prediction of the magnitude of interactions using mechanism-based PK-PD modeling may help in this matter (Stepensky and Rimon 2015). This is now demonstrated in the current hasty search for best therapy regimens to treat Covid-19 (Venisse et al. 2020).

Some examples of typical pharmacodynamic drug-drug interactions are listed in Table 1.

Pharmacokinetic Interactions

Pharmacokinetic DDIs are a major cause of adverse events. As most drugs are administered orally, the different levels of ADME name absorption, distribution, metabolism, and elimination a crucial for putative drug-drug interaction leading to changes of pharmacokinetic profiles. In essence, there are three types of interactions that need to be distinguished:

(a) The PK of the investigational drug is affected by another drug (victim drug).
(b) The investigational drug inhibits drug-metabolizing enzymes or transporters leading to changes of the PK of other drugs (perpetrator drug).
(c) The investigational drug induces drug-metabolizing enzymes or transporters leading to changes of the PK of other drugs (perpetrator drug).

Knowledge about the properties of a drug being a victim or a perpetrator is of major importance in clinical routine when drug therapy regiments are changed by adding further drugs.

Regulatory Requirements

Due to the potential significance of DDI, possible interactions have to be appropriately assessed already during drug development. Particular emphasis by regulatory authorities has been given to pharmacokinetic drug-drug interactions on the level of drug metabolism and transporters. Guidelines of the US Food and Drug Administration (FDA), European Medicines Agency (EMA), and Ministry of Health, Labor and Welfare (MHLW) of Japan have been widely harmonized in the recent years proposing systematic methods and procedures for an objective and scientific evaluation of DDI potential as excellently reviewed and summarized by Iwatsubo (2020).

According to the FDA "Clinical Drug Interaction Studies – Cytochrome P450 Enzyme- and Transporter-Mediated Drug Interactions Guidance for Industry" (Sudsakorn et al. 2020), an investigational drug causing P450 inhibition can be classified as a strong, moderate, or weak inhibitor based on its effect on an index CYP substrate:

- Strong: Increment of the AUC of a sensitive index P450 substrate $\geq$5-fold
- Moderate: Increment of the AUC of a sensitive index P450 substrate by $\geq$2- to <5-fold
- Weak: Increment of the AUC of a sensitive index P450 substrate by $\geq$1.25- to <2-fold

Drug Interactions, Table 1 Examples of additive and antagonistic pharmacodynamic drug-drug interactions

Drug A	Drug B	Putative effect
Additive interactions		
NSAID	SSRI, VKI	Elevated bleeding risk
NSAID	Glucocorticoids	Elevated gastric bleeding risk
ACE inhibitor	Spironolactone, amiloride	Hyperkalemia
SSRI	MAO inhibitors	Serotonin syndrome
Tricyclic antidepressants	Low potent neuroleptics	Augmented anticholinergic effects
Fluoroquinolones	Macrolides, citalopram	QT_c interval prolongation, torsade de pointes
Hydroxychloroquine	Azithromycin	QT_c interval prolongation, torsade de pointes
Antagonistic interactions		
ASS	Ibuprofen	Attenuation of platelet inhibition
ACE inhibitors	NSAID	Attenuation of blood pressure lowering
Levodopa	Typical neuroleptics	Attenuation of dopaminergic effects
Warfarin	Vitamin K	Attenuation of anticoagulation

SSRI, serotonin reuptake inhibitor; VKI, vitamin K antagonist; MAO, monoamine oxidase; NSAID, non-steroidal anti-inflammatory drug

These categories typically describe the effect of the investigational drug when given at the highest clinical dose and the shortest dosing interval within its therapeutic dose range/dosing regimen.

DDI on the Level of Adsorption

Early interactions within the dietary tract may occur through formation of complexes that can considerably reduce the bioavailability of drugs, having the potential to interact with multivalent cations such as Ca^{2+}, Mg^{2+}, Al^{3+}, Zn^{2+}, Fe^{2+}, or Fe^{3+}. In particular bisphosphonates applied in therapy of severe osteoporosis such as alendronate are affected due to their considerably low bioavailability of only 0.5% to 2% that is further reduced in presence of calcium ions in mineral water or milk (Itoh et al. 2016). Anti-infectives such as tetracyclines or quinolones are also known to form complexes with multivalent cations that can also reduce the bioavailability of orally applied levothyroxine (Liwanpo and Hershman 2009). Further the bioavailability of drugs having a catecholamine structure as applied in Parkinson disease (levodopa, carbidopa) may be decreased iron ions (Campbell and Hasinoff 1989). As a consequence, the simultaneous intake of calcium-containing food, neutralizing antacids containing aluminum or magnesium ions, or supplements containing multivalent ion salts must be avoided.

Basic anion exchangers such as cholestyramine are not resorbed in the intestine due to their molecular structure. These amphiphilic drugs are able to build complexes with a number of cationic drugs and must be administered at least 2 h before.

In addition, the change of the gastric pH, e.g., through proton pump inhibitors like pantoprazole, may affect the bioavailability of certain drugs, such as the antiviral drug atazanavir or the bisphosphonate alendronate (Ogawa and Echizen 2011). In a clinical study investigating the protective benefit of alendronate, patients receiving proton pump inhibitors at the same time showed a higher frequency of hip fractures (Abrahamsen et al. 2011).

Interactions on the Level of Drug Transporters

Active or facilitated transport across tissue barriers is a major determinant of drug disposition in the human body. There are more than 400 transporters in the human genome, and about 30 are involved in the pharmacokinetics of drugs. Major

drug-drug interactions take place on the level of efflux transporters in the intestine, on hepatic uptake transporters, and uptake and efflux transporters in the kidney (Zhang et al. 2011). In contrast to drug-metabolizing enzymes, however, there is almost no drug which is exclusively a substrate of a specific transporters; there is partly a large overlap of specificity to between uptake and efflux transporters (Gessner et al. 2019). In addition, many drugs are substrates of drug-metabolizing enzymes as well making it difficult to distinguish clear drug-drug interactions solely based on the level of drug transporters. As a consequence, the prediction of drug transporter interactions in vivo is sometimes difficult to be made from in vitro experiments alone. Nevertheless, today firm data on the properties of drugs being a substrate, inhibitor, or inducer is mandatory during drug development process and is outlined in the drug label upon approval.

Several efflux and uptake transporters may interact with drugs in clinical use. Particular emphasis by regulatory authorities is given to P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), organic anion-transporting polypeptide 1B1/1B3 (OATP1B1, OATP1B3), organic anion transporter 1/3 (OAT1/OAT3), multidrug and toxin extrusion (MATE) proteins (MATE1/MATE2-K), as well as the organic cation transporter 2 (OCT2). A list of substrates for five classes of transporters is shown in Table 2. Substrates in bold have been recommended by the FDA as transporter-specific victim drugs to be used for DDI during clinical development of drugs (FDA 2020).

The ABC transporter P-gp (ABCB1) restricts the distribution of its substrates in the intestine and also the brain, placenta, and testes. Moreover, it acts as an excretory pump in the liver and the kidneys. It has a wide spectrum of substrates that overlap much with CYP3A4 and also to some extent with BCRP (ABCG2) (Cascorbi 2011).

Inhibition of P-gp is mostly caused through competitive inhibition by perpetrator drugs, having a low Ki. Inhibition of intestinal expressed P-gp leads usually to an elevation of C_{max} and AUC, but the clearance and related half-life is less affected (Fig. 1). Elevation of systemic exposure of more than 25% at concentrations ten times the Ki-value is considered as clinically relevant. However, as mentioned above, many compounds are also substrate or inhibitors of CYP3A4/5, affecting also the elimination. Established inhibitors are listed in Table 3; some are listed for more than one transporter demonstrating the low specificity also of many inhibitors. Some inhibitors are frequently prescribed anti-infectives such as the macrolide clarithromycin or the systemic azole antimycotic itraconazole and the antiarrhythmic drugs amiodarone and dronedarone.

Since the phenomenon of efflux transporter-mediated multidrug resistance was shown in particular in various malignancies, the idea came up to inhibit the upregulated efflux of anticancer drugs out of the cancer cell by inhibition of P-gp or BCRP. Strong inhibitors have been developed (Table 3); however since these ABC transporters are expressed at many interfaces of the body, systemic toxicity could increase as well, making this concept so far not suitable in clinical practice (Choi and Yu 2014).

The clinical relevance of P-gp inhibition has been shown for many drugs in the past but came into focus also in more recent time when novel non-vitamin K-dependent anticoagulants (NOACs) have been developed aiming to overcome the broad inter- and intra-individual variability of the vitamin K antagonists warfarin and phenprocoumon that require routine INR monitoring. Dabigatran etexilate, the oral prodrug of the thrombin inhibitor dabigatran, is a substrate of P-gp in the intestine, making it a victim drug to P-gp inhibitors, whereas the active drug dabigatran is not. Therefore, although dabigatran is not metabolized and entirely renally excreted, DDIs may take place on the level of P-gp and have to be considered (Akamine et al. 2019). According to the product information, the AUC of dabigatran (150 mg dabigatran etexilate) increases after a single dose of 40 mg ketoconazole by a clinically significant factor of 2.35, whereas 2 × 500 mg/d clarithromycin causes only an increase of the AUC by 1.19, which is considered not to be clinically relevant. The PK of the factor X inhibitors apixaban, edoxaban, and rivaroxaban are less affected by P-gp inhibition but are additionally

Drug Interactions, Table 2 Substrates of uptake and efflux transporters (SOLVO Biotechnology knowledge center)

OATP1B1/3	OAT1/3	OCT2, MATE-1, MATE-2 k	ABCB1 (P-gp)		ABCG2 (BCRP)
Statins	Antibiotics	Various	Opioids	Statins	Various

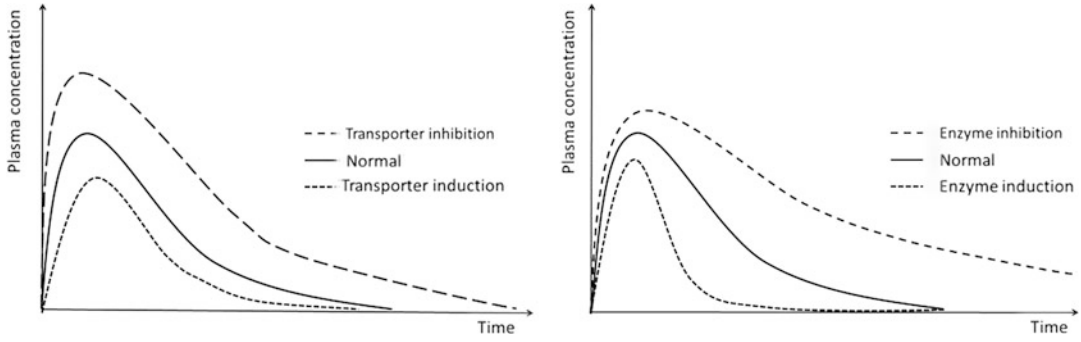
Repaglinide				Rhodamine 123	
Tacrolimus					

Substrates in **bold** are recommend by the US Food and Drug Administration for clinical investigation of drug interactions during drug development (FDA 2020)

substrates of CYP3A4 (Voukalis et al. 2016). Typical examples of victim and perpetrator drug pairs on the level of intestinal distribution are exemplified for non-vitamin K-dependent anticoagulants in Table 4.

Hepatic uptake transporters facilitate the transport of anionic or cationic compounds from the portal veins into hepatocytes. Hence inhibition may cause a higher systemic exposure since hepatic metabolism or elimination into the biliary tract clearance may be decreased (Konig et al. 2013). As a consequence, C_{max}, AUC, but also the half-life may increase. A typical clinically relevant example of DDIs on the level of hepatic uptake transporters is the inhibition of OATP1B1 (SLCO1B1) by the anti-infective macrolide clarithromycin causing drastic elevation of the systemic exposure of the cholesterol-lowering drug simvastatin (Hougaard Christensen et al. 2020). In particular at higher doses, this interaction may cause side effects such as myopathy. Again, overlap with cytochrome P450 enzymes



Drug Interactions, Fig. 1 Consequences of drug-drug interactions for the pharmacokinetics on the level of drug transporters (left) and drug-metabolizing enzymes (right) as exemplified for an intestinal P-gp substrate (e.g., dabigatran-etexilate) and a cytochrome P450 3A4 substrate (e.g., cyclosporine)

Drug Interactions, Table 4 Interactions of non-vitamin K-dependent oral anticoagulants (NOACs) mediated by the efflux transporter P-gp (ABCB1). (Adapted from Gessner et al. 2019)

Oral anticoagulant class	Oral anticoagulant	Perpetrator drug	PK change of victim drug	Possible clinical consequence
FII-NOAC	Dabigatran etexilate	Dronedarone	AUCa ↑ (2.1-fold)	Elevated bleeding risk
FII-NOAC	Dabigatran etexilate	Ketoconazole	AUCa ↑ (2.4-fold	Elevated bleeding risk
FII-NOAC	Dabigatran etexilate	Rifampicin	AUCa ↓ (−67%)	Elevated thrombosis risk
FX-NOAC	Apixaban	Ketoconazole	AUC ↑ (twofold)	Elevated bleeding risk
FX-NOAC	Apixaban	Rifampicin	AUC ↓ (−54%)	Elevated thrombosis risk
FX-NOAC	Edoxaban	Erythromycin	AUC ↑ (+85%)	Elevated bleeding risk
FX-NOAC	Edoxaban	Cyclosporin	AUC ↑(+73%)	Elevated bleeding risk
FX-NOAC	Rivaroxaban	Ritonavir	AUC ↑ (2.5-fold)	Elevated bleeding risk

FII-NOAC: coagulation factor II (thromboxane) inhibitor, FX-NOAC: coagulation factor X inhibitor

has to be considered since simvastatin is a CYP3A4 substrate as well and clarithromycin a CYP3A4 inhibitor. Further examples of typical victim and perpetrator drugs and their clinical consequences on the level of hepatic drug transporters are shown in Table 5.

As excellently reviewed by Gessner et al. (2019) and Ivanyuk et al. (2017), renal transporters are also involved in a significant number of drug-drug interactions. In the kidney, the competitive inhibition of transporters contributing to the secretion of drugs may lead to accumulation of the victim as exemplified for penicillin and probenecid that is a known OCT inhibitor. Whereas the penicillin/probenecid interaction was considered as beneficial in earlier years, the simultaneous administration of methotrexate and an OCT inhibitor may cause life-threatening toxicity (Titier et al. 2002). The antidiabetic drug metformin is subject to renal excretion. Hence monitoring of the kidney function is of importance to avoid side severe effects such as lactacidosis, but also drug interactions on the level of renal transporters may lead to accumulation. For example, co-administration of cimetidine leads to a 1.5-fold increase and of dolutegravir (an HIV integrase inhibitor) to a 2.5-fold increase of metformin AUC (Gessner et al. 2019). These interactions are due to inhibition of OCT2, MATE1, and MATE-2K (for more examples, see Table 6).

Pharmacokinetic Interactions on the Level of Metabolism

Drug-drug interactions caused by competitive inhibition or induction of drug-metabolizing enzymes are best investigated and categorized. Broad knowledge on the metabolic pathways of frequently prescribed drug classes as well as of specific inhibitors and inducers of the various cytochrome P450 enzymes, further phase 1 as well as phase 2 enzymes, has contributed already a lot for drug safety and lowering of unintended overdosing or lack of efficacy (Cascorbi 2012). However, there is still need of education and further development and implementation of easy to use clinical decision support system when prescribing drugs in particular to multi-morbid patients (Tolley et al. 2018).

Likewise, for drug transporters each product description of drugs contains comprehensive data on elimination pathways and putative interactions with other drugs. Hence knowledge has to be gained already during preclinical drug development and to be confirmed in clinical phases. Hereby, physiologically based pharmacokinetic modeling (PBPK) plays a major role to allow prediction of possible interactions (Min and Bae 2017). Despite renal or biliary excretion, metabolism in the liver is the predominant elimination pathway. The phase I metabolism is primarily

Drug Interactions, Table 5 Interactions of statins mediated by the hepatic organic anion uptake transporters OATP1B1, 1B3, and 2B1. (Adapted from Gessner et al. 2019)

Statin	Perpetrator drug	PK change of victim drug	Possible clinical consequence
Pitavastatin	Clarithromycin	AUC ↑ (4.6-fold)	Elevated risk of myopathy
Pravastatin	Cyclosporin	AUC ↑ (twofold)	Elevated risk of myopathy
Rosuvastatin	Cyclosporin	AUC ↑ (7.1-fold)	Elevated risk of myopathy
Rosuvastatin	Gemfibrozil	AUC ↑ (1.9-fold)	Elevated risk of myopathy
Rosuvastatin, pitavastatin	Rifampicin	AUC ↑ (5.7-fold, 4.4-fold)	Elevated risk of myopathy

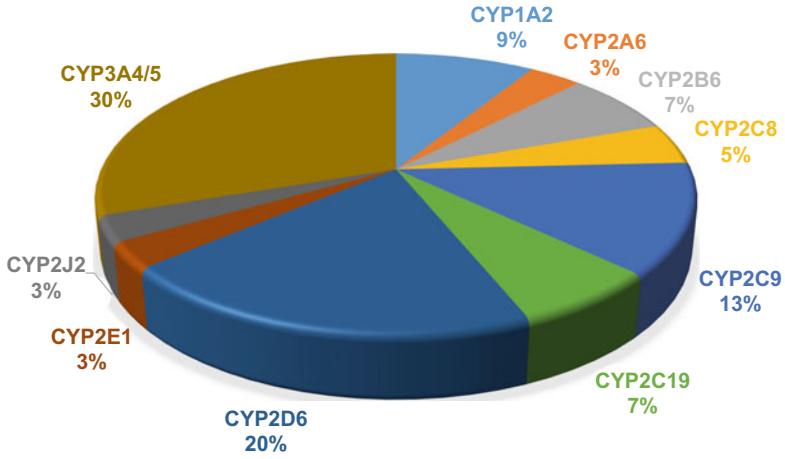
Drug Interactions, Table 6 Interactions of selected drugs mediated preferentially by the renal drug transporters adapted from Gessner et al. (2019)

Victim drug	Perpetrator drug	Transporter	PK change of victim drug	Possible clinical consequence
Metformin	Cimetidine	OCT2, MATE1, MATE2-K	AUC ↑ (1.5-fold) Cl_R ↓ (27%)	Not known
Metformin	Pyrimethamine	MATE1, MATE2-K	C_{max} ↑ (1.4-fold) AUC ↑ (1.4-fold) Cl_R ↓ (−33% to −35%)	Not known
Metformin	Trimethoprim	OCT2, MATE1, MATE2-K	C_{max} ↑ (1.2-fold to 1.4-fold) AUC ↑ (1.2-fold to 1.3-fold) Cl_R ↓ (−26%)	Not known
Metformin	Dolutegravir	OCT2, MATE1, MATE2-K	C_{max} ↑ (2.1-fold) AUC ↑ (2.5-fold)	Not known
Lamivudine	Trimethoprim/ sulfamethoxazole	OCT2, MATE1, MATE2-K	AUC ↑ (1.4-fold) Cl_R ↓ (−35%)	Not considered as clinically relevant
Chloroquine	Cimetidine	MATE1	Cl_0 ↓ (−53%) Ae ↓ (−43%)	Not known
Furosemide	Probenecid	OAT1, OAT3	Cl_R ↓ (−78%) Cl_0 ↓ (−63%)	Decreased efficacy

mediated by cytochrome P450 enzymes. As can be seen from Fig. 2, CYP3A4 and CYP3A5 are the most important ones (Zanger and Schwab 2013). About 30% of all metabolized drugs are subject to this class of oxidative enzymes. Accordingly, the majority of drugs is metabolized at least partly by these enzymes, and many have a low Ki acting as competitive inhibitors. Table 7 lists substrates of the major cytochrome P450.

It should be noted that drugs metabolized by one of these enzymes having a narrow therapeutic index are most prone to DDI. Typical examples are immunosuppressants like cyclosporine that is metabolized predominantly by CYP3A4 as well as tacrolimus and sirolimus that are metabolized predominantly by CYP3A5. The metabolism of all three drugs can by strongly affected by concomitantly administration of CYP3A4/5 inhibitors such as macrolides of azole antimycotics. Therefore, such drugs should be avoided, or dose reduction according to the actual plasma concentrations should be performed.

As noted before, simvastatin is strongly metabolized by CYP3A4. Strong inhibition bears the risk of up to 13-fold increase of the AUC leading to severe side effects such as rhabdomyolysis (Damiani et al. 2020). Such a deleterious interaction was observed when simvastatin was administered together with CYP3A4 inhibitors (Hodel 2002). Due to such severe interactions occurring



Drug Interactions, Fig. 2 Proportion (%) of hepatic cytochrome P450 enzymes to the number of drugs, undergoing phase I metabolism. (Adapted from Zanger and Schwab 2013)

in the course of concomitant treatment with simvastatin, mibefradil, a calcium T-channel blocker used in cardiovascular diseases, was withdrawn from the market in 1998.

Cerivastatin, a statin frequently earlier prescribed globally, was considered as safe due its known metabolism pathway. However, parallel use with the fibrate gemfibrozil caused a surprisingly high rate of rhabdomyolyses later known to be based on competitions on a metabolic pathway (CYP2C8) and on an uptake transporter (OATP1B1), leading to high systemic exposure. The comparably higher rate of severe side effects led to the withdrawal of cerivastatin by the manufacturer in 2001 (Jamal et al. 2004).

Despite approved drugs, some ingredients of natural products may also cause severe interaction. Best known and frequently reported also in lay press is grapefruit that contains considerable contents of the flavonoid naringin, a potent inhibitor of CYP3A4. As demonstrated in a clinical study in healthy volunteers, just one glass of grapefruit juice increased significantly the oral bioavailability of midazolam, a drug used as a probe drug for CYP3A4 (Greenblatt et al. 2003). The effect could be observed until 3 days of intake indicating an irreversible non-competitive effect of naringin. It should be noted however that other citrus fruits like lemons or oranges contain much lower amounts of naringin, causing no or very mild interactions.

Inhibition of metabolic pathways however can also lead to lack of efficacy in cases when the activation of a prodrug to the active moiety is affected. A typical example is the activation of the P2Y12 ADP receptor clopidogrel by CYP2C19. Inhibition by proton pump inhibitor omeprazole may lead to decreased platelet aggregation with a higher risk thrombosis risk in cardiovascular patients undergoing PCI or suffering from peripheral occlusive disease (Ho et al. 2009). Further, the activation of codeine to morphine through CYP2D6 can be inhibited by the antidepressant fluoxetine (Yee et al. 2014) leading to lack of analgesic efficacy.

Further groups of substrates and inhibitors are listed in Tables 7 and 8, respectively.

Induction of Transport and Metabolism

The above entries on drug transport and metabolism focused on inhibition of pathways leading in most cases to a higher risk of adverse drug events. However, induction of transporters and metabolic enzymes by selected drugs and natural products is a considerable threat to effective medication. Originally, induction is an evolutionary defense mechanism leading to accelerated extrusion or metabolic detoxification of xenobiotics. In humans, two important members of the NR1I nuclear family, the constitutive androstane receptor (CAR) and the pregnane X receptor (PXR), function as sensors

Drug Interactions, Table 7 Interactions on the level of cytochrome P450 enzymes: selection of relevant substrates for which combinations with inhibitors or inducers of the same enzyme lead to increased occurrence of adverse or weakened effects. of toxic byproducts of endogenous metabolism and of exogenous chemicals and enhance their elimination (Wang et al. 2012). There is current knowledge that PXR is involved in the regulation of more than 500 genes; it acts in upregulation but also in the downregulation of the expression in primary human hepatocytes (Kandel et al. 2016).

After activation by a ligand such as rifampicin, PXR forms a heterodimer with 9-cis retinoic acid receptor RXR and binds to a hormone-responsive

Drug Interactions, Table 9 Inducers of major cytochrome P450 enzymes. Colored roman drugs: red, strong inducers (≥80%); orange, moderate inducers (≥50% to <80%); yellow, weak inducers (≥20% to <50%) that decreases the AUC of sensitive index substrates of a given metabolic pathway according to FDA (FDA 2020). Additional drugs in *italic* are derived from Flockhart (2007)

							Troglitazone

(also phenobarbital-responsive) element of the respective DNA (details are reviewed by (Pavek 2016). For drug metabolism and transport, most important is the induction of CYP3A4/5 and P-gp, but CYP2B6, CYP2C8, CYP2C9, and CYP2C19 as well as BCRP and some uptake transporters such as OATP2 are upregulated as well. CYP2D6 expression is not affected by PXR.

Induction of the elimination pathways may lead to ineffective drug concentrations of a large number of victim drugs of P450 enzymes and transporters. Hence knowledge about PXR ligands is crucial. Typical inducers are the old anticonvulsants phenobarbital, phenytoin, and carbamazepine, the tuberculostatic drug rifampicin, and hypericin, a constituent of the herbal drug St. John's wort. Later on, additional drugs were identified such as the anti-HI-viral drug efavirenz and the androgen receptor antagonists used in prostate cancer enzalutamide and apalutamide (see Table 9).

The induction of gene expression takes place after 1–2 days, and stable induction can be observed after repeated intake of, e.g., 600 mg rifampicin over 1 week. To classify an investigational drug as inducer in vitro, several methods have been established, e.g., determination of the fold-change of mRNA levels (≥2-fold and concentration-dependent changes or <2-fold and ≥20% of positive control) and correlation methods by calculating relative induction scores (Iwatsubo 2020). Distinction on a clinical level is made into strong, moderate, and weak inducers that decrease the AUC of sensitive index substrates of a given metabolic pathway by ≥80%, ≥50% to <80%, and ≥20% to <50%, respectively (FDA 2020).

Interactions between inducers and victim drugs may lead to life-threatening events. For example, the biodistribution of the immunosuppressants cyclosporine, tacrolimus, and sirolimus can be considerably reduced by co-administration of CYP3A4 inducers leading to acute transplant rejection. This can be even the case with self-administered herbal drugs as shown by St. John's wort in patients who had undergone heart transplantation (Ruschitzka et al. 2000). Later on it was demonstrated in clinical studies in healthy volunteers that the PK of drugs like digoxin (Johne et al. 1999) or amitriptyline (Johne et al. 2002) is significantly affected by the intake of St. John's wort. Attention should be also taken to other CYP3A4 and P-gp substrates such as the oral anticoagulants phenprocoumon or warfarin (Barnes et al. 2001), possibly also to NOACs.

Less strong are the effects of extracts of the herbal plant *Echinacea purpurea* (Awortwe et al. 2019); further clinical evidence of this frequent over-the-counter drug is required.

In addition, the aromatic hydrocarbon receptor (AhR) factor acts in a similar way by inducing enzymes involved in oxidative pathway of

aromatic xenobiotics and some drugs. More recently, also a number of endogenous ligands were identified (Kawajiri and Fujii-Kuriyama 2017). Some drugs like omeprazole, but also cigarette smoke or dietary plants like broccoli, may induce CYP1A2 leading to lower levels of theophylline or fluvoxamine (Tables 7 and 9).

Conclusions

Drug-drug interactions contribute to adverse events and consequently to global health burden; hence knowledge on the interaction potential of drugs currently on the market is required to avoid unintended adverse events by the choice of the right drug and the right dose for the right patient. However, with increasing polypharmacy in an increasing proportion of elderly people, the ideal combination of drugs is a challenge that often requires clinical decision support. In addition, pharmacogenetic traits contribute further to inter-individual variation of drug response. Although information on potential interaction is given comprehensively in the drug label, its relevance is often unclear and requires further explanation. Hence certain software approaches have been implemented in electronic prescription systems assisting physicians while prescribing medications. However, even the best programs can't work efficiently if not all information on patient's medications is available; moreover multiple pairs of drugs are still difficult to assess. Furthermore, multiple (and sometime false) alarms may lead to an attenuation of alertness. Hence both education on major drug-drug interactions and help from clinical decision support systems based on reliable data sources are required to further improve drug safety.

Definition

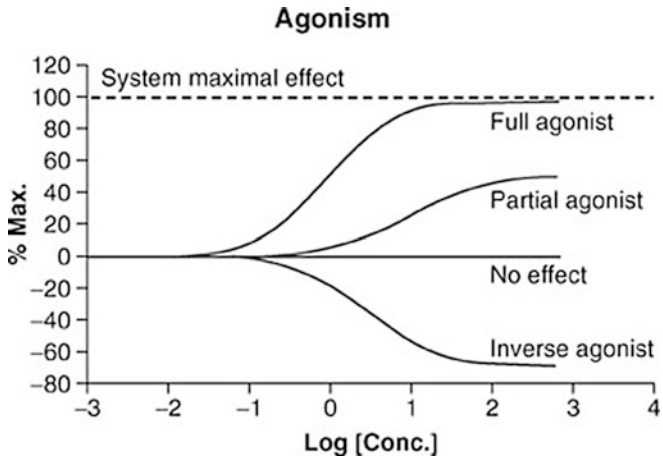
Mathematical models of the interaction between drugs and receptors, based on Michaelis–Menten kinetics, are utilized to create the quantitative tools currently used in receptor pharmacology to quantify drug effect in biological systems. Such tools are necessary since drugs almost always are tested in surrogate systems until they are known to be sufficiently active and safe for therapeutic use. The aim of receptor pharmacology is to define the molecular properties of affinity and intrinsic efficacy of drugs; these can be used to predict drug effect across different biological systems. It will be seen that the properties of affinity and efficacy are sufficient to describe the case of the interaction of a single molecule, target receptor, and cell. For an extended system of two interacting molecules (e.g., agonist and antagonist), target receptor and cell, it is useful to know additional information, namely knowledge as to whether the interaction is orthosteric or allosteric, and (optionally) the kinetics of interaction of the molecules with the target (target residence time) in order to fully characterize drug activity.

Basic Mechanisms

A basic premise in receptor pharmacology is that all drugs have affinity for receptors (the chemical property that unites the drug with the receptor), and some drugs have efficacy, the chemical property that causes the receptor to change its behavior toward its host cell. Drugs that have efficacy can produce concentration-dependent responses in physiological systems, characterized by a concentration–response curve (also often referred to as a dose–response curve).

Drugs that produce pharmacological activation of a system are called *agonists*, those that inhibit activation of a receptor system are called *antagonists*, and those that reverse spontaneously active receptor systems (Constitutive receptor activity) are called *inverse agonists* (Fig. 1). This latter class of drugs reduce elevated basal responses. Agonism is the observed effect of a ligand-producing stimulus to a receptor. The host cellular system processes that stimulus and yields an observable response.

The common currency of drug receptor pharmacology is the dose–response curve, as it defines the relationship between concentrations of drug and the resulting effect. Dose–response curves have three basic properties with which they can be described: threshold abscissal value, slope, and maximum asymptote. The location parameter of the dose–response characterizes drug potency; most often this is quantified as the EC_{50} or the molar concentration of drug producing half the maximal effect to that drug. Given tissue systems have maximal capabilities to return drug response. When an agonist produces a maximal response that is equal to the system maximal response it is referred to as a *full agonist* (Fig. 1). If an agonist produces a submaximal system response it is called a *partial agonist* (Fig. 1). While the potency of an agonist is quantified by the location



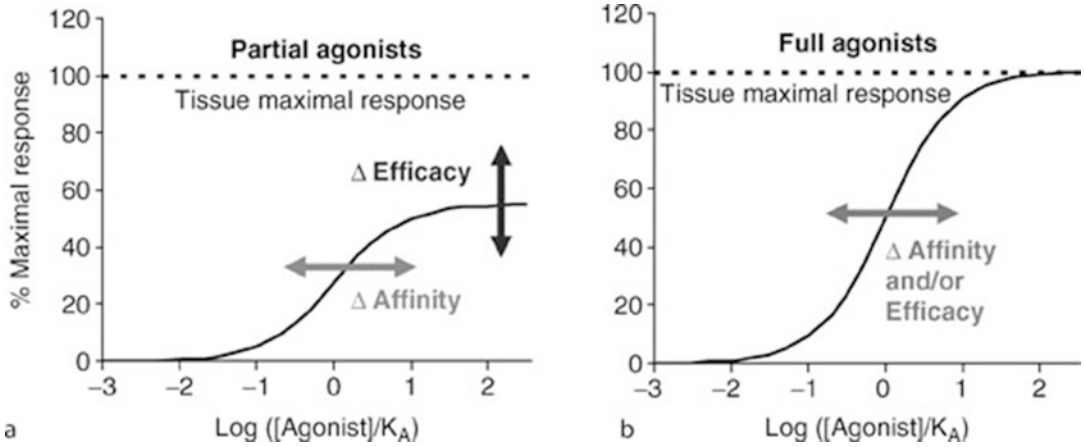
Drug–Receptor Interaction, Fig. 1 Dose–response curves to drugs that have direct effects on physiological systems. A drug that produces the maximal effect capable from the system is a *full agonist*. A submaximal effect is produced by a *partial agonist*. Drugs may not produce directly observable effects but may be present on the receptor to produce antagonism (see Fig. 3). If a system is constitutively active and shows an actively elevated basal response, then a drug that reduces this is termed an *inverse agonist*

parameter of the dose–response curve (EC_{50}), a reflection of (but not a direct measure of) the intrinsic efficacy of an agonist is given by its maximal response.

The term efficacy for this discussion is defined as the change in behavior of the target (receptor) towards its host (the cell) produced by the binding of a ligand. In this sense there are many efficacies possible for receptors including production of second messengers in cells, internalization from the cell surface, internalization with subsequent coupling to response elements, etc. It is important to note that both the quality and quantity of biological response obtained with a given drug depends very much on the assay system used to make the measurement. If the assay does not have the means to detect a given efficacy, then none will be observed; this should not be taken to mean that the drug does not have that particular efficacy. A common case in point is the failure of nonconsitutive receptor systems to detect negative efficacy (inverse agonism). For this particular efficacy to be detected, an especially engineered assay must be used. Similar effects are observed in the receptor-mediated signaling effects. While most agonist-bound receptors activate G-proteins, some initiate the binding of intracellular proteins such as beta-arrestin to induce kinase signaling. There are cases, such as for the β-adrenoceptor antagonist ICI 118,551, where the same drug will have a negative efficacy for one response system (i.e., G-proteins) and positive efficacy for another (beta-arrestin kinase stimulation).

In general, if a drug generates a direct response in a system, and if that response is lower in magnitude than the system maximal response (i.e., it is a partial agonist, see Fig. 1), then the location of the concentration–response curve along the concentration axis is determined by the affinity of the agonist and the maximal response is determined by the magnitude of the efficacy (Fig. 2a). If the agonist produces the full system maximal response (it is a full agonist), then it is not possible to assess efficacy (since the maximal response is constant) and the location of the concentration–response curve is determined by a complex function of both affinity and efficacy (Fig. 2b).

The inhibition of agonist response is termed antagonism. The effect that a given antagonist has on the dose–response curve to an agonist can be a clue to the mechanism of action of that antagonists' interaction with the receptor. In the presence of an antagonist, more agonist must be present in the receptor compartment to produce a response that would be necessary in the absence of the antagonist. A singular characteristic of an



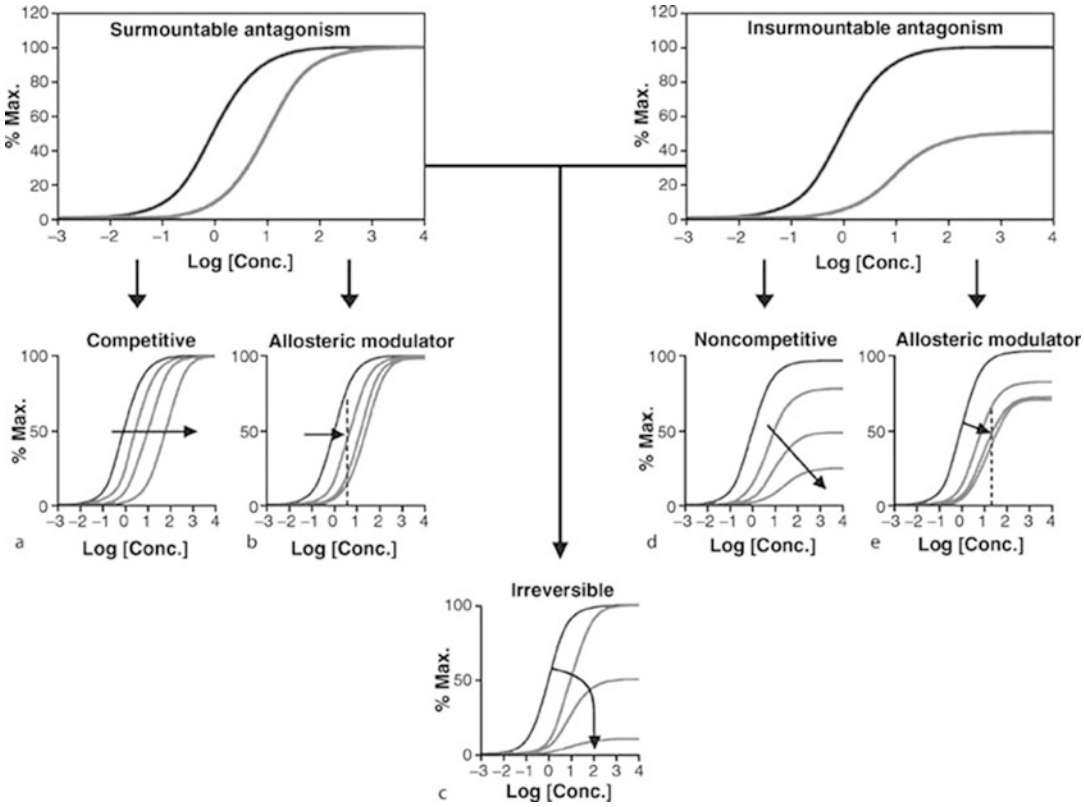
Drug–Receptor Interaction, Fig. 2 Relationships between affinity and efficacy with different agonist response patterns. (**a**) For partial agonists, differences in maximal responses between agonists relate to differences in efficacy. Differences in the location parameter of the concentration–response curve (potency) indicate differences in affinity. (**b**) For full agonists, differences in potency indicate differences in either affinity, efficacy, or both

antagonist is its effect on the maximal capability of an agonist to overcome the presence of the antagonist and produce the system maximal response. If enough agonist can be added to produce the agonist maximal response in the presence of the antagonist, the antagonism is referred to as surmountable antagonism (see Fig. 3). If no amount of agonist will produce the maximal response, the antagonism is referred to as insurmountable (see Fig. 3).

A basic concept in receptor pharmacology is the idea of orthosteric and allosteric interaction. Orthosteric interaction occurs when two molecules compete for a single binding domain on the receptor. With allosteric interactions two molecules each have their own binding domain on the receptor and the two interact through effects on the protein (conformational change). Thus, with orthosteric interactions only one molecule may occupy the receptor at any one instant whereas with allosteric interactions both molecules can bind to the receptor at the same time. There are implications for pharmacological activity, especially for antagonists, that arise from these two molecular mechanisms (vide infra).

There are certain molecular mechanisms of antagonism associated with these observed patterns on dose–response curves. Thus, competitive antagonists produce parallel shifts to the right of agonist dose–response curves with no diminution of maximal response through an orthosteric interaction of antagonist and agonist (Fig. 3a). Theoretically, there is no limit to the degree of dextral displacement a given competitive antagonist can produce on a dose–response curve. Schild analysis is used to measure the affinity of competitive antagonists. This same pattern of response also can occur with allosteric modulators (Fig. 3b) but in this case the shift of the agonist dose–response curve is limited to a maximal value defined by the molecular cooperativity factor of the antagonist. Thus, a hallmark of allosteric inhibition is that it is saturable and reaches a maximal asymptotic value. In some cases, irreversible antagonists can produce parallel shifts to the right of dose–response curves if there is a receptor reserve for the agonist (Fig. 3c). This latter mechanism can be detected with increasing concentrations of irreversible antagonist since these eventually cause depression of the maximal response.

In cases where insurmountable antagonism is observed, this can be evidence of noncompetitive antagonism. This can result from an inhibiton of



Drug–Receptor Interaction, Fig. 3 Various patterns of antagonism of drug effect. Antagonism is classified according to effects on the dose–response curve to the agonist (blue lines). Two general classifications are surmountable antagonism (maximal response to the agonist retained – top left panel) or insurmountable antagonism (depressed maximal response to the agonist – top right panel). These general patterns can be the result of different molecular mechanisms. (**a**) Orthosteric competition between the agonist and antagonist for the same binding site on the receptor. (**b**) Binding of an allosteric modulator to its own binding site to modify the affinity or efficacy of the agonist in a saturable manner. (**c**) Irreversible blockade of receptors in a system with *receptor reserve* (parallel shift to the right followed by depression of the maximal response at higher concentrations of antagonist). (**d**) Blockade of receptor function or access of agonist to the receptor either orthosterically or allosterically in a system with little receptor reserve for the agonist. (**e**) Saturable allosteric modulation of receptor function by an antagonist in a system with little receptor reserve for the agonist

receptor function (either orthosteric or allosteric) or be due to antagonist-mediated modification of receptor reactivity to the agonist (Fig. 3e). The *method of* Gaddum is used to measure the affinity of noncompetitive antagonists for receptors. Parenthetically, similar effects on dose–response curves are produced by irreversible antagonists when there is no receptor reserve for the agonist.

While antagonist potency (quantified as the equilibrium dissociation constant of the antagonist–receptor complex, specifically the rate of offset of the antagonist away from the receptor divided by the rate of onset toward the receptor) usually is used as a measure of the therapeutic utility of an antagonist (i.e., high potency leads to the use of low dose with the concomitant avoidance of high concentrations that may produce side effects), the kinetics of receptor antagonism also are important. Thus, if antagonist negation of receptor function is the desired effect, then for two antagonists of equal potency, the one with the most persistent binding (slowest rate of offset from the receptor) is preferred. This is referred to as target residence time.

Pharmacological Relevance

An important tenet of receptor pharmacology states that the molecular properties of a drug, namely affinity and intrinsic efficacy, are interpreted and reflected by physiological systems and that this process *controls* what is observed as drug effect. For example, a physiological system requires a certain sensitivity to return response from stimulation by a weak agonist, i.e., the receptor coupling of that system must be of sufficient efficiency to amplify the stimulus into an observable response. When the same weak agonist is tested in a physiological system of lower sensitivity, it might be an antagonist. Thus, it can be seen that the monikers of agonist and antagonist can be system dependent and unreliable as molecular labels for drugs. In the same manner that a system must be of sufficient sensitivity to detect efficacy and return response, it also can be overloaded by a strong stimulus. When this occurs, the system returns the system maximal response and the agonist demonstrates full agonism. A series of agonists of differing intrinsic efficacy may all overload a given system and all return the same (system) maximal response (all be full agonists); this does not imply that these agonists are of equal efficacy but only that the system was unable to discern different efficacies beyond a certain level. For this reason, the labels of full and partial agonist are also system dependent and not useful for molecular characterization of drugs.

Since drugs are tested in many surrogate systems, it is necessary to develop methods to quantify drug effect in a system-independent manner. Absolute scales are not practical, or in some cases, even possible, in this process. As discussed previously, while an absolute potency for an agonist can be determined by the EC_{50}, the magnitude of this value depends on the sensitivity of the particular measuring system and thus it cannot be extrapolated to other systems. Rather, the relative potency of agonists (ratios of EC_{50}values) is used to quantify agonist power to induce response. This process utilizes the null method and isolates only the intrinsic ability of the agonists to produce response at the receptor level. This allows for the resulting potency ratios to be a measure of relative agonist activity that is comparatively independent of the system in which the measurement is made. This ratio transcends the particular system in which it is measured and is applicable to all systems in which the agonists produce maximal response. Under optimal conditions, the therapeutic profile of the standard agonist will be known in humans, therefore the agonist potency ratio can be used to gauge the expected activity of the experimental agonist in the therapeutic arena. It should be noted that there are exceptions to this rule for agonists that produce biased signaling whereby, through the formation of a unique receptor active state, the agonist activates some cellular pathways at the expense of others to produce a skewed signal.

In the case of antagonists, absolute measures of potency are theoretically possible since these are chemical terms describing the affinity of the drugs for receptor protein. However, physiological systems can also control the observed antagonism. For example, a noncompetitive antagonist will produce a diminution of the maximal response to an agonist in a system where the response is linearly related to the receptor occupancy (Fig. 3d). However, if the receptors in a system are coupled with high efficiency and the agonist has high efficacy, then maximal responses may be achieved with less than maximal agonist receptor occupancy, i.e., there may be a receptor reserve for the agonist. Under these circumstances the agonist may still produce the maximal response even when the antagonist completely inactivates a portion of the receptors. When this occurs the antagonism resembles competitive antagonism at low concentrations and noncompetitive antagonism at higher concentrations (resembling the profile in Fig. 3c). This would be system dependent and not necessarily indicative of the molecular mechanism of the antagonist.

Another example of where the set point of the physiological system can change the observed behavior of drugs is the absence of direct effects of inverse agonists in nonconstitutively active

receptor systems. A receptor system must be constitutively active (elevated basal response) to detect inverse agonism (Fig. 1). In non-constitutively active receptor systems, inverse agonists behave as simple competitive antagonists.

In general, receptor theory uses indirect mathematical models to estimate descriptors of drug effect. These descriptors still must be used with the proviso that biological systems may still modify drug effect in a system-dependent manner and thus predictions of therapeutic effect must be made with caution across different systems.

Definitions

Emesis usually refers to vomiting, the forceful oral expulsion of gastric contents; an "emetic" stimulus (often a chemical) is one capable of inducing vomiting. Paradoxically, treatments described as "antiemetics" are considered to affect both vomiting and the sensation of nausea which usually precedes. Nausea is a self-reported unpleasant sensation associated with an awareness of an urge to vomit that is commonly accompanied by cold sweating, facial pallor, increased salivation, and introversion. The sensation is often perceived in the pharyngeal area but the substernum, epigastrium, and head are also sites of perception; it is not clear how these sites relate to the underlying cause (Stern et al. 2011; Koch and Hasler 2017). When protracted, nausea waxes and wanes, described as coming in "waves" and hypothesized to reflect relative sympathetic and parasympathetic nervous system activity (see below), changes in the level of visceral perception ("interoception" or degree of disruption of gastric motility, but these proposals await confirmation. Distinguishing between vomiting and nausea has implications for diagnosis of the cause and the choice of treatment, since while the initiating stimuli can be identical, the ultimate mechanisms are different; the sensation of nausea is generally harder to treat than the motor event of vomiting.

Biologically, vomiting and diarrhea provide routes by which food contaminated by toxins not detected by vision, smell, or taste can be ejected in bulk prior to substantive absorption. Nausea provides a warning (analogous to pain) resulting in cessation of feeding and of equal significance, which leads to learned aversion to the food and future avoidance. However, the systems which evolved to defend against ingested toxins can also be activated by a diverse range of therapeutic drugs (e.g., anticancer cytotoxins, the mu-opioid receptor agonist morphine, glucagon-like peptide-1 receptor agonists such as exenatide and the dopamine$_2$ receptor agonist ropinirole) and diseases (e.g., delayed gastric emptying, gastroparesis, migraine, vestibulitis, and myocardial infarct), when nausea and vomiting become side-effects and symptoms, respectively, requiring treatment with antiemetics (see below) (Sanger and Andrews 2018).

The ability to vomit is common among mammals (e.g., dogs, ferrets, and sperm whales) but rodents (e.g., rats and mice) and lagomorphs (e.g., rabbits) appear to have lost this capability during their evolution; this has implications for selection of animal models for research in this area (Stern et al. 2011). Mammals capable of vomiting show behavioral changes prior to vomiting and in rodents these may be the only external indication that a stimulus capable of inducing vomiting in other species has been administered. However, as nausea is a self-reported human sensation, the nature of the experience of animals in response to a stimulus inducing nausea in humans is impossible to know (Stern et al. 2011). Nevertheless, in rodents, learned taste aversion and avoidance occur following administration of a range of emetics, suggesting a negative hedonic perception. The significance of the behavioral changes to emetics in nonhuman animals is a matter of debate but is of great importance when attempting to identify novel therapeutic approaches to treat nausea as opposed to vomiting.

Basic Mechanisms

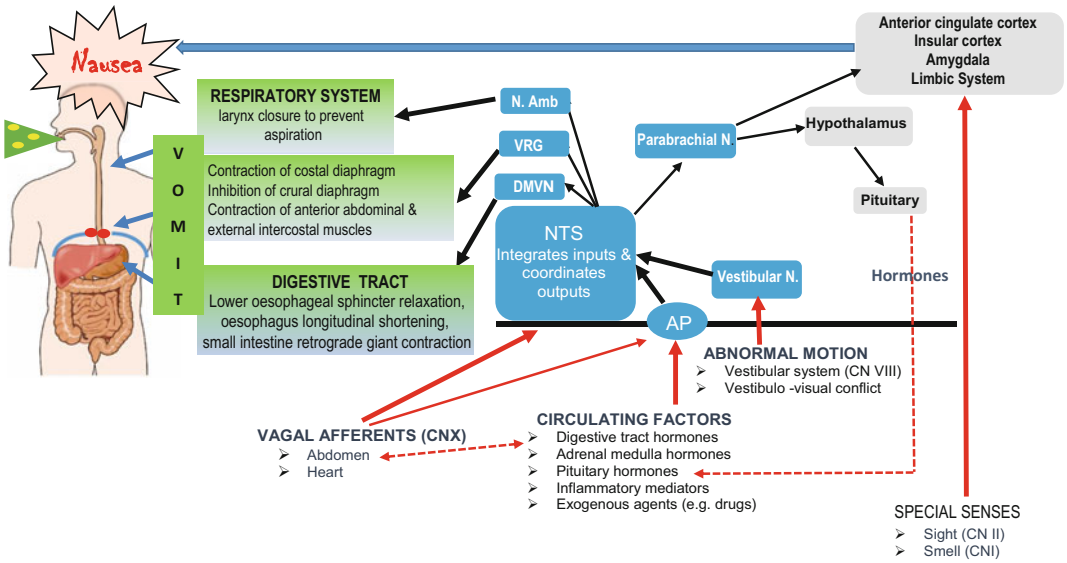
Mechanistically, vomiting is better understood than nausea. The final motor act of vomiting and

the experience of nausea involve different "integration/command" (vomiting) and "conscious sensation" (nausea) brain nuclei, with different outputs (Stern et al. 2011; Koch and Hasler 2017). However, both are induced by many different stimuli acting via the same major primary pathways.

Vomiting

Vomiting is induced by diverse stimuli activating different pathways (the sensory inputs) which converge on the *nucleus tractus solitarius* (NTS) in the dorsal brainstem, which coordinates the motor response (Fig. 1). In brief, in humans, the NTS receives major inputs from:

- The area postrema (AP), a heavily vascularized circumventricular organ not protected by the blood-brain barrier and located in the fourth ventricle. The AP is also called the "chemoreceptor trigger zone" (CTZ) for emesis, as when activated by systemic agents (exogenous or endogenous) it can induce vomiting (and nausea) via its connections with the NTS.
- Vagal afferents from the abdominal viscera (particularly stomach and small intestine) and the heart.
- The brainstem vestibular nucleus which itself receives inputs from the vestibular system (balance and orientation, acceleration) via the vestibulocochlear nerve (cranial nerve VIII).



Emesis, Fig. 1 Major pathways for the induction of nausea and vomiting. Stimuli which can induce vomiting inform the brain via activation of several pathways (red arrows) converging on the brainstem *nucleus tractus solitarius* (NTS) which integrates the inputs and coordinates the outputs for nausea and vomiting. Input pathways include vagal afferents, circulating factors acting via the area postrema (AP) and abnormal motion via the vestibular system. The NTS communicates with other brainstem motor nuclei forming a network (conceptually this network can be regarded as the "vomiting center" (VC) but it should be recognized that there is no single anatomical substrate for the VC as was previously thought) to initiate the different motor components that are required for vomiting. The main outputs for vomiting are to the digestive tract (DMVN) and respiratory system particularly the costal (◠) and crural (●) regions of the diaphragm. Note that the AP can be accessed by circulating factors which include digestive tract, adrenal and pituitary hormones, as well as exogenous drugs. The hormones may also modulate vagal afferent activity either directly or indirectly via gastric motility changes. Nuclei in blue are all in the brainstem/pons but induction of nausea requires projection of information from the NTS to "higher" brain areas particularly those involved in interoception (e.g., anterior cingulate cortex). Vomiting induced by horrific sights, unpleasant smells, and psychogenic stimuli is probably mediated by their inputs to higher brain regions which then activate the brainstem motor pathways (not shown). AP: area postrema; CN: cranial nerve; DMVN: dorsal motor vagal nucleus; N. Amb: Nucleus ambiguus; NTS: nucleus tractus solitarius; Parabrachial N: Parabrachial nucleus; Vestibular N: Vestibular Nucleus; VRG: ventral respiratory group of neurones

- The brainstem trigeminal and facial nuclei which receive inputs from cranial nerves V and VII, respectively.
- A number of "higher" brain regions including the limbic system and cerebral cortex.

The NTS is therefore provided with information on emetic stimuli that circulate in the blood (via the AP and which may be endogenous [hormones] or exogenous [drugs-see below]), originate from the gastrointestinal tract (e.g., food poisoning) and other viscera (e.g., heart; nausea preceding an infarct), arise because of abnormal motion (e.g., vestibular system and vestibulovisual conflict inducing motion sickness), result from facial pain and migraine (e.g., trigeminal nucleus), and psychogenic stimuli (e.g., horrific sights via the cerebral cortex).

The NTS integrates the signals from each input and if it reaches a threshold, sends outputs to the main motor pathways for vomiting, namely the dorsal motor nucleus of the vagus (lower oesophagus, stomach, intestine), the nucleus ambiguus (pharynx, upper esophageal sphincter), and the ventral respiratory group (connecting to cervical spinal phrenic nerve nucleus). Vomiting requires coordination between the digestive tract and the respiratory system and between both visceral and somatic divisions of the peripheral nervous system to produce the unique motor pattern. The motor events of vomiting only require the integrity of the brainstem and spinal cord with the NTS playing the pivotal role. As the NTS is also involved in nonvomiting, routine homeostatic functions (breathing, digestion), vomiting provides an interesting example of "motor program switching" by this area of the brain.

Vomiting is a dramatic, externally visible event, but as the stomach is the only site from which ingested material can be forcibly ejected, the events in the digestive tract which precede ejection are important and are listed below in temporal sequence.

- Relaxation of the proximal (corpus, fundus) stomach and inhibition of distal stomach (antrum) motility, delaying gastric emptying and reducing the movement of toxin-contaminated food to the intestine. These motor changes are mediated by vagal efferent activation of enteric inhibitory neurones (using nitric oxide in humans) and reduced drive to the enteric cholinergic neurones.
- Initiation of a single retrograde giant contraction (RGC) in the distal small intestine progressing to the stomach. This large amplitude contraction is mediated by the vagal efferents involving acetylcholine (blocked by the muscarinic receptor antagonist atropine) and pushes intestinal contents (which may contain bile) into the already-relaxed stomach.
- Once the RGC reaches the stomach, retching (derived from the Anglo-Saxon *hraecan* "to cough up phlegm") begins and while externally this appears similar to vomiting there is no ejection of gastric contents. The function of retching is unknown but unproven hypotheses include preparing the muscles for the more intense activity during vomiting, "wind up" of the central neural circuitry and testing the fluidity of the gastric contents. While some retching normally precedes vomiting it is not essential, as exemplified by projectile vomiting caused by hypertrophic pyloric stenosis and acutely raised intracranial pressure. Retching is caused by rhythmic contraction of the anterior abdominal muscles (spinal motor neurones) and contraction (descent) of the entire diaphragm (phrenic nerve) and although the stomach is compressed, material is not ejected because the antireflux mechanisms at the gastro-esophageal junction are functional. Vomiting follows retching when the crural muscle fibers of the diaphragm which encircle the lower esophagus and are differentially controlled from the remaining diaphragm, become inactive and the smooth muscle lower esophageal sphincter at the gastro-esophageal junction relaxes (via vagal efferents). These two actions, together with an overall longitudinal shortening of the esophagus, remove the resistance to expulsion of gastric contents, which are finally ejected by enhanced and protracted

abdominal muscle contraction compressing the stomach. The resulting intraluminal pressure in the stomach is up to 300 mmHg, ejecting liquid contents over several feet.

Nausea

Nausea is an unpleasant sensation and difficult to study experimentally in healthy volunteers. Increasing evidence obtained by neuroimaging supports the idea that the recognition of nausea occurs during increasingly intense activation of brain nuclei involved in interoception – the self-awareness of body sensations and internal physiological events. These involve, in particular, the anterior cingulate cortex ("visceromoror cortex"), inferior frontal gyrus, insular cortex, and amygdala (Stern et al. 2011; Koch and Hasler 2017) (Fig. 2). Their basic role is to process stress and the awareness of fear, generating fundamental "defensive" activities including modulation of autonomic outflows. The latter is responsible for physiological changes such as increased salivation, sweating (forehead), and reduced cutaneous blood flow (face and fingers) which accompany nausea. In humans, nauseogenic stimuli usually cause secretion of a high concentration of arginine vasopressin from the hypothalamus and although it may be causally involved in nausea (action on the AP, disruption of gastric motility), its function may also be water retention in anticipation of vomiting and cardiovascular adjustments (Koch and Hasler 2017). However, when these central pathways are activated in a sustained manner, subjects report severe nausea and strong stomach awareness. This suggests that nausea is the result of an increasingly intense and sustained input into these areas caused perhaps, by simultaneous activation of multiple mechanisms. The latter may explain why, in general, nausea is harder to treat by drugs than is vomiting.

Pharmacological Interventions

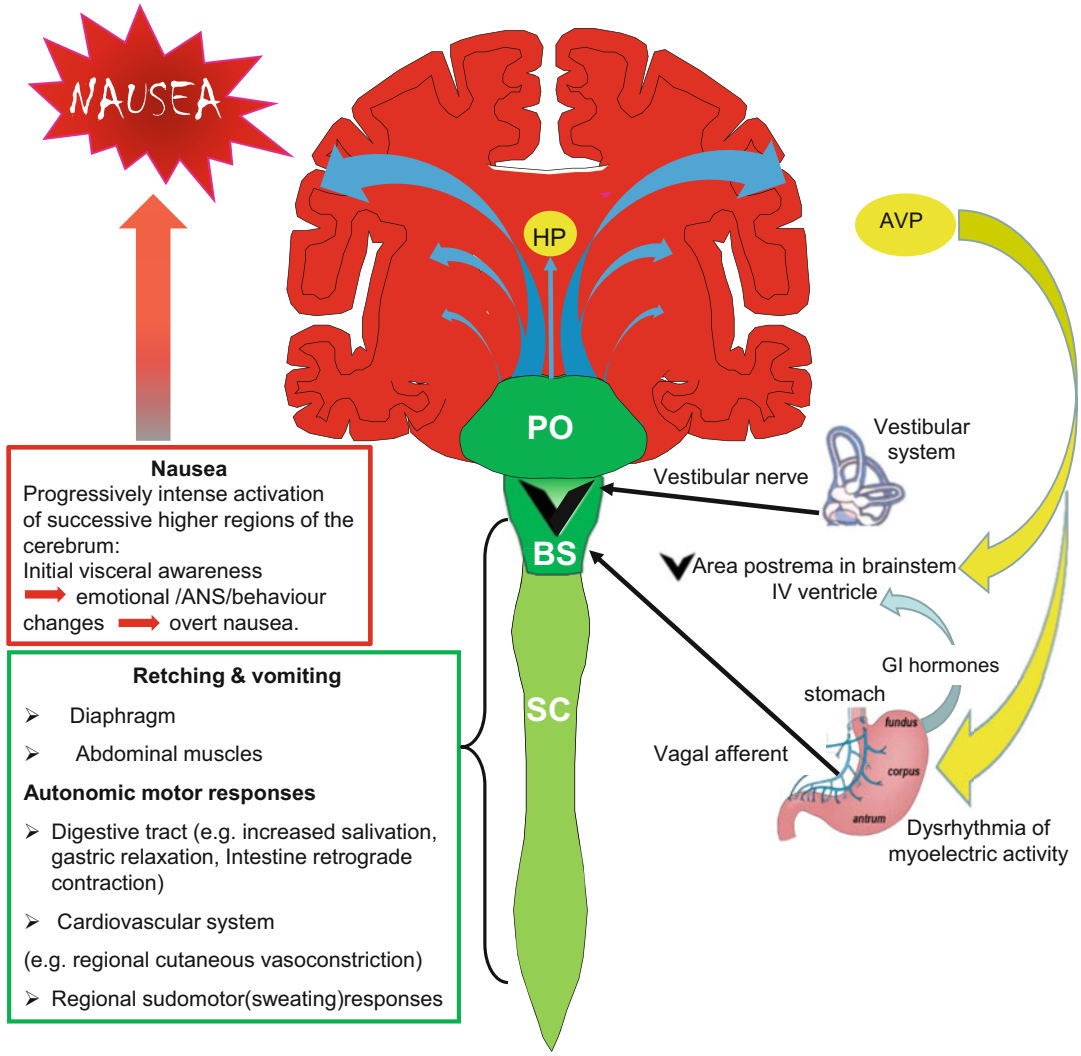
Drugs which inhibit or prevent nausea and vomiting are usually called "antiemetic" drugs. It is important to emphasize that currently there is no "universal antiemetic" drug preventing both nausea and vomiting induced by all the above pathways. Instead, particular drugs control "motion sickness" (by acting mostly within the vestibular nucleus), nausea, and vomiting originating from the viscera (by inhibiting vagal afferent functions) or induced by systemic (endogenous or exogenous) stimuli activating the AP. Table 1 lists some of the major antiemetic drugs and describes their main pharmacological actions. With few recent exceptions, most drugs were discovered by serendipity (Sanger and Andrews 2018) and tend to have multiple actions which confer both benefits and side-effects, reflecting their receptor binding profiles (Table 1).

Muscarinic Receptor Antagonists (Sanger and Andrews 2018)

Motion sickness is controlled by muscarinic receptor antagonists (e.g., hysoscine) acting primarily at the M_5 receptors in the vestibular nucleus. Although the properties of extracts of deadly nightshade (*Atropa belladonna*) and henbane (*Hyosyamus niger*) were known from antiquity, the efficacy of muscarinic antagonists was not established by formal clinical trials until World War II, when trials were conducted to improve the well-being of soldiers during transport by sea and before beach landings.

Histamine H_1 Receptor Antagonists (Sanger and Andrews 2018)

Drugs which antagonize the histamine H_1 receptor were being evaluated for the control of hay fever and urticaria in 1947 when it was observed that motion sickness could also be controlled. Today, these drugs are also readily available to aid sleep (H_1 receptor antagonism within the brain causes somnolence) but when combined with the stimulant 8-chlorotheophylline to counteract the drowsiness, drugs such as diphenhydramine became available for treatment of motion sickness. Some, such as diphenhydramine, were later found to have affinity for the muscarinic receptors (Table 1) so their precise antiemetic mechanism (s) of action is unclear. Cyclizine is another example of an H_1 receptor antagonist widely prescribed



Emesis, Fig. 2 Flow of information that leads to vomiting and nausea. The motor components of retching and vomiting only require the brainstem (BS) and spinal cord (SC), triggered by the main inputs of abdominal vagal afferents, the area postrema (including by gastrointestinal hormones), and vestibular system (see text for details). Nausea requires projection of information from the brainstem to progressively "higher" regions of the brain (amygdala, insular cortex, cingulate cortex) resulting in progressively more visceral awareness and responses controlled by the autonomic nervous system (ANS; endocrine and cardiovascular). The hypothalamic pituitary axis (HP) is also activated and of particular relevance to nausea is arginine vasopressin (AVP) which is hypothesized to act on the stomach to induce gastric dysrhythmia (associated with nausea) and possibly the area postrema; the consequences of either would be to reinforce the original emetic stimuli

as a treatment of motion sickness but also as a "first line" antiemetic if the cause of emesis is uncertain (e.g., during palliative care). Although it was taken on the Apollo space missions, cyclizine is such an old drug that very little is known about it!

Dopamine D_2 Receptor Antagonists (Sanger and Andrews 2018)

Dopamine D_2 receptor antagonists are presumed to be antiemetic because they block D_2 receptors within the AP. It is assumed, therefore, that they are effective against vomiting that is induced by

Emesis, Table 1 Receptor affinities of antiemetic drugs. Modified from Sanger and Andrews (2018). Data are from http://www.guidetopharmacology.org/ and are given as pK_i values for the human receptor; primary affinities are in bold. circulating agents which reach the AP and induce somehow induce D_2 receptor activation; surprisingly however, relatively little is known about the relationships between dopamine and D_2 receptors in the human AP (Koch and Hasler 2017). One class of receptor antagonist, the phenothiazines (first synthesized in 1883), arose from research into the role of dopamine in schizophrenia. These drugs include chlorpromazine, prochlorperazine, and fluphenazine. They are brain penetrant D_2 receptor antagonists but some have additional affinity for the H_1 receptor (prochlorperazine, fluphenazine) causing a degree of somnolence (Table 1). A disadvantage of brain penetrance is that D_2 receptors involved in motor functions may also be antagonized, leading to "extrapyramidal side-effects" such as akathisia, pseudo-Parkinsonism, and tardive dyskinesia.

A second, and important, class of drug that antagonizes the D_2 receptor are the substituted benzamide's, exemplified by the first of these, metoclopramide. In addition, metoclopramide is a 5-hydroxytryptamine$_4$ (5-HT$_4$) receptor agonist (leading to stimulation of gastric movements) and a 5-hydroxytryptamine$_3$ (5-HT$_3$) receptor antagonist (providing additional antiemetic activity; see below). In terms of receptor affinity, this is highest for the D_2 receptor. However, amplification of the response to 5-HT$_4$ receptor activation within the enteric cholinergic neurons (facilitating the release of acetylcholine to increase GI motility) means that metoclopramide is a 5-HT$_4$ receptor agonist (and gastric prokinetic agent) and D_2 receptor antagonist (antiemetic) at approximately similar doses in vivo (Table 1). Because of its ability to act as a gastric prokinetic, this action, together with the antiemetic activity, means that the drug is often provided for patients with upper GI disorders such as gastroparesis, a disorder characterized by delayed gastric emptying together with symptoms of nausea or vomiting, early satiety, pain, and abdominal or gastric bloating (see below). Extrapyramidal side-effects can occur with metoclopramide but are not usually serious. Of great significance is that higher doses of metoclopramide are able to antagonize the 5-HT$_3$ receptor, activity of fundamental importance in expanding the therapeutic utility of metoclopramide and in the later discovery that emesis caused by highly emetogenic anticancer therapy could be prevented by selective 5-HT$_3$ receptor antagonists (see below).

The third class of D_2 antagonist is represented by domperidone, designed not to cross the blood brain barrier. This drug is therefore normally free of extrapyramidal side-effects but by acting at the AP (not protected by the blood-brain barrier), retains antiemetic activity; some evidence exists to suggest that in patients with delayed gastric emptying, domperidone may increase gastric emptying. Domperidone is also a D_3 receptor antagonist and animal studies suggest that such activity enhances the antiemetic activity of D_2 antagonism. Domperidone has not been registered for use in the USA and the discovery that this drug is able to block the human ether-a-go-go potassium channel (*h*ERG) at clinically relevant concentrations (potentially leading to cardiac arrhythmia) has further restricted its use.

5-Hydroxytryptamine$_3$ (5-HT$_3$) Receptor Antagonists (Sanger and Andrews 2018)

The muscarinic, histamine, and dopamine receptor antagonists were largely discovered before it was possible to screen compounds for activity against a bank of recombinant human receptors (meaning that nonselectivity of action is not uncommon) and without being directed towards the nausea and vomiting associated with any particular clinical condition. This changed with the introduction of cisplatin-based anticancer drugs which cause chemotherapy-induced nausea and vomiting (CINV), in common with most cytotoxic anticancer drugs (Sanger and Andrews 2018). However, the severity of the vomiting induced by these drugs could not be prevented by any of the above antiemetic drugs, greatly limiting their use in cancer patients and seriously reducing quality of life during treatment; a single treatment can cause patients to experience severe nausea and vomiting during the first 24 h after administration ("acute phase") and then after some recovery, the symptoms return ("delayed phase") for a further 3–5 days. This type of severe vomiting was not prevented by high-dose D_2

receptor antagonists or cannabis (acting at CB_1 receptors). Metoclopramide also proved ineffective but surprisingly, when given at higher doses, successfully controlled cisplatin-evoked vomiting. Together with the knowledge that high concentrations of metoclopramide antagonize at the 5-HT_3 receptor (Table 1), this led to an understanding of the mechanisms of this type of severe vomiting and the development of selective 5-HT_3 receptor antagonists for treatment of chemo- and radiotherapy induced emesis. The drugs are effective when given before treatment or after emesis has begun, because they block the actions of 5-HT released from the enterochromaffin cells of the small intestine to both activate and sensitize the peripheral terminals of the abdominal vagal afferents. Projections from these afferents, largely to the NTS, initiate nausea and vomiting. The 5-HT_3 receptor antagonists are also registered for the treatment of post-operative nausea and vomiting but the causal mechanism is not fully known. Today, cancer patients receiving "moderately severe emetogenic treatments" receive a 5-HT_3 receptor antagonist together with the corticosteroid dexamethasone; the latter has anti-inflammatory and other actions which help to reduce the delayed emesis and when given with a 5-HT_3 receptor antagonist achieves good control of vomiting. It is recommended that cancer patients receiving "severe emetogenic treatments" (e.g., platinum-based therapies) are given a 5-HT_3 receptor antagonist, dexamethasone, and also an NK_1 receptor antagonist, the most recent novel class of antiemetic drug (see below). A recent addition to the family of selective 5-HT_3 receptor antagonists is the drug palonosetron, a compound with high affinity for the receptor and a long plasma half-life (42 h) in healthy volunteers (Sanger and Andrews 2018). Compared with the earlier 5-HT_3 receptor antagonists, palonosetron appears to have a superior ability to inhibit both acute and delayed phases when given alone. Further studies suggest that palonosetron binds allosterically to the receptor, in a manner which provides prolonged activity at the receptor and its internalization; the internalized complex is suggested to "cross-talk" with NK_1 receptor signaling pathways, inhibiting the functions of its major ligand, substance P, and thereby explaining the superior antiemetic activity.

Neurokinin$_1$ (NK_1) Receptor Antagonists (Sanger and Andrews 2018)

NK_1 receptor antagonists block the ability of the tachykinin peptides, most notably substance P, to activate the NK_1 receptor. Substance P is released from gut enteroendocrine cells to act on peripheral vagal afferent terminals (cf. 5-HT), and also from the central terminals of the vagal afferents and from NTS neurons, providing a greater ability to inhibit vomiting, compared with the 5-HT_3 receptor antagonists which inhibit only the activation of the vagal afferent nerve by 5-HT. When combined together with a 5-HT_3 receptor antagonist and dexamethasone, maximum efficacy is achieved in cancer patients receiving highly emetogenic chemotherapy, against both the "acute" (first 24 h) and delayed forms of CINV.

Treating Nausea: A Remaining Challenge

Despite great improvements in the control of nausea and vomiting in cancer patients, for many, the problem of persistent nausea remains with a major impact on quality of life. To try and achieve added nausea control, the benefits of the more recently developed antipsychotic medications are being explored. Most notable among these is olanzapine, an antagonist at D_1, D_2, D_3, D_4, 5-HT_{2A}, 5-HT_{2C}, 5-HT_3, 5-HT_6, α_1 adrenergic, H_1 and m_1, m_2, m_3, m_4 receptors. When given to cancer patients together with a 5-HT_3 receptor antagonist, dexamethasone, and an NK_1 receptor antagonist, some further reduction in nausea has been reported (in addition to a degree of somnolence). The enhanced efficacy of these multidrug combinations antagonizing multiple receptors (up to 17!) may reflect the activation of multiple pathways with differing receptor combinations (see above).

Nausea is also a common symptom of many diseases. For example, among the "functional bowel disorders" nausea is particularly present in gastroparesis (idiopathic and diabetic), chronic unexplained nausea and vomiting and functional

dyspepsia (Yu et al. 2017). At present only metoclopramide is registered for the treatment of gastroparesis within the USA and a recent analysis is consistent with a beneficial action of this drug, despite extrapyramidal side-effects. In these patients, other drugs may have beneficial activity but have restricted use (e.g., domperidone) or as yet, have not demonstrated a consistent benefit (e.g., 5-HT_3 or NK_1 receptor antagonists). New approaches (e.g., ghrelin receptor agonism, to achieve a gastric prokinetic activity together with an ability to inhibit vomiting) are currently under examination. New causal mechanisms of nausea are also being explored (Grover et al. 2019). In particular, it is thought that the activity of the pacemaker cells within the wall of the stomach (e.g., the interstitial cells of Cajal) may become disrupted during gastroparesis. These cells spontaneously depolarize to generate slow waves of electrical activity that pass circumferentially through the stomach towards to the pyloric sphincter; it is believed that such activity is communicated (via gap junctions) to the muscle to promote gastric contractions which empty contents into the intestine. Disruptions in slow wave activity and the consequential contractile changes are thought to be detected by vagal mechanoreceptors for transmission to the NTS and interpretation by higher brain centers as nausea. These disruptions may follow damage to the pacemaker cells caused by macrophage invasion in certain patients with gastroparesis or perhaps in other patients', changes are secondary to the induction of nausea by a stimulus acting away from the stomach (e.g., motion sickness). Apart from gastroparesis, dysrhythmic gastric electrical activity has been observed in many patients with nausea (e.g., motion sickness, chronic renal failure, cyclical vomiting syndrome, pregnancy sickness). Drugs which can modulate pacemaker cell disturbances and hence alleviate nausea have not yet been identified.

Genomics and Emesis

Only limited pharmacogenomics studies have been applied to nausea and vomiting. In addition to those which apply to drug metabolism and transport (e.g., ondansetron metabolized mostly by the cytochrome P450 CYP2D6 which exhibits genetic polymorphism; *ABCB1* polymorphisms and granisetron efficacy), genetic variations are known to exist for the genes encoding the opioid mu-1 receptor and the different subunits comprising the 5-HT_3 receptor (a ligand-gated cation channel assembled as a pentamer) (Aroke and Hicks 2019).

Synonyms

Endogenous agonists of cannabinoid receptors

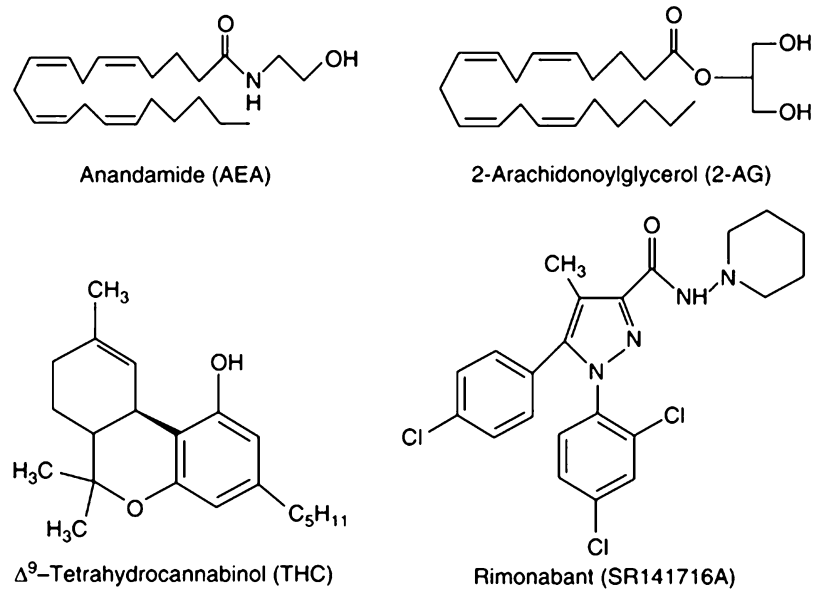
Definition

Endocannabinoids are endogenous mediators acting via the binding to, and activation of, cannabinoid receptors, CB_1 and CB_2 (Pertwee 2006). *N*-arachidonoyl-ethanolamine (AEA, anandamide) and 2-arachidonoyl-glycerol (2-AG) (Fig. 1) are the two most potent and efficacious endocannabinoids. In the nervous system, endocannabinoids act as neuromodulators. In peripheral non-nervous tissues, they act as autocrine or paracrine regulators of the homeostasis of other chemical mediators.

Basic Characteristics

Endocannabinoid Biosynthesis

It is commonly accepted that both AEA and 2-AG are biosynthesized "on demand" and released from cells immediately after their production. These events are usually triggered by the enhancement of intracellular Ca^{2+} concentrations that follows cell depolarization or the mobilization of intracellular Ca^{2+} stores subsequent to stimulation of $G_{q/11}$ protein-coupled receptors (Howlett 2005). However, some preliminary evidence is emerging to suggest that endocannabinoids might be secreted in extracellular vesicles (Ligresti et al. 2016). At any rate, in many cases, the levels of the two main endocannabinoids are regulated in different and sometimes even opposing ways via the modulation of the activity and/or expression of either their different biosynthetic or degrading enzymes. AEA is produced from the processing of *N*-arachidonoyl-phosphatidylethanolamine (NArPE), which in turn is obtained from the enzymatic transfer of arachidonic acid esterified on the *sn*-1 position of phospholipids to the nitrogen atom of phosphatidylethanolamine, via Ca^{2+}-independent and, more often, -dependent *N*-acyltransferases (Ligresti et al. 2016). The enzyme catalyzing the one-step conversion of NArPEs and other *N*-acylphosphatidylethanolamines (NAPEs) into AEA and other *N*-acylethanolamines, respectively, is the same and is termed NAPE-selective phospholipase D (NAPE-PLD). It is: (i) enzymatically distinct from other PLD enzymes, (ii) stimulated by Ca^{2+}, and (iii) a member of the β-lactamase fold of the zinc-metallo-hydrolase family of enzymes. Its over-expression in cells leads to higher cellular levels of AEA and correspondingly lower levels of NArPE, thus supporting its role in the biosynthesis of this endocannabinoid. However, three more pathways have been identified that can transform NArPE into AEA. In macrophages, a phospholipase C (PLC) converts NArPE into AEA via phospho-AEA. PTPN22, a protein tyrosine phosphatase, is the



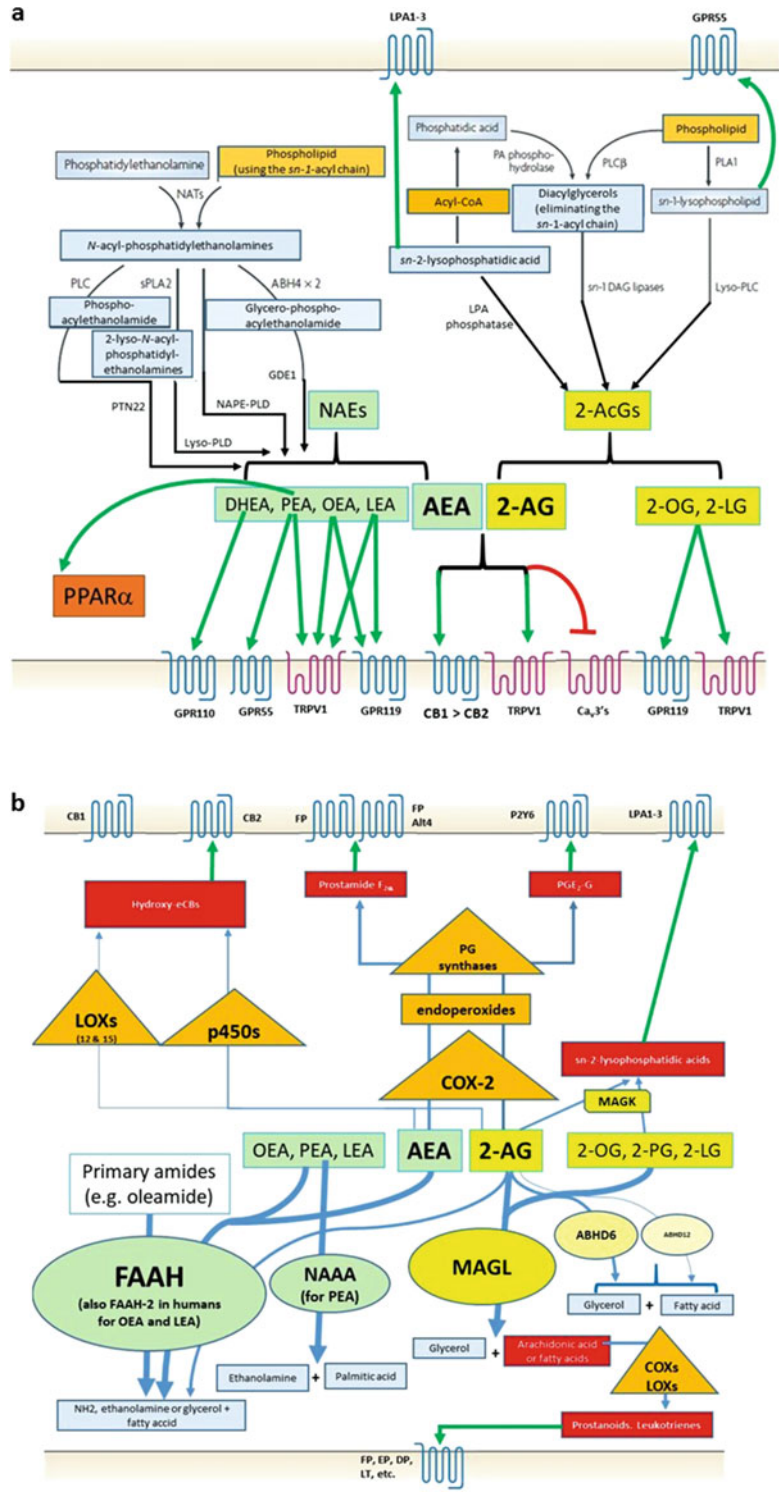
Endocannabinoids, Fig. 1 Chemical structures of the two most studied endocannabinoids, anandamide and 2-arachidonoylglycerol, of *Cannabis sativa* psychoactive principle, Δ^9-tetrahydrocannabinol, and of the CB_1 receptor antagonist/inverse agonist, rimonabant

enzyme catalyzing phospho-AEA hydrolysis to AEA. In brain homogenates, NArPE can be converted into 2-lyso-NArPE, via the action of a groupIB soluble phospholipase A_2, or into glycerophospho-AEA, via alpha/beta-hydrolase 4. AEA is then formed via the hydrolysis of 2-lyso-NArPE by a selective lysophospholipase D, or of glycerophospho-AEA by glycerophosphodiester phosphodiesterase 1 (GDE1), respectively (Fig. 2). Studies using NAPE-PLD/GDE1 double knockout mice have confirmed that these two enzymes can concur to the production of at least part of AEA and other *N*-acylethanolamines in the brain.

2-Arachidonate-containing DAGs are the most frequent biosynthetic precursors of 2-AG. They are produced from the hydrolysis of phosphoinositol-bis-phosphate ($P1P_2$), catalyzed by the PIP_2-selective PLC, or, in some cases, from the hydrolysis of phosphatidic acid, catalyzed by a phosphohydrolase. DAGs are then converted into 2-AG by the action of two plasma membrane *sn*-1-selective DAG lipases, DAGLα and DAGLβ (Fig. 2). These two enzymes (i) contain the typical lipase-3 and Ser-lipase signature sequences, in which two highly conserved amino acid residues, Ser443 and Asp495, are necessary for enzymatic activity, (ii) exhibit also four hydrophobic, possibly *trans*-membrane, domains near their N terminus, (iii) are stimulated by Ca^{2+}, and (iv) do not prefer DAGs with any particular fatty acyl chain in the *sn*-2 or *sn*-1 position, although they exhibit strong selectivity for DAGs over phospholipids, monoacyloglycerides, triacylglycerols, and fatty acid amides. DAGLα is more abundant in the adult brain and DAGLβ in the developing brain. Both enzymes are co-localized with CB_1 receptors in neuronal axons of the perinatal nervous system, and "move" to postsynaptic neurons in the adult brain. DAGLα is found in postsynaptic dendritic spines establishing synapses with CB_1 expressing axons, thus supporting the proposed roles for 2-AG as a retrograde messenger of synaptic plasticity in the adult brain. In adult rodents, DAGLβ is often more abundant than DAGLα in non-neuronal cells in both central and peripheral tissues, for example, microglia, hepatic stellate cells, dendritic cells, and macrophages. Importantly, the two DAGL isoforms are responsible for the production of other long chain 2-acy-glycerols, which, like the non-endocannabinoid *N*-acyl-ethanolamines, are no longer considered devoid of biological actions (Di Marzo 2018).

Endocannabinoid Action

Once released from cells, endocannabinoids bind to cannabinoid receptors and elicit typical CB_1- and CB_2-mediated intracellular signaling events, thereby leading to biological responses typical of cannabinoid receptor agonists (Pertwee 2006; Howlett 2005). However, the functional role of endocannabinoids cannot be inferred only from the knowledge of the pharmacological effects of Δ^9- tetrahydrocannabinol (THC) and synthetic cannabinoids for several reasons: (i) because of the mechanisms underlying their biosynthesis and because of their rapid metabolism, endocannabinoids appear to be produced only "when and where" needed. Thus, for example, if endocannabinoids are being made and released to protect a neuron from glutamate-induced excitotoxicity, they will be released only from the postsynaptic neuron undergoing excessive stimulation by glutamate, to inhibit only glutamate release from the presynaptic glutamatergic neuron, without inhibiting the activity of GABA-ergic interneurons, which, by releasing GABA, also tone down excitotoxicity. This specificity of endocannabinoid action is not always maintained when CB_1 receptors are activated by exogenous agonists, (ii) in some cases endocannabinoids are biosynthesized together with congeners that are inactive per se at cannabinoid receptors, but can nevertheless modulate the activity of AEA and 2-AG or act at different receptors (see below), (iii) endocannabinoids can act also at non-cannabinoid receptors, including ion channels and receptors for neurotransmitters or other neuromodulators, (iv) both AEA and 2-AG can be oxidized by enzymes of the arachidonic acid (AA) cascade, thereby producing metabolites that are not necessarily inactive at cannabinoid receptors (as in the case of lipoxygenase or epoxygenase metabolites) or act on other targets (as in the case of the cyclooxygenase-2 metabolites) (see below), and finally (v) AA produced from the degradation of 2-AG can be used in some tissues, including the brain under inflammatory conditions, to generate



Endocannabinoids, Fig. 2 The endocannabinoid system. Proteins and pathways for the biosynthesis (**a**) and degradation (**b**) of endocannabinoids and their congeners. Receptors for endocannabinoids and endocannabinoid

eicosanoids acting at their own targets (Di Marzo 2018) (Fig. 2). Therefore, to understand endocannabinoid action at cannabinoid receptors, pharmacological studies using selective cannabinoid CB_1 and CB_2 receptor agonists and antagonists/inverse agonists, or recently emerging allosteric modulators of these two receptors, must be used. The study of the pharmacological effects of inhibitors of endocannabinoid biosynthesis or catabolism under physiological and pathological conditions (see below) must be accompanied by observations on the phenotype of CB_1, CB_2, and metabolic enzyme (preferably tissue-specific and conditional) "knock-out" mice and, most importantly, by the quantification of anandamide and 2-AG levels in various tissues following treatment (Ligresti et al. 2016; Di Marzo 2018).

It was established that, in the brain, endocannabinoids act as retrograde messengers acting on presynaptic CB_1 receptors in both short-term and long-term forms of synaptic plasticity. These retrograde actions underlie at least part of CB_1-mediated regulation of cognitive and emotional functions in the brain, reinforcement of substances of abuse in the mesolimbic system, induction of appetite or reduction of satiety in the hypothalamus and brainstem, and control of movement and posture in the basal ganglia and cerebellum. Neuromodulatory, CB_1-mediated actions of endocannabinoids in the sensory and autonomic nervous systems result in the regulation of, among others, circulatory and gastrointestinal functions and the hypothalamic-pituitary-adrenal axis. Direct autocrine or paracrine actions in nonneuronal cells underlie the several CB_1- and CB_2-mediated effects of these compounds on, among others, female and male reproduction, bone formation, immune response and adipocyte and β-cell function (Ligresti et al. 2016).

Endocannabinoid Inactivation

AEA is inactivated through intracellular enzymatic hydrolysis to arachidonic acid and ethanolamine (Fig. 2). The enzyme catalyzing this reaction was named "fatty acid amide hydrolase" (FAAH) as it recognizes as substrates also other long chain fatty acid amides, including *N*-acylethanolamines, primary amides, some *N*-acyl-aminoacids, and *N*-acyl-taurines. FAAH catalyzes efficiently also the hydrolysis of long chain fatty acid esters, including 2-AG. The physiopathological role of FAAH as a major endocannabinoid-inactivating enzyme has been assessed through: (i) the study of the phenotype of transgenic mice lacking the enzyme, that is, the FAAH "knockout" mice, (ii) the design and pharmacological testing in vivo of specific FAAH inhibitors, (iii) immunohistochemical studies describing the tissue and cellular distribution of the enzyme and its relationship with cannabinoid receptor distribution, and (iv) the identification of *Faah* gene polymorphisms associated with disorders such as obesity, propensity to drug addiction and schizophrenia. A second FAAH,

Endocannabinoids, Fig. 2 (continued) congeners, biosynthetic precursors, and metabolic products are also shown. Abbreviations used: 2-AcGs, 2-acyl-glycerols; 2-AG, 2-arachidonoyl glycerol; Abh4 or 6 or 12, alpha/beta-hydrolase 4 or 6 or 12; Ca_{v3s}, T-type calcium channels; COX, cyclooxygenase; DAGL, *sn*-1-selective diacylglycerol lipase; DHEA, *N*-docosahexaenoyl-ethanolamine; DP, EP, FP, receptors for prostaglandins of D, E and F type; FAAH, fatty acid amide hydrolase; GDE1, glycerophosphodiester phosphodiesterase 1; GPR, orphan G-protein-coupled receptor; FP Alt4, alternative splicing variant 4 of the FP receptor making an heterodimer with the FP receptor; LEA, *N*-linoleoyl-ethanolamine; 2-LG, 2-linoleoyl-glycerol; LOX, lipoxygenase; LPA, sn-1-lyso-2-acyl-phosphatidic acid; LPA1-3, lysophosphatidic acid receptors 1–4; MAGK, monoacylglycerol kinase; MAGL, monoacylglycerol lipase; NAAA, *N*-acyl-ethanolamine acid amidohydrolase; NAEs, *N*-acyl-ethanolamines; NAPE-PLD, *N*-acylphosphatidyl-ethanolamine-selective phospholipase D; NATs, *N*-acyl-transferases; lyso-PLD, lysophospholipase D; 2-OG, 2-oleoyl-glycerol; OEA, *N*-oleoyl-ethanolamine; p450, cytochrome p450 monoxygenase; P2Y6, purinergic receptor 2Y6; PEA, *N*-palmitoyl-ethanolamine; 2-PG, 2-palmitoyl-glycerol; PG, prostaglandin; PLA_2, phospholipase A_2; PLC, phospholipase C; PPARα, peroxisome proliferator-activated receptor-α; PTPN22, protein tyrosine phosphatase N22; $sPLA_2$, soluble phospholipase A_2; TRPV1, transient receptor potential vanilloid type-1 channel. Arrows denote activation, transport, or transformation. Thicker arrows denote a more important role of the enzyme in the process. Adapted from: Veilleux et al. (2019) Curr Diab Rep. 19(11):117

named FAAH-2, has also been identified, although so far only in human tissues, and shown to prefer non-AEA long chain *N*-acylethanolamines as substrates.

In addition, a monoacylglycerol lipase (MAGL) was cloned from the rat and evidence for its role in 2-AG degradation in isolated cells was provided by the use of silencing RNA techniques (Fig. 2). The cloned MAGL seems to account for the vast majority of 2-AG-hydrolyzing activity in soluble fractions of rat brain, and other enzymes, such as alpha/beta-hydrolase 6 and 12, have been suggested to play a role in 2-AG inactivation under particular circumstances (Fig. 2). The cloned MAGL recognizes as substrates both *sn*-1 and -2-acylglycerols with almost any unsaturated long chain fatty acid esterified to the glycerol backbone, but is inactive with fatty acid amides. It is distributed in the CNS in the same brain regions as CB_1 receptors and is a presynaptic enzyme, in agreement with the necessity of inactivating 2-AG acting as a retrograde signal.

Enzymes of the arachidonate cascade can also recognize AEA and 2-AG as substrates, thereby producing bioactive metabolites that, in the case of cyclooxygenase-2, have been isolated in tissues, and named prostaglandin-ethanolamides (or prostamides) and prostaglandin-glycerol esters (Fig. 2). Neither of these types of metabolites act on cannabinoid or prostaglandin receptors, and both seem to produce biological effects via other yet-to-be-fully-characterized receptors (Di Marzo 2018).

Endocannabinoid Membrane Transport

AEA and 2-AG need to be transported across the membrane in order to interact with intracellular hydrolyzing enzymes (Ligresti et al. 2016). It is still being debated whether or not endocannabinoid uptake by, and release from, cells occurs via a membrane transporter, and not via simple passive diffusion. Intracellular degradation of AEA by FAAH was suggested to be the only drive behind its cellular uptake. However, strong indirect evidence exists for specific proteins facilitating the membrane transport of both AEA and 2-AG. Experiments carried out using cells from FAAH knockout mice, confocal microscopy to assess the spatial and functional separation between anandamide uptake and hydrolysis, and synthetic inhibitors capable to distinguish between FAAH and proteins responsible for the cell membrane binding/cellular uptake of AEA favor the existence of one or more specific proteins for AEA transport. Nevertheless, no such protein has been cloned or identified to date.

The Endocannabinoidome

The ever increasing realization that AEA and 2-AG: (i) modulate the activity of receptors other than CB_1 and CB_2, (ii) are produced and metabolized by concurrent and redundant pathways, and often converted to other bioactive lipids, and (iii) are accompanied in tissues by other long chain fatty acid derivatives that, like the congener *N*-acylethanolamines and 2-acylglycerols, share with endocannabinoids both biosynthetic and catabolic enzymes and pathways, as well some of their non-cannabinoid receptors (Fig. 2), or, like the *N*-acyl-aminoacids (or l*ipoaminoacids*), *N*-acyl-serotonins and *N*-acyl-dopamines, may share with endocannabinoids non-cannabinoid receptors and only in some cases catabolic enzymes, led to the notion of the "expanded endocannabinoid system" or "endocannabinoidome" (Di Marzo 2018). The endocannabinoidome is now thought to include hundreds of endocannabinoid-like molecules and tens of receptors and metabolic enzymes. Its existence complicates the development of therapeutic drugs from inhibitors of endocannabinoid biosynthetic or degrading enzymes, in as much as these substances may end up indirectly modifying the activity also of non-cannabinoid receptors.

Drugs

Pathological Conditions in Which Endocannabinoids Are Involved

Endocannabinoid levels often undergo dramatic tissue-specific changes in both animal models of disorders and in human diseases (Table 1) (Ligresti et al. 2016). During some acute pathological states or transient near-physiological perturbations of the normal homeostasis of the

organism, the levels of at least one endocannabinoid are elevated only in the tissues specifically involved in the disorder to help re-establishing the levels of other endogenous mediators. This occurs, for example, following insults or stressful stimuli ranging from brief food deprivation, restriction-induced stress, and retrieving of aversive memories to administration of acute painful stimuli, head injury, and ischemia. In the case of progressive/chronic disorders, endocannabinoid levels can become permanently elevated, although again in a tissue-selective way. This might lead again to homeostatic (e.g., anti-inflammatory or cell protective) effects in ways mediated by CB_1- or CB_2 receptors (or also by non-cannabinoid receptors), as in the case of some types of cancer (breast and colorectal carcinoma, glioma, etc.) or inflammatory gastrointestinal disorders (colitis, diverticular disease, celiac disease). However, a chronic over-activity of CB_1 receptors might eventually contribute to the development of also some of the symptoms typical of the disorder. This situation has been described for some experimental models of Parkinson's disease (PD) and Alzheimer's disease (AD), where the protective or disease exacerbating action of CB_1 receptor might depend on the phase and severity of disorder, and in models of genetic and diet-induced obesity, and of hepatic fibrosis, osteoporosis, paralytic ileus, and noxious hypotension. In the female reproductive system, a critical balance between anandamide biosynthesis and degradation in mouse embryos and oviducts creates the appropriate conditions for normal development of embryos and their oviductal transport, the malfunctioning of which possibly explains the association observed between lower FAAH/higher AEA levels in the blood of pregnant women and preterm abortion. Finally, a reduction of endocannabinoid levels is found in the brain of mice with experimental allergic encephalomyelitis, a mouse model of multiple sclerosis, in animal models of Huntington's chorea, and in patients with migraine. The subsequent impaired CB_1 signaling might explain some of the clinical hallmarks of these disorders (Table 1).

Endocannabinoids, Table 1 Select examples of observed alterations of endocannabinoid levels during pathological conditions and subsequent possible pharmacological interventions

Disorder	Effects on endocannabinoid levels	Potential drugs
Neurodegenerative/neuromotor disorders:		
1. Parkinson's disease (PD)	1. In a nonhuman primate model of PD endocannabinoid levels are elevated in the basal ganglia and may contribute to the generation of parkinsonian symptoms and/or to expression of levodopa-induced dyskinesia. The cerebrospinal fluid of untreated PD patients contains elevated levels of AEA	1. CB_1 antagonists or biosynthesis inhibitors
2. Alzheimer's disease (AD)	2. In the hippocampus of β-amyloid-treated rats, an animal model of AD, 2-AG levels are elevated and exert neuroprotection but also participate in memory retention loss	2. Inhibitors of degradation or CB_1 antagonists, possibly depending on the phase of the disorder
3. Amyotropic lateral sclerosis (ALS)	3. AEA and 2-AG increase in the spinal cord of SOD1 transgenic mice, a model of ALS, to inhibit disease progress	3. CB_2 receptor agonists or inhibitors of degradation
4. Multiple sclerosis (MS)	4. In rats with EAE, an animal model of multiple sclerosis, AEA and 2-AG levels are decreased in the striatum and midbrain. This might be associated with motor impairment. However, in mice with chronic relapsing EAE, endocannabinoid levels are increased in the brain and spinal cord concomitantly with the spasticity phase of the disorder, and this could represent an adaptive protective mechanism	4. Inhibitors of enzymatic hydrolysis and cellular re-uptake

(continued)

Endocannabinoids, Table 1 (continued)

Disorder	Effects on endocannabinoid levels	Potential drugs
Neuronal excitotoxicity	AEA levels are elevated in the hippocampus of mice treated with kainic acid. 2-AG levels are elevated in rats treated with pilocarpine. These are two animal models of epileptic seizures, where the endocannabinoids play an anticonvulsant and protective function	Inhibitors of enzymatic hydrolysis and cellular re-uptake
Neuropathic pain	Endocannabinoid levels are elevated in periaqueductal grey, rostral ventral medulla, and spinal cord during chronic constriction injury of the sciatic nerve in the rat, probably to inhibit pain	Inhibitors of enzymatic hydrolysis and cellular re-uptake
Gastrointestinal disorders:		
1. Colon inflammation	1. Endocannabinoid levels are elevated in the colon of DNBS-treated mice and in the colon submucosa of TNBS-treated rats, two animal models of inflammatory bowel diseases, and in the biopsies of patients with ulcerative colitis, possibly to control inflammation	1. Inhibitors of enzymatic hydrolysis and cellular re-uptake
2. Cholera toxin-induced diarrhea	2. Increased AEA levels after administration of cholera toxin to mice, a model of diarrhea, exert antisecretory action in the small intestine	2. Inhibitors of FAAH or AEA cellular reuptake
3. Diverticular disease	3. Increased AEA levels in colon strips from patients with diverticular disease participate in alterations of neural control of colon motility	3. None tested
4. Paralytic ileus	4. Increased AEA levels participate in inhibition of small intestine motility	4. CB_1 antagonists
5. Colorectal cancer	Endocannabinoid levels are elevated in the colon of azoxymethane-treated mice and the biopsies of patients colorectal cancer, possibly to counteract cancer cell proliferation	5. Inhibitors of enzymatic hydrolysis and cellular re-uptake
Eating and metabolic disorders:		
1. Anorexia nervosa (AN) and binge-eating disorder (BED)	1. Increased blood levels of AEA in patients with AN and BED may participate in reward aspects of aberrant eating behaviors	1. None tested
2. Obesity and hyperglycemia	2. 2-AG levels are elevated in mouse adipocytes and epididymal of mice with DIO. AEA and 2-AG levels are elevated in rat insulinoma β-cells, in pancreas of mice with DIO, and in obese women. Patients with obesity or hyperglycaemia caused by type 2 diabetes exhibit elevated levels of 2-AG or of both endocannabinoids in visceral fat or blood, respectively. AEA levels are elevated in the liver of DIO mice	2. CB_1 antagonists
Cancer	Elevated levels of AEA in glioblastomas, increased levels of 2-AG in meningiomas, with possible antitumor action	Inhibitors of degradation (both FAAH and cellular re-uptake)

Selected data are shown on those pathological conditions in which endocannabinoid levels are found to be altered in the tissues or organs affected by the disorder. Depending on the possible functional significance of these changes, pharmacological intervention with degradation inhibitors/agonists or with biosynthesis inhibitors/antagonists is suggested as a possible therapeutic strategy.
AEA anandamide, *2-AG* 2-arachidonoyl glycerol, *EAE* experimental autoimmune encephalomyelitis, *DIO* diet-induced obesity

Endocannabinoid-Based Drugs

Based on the role of endocannabinoids and cannabinoid receptors in several pathological conditions, the pharmacological manipulation of their levels or action is being developed as a therapeutic strategy. Enhancement of endocannabinoid signaling would be useful when this plays uniquely a protective role, whereas inhibition of endocannabinoid signaling would be beneficial in those conditions in which tissue endocannabinoids have lost the specificity of their pro-homeostatic action. These therapeutic strategies may be effected in a safer way using: (i) cannabis extracts in which the presence of nonpsychotropic cannabinoids with therapeutic activity per se mitigates the unwanted CB_1-mediated effects of THC and potentiates those of more therapeutic value, acting also through the modulation of proteins of the endocannabinoidome, (ii) synthetic compounds specific for CB_2 receptors, which seem to have less potential for addiction and unwanted central side effects than CB_1 receptors, (iii) inhibitors of endocannabinoid degradation or biosynthesis, which are likely to act more selectively in those tissues where there is an ongoing defective or excessive "tone" of endocannabinoids, but can also interfere with other endocannabinoidome mediators, and hence produce effects at other receptors, and (iv) positive or negative allosteric modulators of CB_1 and CB_2 receptors that, because acting preferentially in the presence of defective or excessive endocannabinoid levels, respectively, should preserve or restore the space- and time-selectivity of endocannabinoid pro-homeostatic action (Ligresti et al. 2016; Di Marzo 2018). The marketing in Europe of a CB_1 receptor antagonist/inverse agonist (rimonabant, Acomplia®) (Fig. 1), which proved to be very effective against obesity and the metabolic syndrome in several clinical trials, was interrupted in 2008 due to adverse psychiatric effects. These latter were likely due to the important pro-homestatic role played by brain CB1 receptors, which is also the reason why THC or its synthetic analogue, nabilone, have found so far limited use as therapeutic drugs. The current marketing in several countries of nabiximols, a standardized cannabis extract in which the psychotropic effects of THC are somehow tamed by approximately equal amounts of the non-psychotropic cannabinoid, cannabidiol, against spasticity and neuropathic pain in multiple sclerosis, and the recent approval in the USA and Europe of purified botanical cannabidiol, which has been suggested to act, among others, on several endocannabinoidome targets, against rare forms of untreatable pediatric epilepsies, demonstrate that it is possible to interact safely with the "expanded" endocannabinoid system (Pacher et al. 2019). Clinical studies are ongoing with more selective, synthetic drugs targeting receptors and metabolic enzymes of the endocannabinoid system in several disorders.

Definition

Endothelins comprise a family of three vasoactive isopeptides of 21 amino acids acting via two subtypes of endothelin receptors (ET_A and ET_B). Endothelins have an essential role in the regulation of the vascular tone, control of renal natriuresis, and neural crest development. Endothelins are also involved in nociception and may have a critical role in the progression of prostate and ovarian cancer. Several endothelin receptor antagonists are registered for the treatment of primary pulmonary arterial hypertension (PAH).

Basic Characteristics

Endothelin and Endothelin-Converting Enzymes

In 1985 a peptide was described in the supernatants of endothelial cells that mediated vasoconstriction. This peptide was isolated, sequenced, and the cDNA was cloned. According to its origin from endothelial cells, it was named endothelin (Yanagisawa et al. 1988).

Three endothelin isoforms are known (ET-1, ET-2, ET-3), encoded by different genes, of which ET-1 is the most abundant in humans (Warner 2001). Endothelins are synthesized as prepropolypeptides of approximately 200 amino acids (Table 1). The biological active endothelins are generated in a two-step proteolytic process (Fig. 1). In the first step, furin-like proteases generate big-endothelins (big-ETs) of 38–41 amino acids that are biologically inactive. In a second step, specific endothelin-converting enzymes (ECEs) specifically cleave big-ETs between tryptophan 21 and valine/isoleucine 22, thereby producing the mature endothelins. Big-ET-1 was also found to be cleaved by mast cell chymase resulting in ET-1(1–31). While ET-1(1-31) is not a substrate of ECEs, it is further processed by neutral endopeptidase (NEP) to the biological active ET-1. Matrix metalloproteinase 2 (gelatinase A) also cleaves big ET-1 and yields ET-1(1–32) (Warner 2001). Whether ET-1(1-32) is also a substrate of NEP remains to be shown.

ECEs are metalloproteinases that are homologous to the neutral endopeptidase (NEP, E-24.11, neprilysin); unlike NEP, however, they form disulfide-bonded homodimers. In man, with ECE-1 and ECE-2, two isoforms are known, which are encoded by two separate genes (Warner 2001). For ECE-1, four different variants have been identified (ECE-1a–d), which are generated by alternative promoters. The ECE-1 isoforms only differ in their N-terminal amino acid sequence. For ECE-2, a single gene product has been described in man. In calf, an ECE-3 isoform has been isolated from iris microsomes and the choroid plexus, which is specifically involved in the conversion of big-ET-3 to ET-3. A human homologue of bovine ECE-3 has not been identified.

The ECE isoforms show different subcellular distributions and enzymatic characteristics. While ECE-1 activity is highest at neutral pH at 6.8–7.2, ECE-2 requires an acidic environment of pH = 5.0–5.5. ECE-1a and ECE-1c are mainly expressed at the cell surface, whereas ECE-1b, ECE-1d, and ECE-2 are expressed intracellularly. ECE-1b is found in the transGolgi network, late endosomes, multivesicular bodies, and secretory vesicles, ECE-1d in recycling endosomes, and ECE-2 in endosomes/lysosomes and autophagic vesicles. Plasma membrane-bound ECE cleaves bigET-1 circulating in the blood, whereas intracellular ECE isoforms are involved in the

Endothelins, Table 1 Human endothelin isoforms

	Number of amino acids in		Chromosome	Diseases
	prepro-ET-1	big ET-1		
hET1	212	38	6p23-24	The G allele at rs9349379 is associated with increased risk of CAD/MI but lower risk of migraine headache, cervical artery dissection, fibromuscular dysplasia, and hypertension. G allele at rs9349379 is associated with higher EDN1 expression and higher ET-1 secretion

Endothelins, Fig. 1 Processing of prepro-ET-1. ET-1 is generated as a preprohormone consisting of 212 amino acids. Amino acids 53 to 90 represent big-ET-1, amino acids 53–73 mature ET-1. Amino acids that vary between the three endothelin isoforms are depicted by hatched circles (only variant amino acids of the mature ET-1 moiety and of the ECE-cleavage site are indicated). The amino acids present in ET-2 and ET-3 are depicted by light or dark grey circles, respectively. The signal peptide (grey cylinder) is cleaved off in the endoplasmic reticulum by the signal peptidase. Big-ET-1 is generated by proteolytical processing (furin-like proteases), which recognize dibasic amino acids motifs. Mature ET-1 is formed after processing through the endothelin converting enzyme. Mast cell chymase generates ET-1(1-31) which is further processed by NEP to yield ET-1

generation of mature endothelins. In addition, ECEs (as well as NEP and the insulin-degrading enzyme) contribute to the degradation of amyloid β (Aβ) protein. The relevance of ECE-1, ECE-2, and NEP-mediated amyloid β breakdown and in the development or progression of Alzheimer's disease still remains elusive.

Human umbilical vein endothelial cells (HUVEC) express the isoforms ECE-1a, -1b, -1d, and ECE-2. In these cells, ET-1 is secreted *via* both a constitutive and a regulated pathway. The ratio of released ET-1:big ET-1 is 4:1. About 80% of the ET-1 is secreted at the abluminal cell surface of endothelial cells. ECE-isoforms are

abundantly expressed on the cell surface of endothelial cells and to a lower level also on vascular smooth muscle cells. In atherosclerotic lesions of vessels, however, ECE expression in smooth muscle cells is upregulated. ECE isoforms expressed in smooth muscle cells contribute significantly to the generation of mature ET in normal and in particular atherosclerotic vessels (Warner 2001).

Endothelial cells are the major source of ET-1-synthesis. ET-1 is also produced by astrocytes, neurons, hepatocytes, bronchial epithelial cells, and renal epithelial and mesangial cells. Physiological stimuli of ET-1-synthesis in endothelial cells are angiotensin II, catecholamines, thrombin, growth factors, insulin, hypoxia, and shear stress. Inhibitors of ET-1 synthesis are atrial natriuretic peptide, prostaglandin E2, and prostacyclin. ET-2 is mainly synthesized in kidney, intestine, myocardium, and placenta, and ET-3 is predominantly produced by neurons, astrocytes, and renal epithelial cells (Warner 2001).

Endothelin Receptors

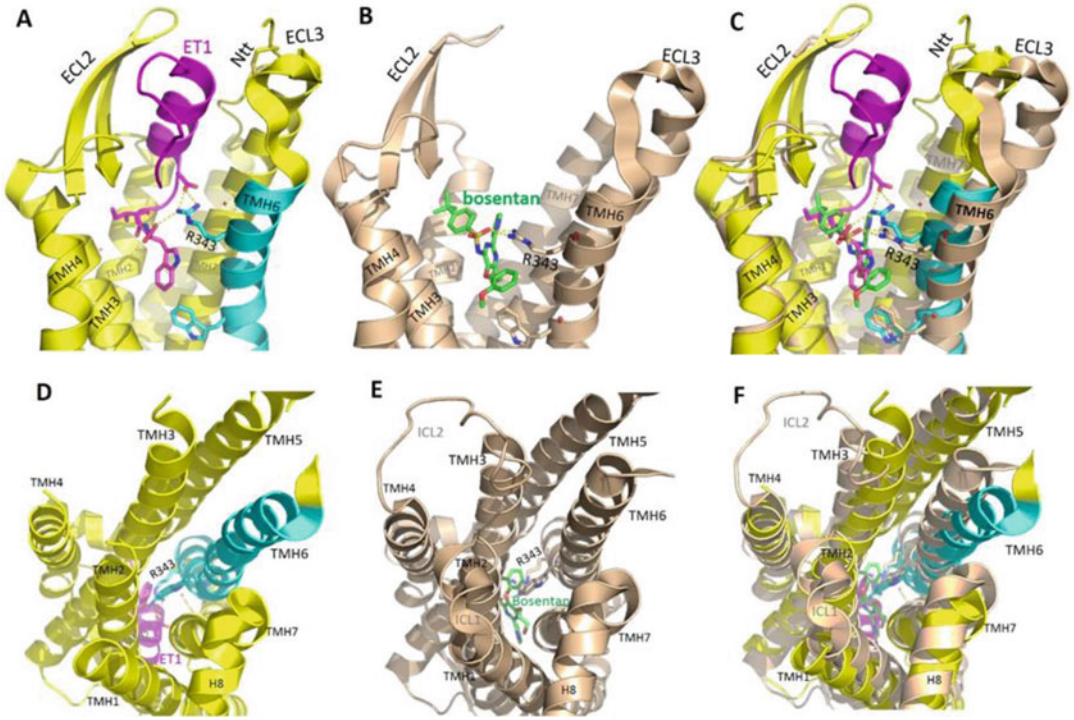
Endothelins exert their diverse actions *via* the two G protein-coupled receptors endothelin A (ET_A) and endothelin B (ET_B), which share an identity of about 64% in their amino acid sequences. Both receptors display a signal peptide that is required for the correct biogenesis. After the N terminus is accessible in the ER lumen, the signal peptide is cleaved off (comprises 20 and 26 amino acids in ET_A and ET_B receptors, respectively). Further posttranslational modifications are Asn-linked glycosylation of the extracellular N terminus (hET_A: Asn29, Asn 62; hET_B Asn 59) and palmitoylation of cysteine residues in the intracellular C terminus. Mass spectometry of the bovine ET_B receptor revealed that cysteine residues 402 and 404 are palmitoylated. The palmitoylation of endothelin receptors is essential for the activation of G proteins, since palmitoylation-deficient ET_A and ET_B receptors fail to stimulate $G_{q/11}$ and G_i proteins, respectively. Crystal structure of the ET_B receptor has demonstrated two disulfide bonds between cysteine residues of the 1st (ET_B: Cys174) and the 2nd extracellular loop (ET_B: Cys255) as well as between cysteine residues in the extracellular N terminus (ET_B: Cys90) and the 3rd extracellular loop (ET_B: Cys359) (Shihoya et al. 2016, 2017). All four cysteine residues are conserved in the ET_A receptor suggesting that two disulfide bonds are formed between the N terminus and the 3rd extracellular loop (Cys69 and Cys341, respectively) and the 1st and 2nd extracellular loop (Cys158 and Cys239, respectively). The extracellular N terminus of the ET_B receptor undergoes agonist-induced limited proteolysis. Upon binding of ET-1 the N terminal 38 amino acids are cleaved off by a metalloprotease. The cleavage involves the single Asn-linked glycosylation site, resulting in a nonglycosylated receptor. The functional role for the N-terminal cleavage is not known, yet. However, genetic deletion of the N terminus or proteolytic removal results in an ET_B receptor with an altered signal transduction.

The endothelin receptor subtypes show differences in their signal transduction, ligand binding, and tissue distribution. The ET_A receptor is isopeptide-selective and binds ET-1 and ET-2 with the same and ET-3 with 70–100 fold lower affinity. The ET_B receptor binds all three isoforms with the same affinity (Warner 2001). Pharmacological studies provided evidence for two subtypes of ET_A (ET_{A1}, ET_{A2}) and ET_B receptors (ET_{B1}, ET_{B2}), although genetic studies revealed only two different genes. Thus, the additional receptor subtypes may be derived from (i) alternative splicing, (ii) differences in posttranslational processing, or (iii) protein-protein interactions. For the ET_B receptor, splice variants have been described. However, these isoforms most likely do not account for the postulated second receptor subtype. One splice variant harbors 10 additional amino acids in the 3rd intracellular loop and has normal binding characteristics and functional activity (IP and cAMP formation). The second splice variant, which carries a completely altered intracellular C terminus, has normal binding properties but lacks functional activity. In vitro, homo- and heterodimerization of endothelin receptor subtypes has been demonstrated, but these receptor-receptor interactions are unlikely to account for the observed subtypes of ET_A and ET_B receptors: Pharmacological binding profiles of ET_A/ET_B receptor heterodimers

were essentially similar to those of individually expressed ET_A and ET_B receptors.

The identification of the crystal structures of the ET_B receptor bound to ET-1 and of the receptor bound to the antagonist bosentan allows conclusions about the molecular mechanisms of ET_B receptor activation and inhibition (Shihoya et al. 2016, 2017). The N-terminal tail, the three extracellular loops (ECL1–ECL3), and the six TM helices (TM2–TM7) form the binding pocket for ET-1 (Fig. 2a). The C-terminal tail of ET-1 binds to the ET_B receptor between the transmembrane helices (TMH) interacting tightly with Arg343 (6.55) in TM6, thereby causing a strong attraction of TM6 at the extracellular side. At the intracellular side, an outward movement occurs due to a helix-kink in of TM6 (Fig. 2d) allowing the interaction with the G protein. The antagonist bosentan (Fig. 2b) occupies the site similar to the C-terminal tail of ET-1, but prevents the close attraction of TMH6 and thereby the intracellular outward movement of TM6 (Fig. 2e) restraining the ET_B receptor in its inactive state. The relative movement of TM6 at the extra- and intracellular areas is visualized by overlaying ET-1 and bosentan-bound structures (Fig. 2c, f).

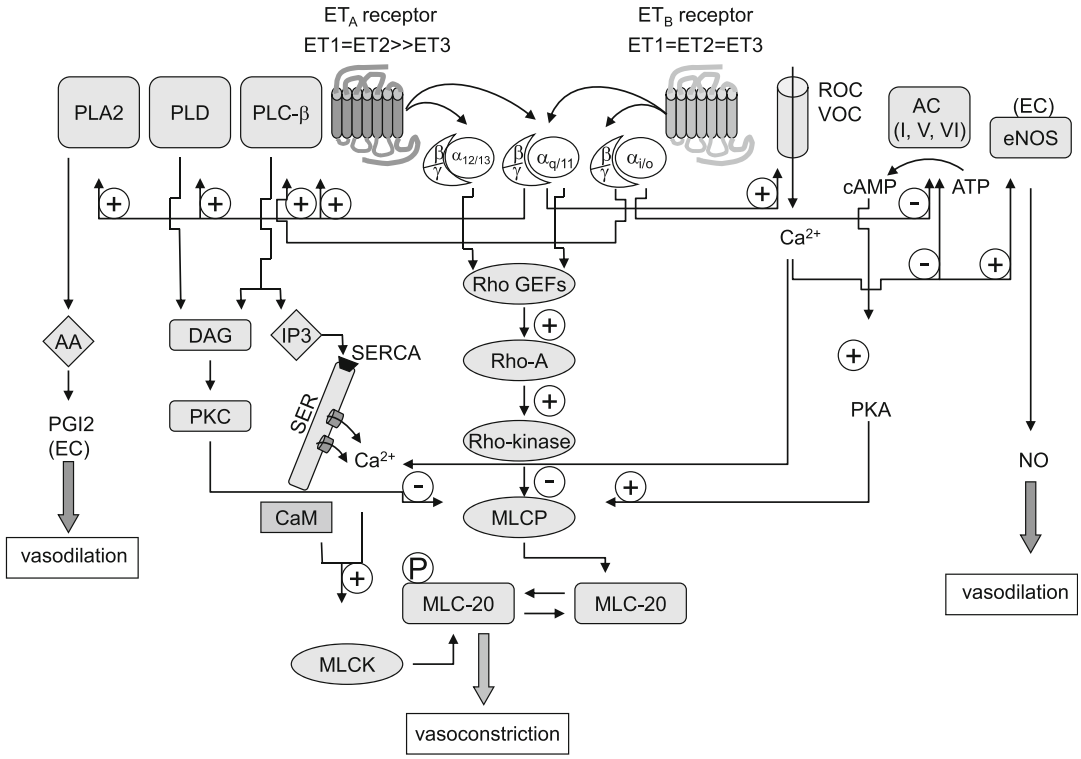
The ET_A receptor activates G proteins of the $G_{q/11}$ and $G_{12/13}$ family. The ET_B receptor stimulates G proteins of the G_i and $G_{q/11}$ family (Fig. 3). In endothelial cells, activation of the ET_B receptor



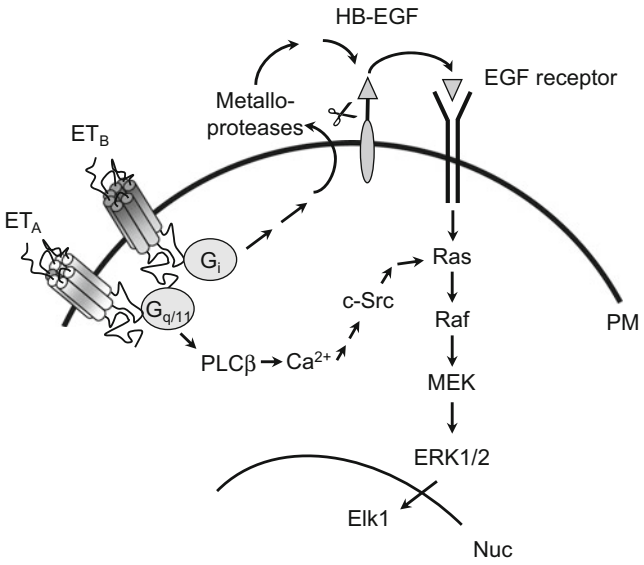
Endothelins, Fig. 2 Crystal structures of ET-1-bound and bosentan-bound ET_B-receptors. (**b**) PDB: 5XPR Inactive conformation of the ET_B receptor (beige) with antagonist bosentan (green). (**c**) Overlay of both crystal structures to visualize relative movement of TM6 by the agonist-bound state: ET-1 attracts transmembrane helix TM6 inwards (cyan) via R343 compared to antagonist bosentan (TM6 depicted in beige). (**d–f**) Respective views of the ligand-bound ET_B receptors from the intracellular side. (**d**) ET-1-bound state results in an intracellular outward movement of TM6 due to the kinked TM6 (cyan) opening a crevice that enables G-Protein binding. (**f**) Overlay of both crystal structures to visualize the outward movement of TM6 (cyan) in the ET-1 bound state compared to the bosentan-bound conformation (beige)

stimulates the release of NO and prostacyclin (PGI_2) *via* pertussis toxin-sensitive G proteins. In smooth muscle cells, the activation of ET_A receptors leads to an increase of intracellular calcium *via* pertussis toxin-insensitive G proteins of the $G_{q/11}$ family and to an activation of Rho proteins most likely *via* G proteins of the $G_{12/13}$ family. Increase of intracellular calcium results in a calmodulin-dependent activation of the myosin light chain kinase (MLCK, Fig. 3). MLCK phosphorylates the 20 kD myosin light chain (MLC-20), which then stimulates actin-myosin interaction of vascular smooth muscle cells resulting in vasoconstriction. Since activated Rho inhibits the myosin light chain phosphatase *via* Rho-kinase, the dephosphorylation of the MLC-20 is blocked. The dual action of the ET_A receptor signaling on MLC-20 results in a robust vasoconstriction of vessels. Beside the short-term effects such as vasodilation and vasoconstriction, endothelin receptors also stimulate long-term events (cell growth and differentiation). While stimulation of the ET_A receptor results in a transient, monophasic activation of ERK1/2 via a $G_{q/11}$-proteins, activation of the ET_B receptor elicits a long-lasting, bisphasic ERK1/2 activation involving a $G_{q/11}$- and a G_i-mediated pathway (Fig. 4) (Table 2).

ET-1 also stimulates antiapoptotic signal cascades in fibroblasts, vascular smooth muscle, and



Endothelins, Fig. 3 Summary of short-term signaling events mediated by endothelin. In endothelial cells (EC), the activation of the ET_B receptor leads to the formation of prostacyclin (PGI_2) and NO, thereby eliciting vasodilation. In vascular smooth muscle cells, activation of the ET_A receptor results in a robust vasoconstriction by a dual regulation of the 20 kD myosin light chain (MLC-20). *AA* arachidonic acid, *AC* adenylyl cyclase, *ATP* adenosine triphosphate, *CaM* Calmodulin, *cAMP* cyclic adenosine monophosphate, *DAG* diacyl glycerol, *eNOS* endothelial NO synthase, *IP3* inositol-3,4,5-phosphate, *MLC-20* 20 kD myosin light chain, *MLCP* myosin light chain phosphatase, *Rho-GEF* Rho-guanine nucleotide exchange factor, *SER* smooth endoplasmic reticulum, *IP3R* IP3 receptor, *PKA* protein kinase A, *PKC* protein kinase C, *PLA* phospholipase A, *PLC* phospholipase C, *PLD* phospholipase D



Endothelins, Fig. 4 Diagram of ET_A and ET_B receptor-mediated ERK1/2 activation. ET_A and ET_B receptor stimulate a transient ERK1/2 activation via G proteins of the $G_{q/11}$/PLCβ/Ca^{2+}/c-Src–dependent pathway. In addition, the ET_B receptor stimulates a second, long-lasting phase of ERK1/2 activation via a G_i protein/metalloprotease/HB-EGF/EGF receptor-dependent pathway. *ERK2* extracellular signal-regulated kinase, *HB-EGF* heparin-binding epidermal growth factor, *Nuc* nucleus, *PM* plasma membrane

endothelial cells (*via* phosphatidylinositol-3-kinase and Akt/protein kinase B). In prostate and ovarian cancer, upregulation of endothelin synthesis and ET_A receptors has been associated with a progression of the disease. The inhibition of ET_A receptors results in a reduced tumor growth (Nelson et al. 1995). In malignant melanoma, ET_B receptors are associated with tumor progression. Endothelins can also stimulate apoptosis in stretch-activated vessels *via* the ET_B receptor, which contrasts the above-mentioned effects. The molecular basis for these differential anti- and pro-apoptotic reactions mediated by endothelins remains elusive.

Activation of matrix metalloproteinases (MMP) is also involved in vascular and cardiac remodeling. For example, the fibrillar collagen matrix of the heart maintains the shape of the left ventricle. If the delicate balance between matrix deposition and degradation is altered, cardiac fibrosis (increase of collagen synthesis) or left ventricular remodeling (increase of degradation) occurs. Activation of ET_A receptors leads to a stimulation of MMP-1, -2, and -9 in isolated myocytes and in the myocardium and thereby contributes to ventricular remodeling after myocardial infarction.

Sites of Endothelin Receptor Expression

ET_A receptors are expressed in the smooth muscle cells of the vascular medial layer and the airways, in cardiac myocytes, lung parenchyma, bronchiolar epithelial cells, prostate epithelial cells, astrocytes, and sensory neurons. ET_B receptors are expressed in endothelial cells, in bronchiolar smooth muscle cells, vascular smooth muscle cells of certain vessels (e.g., saphenous vein, internal mammary artery), keratinocytes, in epithelial cells of renal proximal and distal tubules, the renal collecting duct, in the cells of the atrioventricular conducting system and in astrocytes.

In addition, ET_B receptors are upregulated in vessels with atherosclerotic lesions and in pulmonary vessels of patients with severe pulmonary hypertension. The upregulation can be attributed

Endothelins, Table 2 Summary of endothelin receptor antagonists or monoclonal antibodies directed against endothelin receptors registered or in clinical development (as of November 2019)

Drug	Stage of development	Antagonist/inhibitor of	Indication(s)
Bosentan	Registered	ET_A/ET_B receptor	Approved: PAH, Eisenmenger syndrome, Digital ulcers in Scleroderma
Ambrisentan	Registered	ET_A receptor	Approved: PAH also in combination with tadalafil for PAH. Ongoing: treatment of acute kidney injury after renal transplantation, hepatorenal disorders in patients with severe liver failure, portal hypertension in patients with liver cirrhosis
Macitentan	Registered	ET_A/ET_B receptor	Approved: PAH, Pre-registration (EU): CTEPH. Ongoing: Congenital heart defect; Cardiac failure
Sparsentan	Phase 3	dual AT_1 and ET_A receptor antagonist (DARA)	Ongoing: IgA nephropathy; Focal segmental glomerulosclerosis
Clazosentan	Phase 3	ET_A receptor	Ongoing: Intracranial vasospasm following aneurysmal subarachnoid hemorrhage
Aprocitentan	Phase 3	ET_A/ET_B receptor	Ongoing: Essential hypertension; Resistant hypertension
Zibotentan	Phase 2	ET_A receptor	Ongoing: Alzheimer's disease; Intermittent claudication; Scleroderma
GMA-301	Phase 1	ET_A receptor-targeted humanized IgG4 mAb	Ongoing: PAH
PMZ-2123	Clinical	ET_A receptor	Ongoing: Diabetic ketoacidosis, pain and opiate dependence
Sitaxsentan	Withdrawn	ET_A receptor	Withdrawn in 2010 due to risk of fatal liver injury (was approved in 2006 for PAH)

CTEPH chronic thromboembolic pulmonary hypertension, *mAb* monoclonal antibody, *PAH* pulmonary arterial hypertension

to increased ET_B receptor expression in smooth muscle cells and to ET_B receptors expressed on infiltrating macrophages.

In the vascular system, endothelial ET_B receptors mediate a transient vasodilation, whereas ET_A receptors cause a long-lasting vasoconstriction (Fig. 3). The role of ET_B receptors expressed on smooth muscle cells remains elusive. In some vessels, ET_B receptor stimulation causes vasoconstriction which is, however, only of transient nature and quantitatively much lower than that following ET_A receptor activation. In the kidney, ET_A receptors, which are almost exclusively expressed in vessels, regulate renal circulation, whereas ET_B receptors, expressed in the proximal and distal tubule and in the collecting duct, are involved in natriuresis and diuresis (Gupta et al. 2017). The main natriuretic action occurs most likely *via* the inhibition of the amiloride-sensitive sodium channel (ENaC). In the lung, endothelin causes long-lasting vaso- and bronchoconstriction. The contribution of each receptor subtype to the endothelin-evoked pulmonary responses is still controversial. The current data suggest that in the healthy lung ET_A receptors are involved primarily in pulmonary vasoconstriction and ET_B receptors in bronchoconstriction. In the central nervous system, ET_A receptors are expressed on smooth muscle cells of large and small cerebral arteries. In addition, ET_A receptors were also found to be expressed on endothelial cells isolated from capillaries and larger microvessels of the brain, but the physiological role of ET_A receptor expression in endothelial cells in the brain remains elusive. Further, ET_A receptors are expressed in small sensory C fibers. Activation of ET_A receptors in C fibers causes sensitization of tetrodotoxin-resistant sodium channels as well as of the polymodal receptor TRPV1. Interestingly, stimulation of ET_B receptors expressed in keratinocytes leads to the release of β-endorphines, thereby counter-acting ET_A receptor-mediated pain (Khodorova et al. 2003). Neurons, in particular those of the level III and IV of the cortex predominately express ET_B receptors. In isolated astrocytes, both receptor subtypes were found to be expressed at the cell surface.

Genetic Studies and Human Diseases

Mice homozygous for an ET_A receptor gene disruption show craniofacial malformations, such as cleft palate, micrognathia, microtia, and microglossia. ET_A (-/-) mice die shortly after birth due to respiratory failure. Mice with an ET-1-null mutation show the same cranciofacial malformations and, in addition, cardiovascular disorders (e.g., septal defects, abnormal cardial outflow tract, aortic arch, and subclavian arteries).

Mice with a disruption of the ET-3 or the ET_B receptor gene display pigment disorder and a megacolon. These disorders resemble isolated congenital megacolon (Hirschsprung's disease) or congenital megacolon associated with pigment disorders and cochlear hearing problems (Type 4 Waardenberg syndrome) can be caused by inactivating mutations in the ET-3 and the ET_B receptor gene (about 5% of patients with Hirschsprung's disease have ET_B receptor gene mutations). The lack of ET-3/ET_B receptor results in the absence of parasympathic ganglionic neurons in the myenteric plexus (Auerbach). Mice with an ET-3/ET_B receptor disruption die within two weeks after birth. In transgenic mice, in which the expression of the ET_B receptor is driven by the dopamine-β-hydroxylase promoter, normal myenteric plexus are present and no enteric disorder develops. These mice, however, show a salt-sensitive hypertension, which can be efficiently treated with amiloride, indicating that ET_B receptors are involved in the regulation of natriuresis *via* the amilorid-sensitive sodium channel ENaC.

Genome-wide association studies identified a significant association of intracranial aneurysm with rs6841581 immediately upstream of the EDNRA gene (encoding the ET_A receptor), linking endothelins to intracranial aneurysm pathogenesis. Other studies identified the gene encoding phosphatase and actin regulatory protein 1 (PHACTR1; 6p24) as a risk for coronary artery disease (CAD, increased risk) as well as migraine headache, cervical artery dissection,

fibromuscular dysplasia, and hypertension (reduced risk). By genetic fine mapping, epigenomic profiling, and CRISPR/Cas9 genome editing, G allele at rs9349379 was identified as the causal variant, resulting in higher EDN1 expression (Gupta et al. 2017). The increase in CAD risk, but reduced risk for hypertension, may be attributable to the different actions via ET_A and ET_B receptors, for example, ET_A receptor mediated vasoconstriction and vascular smooth muscle cell proliferation and ET_B receptor-mediated vasodilation and natriuresis and diuresis.

The genetically engineered disruption of the ECE1 gene causes craniofacial and cardiovascular malformations (ET-1/ET_A receptor phenotype), congenital megacolon and pigment disorders (ET-3/ET_B receptor phenotype). The ECE-2 (–/–) mice do not display any abnormality, indicating that ECE-1 is of crucial importance in embryonic development. Strikingly, ECE-1 (–/–) mice and ECE-1 (–/–)/ECE-2 (–/–) mice still have about 60% of wild-type ET-1 levels. This result indicates that alternative pathways in the generation of mature ET-1 exist (e.g., NEP). This alternatively generated ET-1, however, cannot compensate for the embryogenic defects (Yanagisawa et al. 2000).

ECE isoforms are also involved in the degradation of amyloid Aβ protein. A genetic variant of ECE-1 with an increased transcriptional activity is associated with a decreased risk for AD. Thus, the inhibition of ECE in the CNS may increase the risk for the development of Alzheimer's disease (AD).

In malignant prostate epithelial cells, auto- and paracrine release of ET-1 is a critical factor in ET_A receptor-mediated proliferation (Nelson et al. 1995). In addition, the ET-1/ET_A receptor axis has emerged as a potential target in prostate cancer bone metastasis.

Drugs

Clinical Use

Endothelins mediate potent vasoconstrictor effects. A great number of ECE-inhibitors and mixed and selective ET_A and ET_B receptor antagonists have been developed in the past (e.g., acute and chronic heart failure, pulmonary hypertension, subarachnoid hemorrhage, chronic kidney disease, and prostate and ovarian cancer).

For specific inhibitors of ECE, however, only very limited effects on the endothelin system were found and there is no ongoing development reported. The limited potency of ECE inhibition might be due to the generation of mature ET-1 from big-ET-1 by other proteases such as neutral endopeptidase or other currently unidentified proteases. Dual inhibition of ECE and NEP might inhibit ET-1 generation more efficiently; however, dual inhibition of ECE and NEP could also increase the risk for the development of AD, as both enzyme classes are involved in the degradation of Aβ protein.

In the case of receptor antagonists, it is still unknown whether mixed antagonism of endothelin receptors or selective blockade of ET_A receptors is of greater benefit in the treatment of diseases. At present three endothelin receptors have been approved for treatment of pulmonary arterial hypertension (PAH) of which ambrisentan is a selective ET_A receptor antagonists and bosentan and macitentan are mixed ET_A/ET_B receptor antagonists (Table 2). The current data suggest that ET_A receptor is critical for the treatment effect and inhibition of the ET_B receptor may have some additional benefit (due to upregulation of ET_B receptors in pulmonary vascular smooth muscle). However, no direct comparisons of ET_A receptor vs mixed ET_A/ET_B receptor antagonists have been done to explore this question. Several clinical trials with selective ET_A receptor and mixed ET_A/ET_B receptor antagonists are ongoing involving Alzheimer's disease, intermittent claudication, scleroderma, and subarachnoid hemorrhage. Further notable developments are the first dual AT1 and ET_A receptor antagonist (DARA) in IgA nephropathy and focal segmental glomerulosclerosis and the first monoclonal antibody directed against the ET_A receptor in PAH (Table 2). Oncological studies in ovarian and prostate

cancer as well as nonsmall cell lung cancer were investigated in phase 2 and 3 clinical studies but have been discontinued following failures to meet the primary endpoints.

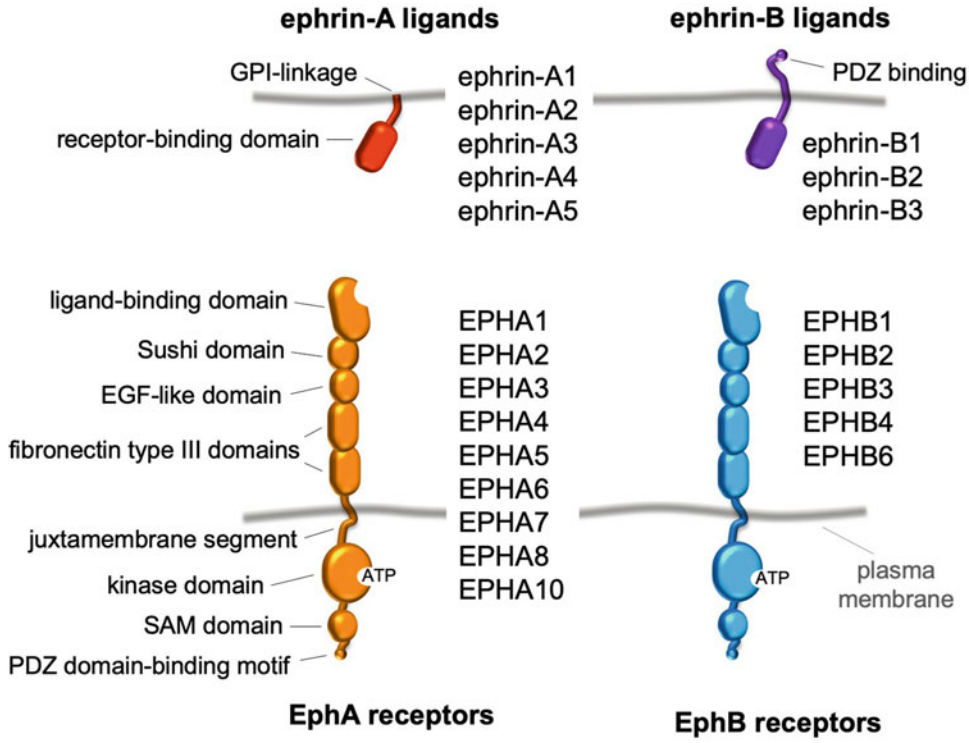
Definition

The Eph receptors are the largest of the tyrosine kinase families. There are nine EphA and five EphB receptors, subdivided based on sequence similarities in their kinase domains (Fig. 1) (Pasquale 2005; Kania and Klein 2016). The subdivision also reflects ligand preferences. The activating ligands for the Eph receptors are the ephrins (*Eph* *r*eceptor-*in*teracting proteins), which include five ephrin-As and three ephrin-Bs (Fig. 1). The EphA receptors preferentially bind the ephrin-A ligands, and the EphB receptors preferentially bind the ephrin-B ligands, but some interactions can also occur between the A and B subfamilies of receptors and ligands. Eph receptors and/or ephrins are expressed in most, if not all, cell types and represent an important cell contact-dependent communication system that regulates many physiological and pathological



Eph Receptors and Ephrins, Fig. 1 Schematic illustrating the domain structure of Eph receptors and ephrins. Both ephrins and Eph receptors are subdivided into A and B subfamilies, whose members are indicated. The ephrin-binding pocket is shown as a cavity in the ligand-binding domain of the Eph receptors, and the ATP-binding pocket in the kinase domain is also indicated (ATP)

processes. Therefore, there is strong interest in developing pharmacological agents capable of targeting them for medical applications.

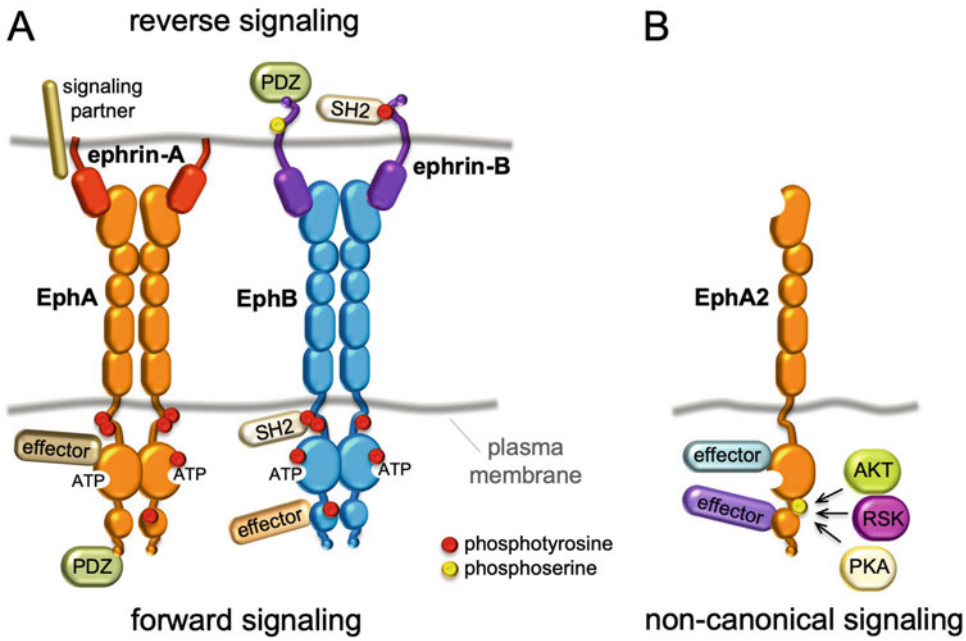
Basic Characteristics

Domain Structure

All Eph receptors have the same domain structure, including an extracellular region containing multiple domains, a single transmembrane helix, and a cytoplasmic region containing the tyrosine kinase domain (Fig. 1). The kinase domains of the EPHA10 and EPHB6 receptors lack residues needed for catalytic activity and are therefore inactive. The ligand-binding domains of the Eph receptors contain a pocket that interacts with a loop from the receptor-binding domain of the ephrins. In the ephrin-As, this domain is followed by a linker and a glycosylphosphatidylinositol (GPI) group mediating attachment to the plasma membrane (Fig. 1). The ephrin-Bs contain a transmembrane helix and a short cytoplasmic region. Alternatively spliced variants and proteolytically cleaved forms of Eph receptors and ephrins increase structural and functional diversity (Lisabeth et al. 2013; Barquilla and Pasquale 2015).

Signal Transduction

Eph receptors and ephrins interact with each other *in trans* across intercellular junctions, which leads to the lateral dimerization and oligomerization of multiple Eph receptor/ephrin complexes and downstream signaling (Pasquale 2005; Kania and Klein 2016). Complexes assembled at sites of cell-cell contact mediate bidirectional signals that affect the behavior of both interacting cells



Eph Receptors and Ephrins, Fig. 2 Eph receptor and ephrin signaling. (**a**) Bidirectional signaling. Eph receptors interact with ephrins across cell-cell junctions. The interaction leads to dimerization of Eph receptor/ephrin complexes, which then can assemble into larger oligomers (not shown). Dimerization and oligomerization cause receptor autophosphorylation on tyrosine residues and increase in kinase activity and binding of signaling effectors resulting in forward signaling. The ephrin-B ligands can also be phosphorylated, for example, on tyrosine residues by associated SRC family kinases and on serine residues by serine/threonine kinases, resulting in reverse signaling. Ephrin-A ligands can also mediate reverse signaling through association with transmembrane signaling partners. (**b**) EPHA2 non-canonical signaling through S897 phosphorylation. The AKT, RSK, and PKA serine/threonine kinases trigger EPHA2 non-canonical signaling through phosphorylation of S897 in the linker connecting the kinase and SAM domains of the receptor. SH2, protein containing an SH2 domain that interacts with an Eph receptor/ephrin-B tyrosine-phosphorylated motif; PDZ, protein containing a PDZ domain that interacts with a binding motif in the C-terminus of an Eph receptor or ephrin-B; effector, protein that transduces downstream signals

(known as "forward signals" for the Eph receptors and "reverse signals" for the ephrins; Fig. 2A). Eph/ephrin complexes can also mediate unidirectional signaling, for example, when proteolytically cleaved ephrin-As function as soluble ligands or when Eph receptors or ephrins are deployed on extracellular vesicles (such as exosomes) to interact with distant cells.

Eph Receptor Signaling

Eph receptor dimerization/oligomerization induced by ephrin binding enables cross-phosphorylation of neighboring receptor molecules (Fig. 2A) (Boyd et al. 2014; Barquilla and Pasquale 2015; Kania and Klein 2016). Three of the resulting tyrosine autophosphorylation sites, two in the juxtamembrane segment and one in the activation loop of the kinase domain (Figs. 1 and 2A), are important for Eph receptor kinase activity. In addition, the phosphorylated tyrosines create binding sites for a variety of effectors, including kinases, phosphatases, guanine nucleotide exchange factors, GTPase-activating proteins, adaptors, and scaffolding proteins (Fig. 2A). A carboxy-terminal PDZ domain-binding motif present in most Eph receptors also mediates association with binding partners that regulate Eph receptor localization and function (Figs. 1 and 2A). In some cases, the Eph receptors regulate the activity of downstream effectors by phosphorylating them.

Like other receptor tyrosine kinase families, the Eph receptors control the activity of central cellular signaling networks, such as those involving the RAS-ERK MAP kinase cascade, PI3-kinase-AKT-mTORC1, ABL-CRK, NF-kB, and the RHO small GTPase family (Pasquale 2010; Boyd et al. 2014; Kania and Klein 2016). However, Eph receptor forward signaling has distinctive characteristics. For example, in many cell types, the Eph receptors inhibit ERK and AKT, whereas other receptor tyrosine kinases typically activate them. Furthermore, while ephrins expressed by neighboring cells promote Eph receptor forward signaling, ephrins co-expressed on the same cell surface can attenuate forward signaling through lateral *cis* interactions with the Eph receptors (Lisabeth et al. 2013).

Besides their "canonical" forward signaling activities, the Eph receptors are capable of additional "non-canonical" forms of signaling. For example, the linker connecting the kinase and SAM domains of EPHA1 and EPHA2 contains a serine (S897 in EPHA2), which is not present in other Eph receptors. The phosphorylation of this serine by kinases such as RSK, AKT, and PKA is responsible for a "non-canonical" form of EPHA2 signaling that does not require ligand binding or kinase activity (Barquilla and Pasquale 2015; Zhou and Sakurai 2017) (Fig. 2B). However, it is not well understood how S897 phosphorylation regulates EPHA2 downstream signaling pathways, such as those involving ephexin4 and leading to the activation of the RAC RHO family GTPase and the PI3-kinase-AKT pathway (Lisabeth et al. 2013).

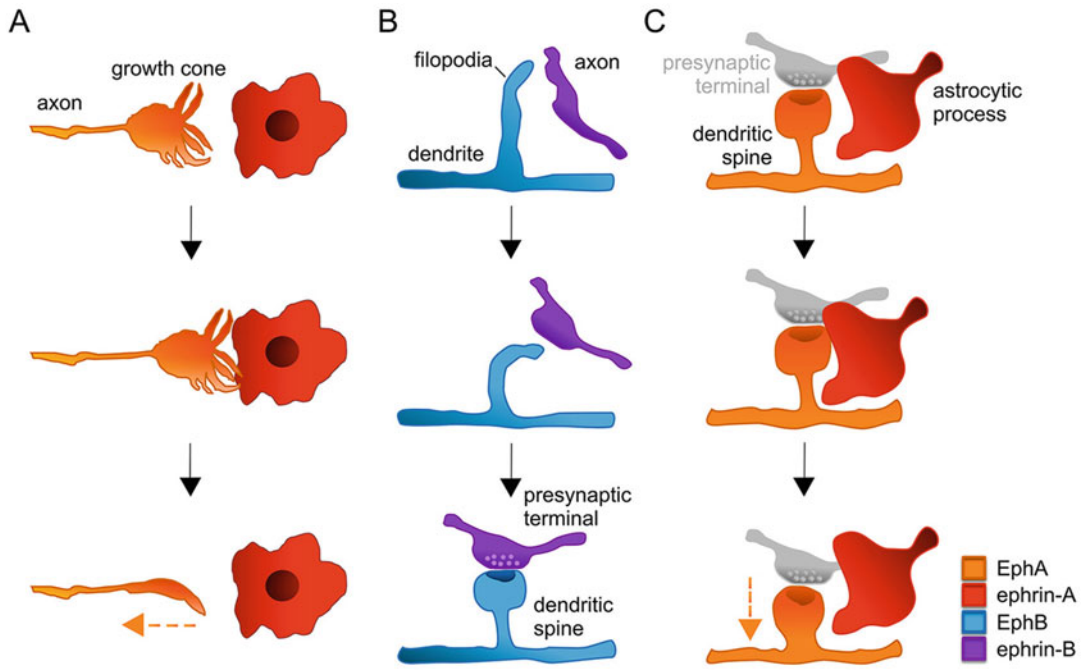
Other Eph receptors are endowed with ligand- and/or kinase-independent signaling ability, which can cause different effects than forward signaling (Pasquale 2010; Boyd et al. 2014). For example, EPHA10 and EPHB6 can signal despite lacking kinase activity (Liang et al. 2019). Their kinase domains can still bind ATP, which regulates folding of the domain and thus the non-catalytic signaling functions of these two pseudokinases. EPHA10 and EPHB6 can also be phosphorylated by other tyrosine kinases, such as other Eph receptors or SRC family kinases, to serve as scaffolds for downstream signaling effectors. In addition, association with EPHA10 and EPHB6 changes the signaling output of other Eph receptors (Liang et al. 2019).

Ephrin Signaling

The ephrin-As do not have a cytoplasmic portion, but can nevertheless transmit reverse signals through association with transmembrane co-receptors such as the RET and TRKB receptor tyrosine kinases and the p75 neurotrophin receptor (Fig. 2A) (Barquilla and Pasquale 2015; Kania and Klein 2016). Upon interaction with EphB receptors, the ephrin-B cytoplasmic region can be phosphorylated on tyrosine and serine residues by various kinases (Fig. 2A), including SRC family kinases. The resulting phosphorylated motifs regulate interactions with effector molecules such as NCK2, STAT3, and RHO family GTPases (Coulthard et al. 2012; Lisabeth et al. 2013; Boyd et al. 2014). Interactions mediated by their carboxy-terminal PDZ domain-binding motif also contribute to ephrin-B reverse signaling (Fig. 2A). Forms of ephrin-B signaling that do not depend on EphB receptor binding have also been reported and involve phosphorylation by several receptor tyrosine kinases or physical association with other transmembrane proteins such as Claudin-5 (Pasquale 2005; Barquilla and Pasquale 2015).

Cellular Effects of Eph Receptor/Ephrin Signaling

Eph receptors and ephrins regulate cell morphology and motility through their effects on the actin cytoskeleton, cell-substrate adhesion, and cell-cell interaction (Pasquale 2005, 2010; Boyd et al. 2014; Kania and Klein 2016). Cell repulsion is the most characteristic response observed after encounters of two cells in which Eph receptors and ephrins engage across adjacent plasma membranes, initiating forward and reverse signaling. These repulsive effects cause one or both of the cells to locally retract, leading to the separation of the two plasma membranes that were initially in contact (Fig. 3). They play a role, for example, in "contact-inhibition of locomotion," cell sorting and growth cone collapse. The repulsive effects are counterintuitive, because Eph receptor-ephrin complexes can mediate a strong adhesion between two cells. Two mechanisms have been described



Eph Receptors and Ephrins, Fig. 3 Eph receptor/ephrin signaling regulates the formation and remodeling of neuronal connections. (**a**) Growth cone collapse. When an Eph receptor-expressing growth cone at the tip of a growing axon encounters an ephrin-expressing cell, the growth cone collapses and the axon may retract before resuming growth in a different direction. (**b**) Dendritic spine formation. When an EphB-expressing filopodial protrusion on a dendrite comes in contact with an ephrin-B-expressing axon, it may form a synaptic connection. In the case of excitatory synapses, EphB forward signaling in the postsynaptic terminal leads to shortening of the filopodium and its maturation into a dendritic spine, characterized by an enlarged head and a narrow neck. (**c**) Dendritic spine remodeling through neuron-astrocyte interaction. When a dendritic spine expressing EPHA4 comes in contact with a perisynaptic astrocyte process expressing ephrin-A3, it locally retracts and may shorten or collapse

that enable cell separation. The first involves extracellular proteolytic cleavage of Eph receptor/ephrin complexes, abrogating their ability to connect two cells. In the second, a cell internalizes vesicles containing intact Eph receptor/ephrin complexes by removing a portion of the plasma membrane from the adjacent cell. In certain cellular contexts, however, Eph receptors and ephrins can also promote cell-cell adhesion (e.g., when repulsive signaling is weak). Other activities of forward and/or reverse signaling include regulating cell proliferation, survival, and metabolism. EPHA2 non-canonical signaling through S897 phosphorylation elicits very different responses, for example, promoting epithelial-mesenchymal transition and cell migration (Barquilla and Pasquale 2015; Zhou and Sakurai 2017).

Physiological and Pathological Functions

Nervous System

Eph receptors and ephrins are crucial mediators of cell-cell communication in the developing and adult nervous system, where many of them are highly expressed. During neural development, the Eph/ephrin system controls neurogenesis, cell sorting and the formation of tissue boundaries, neuronal migration, axon guidance, and the establishment and pruning of neuronal connections (synapses) (Kania and Klein 2016; Henderson and Dalva 2018). A well-known role is to guide the development of highly ordered neuronal circuits by regulating both the position of neurons and the formation of precisely organized connections between them (Pasquale 2005; Kania and

Klein 2016). One of the first recognized roles of Eph receptors and ephrins is as positional labels that regulate the establishment of topographic neuronal connections, such as those in the visual system. Neurons in the retina extend long axons to reach their synaptic partners in the visual centers of the brain. The spatial organization of the retinal neurons is maintained in their connections, so that axons from neighboring retinal neurons form synapses with neighboring brain neurons. This is in part controlled by gradients of Eph receptor and ephrin expression in the retina and the visual centers of the brain. For example, retinal growth cones with high EphA receptor expression avoid regions with high ephrin expression due to the repulsive effects mediated by forward signaling (Fig. 3A).

The Eph/ephrin system also controls the ability of axons to cross the body midline and form connections in the contralateral side. For instance, EPHA4 knockout mice display a hopping gait caused by the inappropriate midline crossing of spinal cord axons, due to their inability to sense the repulsive effects of ephrins expressed at the midline (Kania and Klein 2016). In addition, inactivation of a number of Eph receptor and ephrin genes in the mouse results in anatomical abnormalities in the axonal structures that connect the left and right sides of the brain and spinal cord (commissures). Eph receptor/ephrin repulsive effects also play an important role in the proper development of other long-distance axonal projections, such as the motor axons connecting the brain with the spinal cord or the spinal cord with muscles.

Eph receptors and ephrins also play an important role in the formation of synaptic connections between axons and dendrites. EphB signaling increases the motility of dendritic filopodial protrusions, facilitating contact with ephrin-B-expressing axons (Pasquale 2008; Henderson and Dalva 2018) (Fig. 3B). The contacts may then be stabilized, or lost due to retraction of the filopodium, depending on the kinetics of EphB forward signaling. The interaction between EphB receptors and ephrin-Bs, which can both be expressed either pre- or postsynaptically depending on the type of synapse, also promotes the maturation of functional presynaptic terminals and of the knob-like postsynaptic structures known as dendritic spines (Pasquale 2008; Lisabeth et al. 2013; Kania and Klein 2016; Henderson and Dalva 2018) (Fig. 3B). Dendritic spines are characteristic of excitatory synapses, and their shape is functionally important in the regulation of synaptic transmission by compartmentalizing the postsynaptic space from the dendritic shaft.

Once dendritic spines mature, the repulsive action of the EphA/ephrin-A system regulates their morphology (Fig. 3C). EPHA4 is expressed in mature dendritic spines and interacts with ephrin-A3 in perisynaptic astrocytic processes (Lisabeth et al. 2013; Kania and Klein 2016; Henderson and Dalva 2018). This leads to localized repulsive effects that regulate dendritic spine remodeling. Interestingly, reverse signaling through ephrin-A3 in the astrocyte processes decreases the levels of transporters that take up the neurotransmitter glutamate released during synaptic transmission. This effect is critical for activity-dependent synaptic plasticity, which underlies learning and memory formation.

Eph receptors and ephrins continue to be expressed in the adult nervous system, although typically at lower levels than during development. Besides its role in synapse formation, in the adult nervous system, the EphB/ephrin-B system also regulates synaptic plasticity through effects on ion channels and the actin cytoskeleton (Pasquale 2008; Kania and Klein 2016; Henderson and Dalva 2018). Thus, both EPHA and EPHB receptors are crucial for synaptic plasticity. In fact, many studies implicate EphB/ephrin-B upregulation in the abnormal synaptic plasticity that occurs as a consequence of nerve damage and causes neuropathic pain (Barquilla and Pasquale 2015; Henderson and Dalva 2018). Furthermore, Eph receptors and ephrins are upregulated in multiple cell types in the injured nervous system, where their repulsive effects can negatively affect neural repair and nerve regeneration. Indeed, lowering EPHA4 expression or activity in rodent models can promote functional recovery after stroke and muscle reinnervation after nerve injury (Boyd et al. 2014; Barquilla and Pasquale 2015; Ling et al. 2018). Thus, Eph

receptors and ephrins are considered promising therapeutic targets to treat chronic pain and promote neural repair.

Epithelia

A number of Eph receptors and ephrins are expressed in epithelial cells, for example, in the skin, the lens, and the intestine. In the skin, the Eph/ephrin system plays a role in organizing the stratified layers of proliferating and differentiating keratinocytes, with EPHA2 and ephrin-A1 being particularly important for epidermal homeostasis (Lin et al. 2012). Multiple Eph receptors and ephrins are also expressed in hair follicles, where they affect stem cell position, self-renewal, and differentiation (Lin et al. 2012; Boyd et al. 2014). In the eye, EPHA2 and ephrin-A5 have been implicated in maintaining the integrity of cell-cell junctions in the lens epithelium, which is critical for the transparency of the lens (Lisabeth et al. 2013). Indeed, mutations impairing EPHA2 function can lead to cataracts. The EphB/ephrin-B system plays a critical role in the intestine, where epithelial cells are generated from EPHB2-expressing stem cells at the bottom of the crypts and migrate over several days toward the tips of the villi, before being shed (Pasquale 2008). As the cells migrate and differentiate, they lose EphB expression and acquire ephrin-B expression. The resulting opposite gradients of EphB receptors (highest in newly generated cells in the crypts) and ephrin-Bs (highest in the differentiated cells near the tip of the villi) control the position of the epithelial cells as they migrate along the crypt-villus axis.

Cardiovascular and Lymphatic Systems

Eph receptors and ephrins play critical roles in the development and homeostasis of the cardiovascular and lymphatic systems (Barquilla and Pasquale 2015; Boyd et al. 2014). This is exemplified by the early embryonic lethal phenotype due to severe defects in heart and blood vessel development, caused by inactivation of the EPHB4 or ephrin-B2 genes in the mouse (Boyd et al. 2014; Zeng et al. 2019). Inactivation of other Eph receptor and ephrin genes in the mouse also causes various abnormalities in heart development and function, suggesting roles for multiple family members in different aspects of cardiac development (Barquilla and Pasquale 2015; Boyd et al. 2014).

In most of the vasculature, EPHB4 and ephrin-B2 define venous and arterial endothelial cells, respectively (Boyd et al. 2014; Finney and Orr 2018). Consistent with the importance of these genes, EPHB4 and ephrin-B2 mutations in humans and gene inactivation in animal models have been linked to severe cerebrovascular malformations (Zeng et al. 2019). The EphB/ephrin-B system, particularly ephrin-B2, is also critical for the development of the lymphatic system (Boyd et al. 2014). In the adult, ephrin-A1/EPHA2 and ephrin-B2/EPHB4 are the most important family members that promote pathological forms of angiogenesis, including tumor angiogenesis (Barquilla and Pasquale 2015; Boyd et al. 2014). Interestingly, ephrin-B2 promotes endocytosis of the VEGFR2 and VEGFR3 vascular endothelial growth factor receptors, which surprisingly enhances the signaling ability of these receptors in the vasculature (Barquilla and Pasquale 2015).

Members of the Eph receptor and ephrin families are also expressed in perivascular support cells, such as pericytes and smooth muscle cells, and, in the brain, astrocytes (Barquilla and Pasquale 2015; Finney and Orr 2018). In these cells, they mediate interactions with endothelial cells, which is critical for vascular development and mature vessel integrity. In fact, disruption of Eph receptor/ephrin function in vascular support cells can destabilize blood vessels, leading to hemorrhage or increasing permeability, for example, in cancer, inflammatory processes, and possibly neurodegenerative diseases. In the adult, the EphB/ephrin-B system can also affect blood pressure through regulation of vascular smooth muscle contractility (Finney and Orr 2018; Zeng et al. 2019). In addition, EPHA2 is expressed in multiple cell types involved in the development of atherosclerotic plaques and contributes to disease pathology, thus representing a potentially important target against cardiovascular disease (Funk and Orr 2013; Finney and Orr 2018).

Immune System

Multiple Eph receptors and ephrins have been implicated in immune cell development, trafficking throughout the body, and activation (Pasquale 2008; Darling and Lamb 2019). Eph receptor/ephrin bidirectional signaling is particularly well-suited to play a role in the cell-cell communication processes that are critical for immune cell development and function. For example, the interaction of ephrin-B2 in hematopoietic progenitor cells with EPHB4 in bone marrow stromal cells promotes the release of progenitor cells from the bone marrow into the circulation. Furthermore, Eph/ephrin system-mediated communication between the hematopoietic progenitors that colonize the thymus (thymocytes) and thymic stromal cells controls thymocyte trafficking within the thymus, survival, maturation into T cells, and T cell selection (Pasquale 2008). In lymphoid organs, the interplay between ephrin-B1 expressed by germinal center B lymphocytes and EPHB4/EPHB6 expressed by follicular T helper cells regulates activated T cell trafficking and cytokine secretion and thus B lymphocyte selection and efficient plasma cell formation/affinity maturation during immune responses (Darling and Lamb 2019). EPHB receptors and ephrin-Bs are widely expressed in subsets of T cells and can enhance T cell receptor signaling (Pasquale 2008; Darling and Lamb 2019). High ephrin-B1 and ephrin-B2 levels, however, have also been linked to negative feedback mechanisms that dampen T cell receptor signaling. The EphA/ephrin-A system regulates T cell differentiation and trafficking. In addition, Eph receptor-/ephrin-mediated leukocyte interactions with endothelial cells enable extravasation across the blood vessel wall during routine immune surveillance and in response to damage or infection (Funk and Orr 2013). Furthermore, EPHA2 promotes blood vessel permeability during inflammation, and various other Eph receptors and ephrins play a role in diseases involving inflammatory processes, such as atherosclerosis (see above), inflammatory bowel disease, and arthritis (Coulthard et al. 2012; Funk and Orr 2013; Darling and Lamb 2019).

Other Functions

Given the large number of Eph receptors and ephrins and their widespread expression in most cell types, the Eph/ephrin system has a multitude of diverse physiological and pathological functions besides those outlined above (Pasquale 2008; Boyd et al. 2014). For example, EphA forward signaling and ephrin-A reverse signaling in pancreatic cells play opposite roles in the regulation of glucose homeostasis (Pasquale 2008). In addition, both A and B Eph receptors and ephrins play a role in bone remodeling through the regulation of both osteoblasts and osteoclasts (Pasquale 2008; Boyd et al. 2014). In some cases, the effects of human mutations have revealed unexpected functions. For example, EPHB2 mutations have been linked to functional defects in platelets causing severe bleeding (Darling and Lamb 2019), and ephrin-B1-inactivating mutations cause craniofrontonasal syndrome, a disease involving defects in the fusion of bones in the developing skull (Boyd et al. 2014). In addition, as mentioned above, EPHA2 mutations cause cataracts (Lisabeth et al. 2013), and EPHB4 mutations cause venous malformations (Zeng et al. 2019).

Diseases

Cancer

Many Eph receptors and ephrins, and most notably EPHA2 and EPHB4, are aberrantly expressed in cancer cells, cancer stem cells, and the tumor microenvironment (Pasquale 2010; Boyd et al. 2014; Barquilla and Pasquale 2015). Their activities affect cancer progression through a multitude of complex mechanisms and signaling pathways that can promote but also inhibit cancer malignancy. The effects of Eph receptor/ephrin signaling in tumors depend on the cellular context and interplay with other signaling systems, such as the epidermal growth factor and fibroblast growth factor receptor families, integrins, oncogenic pathways, and metabolic networks.

An opposite regulation of Eph receptor versus ephrin expression in cancer cells often results in low activation of bidirectional signaling (Pasquale 2010). This is consistent with the tumor-

suppressive activities that can be elicited by Eph receptor forward signaling, such as inhibition of the AKT and ERK oncogenic pathways or integrin-mediated adhesion. In addition, forward signaling induced in cancer cells by ephrins present in normal cells surrounding a tumor can limit tumor expansion through repulsive effects. For example, EphB/ephrin-B signaling plays a tumor-suppressive role in the intestine, where precancerous lesions (adenomas) typically express EphB receptors but form in ephrin-B-expressing regions (Pasquale 2010; Barquilla and Pasquale 2015; Kania and Klein 2016). As a consequence, loss of EphB receptor expression can drive colorectal cancer progression. Furthermore, cell repulsion triggered by an imbalance of EPHA2 forward signaling in an epithelial monolayer can lead to the extrusion of a cell in which EPHA2 is upregulated by HRAS (Porazinski et al. 2016). This may represent a safeguard against development of tumors originating from cells that acquire an oncogenic RAS mutation. On the other hand, repulsion between tumor cells expressing Eph receptors and ephrins can lead to their dispersion, increasing the metastatic potential of these more resilient cells (Barquilla and Pasquale 2015).

Eph receptors can promote tumorigenesis through non-canonical signaling mechanisms that do not involve kinase activity (Pasquale 2010; Boyd et al. 2014; Barquilla and Pasquale 2015). This is exemplified by EPHA2 signaling through S897 phosphorylation, which has been shown to promote invasiveness, metastasis, cancer stem cell properties, and drug resistance. Non-canonical oncogenic signaling activities of other Eph receptors have also been documented, but are not as widely studied. Reverse signaling can also promote cancer malignancy. For example, ephrin-Bs have been linked to increased invasiveness in glioblastoma.

Typically multiple Eph receptors are co-expressed in cancer cells and likely assemble together into oligomers whose signaling effects may depend on the Eph receptor composition and mutational status (Boyd et al. 2014). The Eph receptors are highly mutated in cancer, although mutational hotspots are rare and most mutations are heterozygous. Some of the mutations have been shown to disrupt receptor functions such as ligand binding and kinase activity, supporting a tumor-suppressing role for forward signaling (Lisabeth et al. 2013; Barquilla and Pasquale 2015). However, the functional role of most Eph receptor cancer mutations and the extent of their contribution to cancer progression remain to be demonstrated. It will be interesting to determine whether heterozygous mutations in different Eph receptors have synergistic effects in signaling clusters comprising multiple receptors.

Tumors can hijack the physiological activities of the Eph/ephrin system. A well-known example involves tumor angiogenesis, which supports tumor progression, particularly through the activities of ephrin-A1/EPHA2 and ephrin-B2/EPHB4 (Pasquale 2010; Boyd et al. 2014; Barquilla and Pasquale 2015). Another role that is increasingly attracting attention is the modulation of anti-tumor immune responses through interactions of immune cells with various tumor cellular components.

Neurodegeneration

An increasing number of studies suggest that deregulation of Eph receptor/ephrin signaling plays a role in neurodegenerative diseases (Boyd et al. 2014; Barquilla and Pasquale 2015; Henderson and Dalva 2018). For instance, EPHA4 was identified as a modifier gene in amyotrophic lateral sclerosis (ALS), a fatal disease involving a progressive motor neuron degeneration. Studies in ALS animal models suggest that decreasing EPHA4 expression or pharmacological inhibition of EPHA4-ephrin interaction could be of therapeutic benefit. Consistent with this, low EPHA4 mRNA levels or EPHA4 loss-of-function mutations in ALS patients correlate with late disease onset and prolonged survival.

Excessive EPHA4 signaling has also been implicated in Alzheimer's disease, which is characterized by cognitive decline due to a progressive loss of synapses and neurons (Boyd et al. 2014; Barquilla and Pasquale 2015; Henderson and Dalva 2018). Elevated EPHA4 tyrosine phosphorylation has been detected in the brain of Alzheimer's patients and mouse models.

Interestingly, β-amyloid oligomers, which are characteristic of Alzheimer's brain pathology, promote EPHA4 activation leading to neurotoxicity in culture. Furthermore, inhibiting EPHA4 expression or function ameliorates disease pathology in cell culture and mouse Alzheimer's models. In contrast, β-amyloid oligomers cause EPHB2 loss, which contributes to disease pathology since restoration of EPHB2 levels or pharmacological inhibition of EPHB2 interaction with β-amyloid can reverse cognitive and behavioral defects in mouse Alzheimer's models. Thus, it could be therapeutically beneficial to inhibit EPHA4 and increase EPHB2 activity. Several single nucleotide polymorphisms in non-coding regions of the EPHA1 gene and missense mutations in the coding region have been linked to late-onset Alzheimer's disease. However, EPHA1 has limited expression in neural cells, and the pathological role of the polymorphisms and mutations remains to be determined.

Single nucleotide polymorphisms in several Eph receptors have also been associated with Parkinson's disease, a neurodegenerative disorder characterized by motor and cognitive symptoms caused by a progressive loss of dopaminergic neurons (Boyd et al. 2014; Barquilla and Pasquale 2015). In addition, a study has shown that a soluble form of ephrin-A1 (ephrin-A1 Fc) promotes the regeneration of the brain dopaminergic neurons that are lost in a rat Parkinson's model, suggesting a possible strategy for therapeutic intervention. Overall, additional studies are needed to better understand the role of the Eph/ephrin system in neurodegenerative diseases and its therapeutic potential.

Parasitic Infections

EPHA2 can enable or facilitate infections by a wide variety of parasites, including (1) viruses such as Kaposi's sarcoma-associated herpesvirus (KSHV; an oncogenic virus that causes Kaposi's sarcoma and B lymphocyte malignancies), the hepatitis C virus, and the Epstein-Barr virus (which causes mononucleosis and several cancers); (2) the malaria parasite *Plasmodium*; (3) bacterial pathogens such as *Chlamydia* and *Staphylococcus*; and (4) fungal pathogens such as *Candida albicans* and *Cryptococcus neoformans* (Pasquale 2008; Barquilla and Pasquale 2015; Darling and Lamb 2019). EPHA2 may be particularly suitable to promote the uptake of parasites into host cells because of its propensity to move inside the cell by endocytosis or macropinocytosis when bound to a ligand (or a pathogen that mimics a ligand). Non-canonical EPHA2 signaling through S897 phosphorylation has also been implicated in some infections, although the precise mechanism remains to be determined. In some cases EPHA2 has additional roles besides serving as an entry receptor or co-receptor for a pathogen. For example, EPHA2 non-canonical signaling through S897 phosphorylation supports the growth and survival of *Chlamydia*-infected cells as well as promotes proinflammatory responses in *Candida*-infected epithelial cells and antifungal responses in neutrophils. EPHA2 also helps *Cryptococcus* cross the blood-brain barrier. Additional studies are also beginning to implicate other EphA receptors in infectious diseases (Darling and Lamb 2019).

Among the ephrins, ephrin-B2 and ephrin-B3 serve as entry receptors for several henipaviruses, a zoonotic family of viruses that in humans cause highly lethal respiratory and encephalitic pathologies (Pasquale 2008; Barquilla and Pasquale 2015). The preferential expression of the two ephrins in the brain and blood vessels and their conservation in mammals explain the tropism of these viruses and their ability to cross from bats and farm animals to humans.

Drugs

The aberrant expression and activities of Eph receptors and ephrins in many disease processes suggest that they could be exploited as therapeutic targets for a variety of applications. Accordingly, significant progress has been made in the development and preclinical/clinical evaluation of agents that target them.

One of the first strategies used to modulate the function of the Eph/ephrin system is with the recombinant Eph receptor or ephrin extracellular portions (Pasquale 2010; Boyd et al. 2014; Barquilla and Pasquale 2015). In monomeric form, these engineered proteins inhibit both forward and reverse signaling by interfering with endogenous Eph receptors-ephrin interactions (except for the monomeric ephrin-As, which can activate EphA receptors). Furthermore, they target multiple family members due to the promiscuity of Eph receptor-ephrin interactions, which may in some cases increase their effectiveness. To prolong their lifetime in the blood circulation, Eph receptor/ephrin extracellular regions have been coupled to the Fc portion of an antibody or to serum albumin. Fusion to Fc results in dimerization, which increases potency due to higher binding avidity and can confer agonistic properties. For example, ephrin-A1 Fc or ephrin-B2 Fc administered in vivo can inhibit tumor growth and malignancy in glioblastoma and breast cancer mouse xenograft models, respectively, by promoting the tumor-suppressing effects of Eph receptor forward signaling. As another example, EphA Fc proteins have demonstrated anti-cancer activity in mouse tumor models by inhibiting the angiogenic effects of EPHA2 forward signaling in the tumor vasculature (by blocking EPHA2 activation by endogenous ephrin-As). In addition, a portion of the EPHA7 extracellular region can block the oncogenic effects of EPHA2 forward signaling in B cell lymphoma, and fusion of the EPHA7 fragment with the B lymphocyte-targeting anti-CD20 antibody rituximab increases the therapeutic potential of both agents. On the other hand, EPHB4 fused to human serum albumin (sEPHB4-HSA) is under evaluation in multiple cancer clinical trials, alone or in combination with other treatments, as an inhibitor of the EphB/ephrin-B system (clinicaltrials.gov) (Lodola et al. 2017).

Monoclonal antibodies represent another targeting strategy (Pasquale 2010; Boyd et al. 2014; Barquilla and Pasquale 2015; Lodola et al. 2017). Antibodies can exhibit high binding affinity, specificity, and long in vivo half-life. Activating and inhibitory antibodies that recognize Eph receptor/ephrin extracellular regions have been developed, mainly for applications against cancer and pathological angiogenesis. In several preclinical mouse cancer models, activating antibodies targeting EPHA2 can inhibit tumor growth by promoting anti-oncogenic EPHA2 forward signaling and/or EPHA2 degradation. In addition, a humanized EPHA3-activating antibody lacking fucosylation to increase antibody-dependent cellular cytotoxicity (KB004/ifabotuzumab) is cytotoxic for different types of leukemia cells. This antibody is also effective against solid tumors by disrupting tumor stroma and vasculature, which express EPHA3 (Boyd et al. 2014), and is under early clinical testing in cancer patients with promising results (clinicaltrials.gov). Antibodies targeting Eph receptors have also been conjugated to chemotherapeutic agents to enable selective tumor targeting and receptor-mediated drug internalization. For example, EPHA2 antibodies coupled to derivatives of the cytotoxic drug auristatin can inhibit tumor growth and reduce metastasis in several mouse cancer xenografts models. However, toxicity due to severe bleeding was observed with the fully human MEDI-547 EPHA2 antibody-auristatin conjugate in a phase I clinical trial (clinicaltrials.gov). In addition, a humanized antibody to ephrin-A4 (PF-06647263), coupled to the DNA-damaging agent calicheamicin to target tumor-initiating cells in triple negative breast cancer and ovarian cancer, achieved sustained tumor regression in mice carrying patient-derived tumor xenografts (Lodola et al. 2017). A phase 1 clinical trial demonstrated manageable safety of this antibody-drug conjugate but limited anti-tumor activity (clinicaltrials.gov). Antibodies coupled to radioisotopes have also been successfully used in mouse cancer models for in vivo imaging of tumor cells and for targeted delivery of the radioisotope for anti-cancer therapy (Lodola et al. 2017).

Additional therapeutic efforts have aimed at redirecting immune cells to target Eph receptors, and particularly EPHA2, in tumors (Boyd et al.

2014; Barquilla and Pasquale 2015). For example, a bispecific antibody that simultaneously targets EPHA2 and the T cell receptor/CD3 complex can cause T cell-mediated destruction of EPHA2-positive cancer cells in vitro and decreased tumor growth in vivo. Chimeric antigen receptor (CAR) T cells targeting EPHA2-expressing cancer cells have also been successfully developed (Darling and Lamb 2019).

Peptides are also useful for targeting Eph receptors with high selectivity and for modulating their activities (Noberini et al. 2012; Riedl and Pasquale 2015). Several peptides (approximately 10–15 amino acids long) bind specifically to the ephrin-binding pocket of different Eph receptors and antagonize ephrin binding. Information from X-ray crystal structures of peptide-Eph receptor complexes has guided optimization efforts that have yielded peptides specifically targeting the EPHA2, EPHA4, and EPHB4 receptors with low nanomolar affinity. Some of these peptides, or their modified derivatives, are highly resistant to proteases and have substantial in vivo half-life. Most of the peptides are antagonists that inhibit forward signaling (and reverse signaling). Peptide antagonists targeting EPHA4 have applications for the treatment of neurodegenerative diseases and to promote nerve regeneration after injury (Boyd et al. 2014; Riedl and Pasquale 2015). Peptide antagonists targeting EPHA2 and EPHB4 have applications for inhibition of tumor angiogenesis. Interestingly, some of the EPHA2-targeting peptides are agonists that mimic the ephrin ligands in promoting receptor activation and internalization/degradation even in their monomeric form (Riedl and Pasquale 2015). Thus, these peptides could be useful to promote EPHA2 tumor suppressing forward signals and EPHA2 downregulation as well as to facilitate the uptake of chemotherapeutic drugs by tumor cells. Indeed, peptides that bind to EPHA2 or EPHB4 have been successfully used in mouse cancer models to enhance the targeted delivery of drugs, such as paclitaxel or doxorubicin, as well as of nanoparticles loaded with drugs and/or imaging agents (Pasquale 2010; Barquilla and Pasquale 2015; Riedl and Pasquale 2015).

Small molecules that bind to the ephrin-binding pocket or the ATP-binding pocket of Eph receptors (Fig. 1) represent yet another strategy to modulate the Eph/ephrin system. Some small molecules targeting the ephrin-binding pocket have been identified, but typically they have low potency and selectivity for a specific Eph receptor. These characteristics can be improved, but at the cost of an increase in size beyond that of a small molecule (consistent with the large size and flexibility of the targeted pocket) (Noberini et al. 2012; Lodola et al. 2017). Many small molecules that target the ATP-binding pocket in the Eph receptor kinase domain are also known (Noberini et al. 2012; Lodola et al. 2017). These compounds are kinase inhibitors that can bind with nanomolar affinity, but generally exhibit poor selectivity and target multiple kinases (in fact most of these compounds were identified in screens using kinase targets other than Eph receptors). However, high selectivity may not always be desirable, since multi-kinase inhibitors can be more effective, if their toxicity is manageable. Several kinase inhibitors that include Eph receptors among their targets are under evaluation in cancer clinical trials, including dasatinib, tesevatinib/XL647, nilotinib, and bosutinib (Boyd et al. 2014) (clinicaltrials.gov). The inhibitory effects of these compounds on Eph receptor forward signaling should inhibit tumor angiogenesis, but may in some cases promote cancer cell malignancy. Nilotinib and bosutinib are also under evaluation in clinical trials for Alzheimer's disease and other forms of dementia (clinicaltrials.gov), although they do not efficiently cross the blood-brain barrier. The ability of these compounds to inhibit EPHA4 and the downstream ABL and SRC family kinases could provide therapeutic benefits in neurodegeneration, although the contribution of Eph receptor targeting to their therapeutic effects remains to be determined. More selective Eph receptor inhibitors could be obtained in dedicated screens in which an Eph receptor is the primary target, in conjunction with structure-guided and

computational optimization approaches (Noberini et al. 2012).

Small interfering RNAs (siRNAs) and antisense oligonucleotides targeting Eph receptors or ephrins also show promise for the treatment of cancers and neurodegenerative disorders, respectively. Although the efficient in vivo delivery of nucleic acids can present challenges, these agents are highly selective and eliminate all activities of the targeted molecule. In promising examples, delivery of EPHA2 siRNA using liposomes or nanoparticles inhibits tumor growth and metastasis in mouse ovarian cancer xenograft models, particularly in combination with other treatments (Pasquale 2010; Boyd et al. 2014). The EPHA2 siRNA liposomes are now under evaluation in a phase I clinical trial (clinicaltrials.gov). For the central nervous system, a single intracerebroventricular administration of EphA4-antisense oligonucleotides in mice can substantially reduce EphA4 levels in the brain and spinal cord for prolonged periods, promoting reinnervation and functional recovery after sciatic nerve injury (Ling et al. 2018). However, this antisense treatment has not shown beneficial effects in mouse ALS models.

Ongoing efforts to translate Eph receptor/ephrin-targeting pharmacological agents into clinical candidates focus on improving potency, selectivity, and in vivo stability. The complex and incompletely understood biology of the Eph/ephrin system represents a major challenge in predicting the therapeutic or toxic effects of modulatory agents. However, new research findings combined with the results from preclinical and clinical studies increasingly inform the development and refinement of Eph receptor-/ephrin-based therapeutic strategies.

Synonyms

Epigenetic therapy; DNA methylation; Histone methylation; Histone acetylation; Bromodomain inhibitors

Definitions

2-OG – 2-oxogluterate
AML – Acute myelogenous leukemia.
BET – Bromodomain and extra-terminal domain.
BRD – Bromodomain.
CTA – Cancer testis antigen.
DLBCL – Diffuse large B-cell lymphoma.
DNMT – DNA methyltransferase.
DOT1L – Disruptor of telomeric silencing 1-like.
EVR – Endogenous viral RNA.
EZH2 – Enhancer of zeste homolog 2.
FAD – Flavin adenine dinucleotide.
H3 – Histone H3.
HDAC – Histone deacetylase.
HDM – Histone demethylase.
HMT – Histone methyltransferase.
HOX – Homeobox.
IDH – Isocitrate dehydrogenase.
MDS – Myelodysplastic syndrome.
MLL – Mixed lineage leukemia.
NSCLC – Non-small cell lung cancer.
PRC2 – Polycomb repressive complex 2.
PRMT – Protein arginine methyltransferases.
SAM – S-adenosyl methionine.
SET – Su(var)3–9, enhancer of zeste and trithorax.
TET – Ten-eleven translocation methylcytosine dioxygenase.

The fate and function of every cell in an organism can vary significantly despite having identical genetic material. Differentiated cells are characterized by distinct patterns of gene expression due to variations in transcription, translation, or protein modification. Patterns of gene expression that are stably maintained after cell division but not attributed to DNA sequence variation are regulated by epigenetic mechanisms. Epigenetic information is encoded by cytosine methylation, posttranslational modification of histone proteins, and nucleosome positioning (Fig. 1). Writers of epigenetic code catalyze DNA methylation or posttranslational modifications of histones, such as methylation or acetylation of N-terminal histone "tails" extending from the nucleosome

structure. Epigenetic modifications may be recognized and used as points of contact by "reader" proteins that either alter the chromatin architecture further or regulate enzymatic processes such as transcription factor binding and RNA polymerase processivity. Epigenetic modifications may be removed by "eraser" enzymes such as histone deacetylases or demethylases. In addition, chromatin remodelers can mobilize or exchange histones. Together these mechanisms maintain chromatin accessibility patterns that govern interaction of transcription machinery with genes and cis-regulatory regions (Lorch et al. 1987). Mutations in genes that regulate the cellular epigenetic state are among the commonest class of mutations found in cancer (Lawrence et al. 2014). These mutations result in reprogrammed gene expression that can directly contribute to cancer and cooperate with other genetic events such as mutations of oncogenes or tumor suppressor genes affecting cellular proliferation pathways. Because epigenetic marks are reversible, recent work to develop more effective anticancer therapeutics has emphasized identifying and targeting epigenetic mechanisms (Bennett and Licht 2018).

Basic Mechanisms

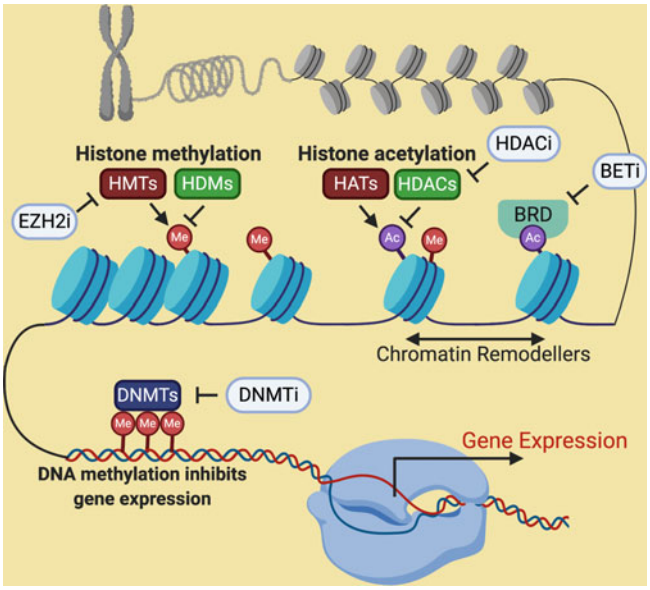
DNA Methylation

DNA methylation almost exclusively occurs on cytosines that precede a guanine (CpG) and plays a key role in regulation of gene expression. Endogenous palindromic methylation patterns are maintained in the genome and transmitted through the germline. CpG dinucleotides are often concentrated within "islands" of CpG-rich DNA regions located near transcription start sites (TSSs) (Saxonov et al. 2006). Hypermethylation of CpG islands may repress expression of the corresponding gene by preventing binding of transcription factors and recruiting methyl-CpG binding proteins that interact with repressive histone modifying enzymes (Herman and Baylin 2003). Changes in both global and individual gene methylation patterns are often found in cancer and aberrant methylation patterns have been used to differentiate tumor subtypes. DNA hypomethylation is often found in tumors due to loss of repeat region methylation and hypomethylation of regions that regulate the expression of proto-oncogenes such as ERBB2 and RAS (Nishigaki et al. 2005). In addition, hypermethylation of specific CpG rich regions has been observed to silence expression of tumor suppressors such as Rb and p16 (Herman et al. 1995; Greger et al. 1989).

The enzymes responsible for establishing and maintaining these patterns of DNA methylation are DNA methyltransferases (DNMTs). DNMT3A and DNMT3B establish de novo DNA methylation patterns that are maintained by DNMT1, which can recognize methylation in DNA and assures methylation of daughter strands after replication (Okano et al. 1999). Demethylation of DNA is facilitated by the TET enzymes which convert methyl cytosine into hydroxymethylcytosine which is not recognized by DNMT1 (Rasmussen and Helin 2016). Loss of function mutations of DNMT3A or TET enzymes are often observed in cancer, upsetting patterns of DNA methylation.

Histone Acetylation

Lysine acetylation of histones is important for regulation of chromatin structure, transcription, and DNA repair. Two competing enzyme families regulate this highly dynamic modification, histone lysine acetyltransferases (HATs), and histone deacetylases (HDACs). HATs transfer the acetyl group from acetyl-coenzyme A to the amino group of a histone lysine thereby neutralizing the positive charge of lysine and diminishing the interaction of histone with DNA. In general, this causes a more relaxed and accessible chromatin structure that favors binding of proteins, such as transcription factors, and thus acetylation of chromatin is associated with transcriptional activation while deacetylation is associated with gene repression (Haberland et al. 2009). HDACs play a key role in gene expression by removal of the activating histone acetylation and may also have other roles in the cell by controlling acetylation of nonhistone and nonnuclear proteins. HDACs are often overexpressed in cancer to silence tumor suppressor genes or they may be aberrantly recruited to target genes by overexpressed transcription factors or chimeric transcription factors



Epigenetics, Fig. 1 Epigenetic control mechanisms govern chromatin accessibility and gene expression DNA is wrapped around histone proteins to form nucleosomes (blue cylinders) which are then condensed into chromatin and ultimately chromosomes. Epigenetic mechanisms regulate nucleosome occupancy and positioning especially at regulatory elements of gene expression. Chromatin remodelers mobilize and reposition nucleosomes. Post-translational modification of N- and C-terminal "tails" of histones that extend beyond the nucleosome regulates nucleosome stability and chromatin compaction and may serve as docking sites for additional proteins such as bromodomain proteins (BRD). Histone methyltransferases (HMTs) catalyze transfer of a methyl group (Me) from S-adenyl methionine onto histone tails while histone demethylases (HDM) remove this mark. Similarly, histone acetyltransferases (HATs) catalyze the transfer of an acetyl group (Ac) from acetyl coenzyme A to histone lysine residues that function to weaken the interaction with DNA and increase chromatin accessibility. Histone deacetylases (HDACs) remove the acetyl mark from histones, decreasing chromatin accessibility and suppressing gene expression. Methylation of DNA at cytosines that precede guanine, CpG, by DNA methyltransferases (DNMT) near transcription start sites precludes the binding of transcription factors to inhibit gene expression. Several classes of inhibitors have been developed to reprogram the cellular epigenetic state in tumor cells (white ovals). EZH2i, such as tazemetostat, specifically inhibits methylation of histone H3 by the catalytic subunit of the polycomb repressive 2 complex that inhibits gene expression. HDACi such as entinostat or vorinostat inhibits histone deacetylation to reactivate gene expression. Inhibitors of bromodomain and extra-terminal domain proteins (BETi) such as JQ1 or BMS-986158 suppress aberrant gene expression driven by increased BRD activity in cancer cells. DNMT inhibitors (DNMTi) such as azacytidine promote DNA hypomethylation and reactivate gene expression

created by chromosomal fusions (Haberland et al. 2009).

Bromodomain-Containing Proteins Recognize Acetylated Histone

One of the best characterized proteins families that recognize epigenetic modifications is the bromodomain and extra-terminal (BET) family that includes BRD2, BRD3, and BRD4 (Kim et al. 2006; Xu and Vakoc 2017). These proteins share a conserved structural element consisting of two bromodomains that recognize acetylated lysine on the N-terminal tails of histones H3 and H4. Importantly, BRD4 associates with P-TEFb protein to promote transcription elongation by RNA polymerase II at paused sites (Yan et al. 2011). BRD4 is enriched at transcription start sites, enhancer and elongated or "super enhancer" regions, and BRD4 promotes expression of many transcription factors that are known to have roles in cancer development and progression such as Myc. BRD2 is overexpressed in B-cell lymphoma and increased BRD4 expression was reported in melanoma tissues and hepatocellular carcinoma

where it is associated with poor prognosis. In addition, the majority of patients that develop midline carcinoma have chromosomal rearrangements that create a fusion protein between BRD3 or BRD4 and the NUT protein (Yan et al. 2011). The BRD-Nut fusion maintains cancer cells in an undifferentiated state of self-renewal by recruiting HATs and sequestering cofactors normally associated with activated, acetylated chromatin away from normal gene targets, causing reduced expression of differentiation associated genes.

Histone Methylation

Posttranslational modification of histone N-terminal and C-terminal tails that extend beyond the nucleosome core influence downstream biological processes such as transcription, replication, and chromosomal stability. Reversible methylation of histones is orchestrated by transfer of a methyl group to the basic amino acids lysine, arginine, or histidine present in histone tails by histone methyltransferases (HMTs), while histone demethylases (HDMs) remove these marks (Fig. 1). Histone lysine residues can be modified to mono-, di-, or tri-methylated forms (me1, me2, or me3) and histidine can be mono-methylated but this modification is rare. Arginine may be mono- or di-methylated by protein arginine methyltransferases (PRMTs). Arginine dimethylation may be either symmetrical, meaning that methyl groups are added to both nitrogen atoms in the side chain or asymmetrical in which two methyl groups are added to only one of the side chain nitrogen atoms. Demethylation of histones is accomplished by two main classes of HDMs: the FAD-dependent amine oxidases and the Fe(II)/2-OG-dependent Jumonji C domain family (Klose and Zhang 2007). Dynamic changes in histone methylation state can occur based on cell type, tissue type, or cell cycle phase and are important for the response to factors such as DNA damage, mitogen signaling, and environmental stress. The balance between the methylated and demethylated states of histones at specific lysine residues can regulate transcriptional activity. For instance, lysine methylation of histone H3 at amino acid residue 4 (H3K4), 36 (H3K36), and 79 (H3K79) are associated with activation of gene expression while methylation at lysine 9 (H3K9), 20 (H3K20), and 27 (H3K27) are associated with repression of gene expression (Barski et al. 2007). Loss or gain of HMT or HDM activity can result from missense mutation, deletion, amplification, or chromosomal rearrangement affecting the genes encoding these enzymes. HMT or HDM dysfunction and the resultant aberrant gene expression have been linked with tumor grade, chromosomal instability, mutation burden, and clinical outcome.

Except for DOT1L1, which has a unique enzymatic domain, the enzymatic activity of all lysine methyltransferases resides in their SET catalytic domain. Type I and type II arginine methyl transferases share a well conserved SAM-binding catalytic core of about 350 amino acids (Klose and Zhang 2007). These enzymatic domains have pockets that bind SAM to be used as a donor cofactor for the transfer of methyl groups to substrates.

EZH2 is the catalytic component of the PRC2 complex that is responsible for trimethylation of H3K27 associated with chromatin compaction and transcriptional repression (Kim and Roberts 2016). EZH2 is an important regulator in several cellular pathways including cell cycle regulation, X-chromosome inactivation, and metastasis and is generally overexpressed in metastatic tumors relative to normal tissues or primary tumor specimens. Gain of function mutations of EZH2 are found in germinal center type diffuse large B-cell lymphoma of and more rarely in thyroid cancer and malignant melanoma (Morin et al. 2010). These heterozygous mutations enhance the ability of the enzyme to trimethylate H3K27. In lymphoma, these gain of function mutations cause aberrant repression of tumor suppressor genes and late B-cell genes, thus locking the B cell in a state of continuous proliferation at the germinal center stage of differentiation. Loss of function and deletion of EZH2 is found in MDS and AML and is associated with global decreases in the repressive H3K27me3 mark which activates oncogene expression (Ernst et al. 2010). Thus, depending on the cellular context or function of dysregulated gene expression, EZH2 can have either an oncogenic or tumor suppressor function.

Pharmacological Intervention

Targeting DNA Methylation

DNA methyltransferases inhibitors (DNMTi) have been developed to target aberrant methylation patterns observed in cancer cells. DNMTi such as 5-azacytidine, decitabine, and guadecitabine cause global hypomethylation, and their use as anticancer agents has been approved for use in patients with myelodysplastic syndrome or certain leukemias to reactivate tumor suppressor genes. These azanucleosides substitute nitrogen for carbon at the C-5 position of the pyrimidine ring and when incorporated into DNA irreversibly bind DNMT1 resulting in DNMT1 degradation and decreased DNA methylation (Ghoshal et al. 2005). The resulting loss of DNA methylation favors the re-expression of aberrantly silenced proteins, including tumor suppressor genes, cancer-associated antigens, and components of the antigen presentation machinery. While hypomethylating agents can reverse promoter methylation and reactivate silenced tumor suppressor gene expression in some instances, many reports attribute their anticancer activity to other mechanisms. For instance, treatment with decitabine causes the formation of DNA-DNMT adducts, subsequent double-stranded DNA breaks, and G2 arrest. In addition, reports suggest that DNMTs may associate with histone-modifying enzymes and a global increase of histone H3 and H4 acetylation has been observed after treatment with Aza. Furthermore, decitabine has been reported to stimulate expression of normally silent endogenous retroviral sequences in colon cancer cell lines to cause a host antiviral response, including activation of interferon response genes, independent of promoter demethylation. Taken together these results indicate that DNA methyltransferase inhibitors can have cooperative functions that contribute to their cytotoxic effect.

Defects in demethylation of DNA have also been reported to drive neoplasia. Mutations in the enzymes IDH1 and IDH2 that normally catalyze decarboxylation of isocitrate to α-ketoglutarate occur in gliomas, AML, chondrosarcomas, and cholangiocarcinoma. Mutant IDH1/2 reduces α-ketoglutarate to 2-hydroxygluterate, a competitive inhibitor of the TET family of DNA hydroxylases (Ward et al. 2010). In addition, mutations and translocations of *TET2* have been observed in numerous hematologic malignancies and associated with poor prognosis in AML (Delhommeau et al. 2009). TET enzymes normally convert 5′-methylcytosine to 5′-hydroxymethylcytosine, an important step in cytosine demethylation and inhibition of this mechanism results in DNA hypermethylation (Figueroa et al. 2010). Pharmacological agents (ivosidenib and enasidenib) that target mutant IDH1 and IDH2, respectively, have been approved for the treatment of AML. These agents block the production of 2-hydroxygluterate by the mutant enzymes, thus restoring TET2 function and reverting DNA methylation and gene expression patterns towards the normal state. In addition, high-dose vitamin C treatment activates TET to induce expression of EVRs, reverse cell lineage commitment, and restore tumor suppressive gene expression programs. High-dose vitamin C administration has been demonstrated to act synergistically with a variety of other anticancer agents such as BET inhibitors or decitabine, and active clinical trials that include vitamin C either as a single agent or in combination therapies are ongoing for patients with almost all types of cancer.

Targeting Histone Acetylation

Numerous HDAC inhibitors (HDACi) have been developed for cancers that display increased HDAC activity or HAT mutations. Because HDACs are Zn^{2+}-dependent, many nonselective broad-spectrum enzymatic inhibitors target the Zn^{2+} ion in the active site. Pan-HDACi such as vorinostat, belinostat, and panobinostat have been shown to reactivate tumor suppressor genes such as p21 and have either been approved or are in clinical trials to for many cancers. In addition, selective HDACi have been developed that target specific HDACs. These include romidepsin that targets HDAC1 and HDAC2 and has been approved for lymphoma patients and ricolinostat an HDAC6 specific inhibitor in clinical trials for patients with multiple myeloma or lymphoma that blocks the clearance of misfolded proteins (Santo et al. 2012).

Targeting Histone Methylation

While many HMTs have been implicated in diseases such as cancer, relatively few effective methyltransferase inhibitors have been identified that are being used clinically. One promising HMT target is DOT1L, a H3K79 methyltransferase that has an important role in *MLL* (KMT2A) leukemias. The DOT1L inhibitor pinometostat inhibits proliferation of cell lines with MLL rearrangements in association with decreases in H3K79me levels at *HOX* genes and is currently in clinical trials for patients with *MLL* rearranged leukemias (Waters et al. 2015). Another HMT target being pursued for anticancer therapies is EZH2 which functions to repress gene expression. EZH2 inhibitors may be useful to restore a balance between forces mediating gene repression and activation for cancers with overexpression or mutation of EZH2, as well as tumors having loss of function mutations of gene activator proteins such as the H3K27 demethylase KDM6A or inactivating mutations of the SWI/SNF proteins (van Haaften et al. 2009; Kim et al. 2015). Tazemetostat is one of the most promising EZH2 inhibitors that was recently approved for use with metastatic sarcoma patients and is in clinical trials as a single agent or in combination with other agents for hematologic malignancies (Knutson et al. 2012; Kurmasheva et al. 2017). In addition, increased histone arginine methylation by PRMT5 has been observed in leukemias and several inhibitors of PRMT5 have been developed such as JNJ-64619178, PF-06939999, and GSK3326595 that are in clinical trials for hematologic malignancies. Other small molecule HMT inhibitors have shown promise as potential anticancer therapeutics but have not yet advanced to the clinic. These include compounds targeting aberrant histone H3K9 methylation such as BIX01294 that targets the methyltransferase G9a which displays increased expression in lung cancer cell lines and inhibitors of SETDB1 which is frequently amplified in melanoma and lung cancers. The frequent disruption of histone methylation patterns in cancer highlights the need for continued development of this class of inhibitors.

Targeting Epigenetic Readers

Treatment of BRD4-NUT expressing cell lines with a small molecular inhibitor of BET domain acetyl-lysine binding led to a reactivation of gene expression and induction of differentiation (Yan et al. 2011). This finding motivated the ongoing development of pharmacological approaches to target BET domain proteins by inhibiting their tandem bromodomains. One of the first BET inhibitors developed, JQ1, induced terminal differentiation of leukemic stem cells in primary AML samples and prevented ovarian carcinoma growth in xenografts. Recently, new classes of improved BET inhibitors have been developed. Three of these, I-BET762, CPI-0610, and OTX015, are in clinical trials for hematologic malignancies and TEN-010 is in clinical trials for NUT midline carcinomas and advanced solid tumors.

In summary, as our understanding of the defective epigenetic mechanisms in cancer has improved so has the motivation for developing strategies to reprogram these dynamic mechanisms back to a normal cell state. Hypomethylating agents, HDAC inhibitors, and agents that reverse cancer associated histone modifications have proven to be clinically useful, particularly for treatment of hematologic malignancies. In addition, emerging therapeutic strategies take advantage of crosstalk between different epigenetic mechanisms. For instance, cooperation between DNA methylation and histone deacetylation in gene expression has led to clinical trials that test combinations of HDAC inhibitors and DNA hypomethylating agents. Furthermore, the widespread adoption of targeted immunotherapies for cancer has led to the need for a deeper understanding of how epigenetic mechanisms may govern immune surveillance escape by tumor cells. A key focus of future epigenetic research will be to leverage mechanistic insights into more effective anticancer therapies.

Epithelial Na^+ Channel

Silke Haerteis[1] and Stephan Kellenberger[2]
[1]Institute for Molecular and Cellular Anatomy, University of Regensburg, Regensburg, Germany
[2]Department of Biomedical Sciences, University of Lausanne, Lausanne, Switzerland

Definition

The epithelial Na^+ channel (ENaC) is a member of the ENaC/degenerin family of non-voltage-gated ion channels. This channel is localized in the apical membranes of Na^+-absorbing epithelia such as the aldosterone-sensitive distal nephron, respiratory epithelia, and distal colon. ENaC forms a heteromeric channel made of homologous subunits – α, β, and γENaC. The human genes encoding these three subunits are named *SCNN1A*, *SCNN1B*, and *SCNN1G* and are located in chromosome 12 (α) and 16 (β γ), respectively. In humans, but not in mice or rat, a fourth subunit, δENaC, exists. So far, little is known about the physiological role and the functional properties of this additional subunit; δENaC may replace the αENaC subunit to form functional heterotrimers.

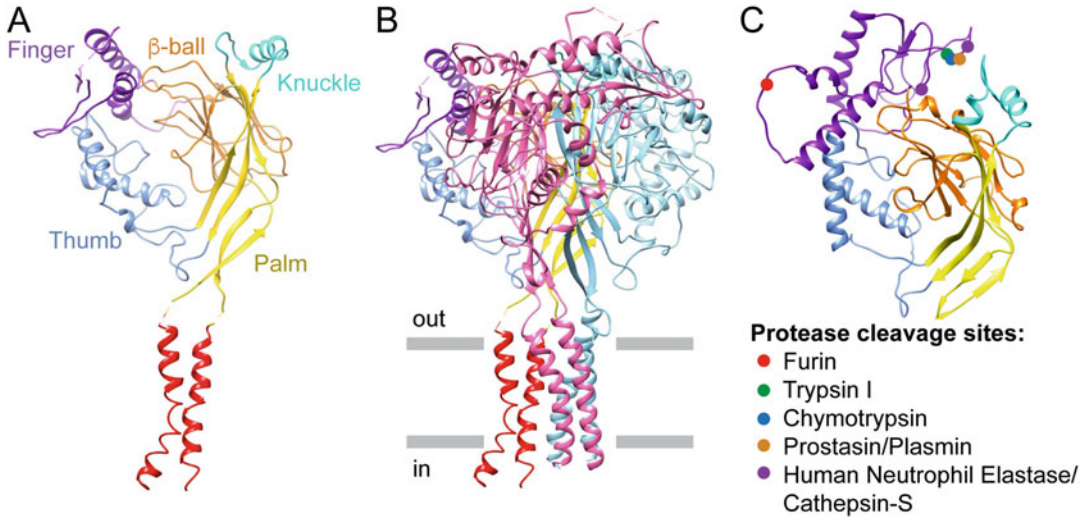
Basic Characteristics

Channel Family and Structural Organization

ENaC belongs to the ENaC/degenerin family of ion channels that include in mammals the neuronal acid-sensing ion channels (ASICs) and the bile acid-sensing ion channels (BASICs), in *C. elegans* the degenerin channel family involved in mechanosensation, and in mollusks the FMRF peptide-gated Na^+ channel FaNaC (Kellenberger and Schild 2002; Hanukoglu and Hanukoglu 2016; Kellenberger and Schild 2015). Soon after the cloning of ENaC subunits, it was concluded from primary sequence analysis and biochemical experiments that each ENaC subunit consists of a large extracellular loop, two transmembrane domains, and short intracellular N- and C-termini

and that the subunits are arranged pseudo-symmetrically around the channel pore. In 2007, the first ASIC structure, obtained from chicken ASIC1a, was published, which shares ~20% homology with human ENaC subunits (Jasti et al. 2007). This, and subsequently published ASIC structures, confirmed the predicted subunit topology and also showed that the assembled channel is a trimer. These structures provide detailed information on the organization of the extracellular and transmembrane domains of ASIC. The shape of the extracellular domain of each subunit was compared to that of a hand holding a small ball, and, consequently, subdomains were labeled as wrist, palm, thumb, finger, knuckle, and β-ball (Fig. 1) (Kashlan and Kleyman 2011; Stockand et al. 2008). Structural models of ENaC, based on the sequence homology to ASICs, allowed then the localization of functionally important ENaC residues and domains. Cleavage sites of proteases (see below) are localized in the finger domains. It was also shown that the selectivity filter is localized in the lower half of the transmembrane segments, whereas the binding site of the pore blocker amiloride is positioned one helical turn above the selectivity filter. The "degenerin site" is localized at a conserved position at the extracellular entry of the pore of ENaC/degenerin channels and is critical for channel activity. It is a Ser in α, β and γENaC. Replacing the degenerin site residue by a larger residue strongly increases the activity of degenerins, ENaC, and ASICs (Eastwood and Goodman 2012).

Very recently, the first cryo-electron microscopy structure of human ENaC was published (Noreng et al. 2018). The ENaC subunits used for the structural analysis were heavily truncated and mutated, and some regions – as the transmembrane regions and parts of the finger domains – could not be resolved. The structural analysis indicated basically the same subunit organization as in ASICs, and a diameter of the extracellular part of the ENaC trimer of 81 Å, and a height of the channel without the cytoplasmic ends (of which no structural information is available) of 120 Å. On the top of the trimer, facing outward, three regions rich in aromatic residues at subunit interfaces were identified, which are known from functional studies to be the target of ENaC



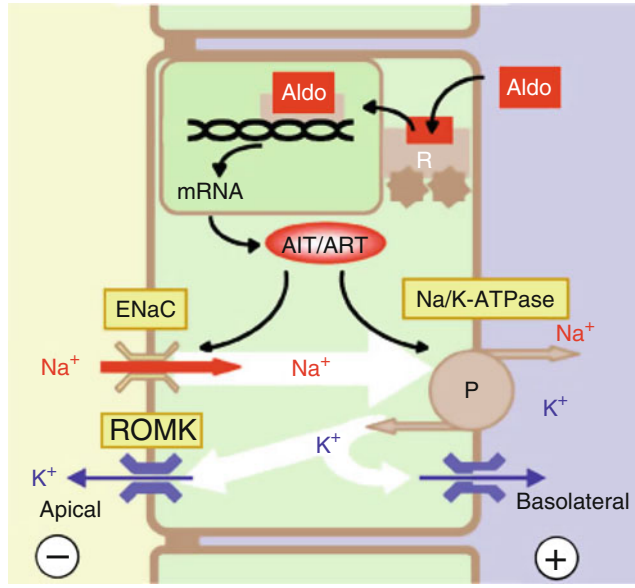
Epithelial Na^+ Channel, Fig. 1 ***ENaC structure.*** A, structural image of αENaC, with indication of the different domains. The interrupted lines indicate portions whose structure could not be determined (Figure based on (Noreng et al. 2018)). B, ENaC trimer, with the α subunit shown in the same colors as in A, β in pink, and γ in light blue. The approximate level of the plasma membrane is indicated. C, indication of the approximate location of cleavage sites by several proteases on γENaC, shown on a structural model of αENaC (Kashlan et al. 2011), since this part is not resolved in the ENaC structure

regulation by proteases. However, the parts containing the cleavage sites were not resolved in this structure.

Physiological Roles

ENaC is located in the apical membrane of polarized epithelial cells where it mediates Na^+ transport across tight epithelia (Marunaka et al. 2011). The most important tight epithelia expressing ENaC include the distal nephron of the kidney, the respiratory epithelium, and the distal colon. The basic function of ENaC in polarized epithelial cells is to allow vectorial transcellular transport of Na^+ ions. This transepithelial Na^+ transport through a cell involves basically two steps, as illustrated in Fig. 2 for a principal cell in the collecting duct of the distal nephron. The large electrochemical gradient for Na^+ ions existing across the apical membrane provides the driving force for the ENaC-mediated entry of Na^+ into the cell. Active Na^+ extrusion across the basolateral membrane is accomplished by the Na^+/K^+-ATPase. The Na^+ absorption in the distal nephron is coupled to K^+ secretion via K^+ channels (ROMK2) located at the apical membrane. ENaC mediates Na^+ absorption in the *aldosterone-sensitive distal nephron* (ASDN), which contains the late portion of the distal convoluted tubule, the connecting tubule, and the collecting duct (Loffing and Korbmacher 2009). This ENaC-mediated Na^+ absorption is critical to balance urinary Na^+ excretion with the daily intake and, thus, for the maintenance of the extracellular fluid volume and blood pressure. ENaC activity is under the control of the hormones aldosterone and vasopressin that are secreted in response to stimuli such as extracellular volume contraction, dehydration, or hyperkalemia. Aldosterone binds to intracellular mineralocorticoid receptors; the ligand-receptor complex is translocated to the nucleus and induces the expression of ENaC and the Na^+/K^+-ATPase proteins via aldosterone-induced transcripts (AITs) and/or aldosterone-repressed transcripts (ARTs). Vasopressin binds to the G-protein-coupled V2 receptor and activates ENaC via the cAMP-dependent pathway. The identification of mutations in genes encoding the ENaC, the mineralocorticoid receptor, and the 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD-2) that cause monogenic forms of hypertension strongly supports this notion.

Gain-of-function mutations of ENaC associated with an increased Na^+ absorption in the distal nephron lead to low plasma aldosterone levels and low plasma renin activity and cause Liddle's syndrome (pseudoaldosteronism), an autosomal



Epithelial Na^+ Channel, Fig. 2 ***Transepithelial ion transport in a principal cell of the cortical collecting duct.*** The figure illustrates the channels and transporters involved in the transepithelial Na^+ transport and the regulation of this transport by aldosterone. Aldo, aldosterone; AIT, aldosterone-induced transcript; ART, aldosterone-repressed transcript

dominant inherited form of salt-sensitive arterial hypertension. Conversely, loss-of-function mutations cause Na^+ salt losing nephropathy (pseudohypoaldosteronism type 1 (PHA-1)) and are characterized by urinary sodium loss, dehydration, hyperkalemia, elevated plasma renin, and aldosterone levels.

Mutations identified in patients with Liddle's syndrome are almost exclusively localized in the β- or γ-subunit of ENaC and mainly affect a conserved proline-rich motif (important for channel endocytosis and degradation) at the intracellular C-terminus of ENaC (Tetti et al. 2018). Recently, a missense mutation in the extracellular domain of αENaC has been reported to also cause Liddle's syndrome, probably by increasing intrinsic channel activity rather than by increasing channel expression at the cell surface (Salih et al. 2017).

ENaC activity in the lung is developmentally regulated and plays a critical role at birth for a rapid and normal fluid reabsorption from the lung which turns from a secretory (fetal) to a reabsorptive (adult) mode. Later in life, ENaC remains important for the ionic composition and the clearance of the airway surface liquid (ASL). The depth of the ASL is mostly determined by the equilibrium between chloride secretion by CFTR (cystic fibrosis transmembrane regulator) having a tendency of increasing this level and Na^+ absorption via ENaC, which will decrease the ASL depth. Dehydration of the airway surface leads to impaired mucociliary clearance and higher risk of infections. In mice, airway-specific overexpression of ENaC results in an increased Na^+ absorption and in a severe spontaneous lung disease sharing features with cystic fibrosis. Conversely, loss-of-function mutations of ENaC, as observed in recessive PHA-1, cause an increase of mucociliary clearance and a decrease in mucous viscosity. Several studies showed an increase of ENaC activity in the absence of CFTR, suggesting a negative control of ENaC activity by CFTR. The relevance of this possible regulation is currently still under debate. Cystic fibrosis (CF) is caused by mutations in CFTR which decrease its expression at the cell surface and/or its activity (Moore and Tarran 2018). In CF, there is a disequilibrium between CFTR and ENaC activity, leading to an increased fluid absorption and a reduction of the ASL depth and thereby to airway obstruction, inflammation, and chronic bacterial infections.

In *the tongue*, ENaC is expressed in taste bud epithelial cells. $\alpha ENaC^{(-/-)}$ mice show strongly reduced salt attraction and Na^+ taste response, indicating a role of ENaC in salt tasting (Chandrashekar et al. 2010).

In *the skin*, ENaC is expressed in keratinocytes of the epidermis and in hair follicles. It may contribute to the barrier function of the skin, since $\alpha ENaC^{(-/-)}$ mice show increased transepidermal water loss and disturbed stratum corneum lipid composition.

E

Mechanisms of ENaC Regulation

(a) Regulation of ENaC by proteases

Mechanisms of ENaC regulation are highly complex, vary from tissue to tissue, and include different aspects like transcription, regulatory proteins, kinases/phosphatases, the lipid environment, proteases, and amphiphilic substances like bile acids. Local factors affecting ENaC function are likely to be important for tissue-specific ENaC regulation. One mechanism, which plays a role in all tissues, is the regulation of ENaC by proteases. Cleavage results in the release of inhibitory peptides and probably activates the channel by changing its conformation. ENaC is cleaved at three furin sites (two in αENaC and one in γENaC) along the biosynthetic pathway before the channels reach the plasma membrane. A second cleavage event in proteolytic ENaC activation takes place at the plasma membrane where γENaC is cleaved by membrane-bound proteases (e.g., channel-activating proteases CAP1-3) and/or soluble proteases in a region distal to the furin site (see Fig. 1C).

The proteases activating ENaC under physiological and pathophysiological conditions have not been identified and may differ between tissues. Putative cleavage sites in γENaC have been described for the cysteine protease cathepsin-S, for the serine proteases prostasin, plasmin, elastase, kallikrein, trypsin, and chymotrypsin (see Fig. 1C) (Haerteis

et al. 2014, 2012a, b; Ray and Kleyman 2015; Kleyman et al. 2009; Rossier and Stutts 2009).

There is evidence that proteolytic ENaC activation by urinary proteases may contribute to Na^+ retention in nephrotic syndrome ("proteasuria") (Artunc et al. 2019). This is supported by data using aprotinin as pharmacological inhibitor of urinary serine protease activity in vivo in nephrotic mice showing protection of these mice from proteolytic ENaC activation and Na^+ retention (Bohnert et al. 2018). Renal diseases may not only affect the activity of proteases but may also shift the balance between endogenous proteases and protease inhibitors (Kitamura and Tomita 2010). Thus, the pathophysiological aspects of proteolytic ENaC regulation await further investigation and the identification of relevant proteases and protease inhibitors along the nephron and in urine samples in various disease states.

(b) Regulation of ENaC by amphiphilic substances (bile acids)

Recently it has emerged that amphiphilic substances, such as bile acids, also regulate ENaC (Ilyaskin et al. 2016; Wang et al. 2019). Bile acid sensitivity is not a unique feature of ENaC but rather a common phenomenon of channel activation that is shared by other members of the ENaC/degenerin ion channel family including BASIC and ASIC1.

Physiologically relevant tauro-conjugated bile acids (e.g., taurochenodeoxycholic, taurocholic, and taurodeoxycholic acid) stimulate ENaC in the human αβγ- and in the δβγ-configuration, whereas nonconjugated bile acids show a robust stimulatory effect only on δβγENaC. The degenerin site region in the channel's β-subunit seems to be critical for the functional interaction of bile acids with the channel. The physiological role of ENaC/BASIC/ASIC activation by bile acids remains still to be elucidated. Bile acids may be physiologically relevant modulators of ENaC function, e.g., in bile ducts where αβγENaC is expressed in cholangiocytes. Next to bile acids, other endogenous amphiphilic substances, capable of binding to the degenerin region of ENaC, may act as local modulators of channel function in a tissue-specific manner.

Drugs

ENaC is blocked from the tubular lumen of the distal nephron by the diuretic amiloride at submicromolar concentrations. By blocking ENaC activity at the apical membrane of the target cell of the distal nephron, the electrochemical gradient favoring the passive secretion of K^+ through ROMK is dissipated and K^+ secretion blocked. Unlike loop diuretics (furosemide and analogs) or distal convoluted tubule diuretics (i.e., *thiazide* diuretics), which cause K^+ secretion and hypokalemia, amiloride and analogs cause K^+ retention (and ultimately hyperkalemia) and are currently used as *K^+-sparing diuretics*. Since the distal nephron reabsorbs under physiological conditions less than 10% of the filtered load of sodium, blockade of ENaC results only in a slight increase in urinary excretion of sodium.

The biophysical characteristics of the block of ENaC by amiloride including voltage dependence and competitive interaction with permeant cations, such as Na^+ or Li^+ ions, strongly suggest that amiloride is a pore blocker which, upon binding to its receptor on the channel, physically occludes the ion permeation pathway (Garty and Palmer 1997). The binding site for amiloride is located in the channel pore, just above the ion selectivity filter, and involves specific amino acid residues on the α, β, and γENaC subunits. Amiloride shares its binding site on ENaC with triamterene which blocks the channel with a lower affinity (Kellenberger and Schild 2015).

Spironolactone, a competitive antagonist of aldosterone for the mineralocorticoid receptor, inhibits epithelial sodium transport and K^+ secretion and belongs to the same class of diuretics.

The development of amiloride analogs targeted to block selectively ENaC in the lung could be useful in the treatment of cystic fibrosis (CF) patients or more generally of patients suffering from chronic bronchitis, a condition in which an increased mucociliary clearance is highly desirable. Inhalation of amiloride has a moderate beneficial effect on lung function in CF patients, which is however limited by its rapid metabolism. Several companies have developed amiloride derivatives with higher potency and longer duration of action. Parion Sciences compounds 552-02 and P-680 showed increased efficacy and selectivity over amiloride. The studies of these compounds were however halted when hyperkalemia was observed in clinical trials. Many other ENaC antagonists have been developed by several companies, and several of them have entered clinical trials. While the development of some of them was stopped, due to lack of effect or the induction of hyperkalemia, several promising amiloride derivatives are currently in clinical trials, including AZD5634 of AstraZeneca, NVP-QBE170 and QBW 276 of Novartis, and BI 443651 of Boehringer Ingelheim (Moore and Tarran 2018). An alternative pharmacological approach is based on the peptide SPLUNC1 (short palate lung and nasal epithelial clone 1), a secreted protein that is abundant in the airways and contains an N-terminal region that binds to ENaC and inhibits ENaC activity. In experiments with a mouse model of reduced mucociliary clearance, the SPLUNC1-derived peptide SPX-101 reduced airway inflammation and increased survival. SPX-101 promotes ENaC internalization, leading to a prolonged reduction of Na^+/ASL absorption. The peptide nature of SPX-101 limits systemic exposure. SPX-101 showed no toxicity or systemic effects in phase I clinical trials, and phase II clinical trials with CF patients are underway (Moore and Tarran 2018; Couroux et al. 2019).

Channel activators are presently not available and will be useful for the treatment of *respiratory distress syndrome* in newborn, *high-altitude pulmonary edema* in adults, or, possibly, lung edema in congestive heart failure. So far, cellular studies have shown a stimulation of human ENaC by the small molecule S3969 and by the cyclic peptide solnatide (Kellenberger and Schild 2015).

Definition

The extracellular matrix (ECM) is a dynamic complex of interwoven fibrils and globular macromolecules, coming together to form the foundation of all biological tissue. Comprising of collagens, glycoproteins, and proteoglycans, as well as associated secreted factors and enzymatic regulators, this supramolecular assembly provides structural support for organs and surrounding cellular compartments and also exerts a great degree of extrinsic regulation over cellular phenotype and function. The ECM establishes the extracellular milieu in which cells exist, providing cells with context-specific cues that vary from tissue to tissue, spatially guiding cellular fate, fine-tuning developmental programs, and maintaining tissue order. Such cues are responsible for switching on and off intracellular signaling programs and establishing spatially distinct cellular phenotypes. In disease, genetic aberrations, or the loss of regulation of ECM homeostasis, are observed, leading to deviations in ECM composition and organization. As a consequence, the ECM's role as a cellular regulator is disrupted, resulting in a microenvironment that imparts a disordered phenotype on the surrounding cells, as well as organ dysfunction on a much larger scale. Our increasing knowledge of the physiology of ECM regulation and the mechanisms that precede and drive a pathological ECM in disease will continue to deliver a deeper understanding of the microenvironmental regulation of cellular phenotype and tissue function, and increase the potential for therapeutically modifying this network in disease.

Basic Characteristics

Characteristics of the Extracellular Matrix (ECM)

The biological function of the ECM can be generally classified as either biochemical or biomechanical in nature. These characteristics are determined by early developmental programs, which create tissue-specific networks necessary for site-specific function at both the cellular and organ level. For example, while tendons require dense and highly organized, fibrillar collagen matrices in order to mediate large tensile forces, the extracellular environment of the brain requires a loosely cross-linked, proteoglycan and glycosaminoglycan-rich network in order to sustain neuronal function (Mouw et al. 2014).

ECM composition is diverse and is largely synthesized by epithelial and distinct stromal cells (such as fibroblasts). Tissue-specific expression profiles determine the abundance of individual extracellular ligands and growth factors that guide resident cell fate and phenotype. ECM composition (i.e., fibrillar vs. globular constituents), density, and post-translational modification (such as cross-linking) result in differential tissue stiffness, porosity, and the overall topological landscape. This in turn influences the osmotic flow of nutrients (i.e., the tight-knit collagen IV–VII basement membrane (BM) lattice) (Pozzi et al. 2017) as well as controls the morphology and migration of resident cell populations. These features also determine overall tissue structure for organ function, for instance, elastin-rich pulmonary ECM for respiration and collagen-bioapatite mineral complexes for bone strength.

At the cellular level, the ECM exerts extrinsic control over phenotype through spatially patterned signaling gradients and hubs in the microenvironment, thus in turn regulating gene expression. These interactions may manifest in the form of cell receptors (i.e., integrins, discoidin domain receptors [DDRs], or syndecans), binding to growth factors (i.e., transforming growth factor beta (TGF-β)), and ECM motifs (e.g., RGD motifs), or biomechanical sensors of extracellular rigidity (i.e., mechanosensitive ion channels, focal adhesion complexes), leading to the activation of

various downstream signaling pathways (Hastings et al. 2019). The activation of these "mechanotransduction" pathways has various biological consequences, including the regulation of cell fate and differentiation. Importantly, it was demonstrated that ECM-mediated signal transduction can also regulate downstream expression of ECM molecules (Nelson and Bissell 2005), as well as their regulatory enzymes. The reciprocal interactions between cells and the ECM are termed "dynamic reciprocity," and this process leads to both positive and negative feedback loops between cells and the microenvironment, which are crucial to both development and disease (Hastings et al. 2019).

In a developmental context, the microenvironment has demonstrated great importance in guiding collective cell interaction during morphogenesis. Cell-cell and cell-ECM interactions in a developing embryo create a dynamically evolving ECM substrate with differential mechanical properties and geometries, which guide the formation of epithelial structures (i.e., intestinal villi) as well as organ structures (i.e., the undulations of the brain). The establishment of these "mechanochemical feedback loops" (Hannezo and Heisenberg 2019) is also observed between neural crest cells and the underlying tissue stiffness during embryogenesis. These dynamic regulatory loops enhance and direct cellular migration during zebra fish and *Xenopus* development (Hannezo and Heisenberg 2019). The specific expression of ECM components also regulates morphogenesis. For example, during the formation of the mammary ductal tree, stromally derived laminin-1 guides epithelial polarity and branching morphogenesis at the frontier of ductal formation (Nelson and Bissell 2006).

The ECM is considered a dynamic entity in that it is in constant flux. Remodeling of the ECM is crucial in producing essential stage-dependant networks during both homeostasis and development. The expressions of secreted factors such as proteases (e.g., matrix metalloproteases, (MMPs)) and their inhibitors (e.g., tissue inhibitor of MMPs, (TIMPs)), as well as protein cross-linkers (e.g., lysyl oxidase (LOX), transglutaminases, and peroxidasin), are central to the fine balance between ECM breakdown, construction, and stability (Filipe et al. 2018).

In situations such as trauma, or injury, stromal cells are recruited to the wound site secreting factors into the extracellular milieu. These include growth factors and structural ECM components necessary to facilitate the wound healing process. The deposition of fibrillar collagens is essential for providing structural support during wound closure, and glycoproteins such as fibronectin provide a transient substrate conducive to cellular proliferation for de novo synthesis of new tissue and wound resolution (Midwood et al. 2004). These transient matrices are then removed by MMPs in order to restore the ECM to its prior state. Similarly, during gestation and mammary involution, the expression of stage-specific ECM components and the subsequent activation of numerous proteolytic enzymes are observed. Together they are critical in the controlled synthesis of lactation-associated ECM and the subsequent degradation to restore the mammary gland ECM to its former state.

The ECM in Disease

In disease, homeostatic and developmental processes either run askew or are co-opted as disease-driving mechanisms, nurturing the progression of ECM pathologies and disrupting cell and organ function. Tissue fibrosis is one of the most prevalent ECM pathologies. Fibrosis results from an asymmetry between ECM synthesis and breakdown in response to chronic injury or exposure to noxious agents, as seen in liver cirrhosis, interstitial lung disease, or renal fibrosis (Wynn 2008). Fibroblast recruitment and activation typically lead to the excessive deposition of fibrillar collagens, which are post-translationally cross-linked by enzymatic mediators (i.e., LOX) into large collagen fibrils and fibers that accumulate, interfering with both cellular and organ functions through the reprogramming of resident cells.

On the contrary, mechanisms associated with aging tissue often result in ECM attrition. Decreased ECM synthesis (due in part to fibroblast senescence) and elevated proteolysis can result in BM thinning. Post-translational modifications that accumulate as a consequence of aging

and disease, such as advanced glycation end-products (AGEs) and extracellular oxidative stress-induced oxidative modifications, alter ligands present throughout the ECM as well as result in a stiffer and less elastic interstitial ECM. This "aged" ECM possesses altered mechanics and arrangement, modulating cell function and contributing to age-related pathologies (Frantz et al. 2010). Similarly, osteogenic diseases which also result in ECM molecule attrition are typically underpinned by increased ECM resorption, decreased deposition, and altered collagen mineralization, leading to bone brittleness and fracture. Analogous to this process is the continual decay and impaired repair of articular cartilage in osteoarthritis, mediated in part by deregulated proteoglycans in the microenvironment. In other situations, aging can lead to aberrant accumulation of ECM complexes, such as heparan sulfate proteoglycan-amyloid fibril complexes in Alzheimer's disease.

The ECM is also dysregulated in almost all solid tumors. The up- or downregulation of components over time may in part be understood in terms of gain of tumor-promoting and loss of tumor-suppressing components in the ECM. In cancer, tumor cell-secreted factors recruit fibroblasts, which in turn produce and remodel the ECM leading to the generation of a microenvironment that is typically conducive to tumor development. These cancer-associated fibroblasts (CAFs) continuously and progressively remodel the tumor ECM, thereby providing pro-tumorigenic signals to tumor cells. Increased collagen deposition and arrangement typically produce a stiffer tumor ECM. In synergy with the numerous differentially regulated glycoproteins, proteoglycans, and growth factors, these cues create a positive feedback loop driving tumor progression. The ECM also presents a barrier to chemotherapy efficacy. For example, increased hyaluronan in the tumor microenvironment is thought to increase solid stress and interstitial pressures, which can in turn decrease vascular patency and thus hinder drug delivery. The stiffness of the tumor ECM also imparts chemoresistance to tumors through mechanisms such as increased YAP/TAZ signaling. As we understand more about how these cues synergize and drive the progression of tumors, we are uncovering new targetable mechanisms to block tumor cell response to the ECM that will likely yield new treatment regimens to improve patient outcomes.

Aside from altered expression levels, variants of ECM genes may also be pathological. Mutations present in ECM genes typically result in either embryonic lethality or severe developmental disorders. For example, while *COL1A1* mutations can be lethal, *COL6A1*, *COL6A2*, and *COL6A3* mutations manifest as myopathies or tendinopathies. Similarly, *LAMB3* and *LAMC2* mutations hinder hemidesmosome formation and thus give rise to significant cutaneous blistering. Other monogenic ECM disorders include Ullrich congenital muscular dystrophy 2 (*COL12A1*), osteogenesis imperfecta (*COL1A1* or *COL1A2*), Ehlers-Danlos syndrome (*COL1A1 COL1A2*, *COL3A1*, *COL5A1*, *COL12A1*, or *TNXB*), and Marfan syndrome (*FBN1*). It is important to note here that the phenotypes of these monogenic mutations typically manifest through the disruption of the interconnected supramolecular assemblies of the ECM and explain why, in the case of diseases such as Ehlers-Danlos syndrome, mutations in several genes appear to underpin the same disease.

Drugs

Targeting the ECM

Historically the ECM was largely neglected as a therapeutic target due a perceived lack of bioactivity. Once theorized as solely the structural matter "outside of cells," the ECM is now understood to be a master regulator of cellular phenotype and is known to play key roles in numerous biological processes within the tissue microenvironment. As such, there are many underexplored therapeutic targets in the extracellular environment.

There are various strategies for therapeutically manipulating the ECM in disease. Approaches span from directly (or indirectly) targeting ECM genes, targeting their expression in specific cell types, or targeting the ECM-synthesizing and ECM-remodeling cells themselves. ECM

molecules and the enzyme families that regulate their assembly and turnover may also be directly targeted in the extracellular milieu, for example, blocking collagen I fibril formation through targeting the LOX family. More recent work has also focused on targeting the downstream effects (i.e., mechanoactivation) induced by a pathological ECM.

Gene Therapy

Due to the genetic or regulatory basis of various ECM pathologies, gene therapy may present a possible avenue for normalizing ECM networks and hence tissue function. Methods such as gene editing (e.g., CRISPR/Cas9, transcription activator-like effector, or zinc-finger nucleases), or the delivery of antisense oligonucleotides, ribozymes, small interfering RNA, short hairpin RNA, microRNA, or recombinant technologies (such as cDNA) to affected sites or organs, may be exploited either to correct genetic aberrations in monogenic ECM disease or to normalize the pathological expression of ECM components (Jarvelainen et al. 2009).

For instance, in junctional epidermolysis bullosa (JEB), which is underpinned by mutations in the *LAMB3* gene and results in severe cutaneous blistering, a combinatorial gene and cell therapy approach has been adopted to alleviate disease symptoms. The autologous transplantation of keratinocyte-derived skin grafts with gene-corrected *LAMB3* produces a fully functional epidermis in JEB patients for up to 21 months, mediated by self-regenerating holoclones (Hirsch et al. 2017). On the other hand, in instances where ECM components are differentially expressed, the synthesis of constituents may be fine-tuned using gene-editing systems to normalize expression levels. A proof-of-concept study has elucidated this potential through the upregulation of *LAMA1* using a skeletal muscle-specific CRISPR-Cas9 system in a preclinical murine model, further demonstrating the validity of ECM gene therapy as a novel therapeutic strategy in Duchenne muscular dystrophy (Perrin et al. 2017).

Genetic material can also be therapeutically administered to buttress the synthesis or suppression of ECM components and associated factors. In the rodent setting, the direct delivery of decorin cDNA alleviated renal fibrosis through the negative regulation of TGF-β-induced glomerulonephritis and fibrosis (Isaka et al. 1996).

MicroRNAs (miRNAs) are known to be a key intracellular regulatory element in gene expression and also ECM synthesis. As a result, promising therapeutic potential in ECM suppression has been observed (Piperigkou and Karamanos 2019). In particular, the miR-29 family has been observed to repress elastin, collagen (I and III), fibrillin-1, and a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS) 9 and 12 expression but is downregulated in hepatic fibrosis (Noetel et al. 2012; He et al. 2013). Exploiting this inhibitory function may be fruitful in targeting fibrotic pathologies. Similarly, collagen I synthesis can be selectively knocked down using small interfering RNA as a means to inhibit scarring and fibrosis long term (Schuppan et al. 2018). However, many ECM molecules exhibit long half-lives in the extracellular environment, spanning from 15 to 100 years for structural collagens in human skin and articular cartilage, respectively. Thus, targeting the expression of specific ECM components in later stages of disease may be ineffective, and hence alternative therapeutic approaches may be required once ECM molecules have been stably incorporated into the extracellular environment.

Direct Targeting of the ECM and Downstream Cellular Effectors

Depending on the rate of accumulation and longevity of ECM components, and the stage of clinical presentation for a given pathology, targeting the ECM at the protein level may present a more effective strategy as opposed to upstream processes involved in synthesis and deposition. Directly targeting ECM components can be achieved through enzymatic degradation of ECM components or through the blockade of cell- or enzyme-mediated ECM-remodeling processes. Otherwise the targeted blocking of specific ECM domains with antibodies or binding peptides, which target ECM-ECM or cell-ECM

interactions, may be employed to inhibit downstream biological consequences.

Targeting specific ECM-degrading enzymes may serve as a treatment in protease-driven disease (Lu et al. 2011). MMPs, ADAMTS, and cathepsins are dysregulated in a range of tissue disorders, including attrition-driven pathologies such as osteoarthritis and chronic obstructive pulmonary disease (COPD), malignant progression, and in cardiovascular disease (CVD). Hence, a range of pharmacological inhibitors have been produced to repress ECM degradation by these enzymes for the treatment of a range of diseases; however they have had limited success in the clinic. MMPs were seen as a promising target in cancer as their expression correlated with tumor stage and were functionally shown to play a role in tumor progression (Gialeli et al. 2011). Inhibitory approaches for MMPs include competitive inhibition using peptidomimetics, zinc chelators, tetracyclines, or TIMPs and have been extensively investigated at the preclinical level (Gialeli et al. 2011). Unfortunately, the preclinical findings did not translate into effective therapy in the clinic, likely due to stage-dependant roles of MMPs and on-target toxicity in healthy tissue (Gialeli et al. 2011).

On the contrary, the delivery of ECM-degrading enzymes has been exploited for therapeutic benefit due to their specificity for ECM constituents. Targeted enzymatic breakdown of hyaluronan (HA) using recombinant human hyaluronidase ($PEGPH_{20}$) is currently being trialed in HA-high breast cancer patients (NCT02753595). Importantly, studies of this nature are trialing the combined administration of hyaluronidase therapy with standard-of-care chemotherapy – in this case eribulin – since $PEGPH_{20}$ is not cytotoxic. $PEGPH_{20}$ has also been shown to successfully degrade HA and decrease pancreatic ductal adenocarcinoma (PDAC) tumor interstitial fluid pressure, normalize vasculature, and, as a result, increase perfusion of standard-of-care chemotherapies, increasing patient outcomes in a subset of HA-high PDAC patients (Hingorani et al. 2018).

The biogenesis of ECM components, such as fibrillar collagen, relies on a number of enzymatic steps that represent viable targets. The LOX family, which include LOX and four LOX-like isoforms (LOXL1-4), are copper-dependant amine oxidases and are essential in collagen and elastin fibril formation. LOXs form intra- and intermolecular cross-links in fibrillar collagen chains and elastin, increasing stability of fibrils by rendering them resistant to proteolytic degradation and fortifying tissues with a stiffened collagen scaffold. Thus, LOXs are a central node in fibrosis and stromal-mediated tumor progression and have been the focus of anti-fibrotic drug development. Some mechanisms of inhibition include copper-chelation via tetrathiomolybdate, inhibition by therapeutic antibodies, and small molecular LOX inhibitors (Leung et al. 2019; Trackman 2016; Chang et al. 2017), some of which are beginning to enter phase 1 clinical trials.

The TGF-β family is established as a key mediator of pro-fibrotic signaling. The canonical TGF-β signaling cascade begins with TGF-β binding to transmembrane type I and II serine/threonine kinase receptors. These heteromeric complexes then transduce signals through the SMAD family of transcription factors, which in TGF-β-activated fibroblasts results in increased ECM synthesis and deposition. Therefore, the efforts in inhibiting TGF-β to block fibrosis are a great example of both direct targeting and downstream inhibition. For instance, neutralizing antibodies generated against TGF-β (e.g., preclinical monoclonal antibodies 1D11 or 2G7) or synthetic or natural binding proteins can be administered therapeutically and are able to sequester the ligand. Blockade as this level inhibits cell-TGF-β interactions and the subsequent transduction of pro-fibrotic signals in effector cells (Katz et al. 2013). The signal transduction process may also be inhibited at the receptor level through the administration of receptor kinase inhibitors, such as SB-431542, inhibiting phosphorylation of SMAD-2 and SMAD-3 (Katz et al. 2013). Finally, peptide aptamers or small molecular inhibitors of intracellular signaling complexes, such as inhibitors of SMAD-2/SMAD-3 complexes formed with SMAD-4 (e.g., Trx-SARA (Katz et al. 2013)), can prevent signal transduction downstream of the TGF-β receptor.

Similarly, if ECM molecules cannot be targeted directly within the microenvironment, then downstream cell-ECM interactions offer a viable therapeutic approach. Cellular sensing of the ECM and cell-mediated adhesions to the ECM are largely mediated by cell surface receptors known as integrins. Integrins bind specific motifs in ECM components within the extracellular microenvironment. Consequently, these interactions initiate the transduction of signals that mediate various physiological functions such as cellular migration during morphogenesis and ECM architecture remodeling, as well as mediating disease progression through the activation of TGF-β-mediated fibrosis and cancer cell invasion (Hamidi and Ivaska 2018). As such, integrins pose an important avenue for the indirect targeting of the ECM.

Of the 24 known integrins, there are only 3 that are currently targeted by FDA-approved drugs (Ley et al. 2016). The first clinical monoclonal antibody targeting an integrin, abciximab, was developed against the platelet integrin αIIbβ3, which is known to bind fibrinogen, fibronectin, and vitronectin for platelet aggregation during haemostasis (Ley et al. 2016). Platelets and megakaryocytes exclusively express αIIbβ3, and thus drug development was suitably aimed at antiplatelet and antithrombotic outcomes. Eptifibatide, a cyclic heptapeptide, is also highly selective for αIIbβ3 and is administered in patients with non-ST segment elevation myocardial infarction and percutaneous coronary intervention (Ley et al. 2016). In cancer, integrins have demonstrated a role at each step of the tumor progression and spread and are largely involved in the development of resistance to chemotherapy (Hamidi and Ivaska 2018). Despite promising preclinical evidence, two clinical trials, CENTRIC EORTC (phase III 26071–22072) and POSEIDON (phase II NCT01008475), failed to improve patient survival when used in combination with standard-of-care therapy in glioblastoma and KRAS metastatic colorectal cancer, respectively (Ley et al. 2016). This may in part be explained by the capacity for cancer cell integrins to signal independently of ECM-ligand interactions (Ley et al. 2016), and thus efforts may benefit from shifting focus to downstream signal transduction.

In cancer, at the stage of clinical presentation, tumor-associated ECM-remodeling processes are typically already well underway and may have been for many weeks and months. These tumor-ECM feedforward processes can potentially be blocked by targeting the downstream cell-mediated ECM-remodeling processes. This has been demonstrated by the inhibition of cytoskeletal-mediated ECM contractility via Rho kinase inhibition, in the preclinical setting (Rath et al. 2017; Vennin et al. 2017). Researchers demonstrated that combination therapies targeting pathways involved in fibroblast activation and subsequent ECM deposition and remodeling in the tumor microenvironment have the potential to normalize the tumor ECM, decrease cancer spread, and improve response to chemotherapy in pancreatic cancer.

Future Considerations in Drug Development

As our understanding of the ECM continues to evolve on a fundamental basis, there are various clinical factors to consider for the optimal design of therapeutics targeting the ECM. Firstly, not all ECM profiles are equal. Not only does ECM composition vary between organs or spatially within a given tissue; stage-dependant ECM networks and patient-to-patient variation within a disease must be accounted for in order to understand patient-specific pathology and therefore accurately predict response to a particular ECM-targeting therapy. Also, in multifactorial diseases such as COPD, CVD, and cancer, the ECM will synergize with intrinsic cellular effectors to drive disease progression. In such instances a combined therapeutic approach, which includes ECM targeting, will likely yield the most promising increase in patient outcomes in the clinic.

Determining the balance between drivers and suppressors of disease within the ECM is another key consideration when designing ECM-targeting drugs. This is highlighted by the observation that complete CAF ablation, and therefore ablation of tumor fibrosis, accelerates tumor progression and decreases survival, suggesting both pro- and anti-tumorigenic roles of the ECM. Similarly, while high ECM stiffness is known to impart tumor cells

with chemoresistance and a pro-invasive phenotype, low stiffness is observed to instate stemlike characteristics, which may be equally problematic in cancer. Thus, rather than ablating the ECM or ECM producing cells, ECM normalization approaches may offer an optimal therapeutic strategy in halting cancer spread.

Finally, the ECM is a complex network and derives its bioactivity from its biochemical and biomechanical composition as well as the numerous ECM-ECM and cell-ECM interactions in the microenvironment. Advances in our understanding of the ECM on a holistic level, such as those established by "The Matrisome Project" (Naba et al. 2012), are providing tools to interrogate systems levels information. Such investigations lay the foundation to uncover deeper biological insights into disease mechanisms that can be applied to the development of new approaches to target the ECM in disease.

Final Thoughts

The ECM is a key regulatory agent of cellular programs and is crucial to overall organ function. Our increasing appreciation of the diverse biological function of the ECM in health and disease has led to a solid fundamental understanding of matrix biology, as well as numerous preclinical and clinical investigations aiming to modify this supramolecular assembly for the attenuation of disease. In principal, drug design may focus at any point along an ECM-mediated pathogenic process, from the synthesis of ECM components to the downstream biological consequences of disease drivers within the ECM. As the ECM is a complex network or system, investigators should aim to understand such a complex interconnected entity at the global level, in order to understand how numerous elements in the ECM act in concert in order to progress disease.

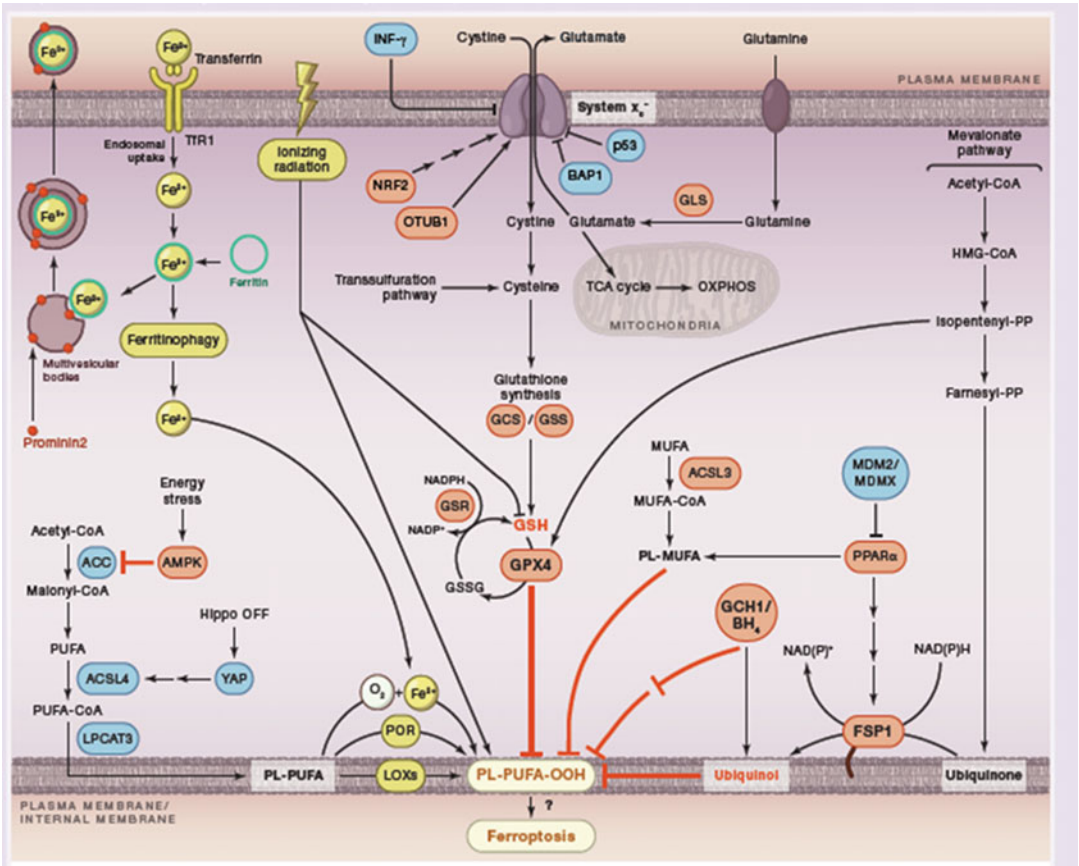
Xc	The cystine/glutamate antiporter
YAP	Yes-associated protein

Regulated cell death is vital for cell division, differentiation, and the development of most multicellular organisms. Ferroptosis is a form of regulated cell death that is caused by iron-dependent lipid peroxidation that is lethal to cellular membranes. It is so designated according to the Nomenclature Committee on Cell Death (NCCD) because it is regulated by genetic and pharmacological modulators. Ferroptosis is different from apoptosis, the classical regulated and programmed cell death and the other forms of regulated cell death such as necroptosis, autophagy, or pyroptosis as its initiation is not characterized by defined canonical effector protein machinery. It is therefore independent of effectors of apoptosis such as the caspases, BAX, and BAK and the receptor-interacting protein kinase 3 (RIPK1/RIPK3) of necrosis. Instead, the induction and the execution ferroptosis are modulated by intracellular metabolic pathways that culminate in lipid peroxidation as a selective distinguishing biomarker.

Dixon et al. (2012) described ferroptosis as a distinct form of cell death that is induced by erastin, a small molecule that inhibits the import of cystine which causes glutathione (GSH) depletion and the subsequent inactivation of the phospholipid peroxidase glutathione peroxidase 4 (GPX4). The substrates during ferroptosis are phospholipids with polyunsaturated acyl tails (PL-PUFAs) which are particularly sensitive to peroxidation reactions (Yang and Stockwell 2016). Hence the regulation of ferroptosis is dependent on the factors that modulate the aberrant accumulation of lipid hydroperoxides (L-OOH) and the processes that inhibit GPX4 and hinder the elimination of toxic peroxides (L-OOH) as non-toxic lipid alcohols (L-OH). The state-of-the-art snapshot of ferroptosis is displayed in Fig. 1 (Hadian and Stockwell 2020). Cell death by ferroptosis is thus mediated by metabolic pathways encompassing biosynthesis and the metabolism of amino acids, GSH, iron, PUFA phospholipids, NADPH, and coenzyme Q10. However, the manifestation of ferroptosis is subject to variability due to different cell types, genetic mutations, type of target organelles, and the pleiotropy and redundancy of metabolites. Moreover, heterogeneity of in vitro cell culture studies of ferroptosis could be confounded by factors that are nonexistent in systemic metabolism (Conrad and Pratt 2019). Nevertheless, ferroptosis as a distinct form of cell death is initiated or inhibited by specific pharmacological and genetic perturbations, and these have been exploited as tools such as metabolomics, lipidomics, small molecule inhibitors, in vitro and in vivo molecular biology techniques to understand the functions of the key metabolites, regulators, and molecular biomarkers of the cell death process (Table 1).

Lipid Peroxidation of Membranes in Ferroptosis

Polyunsaturated fatty acids (PUFAs) are precursors of signaling molecules in the regulation of cellular proliferation, differentiation, and development. They are also vital structural constituents that confer fluidity and dynamic architecture on lipid bilayers of cellular membranes. The substrates during ferroptosis are phospholipids with polyunsaturated acyl tails (PL-PUFAs) which are particularly sensitive to peroxidation reactions. Oxidative disruption or damage to PL-PUFAs in the membrane is pivotal to the manifestation of ferroptosis. Inhibition of acetyl coenzyme A carboxylase (ACC) by AMP-activated protein kinase (AMPK) and energy stress can decrease endogenous biosynthesis of PUFAs needed for PL-PUFA biosynthesis. Free PUFAs are esterified into membrane phospholipids (PL-PUFAs) in reactions that are catalyzed by acyl-CoA synthetase long-chain family member 4 (ACSL4) and lysophosphatidylcholine acyltransferase 3 (LPCAT3) (Fig. 1). Specifically, phosphatidylethanolamines (PEs) containing arachidonic acid (C20:4) or its elongation product,



Ferroptosis, Fig. 1 Metabolic pathways and key molecular processes of ferroptosis. (Hadian K, Stockwell BR. Cell. (2020). SnapShot: Ferroptosis. 181(5):1188–1188. Copyright Permission Cell Elsevier)

adrenic acid (C22:4), are key PL-PUFAs that undergo oxidation by lipoxygenases to execute ferroptotic cell death (Doll et al. 2017, Kagan et al. 2017). Several lines of evidence have shown that the expression of ACSL4 is vital in the regulation and the sensitivity to ferroptosis, and it has been proposed as a marker of ferroptosis (Yuan et al. 2016). Spermidine/spermine N1-acetyltransferase 1 (SAT1) was also shown to promote lipid peroxidation, possibly through lipoxygenases. However, the insertion of monounsaturated fatty acids (MUFAs) into phospholipids by ACSL3 suppresses ferroptosis by a process that is not yet clear.

Although the function of lipid peroxidation in ferroptosis has been deciphered by lipidomic analysis, the ultimate toxic process of peroxides that damage membranes remains unclear. However, an aldehyde ketone reductase, encoded by AKR1C1–3 gene, was shown to inhibit ferroptosis by reducing lipid peroxides to nontoxic alcohol products. It has been proposed that excess peroxides may decrease and destabilize membrane structure, fluidity, and integrity (Kajarabille and Latunde-Dada 2019). Moreover, alteration of membrane components may result in loss of function and the degradation of lipid peroxides that decompose into reactive aldehydes and electrophiles which damage proteins and nucleic acids (Gaschler and Stockwell 2017).

Critically, iron is essential to the two main mechanisms of lipid peroxidation pathways, namely, (a) an autoxidation non-enzymatic and iron-catalyzed spontaneous peroxyl radical-mediated chain reaction and (b) the enzymatic oxidation of lipids primarily mediated by the non-heme iron-dependent lipoxygenase

Ferroptosis, Table 1 Features of ferroptosis

Definition	Ferroptosis is an iron-dependent form of oxidative, non-apoptotic cell death that is tightly linked to metabolism and disease
Morphological	
Cell membrane	Normal spherical cells
Cytoplasm	Diminutive mitochondria with decreased crista and collapsed and ruptured membrane
Nucleus	Normal
Biochemical features	Inhibition of system Xc^- Reduced GSH, inhibition of GPX4. Increased Fe, ROS accumulation, and lipid peroxidation, mitochondrial membrane potential dissipation
Key genes	GPX4, FSP1, TFR1, SLC7A11, NRF2, NCOA4, P53, HSPB1, ACSL4, LOX5, HO-1, GCH1
Pathways	GSH synthesis, trans-sulfuration, mevalonate, lipid oxidation/peroxidation, iron metabolism
Immune features	Pro-inflammatory

(15-LOX) family. Recent evidence has however revealed that LOXs possibly generate hydroperoxides to promote lipid autoxidation as rather being directly involved in the execution of ferroptosis (Shah et al. 2018). Cytochrome P450 oxidoreductase (Zou et al. 2020) has also recently been implicated as a driver of ferroptosis. MDM2/MDMX complex regulates PPARα activity by remodeling lipid profiles to enhance ferroptosis (Fig. 1).

Iron and Ferroptosis

Excess free redox-active Fe(II) has the propensity to cause ROS and oxidative stress that has been associated with various pathologies. Consequently, the regulation of the metabolic pathways of iron absorption, utilization, recycling, and ubiquitination of iron-containing proteins maintains homeostasis during normal physiology in the body. Moreover, iron could act as an intracellular second messenger that is released in response to cytosolic stress to induce cell death. Iron availability is thus an important hallmark of ferroptosis that render cells highly sensitive to erastin and RSL3-induced cell-death process. Hence iron transport and metabolism proteins are important for the regulation and sensitivity to ferroptosis. Inducers of ferroptosis have been shown to enhance the expression of iron import protein, transferrin receptor 1 (TfR1), and heme oxygenase 1 (HO-1) to promote iron availability for ferroptosis. Heat shock protein family B member 1 (HSPB1), also decreases intracellular iron level by inhibiting TfR1 expression to reduce sensitivity to ferroptosis.

Moreover, overexpression of ferroportin (FPN), the iron efflux protein, inhibited erastin-induced ferroptosis, while it's silencing in neuroblastoma cells had the opposite effect (Geng et al. 2018). Silencing of the iron-responsive element binding protein 2, IREB2, a transcriptional regulator of iron metabolism genes, also increases sensitivity to ferroptosis (Hadian and Stockwell 2020). IREB2 inhibits the degradation of TfR1 mRNA and represses the translation of ferritin translation. Inhibition of IREB2 increases the expression of FTL and FTH1, to decrease erastin-induced ferroptosis. Reduced ferritin (FTH) expression in fibroblasts by erastin, however, increased intracellular iron levels in cells. The classical ferroptosis inducer erastin also promotes the expression of CISD1(CDGSH iron-sulfur domain 1), an iron-containing outer mitochondrial membrane protein to reduce ferroptosis. The nuclear receptor coactivator 4 (NCOA4)-mediated autophagy of ferritin (ferritinophagy) plays a vital role in releasing iron to enhance ferroptosis. NCOA4 chaperones ferritin to autophagosomes for lysosomal degradation and the release of free iron (Mancias et al. 2014). This has been shown to enhance erastin-induced ferroptosis in cells. However, hypoxia was shown to inhibit ferritinophagy by repressing the transcription of NCOA4 and coupled with a micro RNA 6862-5p-dependent degradation of NCOA4 mRNA increases mitochondrial ferritin (FTMT) to prevent ferroptosis in macrophages. NCOA4 and FTMT were however not regulated in HT1080 ferroptosis-sensitive cells. Moreover, prominin2 suppresses ferroptosis by facilitating

the formation of multivesicular bodies containing ferritin-bound iron which exports iron out of cells (Fig. 1) (Brown et al. 2019).

Remarkably, nuclear factor-erythroid 2-related factor 2 (NRF2) plays a vital function in modulating cellular redox homeostasis by regulating several genes encoding proteins and enzymes engaged in the induction and inhibition of ferroptosis. These include genes for regulating glutathione activity, NADPH recycling, iron regulation, and lipid peroxidation (Kajarabille and Latunde-Dada 2019). In general, antioxidants, glutamate-cysteine ligase (GCLC), SLC7A11, HO-1, and ferritin are examples of genes that are transcriptionally regulated by Nrf2.

Scavenging and Detoxification of Lipid Peroxides

The deleterious consequences of PL-PUFAs peroxidation in ferroptosis are neutralized and nullified by three main metabolic pathways. These are as follows.

GPX4 employs cysteine-containing tripeptide glutathione as a cofactor to eliminate phospholipid peroxides. System Xc- is a central hub for regulation of ferroptosis, and it is a disulfide-linked heterodimer composed of SLC7A11 and SLC3A2, which imports cystine, the extracellular oxidized form of cysteine, in exchange for intracellular glutamate antiporter to generate GSH (Stockwell et al. 2017). Inhibition of the xc-system by erastin decreases cysteine levels and the depletion of GSH, and this suppresses the function of GPX4 in the reduction and detoxification of hydroperoxides (LOOH) to neutral alcohols (LOH). Another source of cysteine for GSH synthesis is methionine from the transsulfuration pathway, and this can render system Xc redundant in the elimination of peroxidized PL-PUFAs. Loss of cysteinyl-tRNA synthase (CARS) upregulated the genes in the transsulfuration, thereby suppressing erastin-induced ferroptosis. Moreover, a deubiquitylase, Otubain 1 (OTUB), stabilizes SLC7A11 to enhance its function in the GSH/GPX4 axis in preventing ferroptosis. On the contrary, however, the tumor suppressor BRCA1-associated protein 1 (BAP1) also in a deubiquitinating-dependent manner represses SLC7A11 expression. BAP1 reduces cysteine uptake by SLC7A11 and results in elevated lipid peroxidation and ferroptosis. However, tumor protein 53 (TP53) represses SLC7A11 to promote ferroptosis, by increasing sensitivity to ferroptosis via reduced cysteine level, thereby accentuating its role in the cell death process. SLC7A11 with its multiple regulatory effector mechanisms is, thus, a prime target for pharmacological applications of ferroptosis for therapy (discussed further below).

Erastin's function as an inducer of ferroptosis transverses proximal SLC7A11 inhibition to GPX4 degradation via the promotion of lysosomal-associated membrane protein 2a/autophagy. Erastin also binds the voltage-dependent anion channel (VDAC) to cause increasing levels of ROS mitochondrial dysfunction and ferroptosis.

RAS-selective lethal 3 (RSL3), on the other hand, alkylates the nucleophilic active site of selenocysteine of GPX4 and causes its inactivation and loss of function in the hydroperoxides repair process. This causes the accumulation of peroxides that exert a direct enhancement of ferroptosis. Ferroptosis inducing 56 (FIN56) promotes the degradation of GPX4, while $FINO_2$ leads to inhibition of its activity. Several activators and inhibitors of the different processes of ferroptosis in different model systems are shown in Table 2.

Second, Ferroptosis Suppressor Protein 1 (FSP1) (formerly known as apoptosis-inducing factor mitochondrial 2 (AIF-M2)) has been shown as independent of glutathione/GPX4 in the suppression of phospholipid peroxidation and ferroptosis (Doll et al. 2019). FSP1, an NAD(P)H oxidoreductase, reduces ubiquinol to ubiquinone-10 (CoQ10), a lipophilic radical-trapping antioxidant that suppresses the formation of PL-PUFA-OOHs. Remarkably, the mevalonate pathway (MVP) is a nexus that transverses GPX4 and FSP 1 via isopentenyl pyrophosphate GPX4 and ubiquinol (Bersuker et al. 2019). Furthermore, inhibition of MDM2/MDMX expression causes elevation of FSP1 protein and resultant higher levels of coenzyme Q10.

Ferroptosis, Table 2 Some inducers and inhibitors of ferroptosis

	Function	Mode of action
Erastin, piperazine erastin (PE), imidazole ketone erastin (IKE), erastin analogs, sulfasalazine, glutamate, sorafenib	Inhibit system Xc−	Prevents cystine import, causes GSH depletion
Cystine/cysteine deprivation, buthionine sulfoximine (BSO), cisplatin	GSH	GSH depletion
(1S,3R)-RSL3, ML162, diphenyleneiodonium (DPI) compounds	GPX4	Inhibitor of GPX4 induce accumulation of lipid hydroperoxides
FINO2	Lipid peroxidation	Induces lipid peroxidation; indirectly inhibits GPX4
FIN56	Squalene synthase (SQS) and GPX4	Depletes CoQ10; decreases GPX4 levels
Statins	HMGCR	Block CoQ10 synthesis by mevalonate pathway inhibition
Phospholipids with two PUFA tails	Phospholipids	Induce lipid peroxidation
Trigonelline, brusatol	NRF2	Blocks NRF2 proteins
INF-γ	Downregulates expression of system Xc	GSH depletion
Ferroptosis inhibitors		
Ferrostatins, liproxstatins	ROS lipid peroxidation	Block lipid peroxidation
Cycloheximide	Protein synthesis	Suppresses ferroptosis induced by system Xc inhibitors
Vitamin E, alpha-tocopherol, CoQ10, idebenone	Lipid peroxidation	Block lipid peroxidation, inhibition of lipoxygenases
Deferoxamine (DFO), ciclopirox, deferiprone	Deferoxamine (DFO), ciclopirox, deferiprone	Deplete iron
Dihydrobiopterin (BH2), tetrahydrobiopterin (BH4)	Ubiquinol	Antioxidant effect; lipid remodeling
Deuterated PUFAs (D-PUFAs), MUFAs	Lipid peroxidation	Block lipid peroxidation
Lipoxygenase inhibitors (e.g., cinnamyl-3,4-dihydroxy-α-cyanocinnamate (CDC), baicalein and zileuton)	Lipoxygenases	Block lipoxygenase-induced lipid peroxidation
CoQ10, idebenone	Lipid peroxidation	Block lipid peroxidation
Dopamine	Neurotransmitter	Blocks GPX4 degradation
Vildagliptin, alogliptin, and linagliptin	Dipeptidyl peptidase-4 (DPP4)	Block lipid peroxidation

Adapted from Hadian and Stockwell (2020) and Stockwell et al. (2017)

Thirdly, coenzyme Q10 is also a product of GTP cyclohydrolase-1 (GCH1). GCH1 and its metabolite tetrahydrobiopterin (BH4) have a dual function of generating reduced CoQ10 (ubiquinol) and of remodeling lipids to selectively favor the preservation of phospholipids with two polyunsaturated fatty acyl tails while causing the peroxidation of aberrant phospholipids (Kraft et al. 2020). The GCH1-BH4-phospholipid axis thus presents a unique mechanism of ferroptosis resistance through the promotion of the abundance of the antioxidant BH4 and CoQ10 that is independent of the GPX4/glutathione system (Fig. 1).

Ferroptosis and Disorders

Ferroptosis is an iron-dependent form of regulated cell death involving the dysregulation of glutathione/GPX4 activity, iron metabolism, and lipid peroxidation leading to degenerative processes and tumor suppression. A compelling body of evidence over several years independently has revealed the association of tissue iron accumulation, lipid peroxidation and/or decreased levels of GSH and GPX4 in various pathologies. This is particularly pertinent to neurological diseases such as Parkinson's disease (PD), Alzheimer's disease (AD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS). Other neurodegenerative diseases that exhibit features of ferroptosis include acute renal failure drug-induced hepatotoxicity, tissue ischemia/reperfusion injury, T cell immunity, and cancer cell death (Li et al. 2020). Furthermore, the generation of ROS in the presence of iron via Fenton chemistry has also been linked to oxidative stress and diseases. Consequently, regulated GPX4 and FSP1 antioxidant defense machinery against oxidative stress when compromised results in ferroptotic cell death in tissues and organs. For example, in dementia, decreased GPX4 cortical content and impairment, elevated iron levels, and lipid peroxidation biomarkers such as hydroxynonenal, malondialdehyde, and acrolein have been reported. Furthermore, iron chelation, inhibitors of ACSL4 and intervention of vitamin E have been clinically beneficial to AD patients. These hallmarks of ferroptosis are the underlying factors driving a range of degenerative diseases and cancer. Consequently, inhibitors and inducers of ferroptosis can be exploited as targets for therapeutic purposes. Animal models of GPX4 gene deletion have revealed features of ferroptosis in pathologies in the kidney; ischemia-reperfusion injury (IRI) was observed in the liver, heart, and the brain. Glutathione/GPX4 enzymatic activity is essential for the maintenance of membrane integrity by inhibiting and repairing membrane protein damage and the elimination of electrophiles arising from lipid peroxidation. This function can only be partially redundant in the presence of hydrophobic, membrane-restricted chain-breaking radical-trapping antioxidants (RTAs) such as α-tocopherol (vitamin E) or phenothiazine. While overwhelming evidence alludes to ferroptosis as an anticancer process, the molecular mechanisms are intricate. P53, a tumor suppressor protein apart from being a transcriptional regulator of SLC7A11 also modulates the expression of spermidine/spermine N1-acetyltransferase 1 (SAT1) and glutaminase 2 (GLS2) to promote ferroptosis. SAT1 elevates the expression of arachidonate 15 lipoxygenase, while GLS2 increases glutamine levels through glutaminolysis which depending on the context could be equivocal. Other independent inducers of ferroptosis are CD8+ T-driven IFN-ɣ that downregulates the expression of SLC7A11 as well as the effect of radiation which directly induces peroxidation of lipids (Hadian and Stockwell 2020). **A** Yes-associated protein (YAP) is a transcriptional coactivator in the Hippo tumor-suppressing signaling pathway that could also promote ferroptosis.

Chemical compounds that inhibit the activity of GPX4 and lipid peroxidation need to be tested and evaluated in clinical trials for the therapy of degenerative diseases (Stockwell et al. 2017). Conversely, inducers of players of ferroptosis from the proximate to the terminal process such as system xc and ACSL4 could be employed in a regulated manner to promote ferroptosis in cancer therapy. Pharmacological strategies could also be targeted at processes such as the Nrf2 antioxidant system, transsulfuration pathway, ferritinophagy and hypoxia-inducible factors (Fuhrmann et al. 2020), and other pathways that are associated with ferroptosis.

In summary, the discovery of ferroptosis has opened up a new vista that has high potentials for the treatment of a myriad of diseases (Li et al. 2020). Research in ferroptosis is ripe to decipher and clarify issues that are yet to be resolved. For example, there is a need for a clear understanding of ferroptosis regulatory genes and their potentials in different cancer cells or tumors. What are the vital effectors of cell death downstream of lipid peroxidation? Research is required to define the unequivocal role of ferroptosis in tumorigenesis, inflammation, and immunogenicity. Another

important area of interest is to define the nature of the association and interactions of ferroptosis and other forms of cell death. The availability of stable inhibitors of ferroptosis in in vivo situations will facilitate research in the field. The definition of its physiological functions in normal metabolism and the identification of specific and selective biomarkers will be breakthroughs in the field. The definition of physiological functions of ferroptosis in normal metabolism, and the identification of specific, selective and sensitive biomarkers (such as the measurement of real-time GSH/ROS dynamics, analysis of iron-independent expression of TfR1 and lipid peroxidation kinetics) particularly in vivo, will be vital advances in the field.

Summary

Ferroptosis is a form of regulated iron-dependent cell death that is characterized by a lethal accumulation of lipid peroxides and impaired functionality of the antioxidant defense system. Ferroptosis is thus induced by the loss of function of the glutathione/GPX4-dependent antioxidant defenses and lack of the FSP1/ubiquinol compensatory/overlapping mechanism that results in excessive lipid peroxidation and cell death. Lipophilic antioxidants, iron chelators, and chemical compounds that inhibit or induce ferroptosis have potentials for therapy of degeneration diseases and cancer.

Fever

Joachim Roth
Department of Veterinary-Physiology and – Biochemistry, Institut für Veterinär-Physiologie und -Biochemie, Justus-Liebig-University of Giessen, Giessen, Germany

Definition

Fever is defined as a state of elevated body temperature (T_b), which is often part of the defensive responses of the host to the invasion of live or inanimate matter recognized as pathogenic or alien. The febrile rise of T_b is due to a change in the thermoregulatory characteristics, which was formerly called elevation of a "set point," a reference temperature that is compared with the regulated value of T_b. Since a neuronal correlate for such a reference signal does not exist, the term set point should no longer be used or be replaced by the term "balance point." The elevation of T_b under febrile conditions is actively achieved by coordinated behavioral and physiological responses with the aim to reduce heat loss (warm-seeking behavior, peripheral vasoconstriction) and increase heat production (shivering or non-shivering thermogenesis). The threshold T_bs, at which these responses are initiated, are shifted to higher values in the initial phase of fever (Fig. 1).

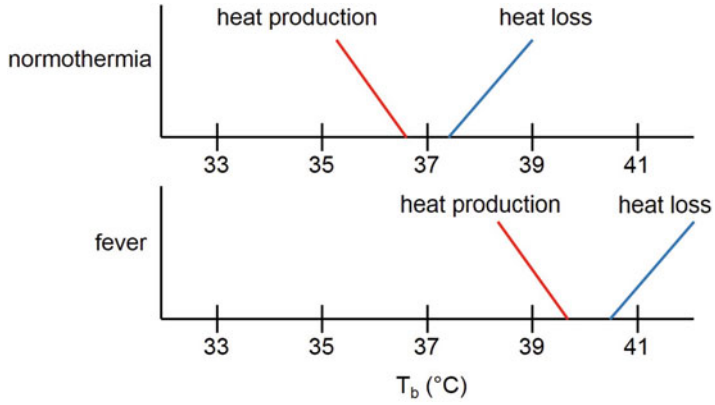
This shift represents the elevated thermoregulatory balance point during fever, which is above that during normothermia. The febrile upward shifts of thermoregulatory thresholds are caused by the action of pyrogenic substances, namely, prostaglandin E_2 (PGE_2), on neurons within the preoptic-anterior hypothalamic area (POA), which control efferent neuronal pathways to thermoregulatory relevant peripheral effector organs (Roth and Blatteis 2014).

Basic Mechanisms

Exogenous and Endogenous Pyrogens

Fever is a critical component within a series of defensive responses that occurs when live or inanimate agents enter the body through a break in one of its natural barriers. Here, they are quickly recognized as foreign or pathogenic by the innate immune system of the invaded host. Many different substances can provoke these responses (Table 1). Since they originate outside the body, they are called *exogenous* pyrogens. These exogenous pyrogens can be microbial or non-microbial or infectious or non-infectious in nature (Roth and Blatteis 2014).

The exogenous pyrogens listed in Table 1 are not the agents that directly cause fever and various other aspects of the acute-phase response (APR). Rather, upon their first contact with the invaded host's immune cells, they stimulate these cells to generate and release a number of factors that are the proximate mediators of the febrile response; these factors are termed *endogenous* pyrogens. The mechanisms whereby exogenous pyrogens are recognized, excite immune cells, and induce the generation of endogenous pyrogens can be briefly summarized as follows. The general assumption of this concept is that after the appearance of an exogenous pyrogen (e.g., lipopolysaccharide, LPS, the most frequently used exogenous pyrogen in experimental studies), the endogenous pyrogen would appear in the circulation of the LPS-treated individual to induce fever.

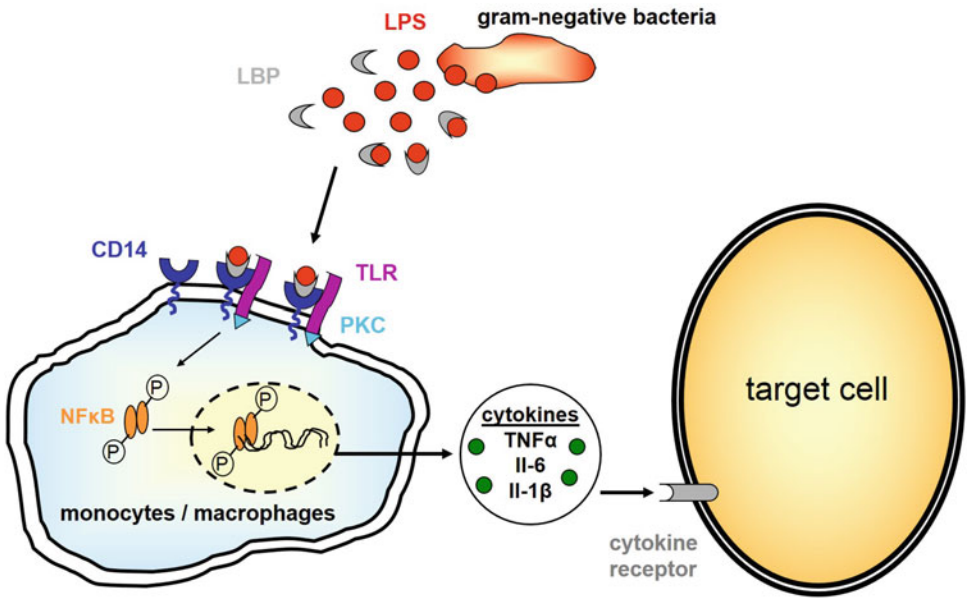


Fever, Fig. 1 Thermoregulatory thresholds in normothermic subjects (upper panel) and under febrile conditions (lower panel). The thresholds represent T_b, at which heat production or heat loss mechanisms are activated, when the subject is exposed to cold or heat. During the rising phase of fever, both thresholds are symmetrically shifted to higher values, indicating the elevated thermoregulatory balance zone. (Modified from Roth and Blatteis (2014))

Fever, Table 1 Pathogenic stimuli of microbial and non-microbial origin (exogenous pyrogens) that induce fever. (Modified from Roth and Blatteis (2014))

Examples for exogenous pyrogens	
1. Microbial	
Viruses	Whole organism, hemagglutinin, single or double stranded RNA
Bacteria	Gram-positive-whole organisms, cell walls, peptidoglycans, muramyl dipeptide, lipoteichoic acids, exotoxins, enterotoxins, erythrogenic toxins, group B polysaccharides
	Gram-negative-whole organisms, peptidoglycans, lipopolysaccharides (lipid A)
Mycobacteria	Whole organisms, lipopeptides (macrophage activating lipopeptide-2, fibroblast-stimulating lipopeptide-1) polysaccharides, lipoarabinomannan
Fungi	Whole yeast, zymosan, capsular polysaccharides, proteins
2. Non-microbial	
Antigens	Bovine serum albumin, bovine gamma globulin, ovalbumin, penicillin
Inflammatory agents	Turpentine, asbestos, silica, UV radiation
Plant lectins	Concanavalin A, phytohemagglutinin
Drugs	Synthetic polynucleotides (e.g., polyriboinosinic-polyribocytidylic acid, cytosine-phosphate-guanine-rich CpG-DNA), imidazoquinolines (imiquimod, gardiquimod), antitumor agents (bleomycin), plant alkaloids (colchicines), synthetic immunoadjuvants
Host-derived	Antigen-antibody complexes, activated complement fragments, inflammatory bile acids, urate crystals, androgenic steroid metabolites, lymphocyte products

Endogenous pyrogens are represented by a family of small proteins termed cytokines (Roth and Blatteis 2014; Garami et al. 2018). With a few exceptions, circulating cytokines are not detected in healthy individuals but appear in the blood during various states of disease to regulate and coordinate innate and adaptive immune responses. Pathogens share highly conserved microbial components called "pathogen-associated molecular patterns" (PAMPS). These activate the innate immune system via "Toll-like receptors" (TLRs) or other pattern recognition receptor families. Employing a number of intracellular adapter proteins, the interaction of a given PAMP with its TLR causes activation of the transcription factor nuclear factor-κB (NF-κB), which then is translocating into the nucleus of the PAMP-stimulated cell (Fig. 2).



Fever, Fig. 2 Schematic illustration of the coupling between exogenous and endogenous pyrogens at the cellular level with LPS from gram-negative bacteria as a representative example for an exogenous pyrogen. After binding of LPS to a LPS-binding protein, this complex is bound to CD14. LPS-loaded CD4 causes the activation of TLR4, the cognate receptor for LPS. In the LPS-stimulated cell, protein kinase C (PKC) and the transcription factor NF-κB are activated. Activated NF-κB migrates into the nucleus and causes the transcription of inflammatory target genes including those coding for the pyrogenic cytokines TNF-α, IL-1β, and IL-6. These cytokines are released, spill over into the bloodstream, and influence many types of target cells, which possess receptors for these cytokines. The target cells, which are relevant for the induction of fever, are located in the brain

Here, the transcription of a number of target genes is initiated, some of which are related to fever. These include the most important pyrogenic cytokines, tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6), which appear in the blood during fever in a characteristic sequence. The following further arguments support a role for peripherally released TNF-α, IL-1β, or IL-6 as endogenous pyrogens. Injections of all the three of these cytokines evoke fevers in man or experimental animals. Pharmacological tools, which aimed to neutralize, antagonize, or block the formation of single circulating cytokines after injection of a given exogenous pyrogen, attenuate the febrile response. Other cytokines, chemokines, adhesion molecules, receptors for inflammatory molecules, and the inducible forms (as opposed to constitutive forms) of the inflammatory enzymes cyclooxygenase-2 (COX-2) and microsomal prostaglandin E synthase-1 (mPGES-1) are further products of target genes, which show enhanced expression due to NF-κB activation. COX-2 and mPGES-1 are strongly coupled in their induction after an inflammatory insult and considered to be the critical enzymes for the generation of PGE_2 during fever (Blomqvist and Engblom 2018). Hepatic and pulmonary macrophages belong to the first cells, in which LPS causes a coupled induction of COX-2 and mPGES-1 (Garami et al. 2018). LPS, the most potent exogenous pyrogen, employs a second, faster way for peripheral formation of PGE_2 by activation of the complement cascade via the alternative pathway, namely, in Kupffer cells of the liver (Roth and Blatteis 2014). The rapid peripheral generation of PGE_2 seems to contribute to the initiation of a febrile response. In addition to TNF-α, IL-1β, IL-6, and PGE_2, there are more peripherally produced molecules with intrinsic pyrogenic properties upon stimulation of TLRs by a given exogenous pyrogen.

Actions of Pyrogens (PGE_2) on the Thermoregulatory System

The mammalian thermoregulatory system consists of a sensory afferent part, a central integrative part, and an efferent part terminating at the distinct effector organs. Information about environmental temperature is generated by peripheral thermosensors (predominantly cold sensors) and transmitted to the spinal dorsal horns. Here, secondary neurons receive and transport the thermal signals via the pontine lateral parabrachial nucleus (LPB) to the thermoregulatory relevant neurons within the POA (Morrison and Nakamura 2019). These structures represent the so-called pyrogenic zone within the POA, where smallest amounts of PGE_2 cause a rise of T_b (Blomqvist and Engblom 2018). The critical neurons within the POA use, in part, gamma amino butyric acid (GABA) as neurotransmitter. These GABAergic neurons exert a tonic inhibitory influence on secondary neurons located in the dorsomedial hypothalamus and in the rostral medullary raphe pallidus nucleus, which directly control thermogenesis and vasomotor tone via the sympathetic nervous system. After disinhibition by external cooling or by the appearance of PGE_2 within the POA, appropriate thermoeffector responses are activated via the descending neuronal pathways to brown adipose tissue (BAT), blood vessels, or skeletal muscles (Morrison and Nakamura 2019). The inhibitory GABAergic neurons are, in part, warm-sensitive and equipped with PGE_2 receptors of the subtype EP3. An inhibition of central GABAergic warm-sensitive neurons by action of PGE_2 on the EP3 receptor is considered as the central drive for the generation of fever (Blomqvist and Engblom 2018).

Transfer of Fever-Generating Signals Across the Blood-Brain Barrier

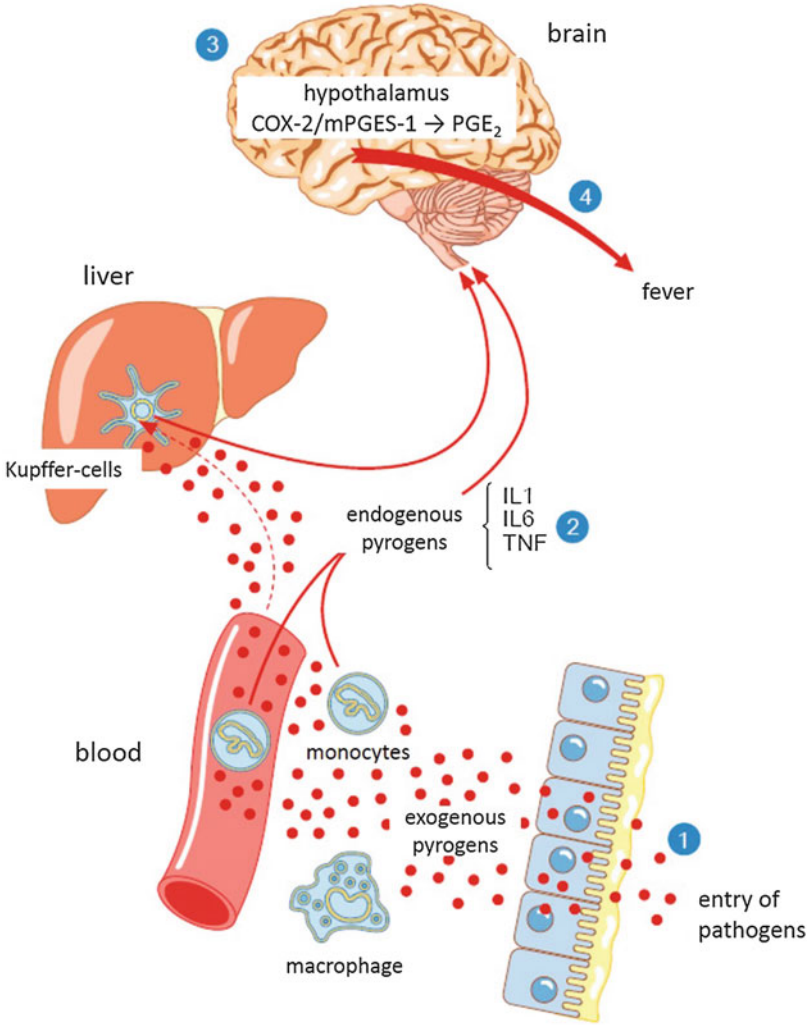
The structures of the POA, where PGE_2 (or any other pyrogenic substance) causes the febrile shift of the thermoregulatory balance point to a higher level, are located inside the blood-brain barrier (BBB). Four possible routes for the transfer of febrile signals to the brain are briefly introduced, (I) the circumventricular organs lacking a tight BBB, (II) cells forming the BBB and acting as relay stations for the transfer of febrigenic signals to the brain, (III) transport of endogenous pyrogens into the brain, and (IV) the activation of afferent nerves by peripherally generated pyrogens (Dantzer 2018). Mechanisms I–III can be summarized as the "humoral pathway for the induction of fever." This predominant pathway is illustrated in Fig. 3.

Sensory Circumventricular Organs (CVOs)

The parenchyma capillaries of the sensory CVOs possess a fenestrated endothelium, thus allowing circulating hydrophilic signal molecules, including endogenous or exogenous pyrogens, to enter the brain. With regard to fever, special attention has been directed to the *organum vasculosum laminae terminalis* (OVLT) due to its close proximity to the POA (Roth and Blatteis 2014). There is an extensive expression of receptors for cytokines and even of TLRs in the OVLT. The sensory CVOs including the OVLT belong to the most responsive sites within the CNS to systemic inflammatory stimulation. Their role as exclusive central sensors for pyrogenic cytokines or PAMPs is challenged by the fact that cells forming the BBB in the surrounding regions of the POA, namely, endothelial cells and perivascular macrophages, are also equipped with receptors for PAMPs and cytokines and are also highly responsive to inflammatory stimulation (Blomqvist and Engblom 2018).

Cells Forming the Blood-Brain Barrier (BBB)

Cells forming the BBB, vascular endothelial cells, and perivascular macrophages, within the entire brain, have the capacity to secrete cytokines (IL-6), PGE_2, and other mediators into the brain parenchyma after their respective inflammatory stimulation from the luminal blood side. Especially brain endothelial cells play an important role in the transduction of inflammatory signals from the blood to the brain (Blomqvist and Engblom 2018). The expression of TLRs and of receptors for pyrogenic cytokines on brain endothelial cells enable their direct responsiveness to many kinds of pyrogens. In brain endothelial



Fever, Fig. 3 Humoral pathway for the induction of fever. Fever is generated in a sequence of four steps. (1) A pathogen (red circles) enters the host through one of the natural barriers (gastrointestinal tract, respiratory tract, urogenital tract, or skin). PAMPs activate TLRs on monocytes or macrophages. A break within the gastrointestinal tract causes the transport of exogenous pyrogens predominantly to the liver, where Kupffer cells are activated by the same mechanisms. (2) Monocytes, macrophages, and Kupffer cells produce endogenous pyrogens/cytokines (TNF-α, IL-1β, IL-6). Cytokines and PAMPs reach the brain via the bloodstream. (3) In the brain (endothelium; OVLT), a coupled induction of COX-2/mPGES-1 occurs, and large amounts of PGE_2 are produced and released abluminally into the POA (hypothalamus). (4) In the POA PGE_2 inhibits warm-sensitive/GABAergic neurons via the EP3 receptor, with the consequence that heat production is activated at a higher T_b – fever develops. (Modified from Roth and Blatteis (2014))

cells, circulating pyrogens thus cause an activation of NF-κB (Fig. 1) and other inflammatory transcription factors (Rummel 2016). In the context of fever, the target genes of these transcription factors include COX-2 and mPGES-1. Like in peripheral macrophages, the coupled induction of COX-2 and mPGES-1 in brain endothelial cells is important for inflammatory formation of PGE_2 in the brain. The co-localized expression of both these inducible enzymes in brain endothelial cells is the prerequisite for sustained PGE_2 synthesis in the POA during fever and the subsequent activation of the EP3 receptor (Blomqvist and Engblom 2018).

Transport of Pyrogens Across the Blood-Brain Barrier

Small amounts of pyrogenic cytokines can pass the BBB through specific saturable trans-endothelial transport systems (Roth and Blatteis 2014). It is a matter of debate whether the amounts of transported cytokines are sufficient to trigger a febrile response. An entry of peripherally derived PGE_2 through the BBB by specialized transporters is also possible and has been suggested to contribute to the early onset of fever prior to the formation of PGE_2 by the cells forming the BBB (Garami et al. 2018).

Inflammatory Signal Transfer from the Periphery to the Brain Via Sensory Nerves

Afferent fibers of the vagus nerve and of somatic nerves have been suggested to contribute especially to the early stage of fever. In the ganglia containing the cell bodies of these fibers, receptors for cytokines and the EP3 receptor for PGE_2 are expressed. This means that afferent nerve fibers can be readily activated by PGE_2, which is released by Kupffer cells in the liver (vagus nerve) or within other inflamed tissues (somatic nerves). Evidence for a role of sensory afferent parts of peripheral nerves in the generation of fever has mainly been obtained in experimental models, which mimic localized peripheral inflammation (Roth and Blatteis 2014; Blomqvist and Engblom 2018; Dantzer 2018). This mechanism might reflect situations, when fever is observed in absence of circulating pyrogens.

Pharmacological Intervention

During infection and inflammation, the prominent febrile increase of body temperature (T_b) is not an isolated event. Fever is rather an integrated component of a complex array of brain-mediated, nonspecific host defense responses to the invasion of the body by pathogens. It is thus a physiological, not a pathological, reaction. These brain-mediated responses include a range of behavioral changes collectively termed "sickness behavior" (Dantzer 2018; Harden et al. 2015). Presumptively the sense of these behavioral changes is to restrict physical activity of the infected host in order to conserve energy for the restoration of health (Dantzer 2018). Antipyretic (self-)administered drugs are routinely used to antagonize other components of the sickness syndrome rather than fever, for example, pain or general malaise. The question of whether fever is of maladaptive value and should thus be treated or rather an adaptive response to improve the fight against infection is still discussed controversially. Experimental studies have shown that nearly all components of innate and adaptive immunity are enhanced and accelerated by febrile temperatures. Meta-analyses of clinical studies could, however, not provide an unequivocal response to the question, whether treatment of fever in populations of patients in intensive care units is beneficial of detrimental (Harden et al. 2015). Two principle strategies are available for interventions with aim to reduce fever: pharmacological therapy with nonsteroidal anti-inflammatory drugs (NSAIDs like ibuprofen) or acetaminophen (paracetamol), on the one hand, or physical therapy by use of cooling mechanisms on the other hand. Pharmacological strategies most frequently interfere with the mechanisms leading to the formation of PGE_2, the final mediator of fever. In this case, active heat production by the infected host is suppressed. Physical cooling reduces T_b without depressing endogenous heat production. The inhibition of PGE_2 formation can be achieved at distinct steps with the signal pathways for fever induction shown in Figs. 2 and 3. Traditionally, COX-inhibitors are used for antipyretic treatment. Non-selective COX-inhibitors block the constitutive (COX-1) as well as the inducible isoform (COX-2). The side effects of these drugs include gastrointestinal bleeding or disturbance of renal blood flow. Selective COX-2 inhibitors, on the other hand, which were approved for clinical use, exert adverse cardiovascular effects when used at higher doses. Especially in experimental studies, other drugs are frequently employed, which antagonize formation and action of pyrogenic cytokines or inhibit inflammatory transcription factors. A summary of antipyretic and anti-hyperthermic strategies is provided in Table 2.

Fever, Table 2 Some antipyretic or antihyperhermic therapies currently in use or under test in experimental studies. (Modified from Roth and Blatteis (2014))

Routine
Acetaminophen (paracetamol)
Glucocorticoids (cortisone, prednisolone)
COX-inhibitors, nonselective (NSAIDs, aspirin, ibuprofen, and others)
COX-2 inhibitors, selective or preferential (celecoxib, meloxicam, and others)
Emergency
Sponging
Ice packs
Cooling blankets
Inhaled or ambient helium-oxygen
Others (mostly experimental)
Antioxidants (catechins, vitamin E, platonin)
LPS sequestrants, anti-lipid A
Anti-inflammatory cytokines (IL-4, IL-10)
Cytokine antagonists (IL-1-receptor antagonist, soluble TNF-receptors, antibodies)
mPGES-1 inhibitors
Phospholipase (PL) A2 inhibitors
Antibacterials, antivirals, antifungals
Complement fragment 5a (C5a) antibodies, synthetic C5aRas
Anti-NF-κB (parthenolide)
Anti-JAK-STAT agents (AG 490)
μ-opioid receptor antagonists (naloxone)

Fibroblast Growth Factors

Paola Chiodelli and Marco Presta
Department of Molecular and Translational Medicine, University of Brescia, Brescia, Italy

Definition

Fibroblast Growth Factors (FGFs) are a family of proteins that regulate a variety of physiological and pathological processes, including embryogenesis, tissue homeostasis, wound repair, and cancer. They exert these functions by binding to Fibroblast Growth Factor Receptors (FGFRs), triggering the activation of multiple signal transduction pathways that modulate the proliferation, differentiation, survival, migration, and metabolism of target cells.

Basic Characteristics

FGFs

The FGF family contains 22 members that act as paracrine, autocrine, or endocrine factors for different cell types. They are divided into seven subfamilies in accordance with their sequence similarity, biochemical function, and evolutionary relationship.

Canonical FGFs encompass subfamilies FGF1/2/5, FGF3/4/6, FGF7/10/22, FGF8/17/18, and FGF9/16/20. To induce their paracrine/autocrine responses, canonical FGFs bind to and activate tyrosine kinase (TK) FGFRs. FGF/FGFR interaction is stabilized by heparan sulfate (HS) proteoglycans (HSPGs), resulting in the formation of biologically active FGF/FGFR/HSPG ternary complexes, fundamental for signal transduction. During development, canonical FGFs are involved in several regulatory functions,

including the patterning of germ cell layers, formation of body axes, morphogenesis, and induction of organogenesis. Moreover, FGFs play a prominent role in the adult, where they contribute to tissue homeostasis, remodeling, and repair.

Intracellular FGF11/12/13/14, also known as FGF homologous factors (FHFs), act at the intracellular level in a FGFR-independent manner. They play a pivotal role in neuronal functions at postnatal stages and in regulating the cardiac rhythm by interacting with the intracellular domains of voltage-gate sodium and calcium channels and with the neuronal mitogen-activated protein kinase (MAPK) scaffold protein islet-brain-2.

The members of the FGF19/21/23 subfamily are hormone-like FGFs that exhibit poor affinity for HSPGs, a characteristic that results in more diffusive properties through blood circulation. They play a crucial role in regulating various metabolic processes, including phosphate, glucose, and lipid metabolism. Besides FGFRs, they interact in a specific manner with Klotho co-receptors to activate intracellular signaling responses (Presta et al. 2017; Giacomini et al. 2016; Ornitz and Itoh 2015).

FGFRs and HSPGs

Four distinct genes encode for FGFRs in mammals (*FGFR1–4*). FGFRs consist of three extracellular immunoglobulin-like (Ig) domains (D1–3), a single transmembrane domain and an intracellular TK domain. D2 and D3 domains are responsible for FGF binding, whereas the acid box between the first and second Ig loop is involved in HSPG interaction. FGFRs exhibit diverse specificities for FGF ligands and the alternative splicing of the D3 domain generates IIIb and IIIc isoforms of FGFR1, 2, and 3 that are endowed with additional ligand-binding properties. Interestingly, FGFR1–3IIIb and FGFR1–3IIIc variants often display a distinct pattern of expression in epithelial and mesenchymal tissues, respectively. Under physiological conditions, a ligand produced by epithelial cells will usually activate a mesenchymal receptor and vice versa, with exceptions.

FGFs can interact with different cell surface co-receptors, thus facilitating their productive binding to FGFRs. Among them, the interaction with HSPGs plays a pivotal role in mediating the biological activity of FGFs. HSPGs are glycoproteins expressed by almost all the cell types as membrane-associated receptors, extracellular matrix (ECM) components, and/or free molecules. They are composed by HS chains covalently linked to a core protein. HSPGs of the ECM may represent a reservoir for FGFs by sequestering the growth factors near the site of action and may allow the formation of FGF gradients that are essential for paracrine signaling. HSPGs are needed for a productive FGF/FGFR interaction. Indeed, HSPGs, FGFs, and FGFRs form 2:2:2 ternary complexes that induce receptor dimerization, a change in the receptor conformation and *trans*-phosphorylation of tyrosine residues in the FGFR TK domain. Multiple signal transduction pathways are activated by receptor phosphorylation, thus generating distinct cellular responses. HS chains can undergo structural modifications that affect FGFR signaling and are responsible for its fine-tuning regulation. At variance with canonical FGFs, the activity of hormone-like FGFs depends on the presence of Klotho proteins as co-receptors. Cell surface β-Klotho and α-Klotho act as co-factors for FGF19/21 and FGF23, respectively. They limit nonspecific/off-target signaling by converting FGFRs into high affinity receptors for endocrine FGFs (Presta et al. 2017; Giacomini et al. 2016).

FGF/FGFR Signaling

FGFR engagement induces the activation of multiple signal transduction pathways. As mentioned above, the phosphorylation of specific tyrosine residues in the TK domain of FGFRs results in the formation of docking sites for adaptor proteins that regulate downstream signaling. The activation of the intracellular specific adaptor protein fibroblast growth factor receptor substrate 2 (FRS2) recruits the adaptor proteins guanine nucleotide exchange factor 2 (GRB2) and son of sevenless (SOS) and activates the RAS/mitogen activated protein kinase (MAPK) pathway, mainly implicated in cell proliferation and

differentiation. In turn, GRB2 recruits GRB2-associated binding protein 1 (GAB1), leading to the activation of the phosphoinositide 3 kinase (PI3K)/RAC-alpha serine/threonine-protein kinase (AKT) pathway associated with cellular survival and cell fate determination. Phospholipase C gamma (PLCγ) is a further target of activated FGFRs. PLCγ hydrolyzes phosphatidylinositol-diphosphate (PIP2) into inositol-triphosphate (IP3) and diacylglycerol (DAG). DAG and cytoplasmic calcium released from the endoplasmic reticulum in response to IP3 lead to the activation of protein kinase C (PKC). This pathway sustains MAPK and AKT signaling and plays a role in cell migration, adhesion, and cell morphology. Other pathways activated by FGFRs include the signal transducers and activator of transcription (STAT)-dependent signaling, p38 MAPK, and ribosomal S6 protein kinase (RSK).

FGFR-mediated signaling is modulated by various intracellular mechanisms. The RAS/MAPK pathway can act as a negative feedback modulator by inhibiting FGFR activation. Sprouty proteins (SPRY) interact with GRB2 in order to inhibit or modulate RAS/MAPK and PI3K/AKT signaling, respectively. SHP2 dephosphorylates and switches off FGFR signaling, whereas MAPK phosphatase-3 (MKP-3) directly dephosphorylates extracellular signal-regulated kinases$_{1/2}$ (ERK$_{1/2}$). Lastly, the transmembrane protein similar expression to FGF (SEF) prevents FGFR activation by binding the extracellular moiety of the receptor and suppresses FGF signaling by inhibiting the RAS/MAPK pathway (Fig. 1).

FGFs in Physiology

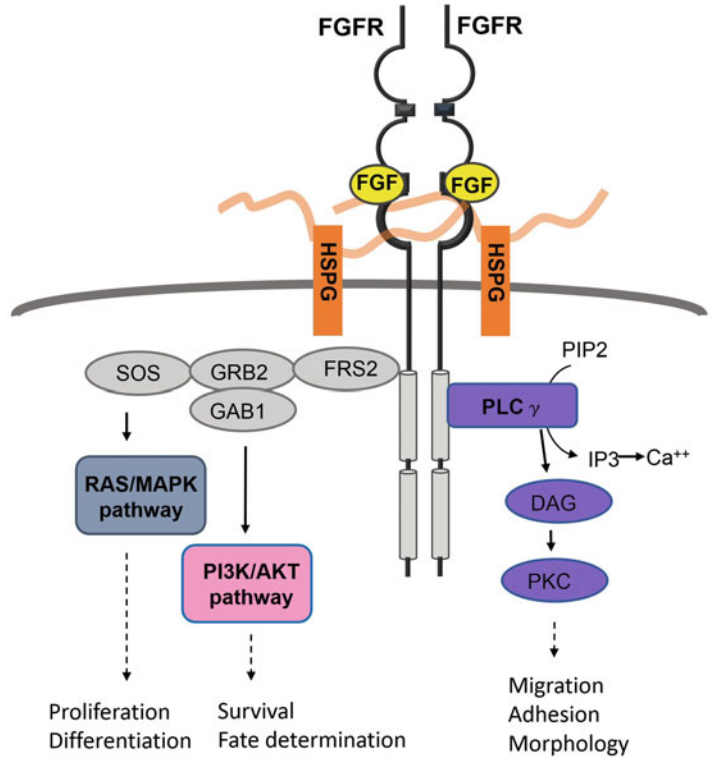
Embryonic Development

FGFs regulates several developmental events, including patterning of germ cell layers, formation of body axes, coordination of morphogenetic movements, induction of organogenesis, and morphogenesis.

Germ cell layer patterning. FGF signaling is highly involved in the specification of the mesoderm and neuroectoderm. Several studies indicate that FGFs act as diffusive signaling proteins implicated in the formation of the mesoderm (axial induction and paraxial maintenance) and of the neural tissue derived from the embryonic ectoderm. FGFs are involved in the induction of the posterior nervous system and are crucial for embryonic morphogenesis during gastrulation by regulating cell proliferation, differentiation, and senescence and by coordinating morphogenetic movements. The concentration gradient of the FGF morphogen across the embryo is regulated by HSPGs and induces cellular responses in a dose-dependent manner. FGF gradients are controlled also by ligand trafficking and secretion, ligand and receptor endocytosis, and by feedback mechanisms triggered by inhibitors of the FGF/FGFR axis.

Axes specification. FGFs are implicated in the patterning of the dorsoventral, anteroposterior, and left/right axes of the embryo. The maternal Wnt/β-catenin pathway and the zygotic bone morphogenetic protein (BMP) pathway contribute with FGFs in the definition of the dorsoventral axis. FGF signaling promotes dorsal fates and inhibits ventral fates by restricting the expression and activity of BMPs. As in dorsoventral patterning, FGF activity regulates anteroposterior patterning by a coordinated action with retinoic acid and Wnt. During anteroposterior extension, the formation of a FGF activity gradient from posterior to anterior that occurs in parallel with an inverse gradient (from anterior to posterior) of retinoic acid activity represents a conserved mechanism that regulates the patterning and timing of differentiation in the posterior region. Regarding the left/right axis determination, FGF signaling is involved in the formation of the node and nodal cilia and in the modulation of the expression of genes that determine the right and left side of the embryo body.

Organogenesis. At first, the FGF/FGFR system plays a crucial role in the specification of the trophectoderm and of the primitive endoderm. Later in development, FGFs exert nonredundant functions in organogenesis, including the formation of the anterior and secondary heart fields, induction of limb and lung buds, and in the development of liver, pancreas, kidney, inner ear, and



Fibroblast Growth Factors, Fig. 1 FGFR-mediated signaling. See text for details (Presta et al. 2017; Giacomini et al. 2016; Turner and Grose 2010)

brain. In this frame, FGF signaling plays a key role in regulating the interaction between epithelial cells and the mesenchyme. As described above, alternative mRNA splicing leads to the production of the IIIb or the IIIc FGFR isoforms. These receptor variants are regulated in a tissue-specific manner and determine ligand-receptor binding specificities. While the FGFR-IIIb isoforms are expressed in epithelial lineages, FGFR-IIIc variants are expressed mainly by mesenchymal lineages. Adjacent tissues produce FGFs specific for the distinct FGFR isoforms, thus generating a directional epithelial-mesenchymal signaling. Even though with some exceptions, branched organs (lung, salivary gland, and lacrimal gland), intestine, liver, and limb bud development are guided by the binding of mesenchymal FGFs (e.g., FGF7 and FGF10) to epithelial FGFR-IIIb variants. Conversely, FGFs expressed by epithelia (e.g., FGF8 and FGF9) can activate mesenchymal FGFR-IIIc isoforms (Dorey and Amaya 2010; Bottcher and Niehrs 2005).

Tissue Homeostasis

FGFs exert homeostatic functions in the adult, being involved in tissue maintenance, repair, remodeling processes, and metabolism. In adults, FGFs/FGFRs are expressed in a cell type-specific fashion to maintain tissue homeostasis and function. FGFR-IIIb variants and their ligands are essential for the homeostasis of different tissues. For instance, FGFR-IIIb receptors are important in the maintenance of skin annexes and epidermal barrier function following their engagement by FGF1, FGF7, FGF10, and FGF22 expressed in different compartments of the skin. Liver homeostasis and regeneration is regulated by the expression of the FGFR2-IIIb variant in hepatocytes. FGF10 signaling is known to play an essential role in cardiac homeostasis. Stromal FGF7/FGF10 and epithelial FGFR2 are important in the maintenance of prostate tissue homeostasis and androgen signaling. FGF2, as well as FGF4, FGF8, FGF9, FGF10, and FGF18, play important roles in bone homeostasis. FGF2/FGFR1 and FGF18/FGFR3 axes have been implicated in the

regulation of articular and intervertebral disc cartilage homeostasis. Finally, the FGFR1-IIIc isoform is involved in vascular permeability.

Hormone-like FGF19, FGF21, and FGF23 coordinate different metabolic pathways. They lack conventional heparin-binding domains, making them able to be readily present in the blood circulation, thus acting in an endocrine-like manner. These factors require Klotho co-receptors that define tissue selectivity and determine their distinct physiological roles. FGF19 (FGF15 in mice) regulates cholesterol/bile acid synthesis and homeostasis, stimulates glycogen and protein synthesis in the liver, represses gluconeogenesis, and governs nutrient metabolism. FGF21 is involved in the control of glucose and lipid metabolism by modulating gluconeogenesis, hepatic lipid oxidation, and ketogenesis. FGF23 plays a critical role in phosphate homeostasis and vitamin D metabolism in the kidney.

As described below, abnormal expression of FGFs and FGFRs and aberrant activation of FGF signaling are observed in various adult tissue-specific pathologies and may cause developmental disorders (Ornitz and Itoh 2015; Itoh et al. 2015; Yang et al. 2015; Steiling et al. 2003).

Wound Healing

The importance of FGFs and their receptors in tissue regeneration and repair is well documented. Wound repair requires the cooperation of various cell types, including keratinocytes, fibroblasts, endothelial cells, macrophages, and platelets. They orchestrate a series of coordinate events, including cell proliferation and migration, ECM deposition and remodeling, wound contraction, and angiogenesis. FGF7, FGF10, and FGF22, all ligands of the FGFR-IIIb variant, exert a prominent role in wound repair. They target epithelial cells, including keratinocytes, stimulating cell proliferation and migration, and reduce reactive oxygen species production, thus preserving cells from apoptosis. In addition, inflammatory cells, vascular endothelial cells, fibroblasts, and keratinocytes produce FGF1 and FGF2 in the acute wound. They act predominantly on stromal cells that express the FGFR-IIIc variant. They play a role in granulation tissue formation, re-epithelialization, angiogenesis, and tissue remodeling, regulating the synthesis and deposition of various ECM components and promoting fibroblast migration. Deregulation of the FGF/FGFR system is associated with chronic wound. Angiogenesis (the formation of new blood vessels from pre-existing ones) represents a key step during tissue repair, delivering nutrients and oxygen to support the energy-consuming process of tissue remodeling. FGF1, FGF2, FGF4, FGF8b, and FGF10 trigger an angiogenic response by acting on FGFR1 and FGFR2 expressed by endothelial cells. They modulate different steps of the angiogenesis process, including endothelial cell proliferation and migration, ECM degradation, morphogenesis, and vessel maturation. FGFs have been implicated also in tumor angiogenesis (Muller et al. 2012; Werner and Grose 2003; Presta et al. 2005; Maddaluno et al. 2017; Beenken and Mohammadi 2009).

FGFs in Pathology

Genetic Diseases

The wide range of disorders observed when the FGF/FGFR axis is genetically mutated reflects the complex function exerted by this system during tissue development and homeostasis. *FGF/FGFR* genes show germline mutations in at least 24 distinct human congenital disorders (Table 1). Most of these syndromes are characterized by skeletal, cranial, and limb abnormalities. At the skeletal level, altered ossification may result in short-limbed dwarfism and craniosynostosis, characterized by the premature fusion of one or several cranial sutures. Gain-of-function mutations of the D3 domain of FGFRs, that cause ligand-independent FGFR dimerization and activation, are observed in this type of syndromes. In addition, genetic disorders characterized by deafness, endocrine or renal abnormalities, and neurological diseases have been described, frequently associated with FGF/FGFR loss-of-function mutations. As for canonical FGFs, FHFs have been implicated in genetic disorders, providing insights about their role in ion channel function (Helsten et al. 2015; Moosa and Wollnik 2016).

Fibroblast Growth Factors, Table 1 Genetic disorders and malignant conditions associated with aberrant FGF/FGFR signaling

	Heritable FGF/FGFR gene mutation	Acquired FGF/FGFR deregulation in malignancy
Gene	**Genetic disorder**	**Type of cancer**
FGF alterations		
FGF1		Ovarian cancer
FGF2		Bladder cancer, prostate cancer, small cell lung carcinoma, melanoma, hepatocellular carcinoma
FGF3	Michel aplasia, labyrinthine aplasia, microtia, and microdontia (LAMM) syndrome	Breast cancer
FGF4		Breast cancer
FGF5	Trichomegaly	Glioblastoma
FGF6		Prostate cancer
FGF7		Lung adenocarcinoma
FGF8	Hypogonadotropic hypogonadism 6 with/without anosmia (Kallmann syndrome)	Breast cancer, prostate cancer, hepatocellular carcinoma, colorectal cancer
FGF9	Multiple synostoses syndrome 3	Colorectal and endometrial carcinomas, non-small cell lung cancer
FGF10	Lacrimo-auricular-dento-digital (LADD) syndrome, aplasia of the lacrimal and salivary glands (ALSG)	Breast carcinoma, prostate cancer
FGF12	Brugada syndrome	
FGF14	Spinocerebellar ataxia type 27 (SCA27)	
FGF16	Metacarpal 4–5 fusion	Ovarian cancer
FGF17	Hypogonadotropic hypogonadism 20 with/without anosmia	Prostate cancer, hepatocellular carcinoma
FGF18		Hepatocellular carcinoma
FGF19		Prostate cancer, hepatocellular carcinoma
FGF20	Renal hypodysplasia/aplasia 2	
FGF23	Hypophosphatemic rickets, Familial hyperphosphatemic tumoral calcinosis	Increased risk of prostate cancer
FGFR alterations		
FGFR1	*Skeletal dysplasia:* Osteoglophonic dysplasia *Craniosynostosis:* Jackson–Weiss syndrome, Pfeiffer syndrome *Others:* Hartsfield syndrome, Hypogonadotropic hypogonadism 2 with or without anosmia, Trigonocephaly 1	Small cell lung cancer, squamous cell lung cancer, breast cancer, ovarian cancer, pancreatic ductal adenocarcinoma, tongue squamous cell carcinoma, melanoma, pilocytic astrocytoma, leukemia, lymphoma, alveolar rhabdomyosarcoma, glioblastoma, myeloproliferative syndrome
FGFR2	*Skeletal dysplasia:* Bent bone dysplasia, *Craniosynostosis:* Antley–Bixler syndrome without genital anomalies or disordered steroidogenesis, Apert syndrome, Beare–Stevenson cutis gyrata syndrome, craniofacial-skeletal-dermatological dysplasia, Crouzon syndrome, Jackson–Weiss syndrome, Pfeiffer syndrome, Saethre–Chotzen syndrome,	Gastric cancer, breast cancer, Cholangiocarcinoma, Endometrial carcinoma

(continued)

Fibroblast Growth Factors, Table 1 (continued)

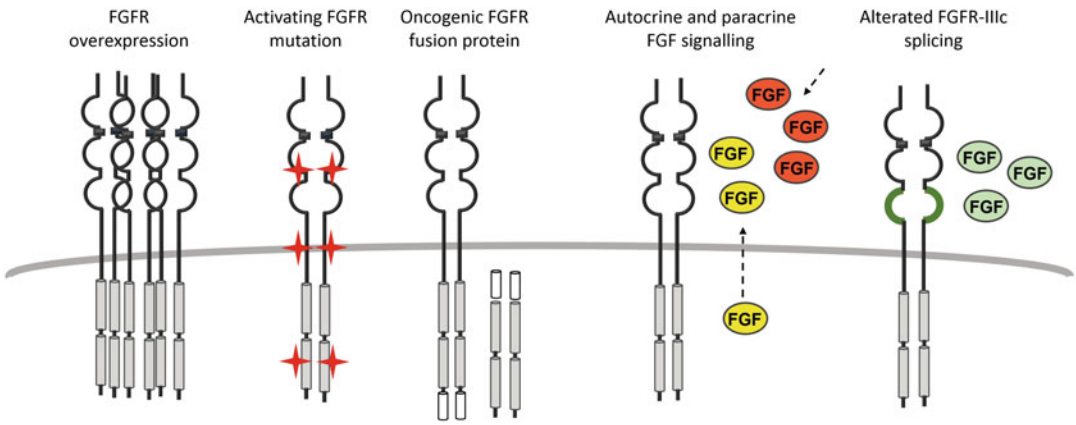
	Heritable FGF/FGFR gene mutation	Acquired FGF/FGFR deregulation in malignancy
	Scaphocephaly, maxillary retrusion, and mental retardation *Others:* LADD syndrome	
FGFR3	*Skeletal dysplasia:* Achondroplasia, Hypochondroplasia, Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN) syndrome, Thanatophoric dysplasia type 1 and 2, *Craniosynostosis:* Crouzon with acanthosis nigricans, Muenke syndrome *Others:* Camptodactyly-tall stature-scoliosis-hearing loss (CATSHL) syndrome, LADD syndrome	Gastric cancer, colorectal cancer, breast cancer, endometrial carcinoma, urothelial carcinoma, bladder tumor, skin tumor, myeloma, Squamous cell lung cancer, bladder cancer, glioblastoma, lymphoma, Colon cancer
FGFR4		Rhabdomyosarcoma, adenoid cystic carcinoma, breast Cancer, Ovarian cancer, hepatocellular carcinoma

Cancer

Tumors are characterized by a tight cross-talk between cancer and stromal cells, including inflammatory cells (e.g., lymphocytes, macrophages, and mast cells), fibroblasts, and vascular components. The various cellular components express different FGFRs and can release FGFs in the tumor microenvironment. This triggers a complex network of autocrine/paracrine loops of stimulation that acts on both the parenchymal and stromal compartments of the neoplastic tissue. Deregulation of the FGF/FGFR system occurs in human tumors, leading to the aberrant activation of ligand-dependent or ligand-independent FGFR signaling (Table 1). Different genetic alterations that occur in cancer cells, including activating *FGFR* gene mutations of the extracellular, transmembrane or TK domain of the receptor, chromosomal rearrangements, *FGFR* gene amplification, translocation, or transcriptional deregulation, may result in aberrant FGFR signaling. Unlike *FGFRs*, somatic *FGF* mutations are rarely observed in human tumors and appear to be limited to *FGF9* mutations as occurs in colorectal and endometrial cancers. Nevertheless, aberrant expression of different FGFs has been observed in a variety of solid and hematological human malignancies, contributing to cancer progression by acting on both parenchymal and stromal compartments. Autocrine and paracrine stimulation by overexpressed FGFs lead to cancer cell proliferation, resistance to cell death, increased motility and invasiveness, enhanced metastatic activity, stem cell maintenance, and resistance to chemotherapy. In addition, FGFs play a pivotal role in the recruitment, activation, and maturation of endothelial cells, fibroblasts, and infiltrating myeloid cells. Due to its impact on human tumors, the FGF/FGFR system may represent a promising target for anticancer therapies (Fig. 2).

Other FGF-Related Pathologies

Even though genetic diseases and cancer represent the predominant pathological conditions related to defects of the FGF/FGFR system, other disorders could be linked to its deregulation. For instance, the FGF/FGFR axis has received considerable attention in recent years for its role in various diseases of the nervous system, including epilepsy and Parkinson's disease, and in psychiatric disorders. Defects of FGF2, FGF21, and FGF23 signaling have been observed in heart diseases in which FGF15/19, FGF21, and FGF23 can be exploited as serum biomarkers. Regarding inflammatory conditions, patients suffering from inflammatory bowel disease show



Fibroblast Growth Factors, Fig. 2 Alterations of the FGF/FGFR system in cancer. See text for details

elevated levels of FGF7 while upregulation of FGF7 and FGF10 has been observed in the psoriatic skin. Finally, the blood levels of FGF23 are increased in patients with fibrous dysplasia, a disorder in which normal bone is replaced by fibro-osseous tissue (Presta et al. 2017; Ornitz and Itoh 2015; Moosa and Wollnik 2016).

Drugs

Several agents have been developed to target the FGF/FGFR system with different selectivity and specificity. Some of these compounds are commonly used in basic research as FGF/FGFR inhibitors, while others have been evaluated in preclinical settings and in clinical trials as therapeutic agents for the treatment of FGF/FGFR-dependent tumors (www.clinicaltrials.gov). Acting at the extracellular or intracellular level, these compounds exert their inhibitory action by preventing the interaction of FGFs with their receptors or by impairing the signal transduction pathways activated by a deregulated autocrine/paracrine FGFR activity. FGF/FGFR inhibitors can be classified as nonselective and selective TK inhibitors (TKIs), neutralizing monoclonal antibodies (mAbs), allosteric inhibitors, and FGF traps.

Nonselective TKIs bind to the ATP-binding domain of the catalytic site of FGFRs, but at the same time they can also suppress the activity of other TK receptors. The advantage of these inhibitors is their ability to concurrently targeting various signaling pathways in tumor epithelial and stromal cells. However, they show a multiplicity of toxic side effects, including proteinuria, cardiotoxicity, gastrointestinal disorders, and cutaneous reactions. Nonetheless, some of these compounds have been approved for their use in combination with chemotherapy or after first-line therapy failure in several cancer types. The nonselective TKI lucitanib (E3810) has shown antitumor/antiangiogenic effects in preclinical models of endometrial, gastric, breast, and lung cancers, leading to significant benefits in patients with solid tumors expressing aberrant FGFRs. By targeting FGFR1–3 and other TK receptors, nintedanib (BIBF1120) has shown an interesting antitumor activity on colorectal, prostate, liver, lung, and female tumors with controllable adverse effects. Encouraging results for the treatment of FGFR1-altered prostate cancers with bone metastases, advanced renal cell carcinoma, multiple myeloma, and squamous cell carcinoma of the lung have been obtained also with the nonselective TKI dovitinib (TKI158). Other nonselective FGFR TKIs, including brivanib, cediranib, lenvatinib, orantinib, pazopanib, ponatinib, regorafenib, and sorafenib, are under evaluation in preclinical and clinical models (Table 2).

Fibroblast Growth Factors, Table 2 FGF/FGFR inhibitors: main intracellular and extracellular drugs

Type of inhibitor		Compound	Target
Intracellular FGFR inhibitors	Nonselective TKIs	AXL1717	FGFRs, VEGFRs, IGF1R
		Brivanib	FGFRs, PDGFRs, VEGFRs
		Cediranib	FGFRs, VEGFRs, c-KIT
		Danusertib (PHA-739358)	FGFR1, BRC-Abl, c-RET, Aurora
		Dovitinib (TKI 258)	FGFRs, PDGFRs, VEGFRs, FLT3, c-KIT
		ENMD2076	FGFR1/2, PDGFRs, VEGFR2, FLT3, c-KIT, Aurora
		Lenvatinib (E7080)	FGFRs, PDGFRs, VEGFRs
		Lucitanib (E3810)	FGFR1–2, VEGFRs, PDGFRs
		MAX40279	FGFRs, FLT3
		MK2461	FGFR1–3, PDGFR, c-met, FLT1/3, Ron, Mer
		Nintedanib (BIBF1120)	FGFRs, PDGFRS, VEGFRs
		Orantinib ()TSU-68	FGFRs, PDGFRs, VEGFR2
		Pazopanib	FGFR1/3, PDGFRs, VEGFRs, c-KIT
		Regorafenib	FGFRs, PDGFRs, VEGFRs, c-KIT, c-RET
		Sorafenib	FGFR1, VEGFR2, FLT3, PDGFRs
	Selective TKIs	ARQ087	FGFR1–3
		ASP-5878	FGFR1–4

Selective FGFR TKIs have been developed in order to limit the side effects of nonselective molecules. Most of them are able to target more than one FGFR. AZD4547 is specific for FGFR1–3 and is under evaluation in combination with conventional therapies for the treatment of different tumors, including breast, lung, and gastric cancers. BGJ398 (NVP-BGJ398) is a FGFR1–3 inhibitor that causes tumor shrinkage in FGFR-aberrant non-small cell lung cancer, bladder carcinoma, and cholangiocarcinoma with tolerable side effects. JNJ-42756493 (erdafitinib) acts onto FGFR1–4 and induces the stabilization of advanced tumors characterized by FGFR translocations or fusions, like glioblastoma, bladder carcinoma, lung and breast cancers. Other selective TKIs (including ARQ-087, BAY-1163877, Debio 1347, LY287445, and TAS-120) are under investigation in preclinical models and in clinical trials on different oncotypes (Table 2). The most significant side effects of these compounds are related to the modulation of the FGF23 pathway that can induce hyperphosphatemia and tissue calcification. In any case, selective TKIs show reduced adverse effects when compared to nonselective TKIs.

New strategies for the treatment of tumors with an aberrant activation of the FGF/FGFR system may consist in the use of neutralizing anti-FGFR mAbs, anti-FGF mAbs, or FGF traps. Neutralizing anti-FGFR mAbs are promising therapeutic agents characterized by a high specificity and possible absence of off-target effects. Among them, MGFR1877S is a specific anti-FGFR3 mAb under evaluation for the treatment of solid tumors and multiple myeloma, whereas the mAb FPA144 binds the FGFR2-IIb variant and inhibits tumor growth in experimental models of gastric cancers.

Compounds able to sequester one or more FGFs may represent a therapeutic option for those tumors characterized by the upregulated expression of these growth factors. In this frame, anti-FGF mAbs have shown encouraging results in different tumor models in vitro and in vivo. Moreover, the anti-FGF23 mAb KRN23 (burosumab) is on clinical evaluation for the treatment of hypophosphatemia in adults and children.

In parallel with mAbs, small molecules acting as pan-FGFs traps are under development. The activity of FGFs is modulated by their interaction with a plethora of molecules present in the extracellular microenvironment. The structural characterization of this “interactome” has been exploited for the development of FGF trapping agents. FP-1039 (GSK3052230) is a FGF ligand trap derived from the extracellular domain of FGFR1. FP-1039 exerts its inhibitory activity on angiogenesis and tumor cell growth in different tumor models and has shown limited side effects when tested in clinical trials. In addition, small molecules derived from the FGF ligands thrombospodin-1 (TSP-1), heparin/HSPGs, and the soluble pattern recognition receptor long pentraxin-3 (PTX3) have been developed and their antiangiogenic and antitumor activity has been demonstrated in different tumor models. Notably, FGF traps show a low toxicity profile when compared to TKIs (Presta et al. 2017; Ghedini et al. 2018).

Free Fatty Acid Receptors

Stefan Offermanns
Department of Pharmacology, Max Planck Institute for Heart and Lung Research, Bad Nauheim, Germany
Medical Faculty, Goethe University, Frankfurt, Germany

Definition

Free fatty acids (FFAs) consist of a carboxylic acid which is linked to an aliphatic tail, and they can be classified according to the chain length of this tail as short-chain fatty acids (SCFAs), which have 1–6 carbon atoms; medium-chain fatty acids (MCFAs), which have 7–12 carbon atoms; and long-chain fatty acids (LCFAs), which have more than 12 carbon atoms. FFAs play important roles as energy carriers, basic components of biological structures, and precursors of various mediators. In addition, FFAs can directly regulate biological processes, such as metabolic and immune functions. Some of these effects are mediated by a subgroup of G protein-coupled receptors (GPCRs). These include four receptors that have been classified as members of the FFA receptor family (FFA1-FFA4). FFA1 and FFA4 are activated by MCFAs and LCFAs, whereas FFA2 and FFA3 are activated by SCFAs. FFA1, FFA2, and FFA3 are structurally related, and their human genes are located in tandem on the long arm of chromosome 19. In contrast, FFA4 shows only minor structural similarity to FFA1-FFA3. In addition to FFA receptor family members, several additional GPCRs have been shown to be activated by FFAs. These include GPR84, a receptor

for MCFAs, and the olfactory receptor OR51E2 (Olfr78 in the mouse) and hydroxycarboxylic acid receptor 2 (HCA2), which are activated by particular SCFAs.

Basic Characteristics

FFA1

FFA1 (Table 1) is activated by MCFAs and LCFAs with chain lengths of ten or more carbon atoms, and this includes both saturated and unsaturated free fatty acids. 20-Hydroxyeicosatetraenoic acid (20-HETE) activates FFA1 with particularly high efficacy. Activated FFA1 couples predominantly to G_q/G_{11} family G proteins. FFA1 is expressed in insulin-producing β-cells of the pancreas. Expression has also been found in enteroendocrine cells, immune cells, taste buds, osteocytes, and cells of the central nervous system. The best-understood physiological function of FFA1 is its ability to mediate a stimulation of glucose-stimulated insulin secretion from β-cells by dietary free fatty acids and by 20-HETE. The latter is produced by β-cells themselves under the influence of glucose and thereby functions as a positive feed-forward mediator (Fig. 1).

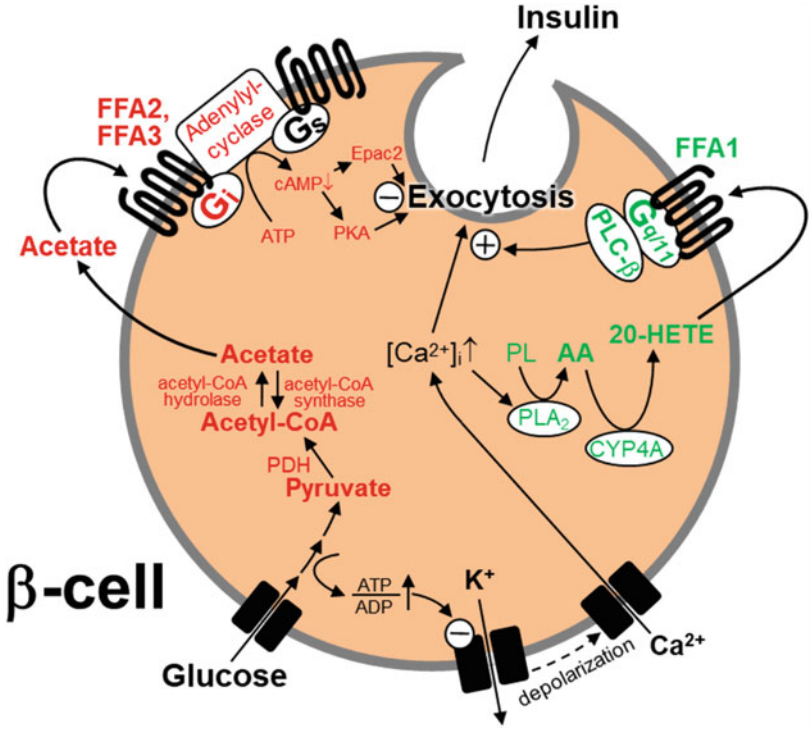
FFA2 and FFA3

Human FFA2 and FFA3 (Table 1) are activated by micromolar concentrations of propanoic acid (C3) and butyric acid (C4). Acetic acid (C2) activates FFA2 but is a relatively poor agonist of FFA3, and valeric acid (C5) and caproic acid (C6) prefer FFA3. Both FFA2 and FFA3 couple to G proteins of the G_i family. FFA2 can also activate G_q/G_{11} family members. FFA2 and FFA3 are expressed in the pancreatic islets, including α- and β-cells and in various enteroendocrine cells. FFA2 has also been described to be expressed in white adipocytes and various immune cells including neutrophils, monocytes, and intestinal Treg cells, whereas FFA3 is expressed in the peripheral nervous system including the sympathetic ganglia and enteric neurons.

Since SCFAs are primarily generated through the fermentation of fiber by the gut microbiota, the by far highest levels of SCFAs in the organism are

Free Fatty Acid Receptors, Table 1 Free fatty acid receptors

Receptor	G protein coupled to	Endogenous ligands	Synthetic ligands	Expression (function)
FFA1 (GPR40)	G_q/G_{11}	Saturated and unsaturated LCFAs	*Agonists:* Fasiglifam (TAK-875), GW-9508, AMG837, AMG1638, MG5262, TUG424 *Antagonist:* GW1100	Pancreatic β-cells (enhancement of glucose-stimulated insulin secretion). Enteroendocrine cells (stimulation of GLP-1 and GIP secretion)
FFA2 (GPR43)	G_q/G_{11}, G_i	SCFAs (acetate, propionate, butyrate)	*Agonists:* Phenylacetamide-1/AMG7703, Euroscreen compounds 1 and 2 *Antagonists:* GLPG0974, Euroscreen compound 3	Pancreatic β-cells (inhibition (in some cases also stimulation) of glucose-stimulated insulin secretion), enteroendocrine cells (stimulation of GLP-1 secretion), adipocytes (inhibition of lipolysis), immune cells (proinflammatory effects)
FFA3 (GPR41)	G_i	SCFAs (acetate, propionate, buryrate)	*Agonist:* AR420626 *Antagonist:* AR399519	Pancreatic β-cells (inhibition of glucose-stimulated insulin secretion), enteroendocrine cells (stimulation of GLP-1 secretion), sympathetic neurons (stimulation of activity)
FFA4 (GPR120)	G_q/G_{11}, G_i	Saturated and unsaturated LCFAs	*Agonists:* GW9508, TUG891, GSK137647A, NCG21 *Antagonist/inverse agonist:* AH7614	Immune cells (anti-inflammatory), adipocytes (increased insulin-mediated glucose uptake), enteroendocrine cells (inhibition of hormone secretion)



Free Fatty Acid Receptors, Fig. 1 Free fatty acid receptors. Regulation of β-cell function through FFA1, FFA2, and FFA3 receptors. Glucose-induced increases in free cytosolic Ca^{2+} concentrations activate phospholipase A_2 (PLA_2), which converts phospholipids (PL) into arachidonic acid (AA). AA is then further converted by CYP4A to 20-HETE, which, in an auto- and/or paracrine fashion, activates FFA1. FFA1 downstream signaling promotes glucose-stimulated insulin secretion. 20-HETE/FFA1 thereby mediates a positive feed-forward mechanism. Glucose is converted through glycolysis and pyruvate dehydrogenase (PDH) into acetate, which is released from β-cells and, in an auto- and/or paracrine fashion, can activate FFA2 and FFA3. FFA2/FFA3 activation via inhibition of cAMP formation inhibits glucose-stimulated insulin secretion. This mechanism functions in particular at high glucose concentrations and might help to avoid overshooting insulin secretion in response to high glucose concentrations. PKA, cAMP-regulated protein kinase

found within the gastrointestinal tract. Given that FFA2 and FFA3 are expressed in enteroendocrine cells as well as in immune cells and neurons of the intestinal wall, multiple studies have analyzed the role of FFA2 and FFA3 in the intestine in part with contradictory results. There is good evidence that FFA2 mediates SCFA-induced stimulation of GLP-1 release from enteroendocrine cells. It appears also to be involved in SCFA-induced inhibition of ghrelin release. The role of FFA2 and FFA3 in regulating intestinal immunity is less clear. Both, anti- and proinflammatory roles of FFA2 activation have been described. In adipocytes, FFA2 can mediate an inhibition of lipolysis as well as of insulin signaling and of glucose uptake. In pancreatic β-cells, FFA2 and FFA3 mediate an inhibition of glucose-stimulated insulin secretion by acetate, which is released from β-cells in response to high glucose concentrations. This mechanism might protect β-cells from overshooting insulin secretion in response to high glucose concentrations (Fig. 1). However, under certain conditions, FFA2 can also mediate a stimulation of glucose-stimulated insulin secretion by coupling to G_q/G_{11}. The physiological, pathophysiological, and pharmacological roles of these mechanisms are still not clear.

FFA4

FFA4 (Table 1) is activated by a similar spectrum of MCFAs and LCFAs as FFA1, but polyunsaturated fatty acids (PUFAs) appear to have higher

efficacy than saturated fatty acids. FFA4 is present in two splice variants. A more common short isoform couples to G_q/G_{11} as well as to G_i-type G proteins and recruits arrestin, while the long isoform recruits only arrestin. Major sites of FFA4 expression are white adipocytes, macrophages and some enteroendocrine cells.

Evidence has been provided that FFA4 on adipocytes can mediate free fatty acid-induced inhibition of triglyceride lipolysis. Controversial data are existing with regard to the role of FFA4 in enteroendocrine cells. In immune cells, FFA4 appears to mediate anti-inflammatory effects. Loss of FFA4 in mice and presence of an FFA4 version with reduced signaling function have been shown to promote obesity and type 2 diabetes.

Drugs and Pharmacological Relevance

Since FFA1 mediates an enhancement of glucose-stimulated insulin secretion, primarily agonists of FFA1 have been developed (Table 1) (Offermanns 2014; Milligan et al. 2017). Fasiglifam (TAK-875) has by far had the greatest impact on understanding the therapeutic potential of FFA1. Fasiglifam showed in phase II and III studies beneficial effects on hyperglycemia and HbA_{1C} levels in diabetic patients without a risk of producing hypoglycemia. However, because of liver toxicity, probably due to an off-target effect due to inhibition of hepatobiliary transporters, further development of fasiglifam was stopped.

Developing potent and selective ligands for FFA2 or FFA3 has been challenging. However, a growing number of synthetic ligands for FFA2 have been reported, in particular orthosteric agonists and antagonists (Table 1) (Bolognini et al. 2016). One compound, GLPG0974, an orthosteric antagonist of FFA2, entered clinical trials in patients with mild to moderate ulcerative colitis. Although GLPG0974 was well-tolerated and reduced neutrophil activation and influx, no measurable clinical effect was observed. While allosteric ligands for FFA3 have been developed (Table 1), no potent orthosteric ligands of FFA3 have been described.

Several lines of evidence suggested that agonism of FFA4 would be beneficial for the treatment of metabolic disorders, such as obesity and type 2 diabetes (Husted et al. 2017; Milligan et al. 2017), and, consequently, the majority of synthetic ligands of FFA4 are orthosteric agonists (Table 1). A few compounds have shown beneficial effects in animal models of metabolic disorders, but no studies in humans have been reported yet.

Definition

γ-Aminobutyric acid (GABA) is the principal inhibitory neurotransmitter in the central nervous system. Structures involved in releasing and binding GABA as a neurotransmitter constitute the GABAergic system. Of pharmacological interest, the GABAergic system is involved in the regulation of vigilance, anxiety, muscle tension, epileptogenic activity, and memory functions (Engin et al. 2018; Olsen 2018; Rudolph and Antkowiak 2004; Rudolph and Knoflach 2011; Sieghart and Savic 2018).

Basic Characteristics

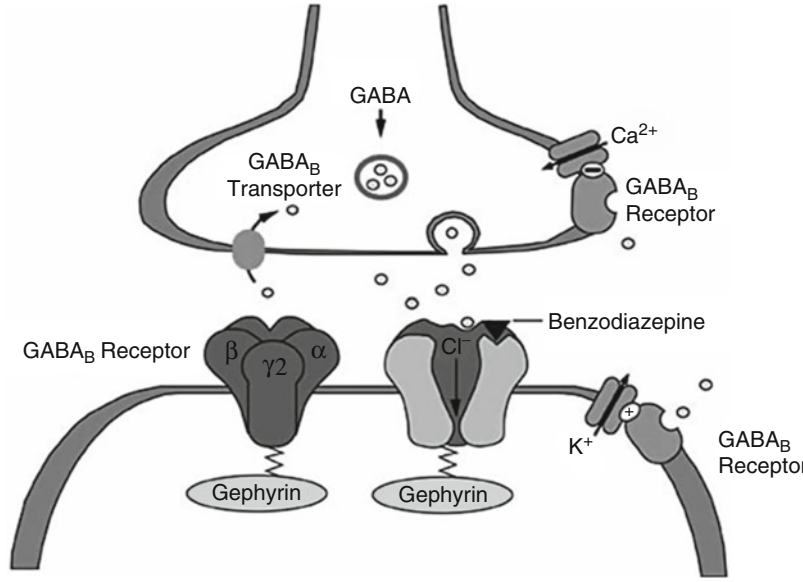
Inhibitory GABAergic neurotransmission in the brain is crucial for temporally precise activity of neuronal circuits and the synchronized oscillatory activity of neuronal populations. By far the most frequent pharmacological interventions of GABAergic neurotransmission target GABA receptors. There are two types of GABA receptors which are both targets of clinically used drugs: ionotropic GABA receptors mediating fast responses, called $GABA_A$ receptors, on which this entry is focused and which are targeted by benzodiazepines, barbiturates, neurosteroids, and some general anesthetics, and metabotropic GABA receptors mediating slow responses, called $GABA_B$ receptors, which are targeted by the $GABA_B$ agonist baclofen, which reduces spasticity. Other pharmacological targets in the GABAergic system are GABA transaminase and GABA reuptake. Vigabatrin, which is effective in the treatment of focal seizures, is a GABA transaminase inhibitor, an enzyme involved in the breakdown of GABA. Tiagabine, which is also used in the treatment of focal seizures, is an inhibitor of the GAT-1 GABA transporter, a GABA reuptake mechanism which removes GABA from the synaptic cleft.

In many brain regions, e.g., cortical regions or hippocampus, interneurons which release GABA modulate the activity of excitatory principal neurons or of other GABAergic interneurons. Receptors for GABA are present on both excitatory and

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

inhibitory interneurons, and some GABA receptors may thus also have disinhibiting functions. In fact, cognitive deficits caused by excess inhibition can be reversed by disinhibition, which thus plays an important role in learning and memory.

$GABA_A$ receptors are typically postsynaptic pentameric complexes that are assembled from a subunit repertoire of at least 19 subunits (α1–6, β1–3, γ1–3, δ, ε, θ, π, ρ1–3) which form a central channel with permeability for chloride ions. They may be linked to the postsynaptic protein gephyrin (Fig. 1), and α5-ontaining $GABA_A$ receptors have been shown to be linked to radixin. GABA-mediated chloride influx results in hyperpolarization of the postsynaptic neuron. $GABA_A$ receptors most frequently contain α-, β-, and γ-subunits. The GABA binding site is formed by the α- and β-subunits, whereas the benzodiazepine site is formed by the α- and γ-subunits. α1β2γ2 is the most abundant GABA receptor subtype, representing approximately 60% of all $GABA_A$ receptors in the brain. α2β3γ2 is the second most abundant $GABA_A$ receptor subtype, representing approximately 15–20% of all $GABA_A$ receptors in the brain. Pharmacologically, $GABA_A$ receptors are most frequently differentiated by their α-subunits, in part as they contribute to the benzodiazepine binding site. $GABA_A$ receptors containing the α1-, α2-, α3-, or α5-subunits are sensitive to modulation by classical, clinically used benzodiazepines, whereas $GABA_A$ receptors containing the α4- and α6-subunits are not. For practical purposes, $GABA_A$ receptors are frequently referred to as, for example, α1-containing $GABA_A$ receptors or α1-$GABA_A$ receptors, which simply indicates that this subunit is part of the pentameric complex, which also contains other subunits. The function of GABA receptor subtype can be assessed in a variety of different ways: studies using gene knockout mice; studies on mice carrying single amino acid point mutations (knock-in mice) changing the pharmacological properties of the respective receptor, e.g., mice with point mutations in α-subunits rendering the respective $GABA_A$ receptors insensitive to modulation by clinically used benzodiazepines, alcohol, and volatile general anesthetics; pharmacological studies using $GABA_A$ receptor subtype-selective compounds; knockdown studies using short hairpin RNA (shRNA) approaches; or knockdowns or other mutational studies using genome editing by CRISPR/Cas-9 or similar systems. Studies with gene knockout mice have to take into account that compensatory regulations of related genes, e.g., upregulation of other $GABA_A$ receptor subunits, may occur, which may make interpretations of results difficult. Knock-in



GABAergic System, Fig. 1 GABAergic synapse. Schematic of a GABAergic synapse, depicting the major elements of signal transduction. Typically postsynaptic $GABA_A$ receptors are pentameric ligand-gated ion channels assembled from various types of subunits. On the cytoplasmic side, they are linked to gephyrin. $GABA_B$ receptors are coupled to calcium or potassium channels

mice with single point mutations generally do not exhibit such compensatory regulations, or if so, to a more limited degree, and have thus been valuable for assigning specific functions to individual $GABA_A$ receptor subtypes. In such experiments, benzodiazepines such as diazepam are tested on mice with a histidine to arginine point mutation which renders the respective receptor insensitive to modulation by classical benzodiazepines. Any benzodiazepine action missing could then be ascribed to the receptor subtype containing the point-mutated α-subunit. Mice have been generated with histidine to arginine point mutations in three out of the four diazepam-sensitive α-subunits. In these mice, diazepam is a highly subtype-specific positive allosteric modulator. Mice with such point mutations in all four diazepam-sensitive α-subunits are insensitive to modulation by clinically relevant doses of diazepam.

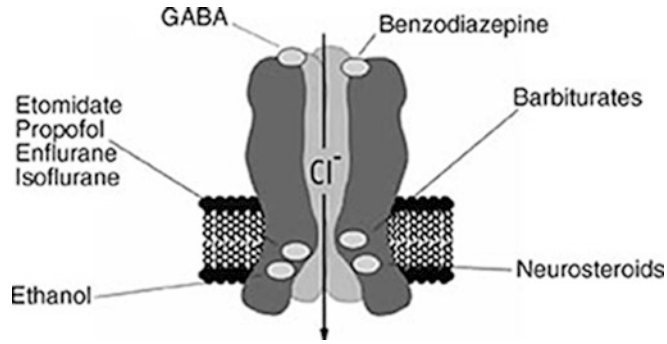
Whereas in other fields of research, e.g., adrenoceptors, the synthesis of subtype-selective compounds has been achieved and contributed significantly to the assignment of functions to specific receptor subtypes, the success of this strategy to $GABA_A$ receptors was more limited. As the similarity between $GABA_A$ receptor subtypes is high, it has been difficult to develop compounds that are truly subtype-specific, and assignment of functions to individual $GABA_A$ receptor subtypes based on the activity of "subtype-selective" compounds has to be done with caution. Specifically, if a compound displays some selectivity for a specific $GABA_A$ receptor subtype and has a certain action, it may be erroneous to conclude that this action is mediated by the subtype for which the compound displays some specificity; it might also be mediated by another $GABA_A$ receptor subtype which the compound also modulates.

In addition to functions of $GABA_A$ receptors that have long been known and are pharmacologically exploited, e.g., by benzodiazepines (see below), studies with knock-in mice and with subtype-selective compounds also revealed previously unrecognized functions of $GABA_A$ receptor subtypes. Such actions may become apparent if a specific subtype-selective compound (or diazepam in knock-in mice) does not positively modulate α1-containing $GABA_A$ receptors, which mediate reduction of motor activity, i.e., sedation. In other words, such actions are not visible with clinically used benzodiazepines simply since they are sedating the experimental animal (or the patient). This includes an antihyperalgesic action that is mediated by α2- and α3-containing $GABA_A$ receptors in the spinal cord in models if inflammatory and neuropathic pain in rodents. These receptors have also been shown to have an itching suppression effect, reducing acute histaminergic and non-histaminergic itch in mice. Positive modulation of these receptors alleviated chronic itch in a mouse model of atopic dermatitis and in dogs sensitized to house dust mites.

Recent studies were able to identify specific neuronal populations in which a defined $GABA_A$ receptor subtype mediates specific actions. The anxiolytic-like action of diazepam was shown to be dependent on α2-containing $GABA_A$ receptors in dentate gyrus granule cells and in hippocampal CA3 pyramidal neurons, whereas the fear-reducing action of diazepam is dependent on α2-containing $GABA_A$ receptors in hippocampal CA1 pyramidal neurons. Moreover, α5-containing $GABA_A$ receptors on PKCδ-positive neurons in the central amygdala mediating tonic inhibition have been shown to modulate anxiety-like behavior. Furthermore, α5-containing $GABA_A$ receptors in dentate gyrus granule cells were found to play a role in the management of interfering memories. In addition to synaptic inhibition, $GABA_A$ receptors are also involved in mediating extrasynaptic inhibition. Some $GABA_A$ receptors, e.g., α5-containing $GABA_A$ receptors in the hippocampus, are located in extrasynaptic locations, where they detect GABA that is spilled over from synapses. These receptors are sensitive to lower concentrations of GABA compared to synaptic $GABA_A$ receptors and have been shown to be involved in learning and memory.

Drugs

Several groups of drugs exert all or some of their action via the GABAergic system (Fig. 2).



GABAergic System, Fig. 2 Model of a $GABA_A$ receptor and its binding sites. In addition to binding sites for the neurotransmitter GABA, $GABA_A$ receptors have modulatory binding sites for a variety of ligands, including benzodiazepines, barbiturates, neurosteroids, and ethanol and general anesthetics such as isoflurane, enflurane, etomidate, and propofol. The positioning and the size of the binding sites are arbitrary. One subunit has been removed to visualize the pore

Benzodiazepines

Benzodiazepines act by shifting the GABA dose-response curve to the left and thus increase the affinity of the receptors for GABA. At a given concentration of GABA in a synapse, the chloride current will be increased. At the molecular level, benzodiazepines increase the opening frequency and thus the number of channels that are opened by a given concentration of GABA. Benzodiazepines have no action in the absence of GABA (use-dependence) and cannot increase maximal physiological stimulation by a high concentration of GABA, i.e., their action is self-limiting, which most likely contributes to the safety of these drugs with respect to overdoses. They are used as anxiolytics, sedatives, anticonvulsants, and muscle relaxants. Experiments with knock-in mice (see above) revealed that the anxiolytic-like action of benzodiazepines is mediated by α2-containing $GABA_A$ receptors, whereas the sedative action, the anterograde amnestic action, and in part the anticonvulsant action are mediated by α1-containing $GABA_A$ receptors. The myorelaxant actions of benzodiazepines have been shown to be mediated by α2- and α3-containing $GABA_A$ receptors.

Barbiturates

Barbiturates act by increasing the conductance level. In contrast to benzodiazepines, they also have direct agonistic actions at $GABA_A$ receptors. Also in contrast to benzodiazepines, their action is not self-limiting, i.e., they can activate the $GABA_A$ receptor to higher levels than high concentrations of GABA alone. These features may be responsible for the fact that overdoses of barbiturates are life-threatening. Studies in β3(N265 M) knock-in mice in which β3-containing $GABA_A$ receptors are largely insensitive to pentobarbital revealed that the immobilizing and in part the hypnotic actions of pentobarbital are mediated by β3-containing $GABA_A$ receptors, but not its respiratory depressant actions.

General Anesthetics

Both volatile and intravenous general anesthetics have been shown to modulate the activity of the $GABA_A$ receptor, and these actions likely contribute to their clinical effects. Amino acid residues in the α- and β-subunits contribute to the binding site for volatile anesthetics. In contrast, only mutations of amino acid residues in the β-subunit contribute to the binding site for intravenous anesthetics like etomidate and propofol. For the intravenous anesthetics etomidate and propofol, using mice with etomidate (and propofol-)-insensitive β3-containing $GABA_A$ receptors [β3 (N265 M)], it was shown that this receptor subtype is required for the immobilizing action and the respiratory depressant action of these drugs

and contributes to the hypnotic action of these drugs. Interestingly, these mice still experience motor sedation in response to etomidate. Studies in mice with etomidate-insensitive β2-containing $GABA_A$ receptors [β2(N265S) mice] have shown that this receptor subtype contributes to the sedative and hypothermic action of etomidate. In β3 (N265 M) mice, higher concentrations (EC_{50}) of the volatile anesthetics like isoflurane, halothane, and enflurane were required to achieve immobilization. In recombinant systems, the ε-subunit, which is found in the amygdala and thalamus, and which is particularly abundant in the subthalamic nucleus, confers insensitivity to general anesthetics, potentially protecting essential physiological functions.

Neurosteroids

Neurosteroids prolong the mean open time of recombinant $GABA_A$ receptor channels. They enhance phasic inhibition (through synaptic $GABA_A$ receptors) and tonic inhibition (through extrasynaptic $GABA_A$ receptors), and as δ-containing $GABA_A$ receptors are also found in extrasynaptic locations, such receptors are particularly sensitive to modulation by neurosteroids. The transmembrane domains of $GABA_A$ receptor α-subunits contribute to a binding site for potentiating neurosteroids. Levels of progesterone-derived neurosteroids fluctuate over the ovarian cycle, with a large increase during pregnancy and a precipitous decline at parturition. In pregnant mice, the $GABA_A$ receptor subunits γ2 and δ are downregulated, which goes along with a decrease in tonic and phasic inhibition in pregnant mice. Mice heterozygous or homozygous for a knockout of the δ-subunit exhibit depression-like behaviors and abnormal maternal behaviors, and in heterozygous δ-knockout mice, abnormal postpartum behaviors can be attenuated by the δ-subunit-selective agonist at the GABA site, THIP (gaboxadol). An intravenous formulation of the endogenous neurosteroid allopregnanolone, brexanolone, showed significant antidepressant activity in postpartum depression in humans and has been approved by the FDA for this indication.

$GABA_A$ Receptor Mutants as Models for Disease

Some $GABA_A$ receptor knockout mice display distinct phenotypes, e.g., α2-knockout mice and heterozygous γ2-knockout mice an anxiety-related and depression-related phenotype, α3-knockout mice have increased dopaminergic activity in the ventral tegmental area and deficits in sensorimotor gating, and α5-knockout mice actually perform better in the Morris water maze, which led to the development of α5-negative allosteric modulators as potential cognitive enhancers, and β3-knockout mice display cleft palate, neurological impairments including hyperresponsiveness to sensory stimuli, motor impairment, and epileptic seizures. β3-knockout mice also display impaired social and exploratory behaviors. Mice with a double point mutation in the β3-subunit which abolishes phosphorylation sites for serine/threonine phosphorylation [β3(S408A/S409A)] and in which modulation by phosphorylation/dephosphorylation is abolished, actually by mimicking a state corresponding to the phosphorylated state, displayed increased phasic and decreased tonic inhibition and exhibited alterations in dendritic spine structure, increased repetitive behavior and decreased social interactions, hallmarks of autism spectrum disorders, and an increase in sensitivity to seizures. Interestingly, phosphorylation of S408/S409 was significantly enhanced in Fmr1 knockout mice, a model of fragile X mental retardation, suggesting that alterations in phosphorylation and/or activity of β3-containing $GABA_A$ receptors may contribute to the pathophysiology of autism spectrum disorders and other neurodevelopmental disorders.

Gene Expression Analysis and Next-Generation Sequencing

Eric L. Lindberg and Norbert Hübner
Cardiovascular and Metabolic Sciences, Max Delbrück Center for Molecular Medicine in the Helmholtz Association (MDC), Berlin, Germany

Synonyms

Gene expression profiling; NGS; RNA-sequencing; Transcriptome analysis

Definition

Next-Generation sequencing technologies enable sequencing of millions of DNA molecules simultaneously. This is facilitated by fragmentation of DNA, adaptor ligation, and immobilization on a solid matrix, from which the nucleotide sequence is read out. Through the prior conversion of RNA into cDNA, NGS also enables the quantification of RNA produced by its coding gene (Gene expression profiling).

Description

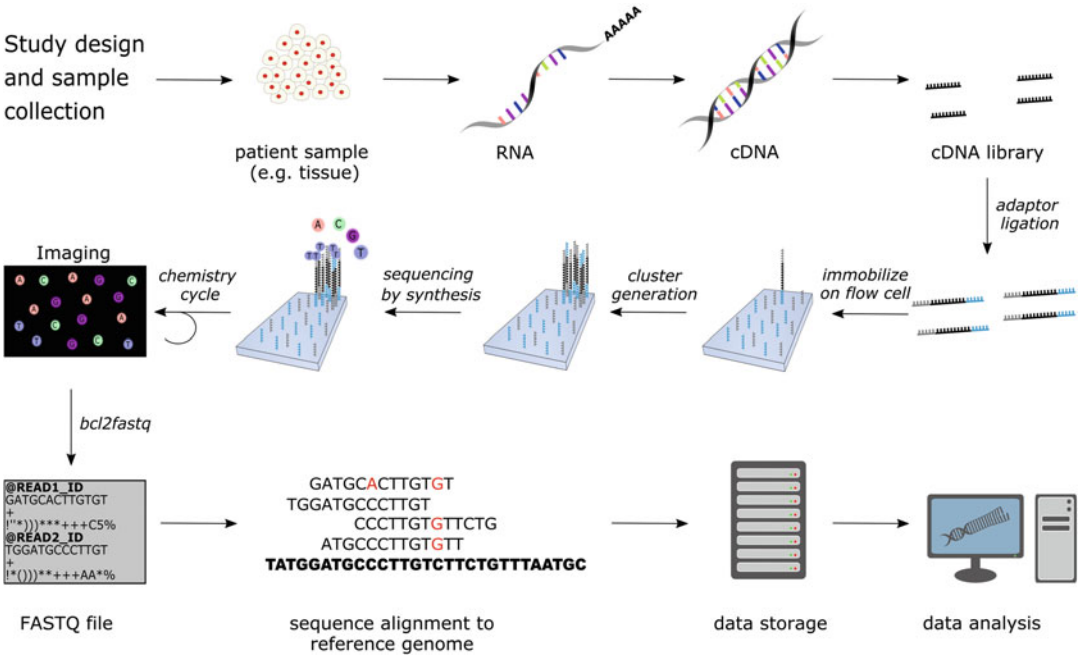
High throughput sequencing technologies such as Next-Generation sequencing (**NGS**) measure gene activity in a highly parallel manner. Current approaches allow sequencing of full **genomes**, epigenomes, exomes, **transcriptomes**, methylomes, and translatomes. Sequencing technologies help us to further our understanding and interpretation of the complexity of the genome, for example, by enabling the identification of single-nucleotide polymorphisms (SNPs), small insertions and deletions (Indels), or copy-number variants (CNVs) (Goodwin et al. 2016). Current NGS protocols for gene expression profiling, or RNA-Sequencing (RNA-Seq), require a **reverse transcription** step from RNA into cDNA, which is sequenced instead. This protocol enables a quantitative measure of gene expression, de-novo identification of splicing events and fusion genes (e.g., in cancer). Microarrays rely in contrast to sequencing technologies on *a priori* knowledge of a reference sequence annotation, which impedes identification of novel sequence alterations or transcript isoforms.

NGS technologies are derived from First-Generation Sequencing technologies, which are based on the chain termination reaction. First-Generation methods include Maxam-Gilbert-sequencing, which was firstly published in 1977 by Allan Maxam and Walter Gilbert and Sanger sequencing, published in the same year by Frederick Sanger. The first automated sequencer based on Sanger dideoxy sequencing was the Model 370A DNA Sequencing System, which was marketed by Applied Biosystems in 1986. This platform revolutionized the field of functional genomics, as it enabled reading of more bases in shorter time with higher accuracy. Despite the currently dominant position of NGS platforms, Sanger sequencing is still used for validation of NGS findings and the verification of DNA sequences such as plasmids, inserts, and genomic mutations. Due to its targeted approach, Sanger sequencing is still a cost-efficient option for low numbers of samples and targets.

NGS, sometimes also termed “deep” or “high-throughput” sequencing, terms a collection of methods which were developed between 1990

and 2000. NGS is characterized by a higher throughput, which is achieved by random fragmentation of DNA followed by simultaneous sequencing of a randomly selected subset. This concept has higher power to discover novel genomic or transcriptomic variations resulting from the higher read coverage of the sequenced product. Further cost efficiency is achieved by the possibility of pooling multiple samples in one sequencing run (multiplexing), allowing the user to achieve a desired, sample-specific sequence depth and hence a pragmatic means to increase sample throughput at limited expense. There are various protocols available, depending on the sequencing platform, e.g., Solexa/Illumina, Roche 454, Ion Torrent /Proton and ABI SOLiD, with Illumina currently being most often used in studies. The protocol of NGS data generation is a multi-step process (Fig. 1): (i) design and sample collection, (ii) isolation of RNA and transcribing into cDNA (this step is not necessary in case DNA is sequenced), (iii) fragmentation and adaptor ligation, (iv) adaptor hybridization to solid matrix (Illumina sequencing), (v) cluster generation and bridge amplification, (vi) sequencing by synthesis with fluorescence-tagged nucleotides, (vii) text file generation (demultiplexing), (viii) read alignment to reference genome, (ix) data storage, (x) statistical analysis and biological interpretation. Bioinformatical processing is often time consuming, as no standard pipelines are available and it requires multiple steps of data processing. NGS technologies so far dominate the market since their development.

Third-generation sequencing (TGS) was developed to achieve longer sequencing read lengths with less sample preprocessing. Despite these advantages, high error rates and cluster cross-talk currently make routine application challenging. At the moment there are three platforms commercially available, i.e., Pacific Bioscience (PacBio) Single Molecule Real Time (SMRT) Sequencing, Oxford Nanopore Technologies sequencing platform (MinION, Promethion, to name a few), and the Illumina Tru-Seq Synthetic Long-Read technology. Some of the currently released TGS devices are portable, e.g., the MinION commercialized by Oxford Nanopore Technology with a weight of approximately 100 g, which will allow



Gene Expression Analysis and Next-Generation Sequencing, Fig. 1 Schematic representation of the experimental process of global gene expression analysis using Illuminas Next-Generation Sequencing protocol

incorporation of sequencing technologies in the clinics and field (Heather and Chain 2016).

Sequencers return base call files, which need to be converted into a text-based format (FASTQ file) for downstream computational analysis. For Illumina platforms, this can be done by using Bcl2Fastq conversion software. FASTQ files contain a sequence identifier, raw sequence letters and ASCII encoded quality scores for each base called. Errors or low-quality base calls can originate during library preparation (e.g., **PCR** artifacts, contamination with foreign DNA, adaptor sequences) or sequencing (e.g., 3'/5' positional bias, repetitive sequences, cluster cross-talk). Diverse tools have been developed to evaluate library quality, which provide summary statistics on quality scores, GC content, sequence length distribution, duplication levels, and overrepresented sequences, to name a few. All previously mentioned criteria are important and help to assess library quality, unintended low-quality base-calls or repetitive sequences are trimmed. Commonly used tools for this are FastQC or PRINSEQ.

Alignment, or mapping, matches sequencing reads to a preexisting reference genome to determine from which region of the genome the read originates from. Examples for alignment programs are TopHat, Bowtie2, or STAR. Human reference genome assemblies are provided by the Human Genome Project (HGP), while diverse gene annotations are available via Ensembl, Havana, RefSeq, NCBI, Gencode, or the USCS Genome Browser. Reads mapping to rRNA, tRNA, or mtRNA are often removed for downstream analysis. After mapping, read coverage per gene is quantified to infer expression levels of each gene. One commonly used tool for this step is htseq, or the quantification option from STAR. Library size normalization is performed either by calculating FPKM (Fragments Per Kilobases of gene per Million reads) or TPM (Transcripts Per Million) values. After library size normalization it is recommended to determine the biological heterogeneity, i.e., the biological and technical variability of all samples in one condition. Commonly this is done by performing a principal-component analysis (PCA). Once expression levels per gene are calculated, statistical tests can be applied to compare expression values of genes between two or multiple conditions (e.g., disease vs. control). Heatmaps, scatter-, MA-, or volcano-plots are commonly ways to visualize differentially expressed genes (DEGs). Diverse methods for differential gene expression analysis have been introduced in the last years, from which edgeR, DESeq2, and limma are most often used.

Once the list of statistically significant DEGs has been generated, the next step is to interpret the biological meaning. For example, gene ontology or pathway enrichment analysis determines whether enriched biological processes or pathways may be of functional relevance to the underlying biological, pathological or therapeutical mechanism (i.e., drug action, safety and efficacy). For further details please see Reimand et al. 2019.

The following are examples of questions which are to be considered in downstream analysis:

- Which protein families are in the list of DEGs (e.g., transcription factors, G protein coupled receptors, kinases, secreted proteins)?
- Which pathways are dysregulated (over- or underrepresented) between conditions?
- How many different pathways are affected?
- Can a molecular mechanism be inferred from the list of DEGs?
- Are the de-regulated pathways tissue specific?
- How does the response mechanism to one compound differ to another compound with known or unknown pharmacological and toxicological properties?
- Is the response mechanism to a pharmacological intervention influenced by the genetic background?

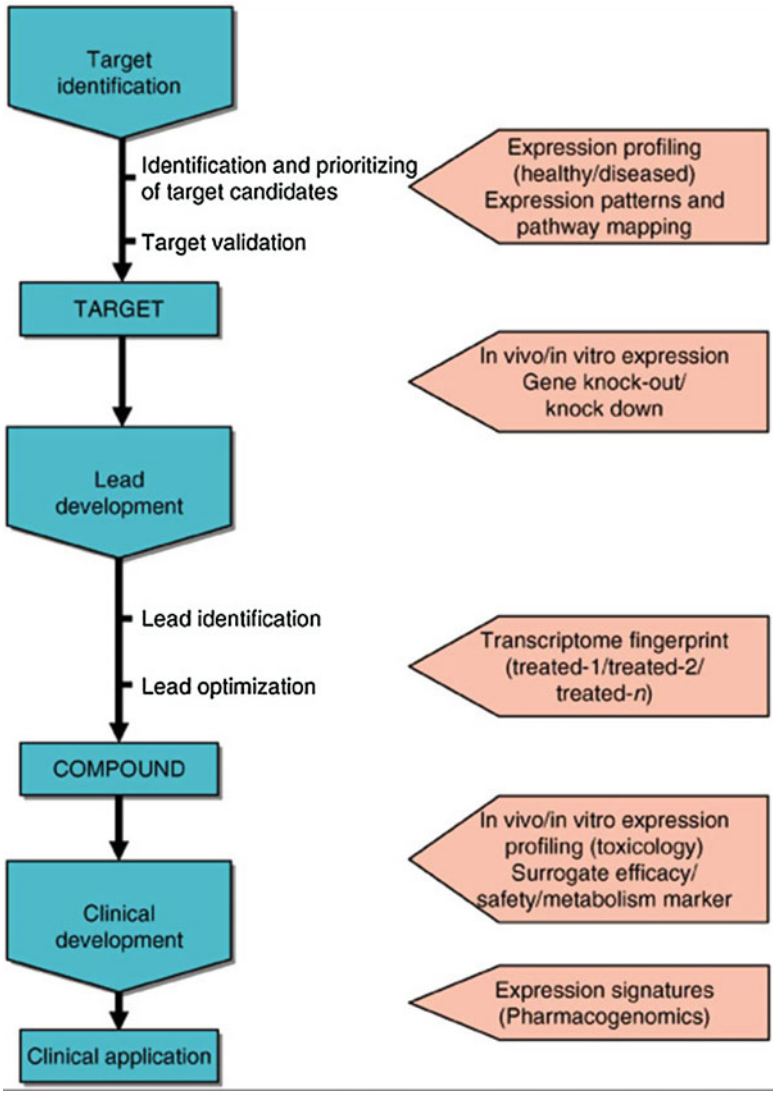
At present, there is no golden standard to address all these questions, but a combination of bioinformatic analysis should be used to address particular question of interest as thoroughly as possible. It is recommended to compare multiple databases and different evaluation pipelines and compare the results to further find support for findings.

Pharmacological Relevance

There are ~20,000 protein coding genes in the human genome, from which ~3000 are estimated to be part of the druggable genome. Approximately 700 proteins are currently targeted by FDA approved drugs, which are dominated by Ion channels, Kinases, G protein coupled receptors, and nuclear receptors (Santos et al. 2016).

Properly designed NGS-based studies, including whole genome sequencing and gene expression profiling of large patient cohorts, have not only an impact on therapeutic target identification, but also on many aspects on the drug discovery process and on drug efficacy. NGS sequencing is used at the following specified steps in the process of drug development:

- Target discovery and **biomarker** identification, to identify genes or pathways with altered expression in diseased human tissues or in animal model of disease which can be used either as a drug target or diagnostic or prognostic marker.



Gene Expression Analysis and Next-Generation Sequencing, Fig. 2 How NGS technologies contribute to the discovery of novel drugs

- Target validation, to determine that a gene product is causative of disease symptoms or that activation of the target protein ameliorates disease symptoms. Agonist/activator or an inhibitor which may be therapeutic can be validated by using NGS.
- **Compound optimization**, to screen a series of therapeutic drug candidates and determine on-target versus off-target effects.
- Toxicology (**toxicogenomics**), to identify potential human and environmental toxicants, and to find correlations between toxic responses to toxicants and changes in the genetic profiles of the objects exposed to such toxicants.
- **Drug metabolism**, determine whether multiple drug interfere with same pathways, or cause drug-drug interactions. This raised particular interest in recent years, as NGS data enable the analysis of variants in Phase I or II metabolizing enzymes such as the cytochrome P450 family, Thiopurine-Methyltransferase (TPMT) and UGT1A1.
- **Drug efficacy**, to identify the individual mode of action and whether drugs in a co-treatment interfere with the same pathways (Fig. 2).

Oncology is currently the biggest driver for drug discovery (Allen 2002). The emergence of diverse "omics" technologies supported this rapid development. One example here is the identification of the $BRAF^{V600}$ mutation. It was identified in ~50% of all melanomas and led to the development of a selective $BRAF^{V600}$ inhibitor, Vemurafenib. Nine years after discovery, the drug was FDA approved in 2011. Trametinib, a MEK inhibitor which targets the same signaling pathway, entered the market 2 years later.

NGS data generation in the clinics can furthermore help to make decisions for a personalized therapy. Some described side effects of chemotherapies are strongly correlating to the mutations of distinct genes. Examples here are the treatment of breast cancer, which depends on the gene expression profile and mutation status. Different molecular subgroups of breast cancer have been defined so far. While Alpelisib (Piqray) is used for HER2-negative breast cancer with PIK3CA mutation, Trastuzumab (Herceptin) is used to treat HER2-overexpressing cancer, just to name a few examples. For these examples, NGS provided additional information for targeted and personalized medicine.

Definition

Gene therapy is, in a broad sense, the delivery of genetic information to a patient's cells in order to positively affect disease course and improve patient outcome. Typically, this is achieved through the introduction of a functional version of a disease-causing mutated gene or by correction of a defective gene by gene editing. Additionally, genes coding for therapeutically beneficial proteins can be introduced to target diseases that are not strictly etiologically genetic, such as infectious and cardiovascular disease. While the concept of gene therapy is fairly simple, the vehicle used to transfer the therapeutic gene is a critical factor for the success or failure of gene therapy trials.

Description

With the progress of the human genome project and functional genomics, the number of genes that could have a therapeutic impact is increasing at an astonishing pace. Advances in molecular biology have also yielded an array of sophisticated genetic tools for editing the genome of living cells, such as TALENs, zinc finger, and CRISPR/Cas9 nucleases that induce double-strand breaks (DSBs) and homology-directed repair. More recently, alternative strategies have been developed that are not based on DSBs including prime editing tools (Anzalone et al. 2019) that can perform search-and-edit or search-and-replace functions on the target genome without DSBs and introduce far fewer off-target instances. However, successful delivery of these therapeutic genes or gene-editing tools depends on the vehicle and is still a major obstacle.

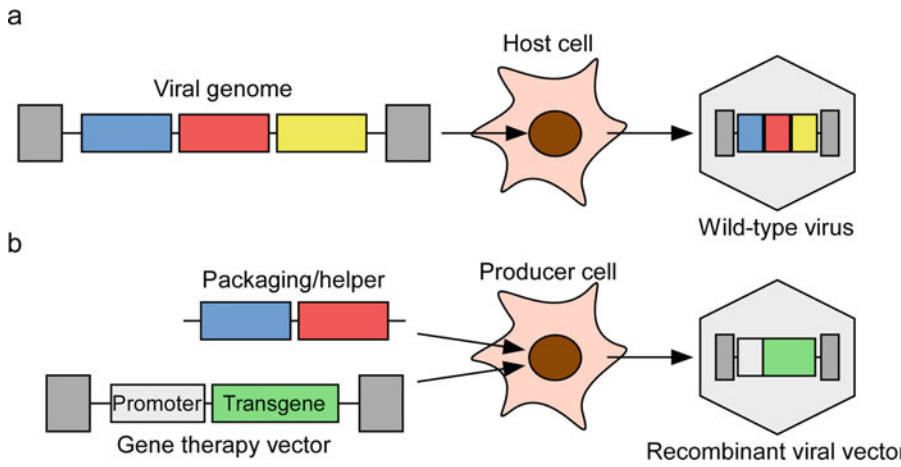
Design of Viral Vectors

Viral vector design focuses mainly on the efficacy of gene delivery and on the biosafety of the engineered viruses. A prerequisite for the use of a virus as gene therapy vehicle is to identify and eliminate pathological or toxic viral genes. Ideally, all viral genes are replaced by the gene of interest (also called transgene) (Fig. 1). The viral gene products required for the assembly of infectious particles and packaging of the vector into these particles are provided in *trans* by the so-called packaging cells, while necessary *cis*-acting factors like packaging signals are incorporated into the vector genome.

Types of Viral Vectors

Adenoviruses

Viral vectors based on adenoviruses (Ad) were among the first used in human clinical trials and are presently used in 19% of all clinical gene therapy trials. Ad contain a 36-kb double-stranded DNA genome and can infect a broad spectrum of cells, including nondividing cells like hepatocytes and neuronal cells. Ad vectors can be produced at high titers (~10^{14} particles/ml) and can efficiently express transgenes in many different cells and tissues. However, transgene expression is only short-lived, because the Ad chromosome does not integrate into the host genome and is maintained as an episome. In addition, adenoviral infection causes a humoral and cellular immune response in immune-competent hosts. This immune response is directed not only against the viral particles but also against the infected cells. An unbalanced, massive immune response directed against Ad can be life-threatening to the



Gene Therapy Vectors, Fig. 1 General design of gene therapy vectors. (**a**) Schematic drawing of wild-type virus genome and life cycle. (**b**) The viral genes required for the production of infectious particles are provided in *trans* and are not packaged. The vector itself carries the gene of interest (transgene) under the control of a specific promoter

patient, especially if a high concentration of Ad vectors is administered (Verma and Weitzman 2005). The strong humoral immune response directed at the viral particles themselves has also severely limited the use of repeated cycles of Ad vector-mediated gene therapy. To limit immune reactions against Ad vectors, gutless vectors have been developed that do not contain viral genes. Transgene expression from these gutless vectors has been reported to be more long-lasting and the host immune response less pronounced (see Pfeifer and Verma (2001)). Replication-competent Ad vectors are especially promising for oncolytic therapy. To this end, Ad vectors, which preferentially replicate in tumor cells, have been designed.

Adeno-associated viruses (AAV)

AAVs are parvoviruses that are nonpathogenic to humans and carry a small genome of only 4.7 kb, consisting of the genes *rep* and *cap*. Entry of AAV into the cell is mediated by binding to heparin sulfate proteoglycan. Integrin avb5 and the fibroblast growth factor receptor 1 act as coreceptors. In the absence of the so-called helper virus (Ad, herpes viruses, or vaccinia viruses), AAV integrates into the host genome (human chromosome 19) and establishes latent infection. Upon co-infection with a helper virus, transcription of the latent AAV genome is activated, and the virus enters the productive stage of its life cycle. To generate recombinant AAV (rAAV) vectors, the *rep* and *cap* genes are replaced by the transgene of interest, rendering the virus replication-deficient. The integration of wild-type AAV is site-specific and requires the presence of the viral Rep protein, which is normally absent from AAV vectors since Rep is provided in *trans* during vector production. Therefore, rAAVs lacking the *rep* gene exhibit no site-specific integration but are more likely than wild-type AAV to integrate at non-homologous sites in the host genome. Overall, rAAV integration rates are still exceedingly low, but long-term transgene expression can nevertheless be achieved, since extrachromosomal rAAV genomes can persist as episomes (Pfeifer and Verma 2001).

Another important issue is the size limitation of AAV vectors: the maximum size of rAAV genomes is ~4.7 kb. While this is sufficient for many applications of gene therapy, the delivery of advanced gene-editing tools with rAAVs may prove difficult. To overcome this size constraint, dual vector systems with split genomes have been developed (Pfeifer and Verma 2001): dual vectors are based on episomal circular multimers formed by the AAV vector genomes. However, the efficacy of the dual vector system has been questioned.

Presently, 8% of all clinical gene therapy trials use AAV vectors as gene-delivery vehicle (Table 1). Although no pathology is known to be associated with AAV, the high frequency of antibodies against AAV (80% of the human population are seropositive for the most common AAV subtype) could be a major limitation for gene therapy using AAV-based vectors (Manno et al. 2006).

Retroviral Vectors

Retroviruses are enveloped viruses carrying an RNA genome with a DNA intermediate, which randomly integrates in the host genome. All retroviruses contain a basic set of three genes: *gag* (the structural virion proteins), *pol* (essential viral enzymes), and *env* (the viral glycoprotein of the envelope). Prototypic retroviruses like murine leukemia virus (MLV) carry only this simple set of genes, while complex retroviruses like lentiviruses carry additional regulatory genes. The first gene therapy vectors were derived from prototypic retroviruses, and they were the first viral vectors to be used in clinical trials. Retroviral virions can accommodate ~7 kb of transgene after reverse transcription in the target cells, although recent attempts at restructuring the genome of lentiviral vectors suggest this could be increased to ~8 kb (Vink et al. 2017). Integration of the proviral DNA is of advantage if long-term (even life-long) vector expression is wanted. However, vector integration harbors the risk of insertional mutagenesis and activation of proto-oncogenes. To cope with the latter problem, self-inactivating (SIN) retroviral vectors have been developed which carry deletions of the essential viral promoter/enhancer sequences. However, incorporation of the SIN mutations can result in a significant reduction of retroviral titers (Pfeifer and Verma 2001; Verma and Weitzman 2005). Additionally, for applications where transient expression is desired (e.g., of gene-editing machinery), integration-deficient retroviral vectors have been developed (Wanisch and Yanez-Munoz 2009).

Gene Therapy Vectors, Table 1 Gene therapy – clinical trials

Vector	%
Adenovirus	19
AAV	8
Retrovirus	17.5
Lentivirus	9.5
Naked/plasmid DNA	15.4

Detailed information can be found at http://www.abedia.com/wiley/

A major drawback of vectors derived from prototypic retroviruses is that they can only transduce dividing cells. Therefore, these vectors cannot be used for gene transfer in many nondividing cells (e.g., muscle and brain cells).

To circumvent this problem, vectors that are based on lentiviruses have been developed. In contrast to prototypic retroviruses, lentiviruses do not require cell division for integration since the proviral DNA can be transported through the nuclear pores. Gene therapy vectors have been developed from a broad spectrum of lentiviruses including human immunodeficiency virus (HIV), simian and feline immunodeficiency virus, as well as visna/maedi virus. The most widely used lentiviral vector system is based on HIV-1. These vectors can efficiently transduce a wide range of dividing and nondividing cells including neurons, hepatocytes, muscle cells, and hematopoietic stem cells (see below) (Pfeifer and Verma 2001; Verma and Weitzman 2005).

To address biosafety concerns, self-inactivating lentiviral vectors and stable packaging cell lines have been developed, which greatly reduces the risk of generating replication-competent viral vectors.

Apart from being a promising tool for gene therapy, lentiviral vectors are also important tools for molecular biology. These vectors efficiently transduce a variety of nondividing cells in vitro. Lentiviral vectors can be used to generate clinically relevant transgenic animal models (lentiviral transgenesis) (for a detailed review, see Pfeifer (2004)). Importantly, lentiviral transgenesis is not restricted to rodents (mouse and rat) but can also be used to generate transgenic animals in medically relevant livestock species (pig, cattle, chicken).

Finally, lentiviral vectors have been shown to transduce human embryonic stem cells. Therefore, this type of gene therapy vector might also be used in stem cell-based therapies.

Retrovirus- and lentivirus-derived viral vectors are used in approximately 27% of all gene therapy trials (Table 1). The gene therapy trial in patients suffering from severe combined immunodeficiency-X1 (SCID-X1) led by Alain Fischer and colleagues initially reported the successful restoration of the immune systems of SCID patients (Verma and Weitzman 2005). In this trial, hematopoietic stem cells were transduced with vectors derived from simple retroviruses. Unfortunately, five of the patients subsequently developed leukemia. Detailed analysis of vector-integration sites revealed that the retroviral vector had integrated close to the proto-oncogenes *LMO2* or *CCND2*, which led to aberrant expression of these genes, presumably through the enhancer-promoter activity of the viral long terminal repeats (LTRs) (Verma and Weitzman 2005). Later trials abandoned the use of viral LTRs to drive transgene expression and instead used the less mutagenic elongation factor 1α promoter. This, together with SIN modifications to remove enhancer-promoter activity of the LTRs, might have reduced the oncogene potential of the vectors derived from simple retroviruses (Hacein-Bey-Abina et al. 2014). In even more recent trials for SCID-X1, the simple SIN retroviral vectors were substituted for SIN lentiviral vectors, which led to more efficient transduction of B-cells and restoration of humoral immunity (Mamcarz et al. 2019).

Delivery, Tropism, and Targeting

In clinical gene therapy, there are two distinct approaches for introducing therapeutic genes into patient cells. The most common approach to date is ex vivo gene therapy. Here, cells are extracted from the patient, treated with gene therapy vectors, and transplanted back into the patient. This type of therapy is typically applied to hematopoietic stem cells or blood cells, when the immune system is the target, e.g., for the treatment of SCID and for CAR-T cell therapy. Recently approved examples of this kind of gene therapy include Strimvelis® (for ADA-SCID) and Kymriah® (CAR-T for B-cell acute lymphoblastic leukemia). Conversely, in vivo gene therapy is applied in cases where the target cells must remain in situ. An example of this is the first clinically approved gene therapy, Glybera®, in which an adeno-associated viral vector carrying the lipoprotein lipase gene is directly injected into the patient's skeletal muscle tissue.

In some cases, the pathology of a genetic disease arises from a cell type that is not amenable to neither ex vivo gene therapy nor local injection of gene therapy vectors. For this, so-called targeted viral vectors are needed. The goal of this is to alter the tropism of viral vectors to enhance transduction efficiency of the target cells in vivo and to avoid off-target effects. This is achieved by changing the epitope of the viral particle that binds to the host cell receptor. A classic example is the modifications done to enhance the tropism of lentiviral vectors. The most used lentiviral vectors derive from the wild-type HIV-1 virus. This virus interacts with its host cells (CD4-positive cells) through the glycoprotein gp160, which resides in the virus lipid envelope. By generating HIV-derived viral vectors that express the glycoprotein from the vesicular stomatitis virus (VSV. G), the tropism of the vector is vastly expanded to virtually any type of cell (Burns et al. 1993). This process is known as pseudotyping. An analogous example for non-enveloped viruses such as AAVs is so-called cross-packaging, where the tropism of AAV vectors is altered by packing the AAV genome, e.g., from AAV-2, into the capsid of other AAV serotypes. Further modification of AAV tropism can also be achieved by shuffling the capsid gene DNA of different AAV serotypes to generate chimeras with novel targeting properties (Vandenberghe et al. 2009).

Finally, specific tropism can be engineered by rational design of antigen-binding epitopes on the viral surface. For example, incorporation of single-chain variable fragments or DARPINs targeted to a specific receptor can mediate highly

accurate targeting of a modified viral vector to a certain cell type (Hartmann et al. 2018).

Regulation of Gene Expression

An important issue is the regulation of gene expression in the target cells and tissues. Although steady-state expression over prolonged time intervals is desired in many diseases, controlled expression of the foreign gene in a reversible manner will be highly desirable (e.g., gene therapy for insulin-dependent diabetes mellitus). To achieve more physiological expression profiles, novel regulatable systems that are controlled by endogenous (e.g., hormones) and/or exogenous (e.g., pharmacological agents) factors have to be developed. In addition, regulation of transgene expression by the gene product itself via negative or positive feedback mechanisms would be an additional desired feature.

Other Viral Vectors

Several vectors based on viruses other than the ones mentioned above have also been designed and used for gene therapy in animal models and clinical trials (these have been reviewed in detail elsewhere) (Anguela and High 2019; Kotterman et al. 2015; Lundstrom 2018). Herpes simplex virus (HSV)-based vectors yield stable long-term expression of transgenes, have an extremely high insert capacity (up to 150 kb for amplicon vectors), and have been used in clinical trials to treat CNS disorders and malignant tumors (oncolytic HSV vectors). The measles virus is an enveloped virus that has been widely used to generate oncolytic viral vectors. The host cell entry mechanism of the measles virus is particularly amenable to engineered tropism, due to the fact that host cell receptor interaction and viral entry are mediated by two distinct viral proteins. This has allowed incorporation of antibody fragments greatly increasing the tropism to various cancer cells. Additionally, VSV vectors have been used, e.g., in preclinical studies to deliver the HIV-1 genes *gag* and *env* in order to elicit a humoral response against HIV-1 infection. Several vectors based on other viruses are also being investigated.

Potential Risks

An important safety issue of viral vectors is whether or not the recombinant viruses are able to replicate in the infected cells. Replication of viral vectors is unwanted in most gene therapy approaches. Therefore, replication-defective vectors have been designed, which are able to perform only one initial infectious cycle within the target cell. In addition, replication-competent vectors have been designed, which are able to productively infect the target cell and to spread in the target tissue, e.g., cancer. Immunological reactions of the host to either the delivery vehicle or its cargo are another concern. The host immune response might not only eliminate the vector particles before they reach the target cells/tissues; it can also be directed at the product(s) of the genes delivered by the vector, especially if a null mutation is replaced with a functional copy of the affected gene (in this case no immunological tolerance would exist for the product of the normal gene).

The development of leukemia in patients receiving retrovirally transduced cells clearly underlines that insertional mutagenesis is a major concern for integrating vectors, although careful engineering of the vectors has greatly reduced the risk of this occurrence. Nevertheless, improving safety profiles of viral vectors remains of critical importance in the development of gene therapies.

Pharmacological Relevance

Although pharmacology still relies heavily on small chemical substances, biologicals like recombinant proteins, cell-based therapies, and gene therapy approaches have great potential for the treatment of a broad spectrum of diseases. Gene therapy has been shown to be particularly versatile and has found application in the treatment of genetic diseases, infectious diseases, and cancer. Therefore, the focus of modern pharmacology should shift toward these innovative therapies.

Gene Therapy Vectors, Table 2 List of most common therapeutic genes used in gene therapy trials (viral and nonviral vectors)

Gene type	%
Antigen	18
Receptor	16.8
Cytokine	13.1
Deficiency	8.5
Growth factor	6.5
Tumor suppressor	6.2
Suicide	6.1

Detailed information can be found at http://www.abedia.com/wiley/

Presently, 2,930 gene therapy trials are underway worldwide (Tables 1 and 2). For details see http://www.abedia.com/wiley/. At present, two thirds of all gene therapy trials target cancer diseases, while 11.5% target monogenic diseases. The vast majority of nonviral gene therapy trials used naked/plasmid DNA (15.4% of all gene therapy trials). Almost three quarters of all trials are based on viral vectors.

Definition

Ghrelin is a pleiotropic gastric hormone that has gained much attention in metabolic research in the past two decades. This is largely due to the fact that ghrelin is a gastrointestinal (GI) hormone that stimulates appetite and possibly weight gain in opposition to a wide array of well-characterized satiety-inducing hormones from the digestive system. Today, we understand that besides appetite regulation, ghrelin signaling plays a role in growth, reward, memory, gastric motility, glucose metabolism, cardiovascular functions, and possibly adiposity (Fig. 1). These functions have positioned the ghrelin receptor as a potential drug target for both agonists and antagonists.

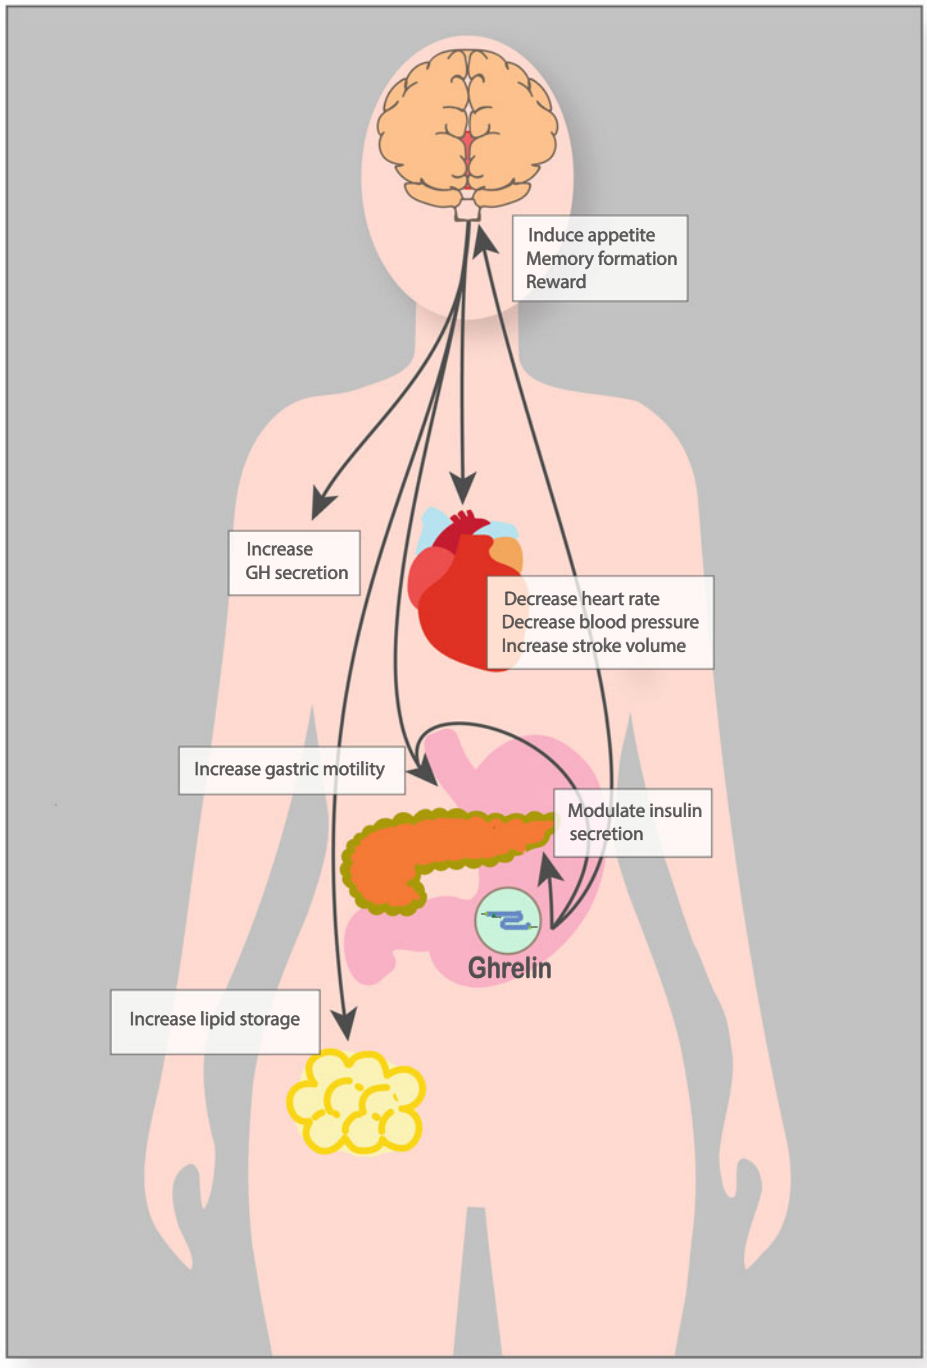
Basic Mechanism

Ghrelin Production and Acylation

In 1999, ghrelin was discovered as the endogenous ligand of the growth hormone secretagogue receptor, later known as the ghrelin receptor (GhrR). Circulating ghrelin is predominantly synthesized in the X/A-like cells in the gastric lumen, while the small intestine has the second largest expression of ghrelin mRNA in humans. Ghrelin consists of 28 amino acids; however, the molecular mass of the purified peptide is greater than the predicted value for a 28-amino acid peptide. This led to the discovery that ghrelin undergoes post-translational modification. A serine octanoylation occurs on the third hydroxyl-containing residue near the N-terminus. This acylation is required for ghrelin to be recognized by the GhrR. The enzyme ghrelin *O*-acyltransferase (GOAT) is responsible for this modification. In humans, GOAT mRNA is mainly expressed in the stomach and pancreatic tissue and has a high degree of co-localization to ghrelin-producing cells within the stomach. Furthermore, GOAT-deficient mice have an absence of plasma acyl ghrelin, demonstrating that GOAT is essential for this acylation process (Yanagi et al. 2018). Ghrelin is synthesized as a prohormone that is processed by prohormone convertase 1/3 to its mature form. The preproghrelin gene encodes ghrelin as well as another hormone, obestatin. Obestatin was initially suggested to act as an endogenous agonist for GPR39, a member of the GhrR family that decreases food intake, but subsequent studies have challenged this observation.

The Ghrelin Receptor and Its Signaling Pathways

The GhrR is the only known receptor for ghrelin, and expression of GhrR mRNA has been detected in several brain regions involved in energy



Ghrelin, Physiological Roles and Clinical Relevance of, Fig. 1 Ghrelin is secreted from the stomach and targets both the brain and peripheral organs. The arrows indicate direct and centrally mediated effects of ghrelin

homeostasis, learning, memory, and reward, as well as in several areas of the periphery, for example, the GI tract and pancreatic tissue (Müller et al. 2015). All ghrelin-mediated functions are dependent on the GhrR, which belongs to the seven-transmembrane G protein-coupled receptor

(GPCR) family. The receptor has been shown to be promiscuous in its signaling pathways, including $G\alpha_{q/11}$, $G\alpha_{i/o}$, $G\alpha_{12/13}$, and β-arrestin recruitment. The orexigenic effect of GhrR activation is thought to be mainly mediated via the $G\alpha_q$-coupled pathway through the phospholipase C-inositol trisphosphate cascade (Hedegaard and Holst 2020). The GhrR exhibits a uniquely high ligand-independent constitutive activity of approximately 50% of maximal capacity and is able to initiate downstream signaling events in the absence of ghrelin (Holst et al. 2003). This high basal activity suggests a ghrelin-independent role for the GhrR.

Role of Ghrelin in the Regulation of Growth Hormone

Since its discovery, ghrelin has been described as a hormone involved in growth hormone (GH) secretion. GhrR mRNA expression has been found in the pituitary gland, and both central and peripheral administrations of ghrelin increase both the basal level and the physiological pulsatility of GH released from pituitary somatotroph cells (Müller et al. 2015).

Role of Ghrelin in the Homeostatic Regulation of Appetite

Appetite is regulated by both physiological demands for nutrients and motivation to eat formed by the sense of reward from former experiences. These two components are classically termed the homeostatic and hedonic regulation of appetite. The homeostatic regulation of appetite balances energy intake and expenditure. Sensory inputs are relayed from the GI tract via both peripheral hormones and the vagal nerve, which are then integrated in the central nervous system, primarily via the arcuate nucleus (ARC) in the mediobasal hypothalamus. Within the ARC, there are two distinct neuronal populations with opposing effects on food intake. Neurons that express pro-opiomelanocortin (POMC) suppress feeding and increase energy expenditure, and neurons that co-express neuropeptide Y (NPY) and agouti-related peptide (AgRP) stimulate food intake and decrease energy expenditure. In the hypothalamus, ghrelin primarily binds and activates GhrRs on the presynaptic terminals of NPY/AgRP neurons and thereby stimulates food intake.

NPY/AgRP and POMC neurons innervate melanocortin-4 receptor (MC4R)-expressing neurons in the paraventricular nucleus (PVN) of the hypothalamus, which then regulate appetite and energy expenditure by projecting to neurons of the lateral parabrachial nucleus in the brainstem, which are commonly referred to as "satiety" neurons. Activation of ARC POMC neurons increases release of α-melanocyte-stimulating hormone (α-MSH), which binds to and activates MC4Rs to decrease food intake. When activated, the terminals of NPY/AgRP axons increase secretion of γ-aminobutyric acid (GABA) that inhibits the activity of postsynaptic POMC neurons to inhibit their anorexigenic effect. Additionally, the AgRP peptide antagonizes MC4Rs, while the NPY peptide acts on Y1 and Y5 receptors in the PVN to stimulate appetite (Yanagi et al. 2018). In rodents, fasting increases plasma ghrelin levels, ghrelin mRNA levels in the stomach, and GhrR mRNA in the hypothalamus and pituitary gland, suggesting a role for ghrelin under calorie deficit. GhrR expression in NPY/AgRP neurons is required for ghrelin's stimulatory effects on acute food intake and GH secretion. It has been shown that the selective reintroduction of the GhrR into AgRP neurons of GhrR knockout (KO) mice partially restores the orexigenic effects of ghrelin (Müller et al. 2015). Additionally, the NPY and AgRP neuropeptides are essential for ghrelin's orexigenic effects as peripheral administration of ghrelin failed to increase food intake in *Agrp:Npy* double KO mice (Müller et al. 2015).

The ARC also contains a population of tyrosine hydroxylase (TH) neurons that mainly release dopamine (DA) as well as GABA and have been shown to have orexigenic effects when activated. Optogenetic stimulation of ARC TH neurons in mice increases food intake through local inhibitory projections onto POMC neurons and inhibitory projections to the PVN and through indirect activation of NPY/AgRP neurons (Hedegaard and Holst 2020). Ghrelin has a direct excitatory action on ARC TH neurons, suggesting that it may also act on this population of neurons to regulate energy homeostasis. Additionally, when ras homolog gene family member A

(RhoA), an intracellular signaling molecule downstream of the $G\alpha_{12/13}$ pathway of the GhrR, was specifically knocked out in TH neurons in mice, there was a prolonged increase in food intake compared to wild-type (WT) mice when peripherally administered with ghrelin. The RhoA KO mice were also prone to overeating and obesity (Skov et al. 2019), suggesting the importance of the $G\alpha_{12/13}$ pathway of the GhrR in this population of neurons.

The lateral hypothalamus (LH) shares direct connections with the ARC and PVN, and there is evidence that ghrelin communicates with hippocampal neurons to regulate appetite as the LH also receives inputs from the ventral temporal subregion of the hippocampus (vHP). Administration of ghrelin directly into the vHP was shown to stimulate feeding by activating LH orexin neurons, indicating that the LH is downstream of vHP ghrelin-mediated orexigenic effects (Yanagi et al. 2018).

Role of Ghrelin in the Hedonic Regulation of Appetite

While the GhrR is present in hypothalamic centers, it is also expressed in the ventral tegmental area (VTA) of the midbrain. The VTA, a key node in the mesolimbic DA motive system, plays an important role in mediating motivational behaviors and the hedonic consumption of highly palatable foods. NPY/AgRP neurons in the ARC project to the LH, where second-order neurons project to the VTA to modulate activity in the mesolimbic DA system (Yanagi et al. 2018). The VTA is largely composed of DA neurons that project to the nucleus accumbens (NAc), ventral pallidum (VP), prefrontal cortex (PFC), amygdala, and hippocampus to regulate hedonic food intake, motivation to obtain food, and cue associations. Direct ghrelin administration into the VTA of mice causes a significant increase in the intake of standard chow, palatable food, and sucrose, while GhrR KO mice have a reduced intake of rewarding food compared to chow (Edwards and Abizaid 2017). Additionally, GhrR signaling in the VTA has been shown to be important for reward-motivated locomotor behaviors (Skov et al. 2017). GhrR immunoreactivity was found in a subset of VTA DA neurons in both mice and rats, and patch clamp recordings showed an increase in the frequency of action potentials of VTA DA neurons in brain slices after the application of ghrelin (Edwards and Abizaid 2017).

In summary, the GhrR has been identified in hypothalamic regions, including the ARC, an important region for controlling appetite, and the peripheral and central administration of ghrelin has been shown to increase appetite. Furthermore, the GhrR is expressed in the VTA, and ghrelin has been shown to play a role in hedonic food intake (Fig. 2).

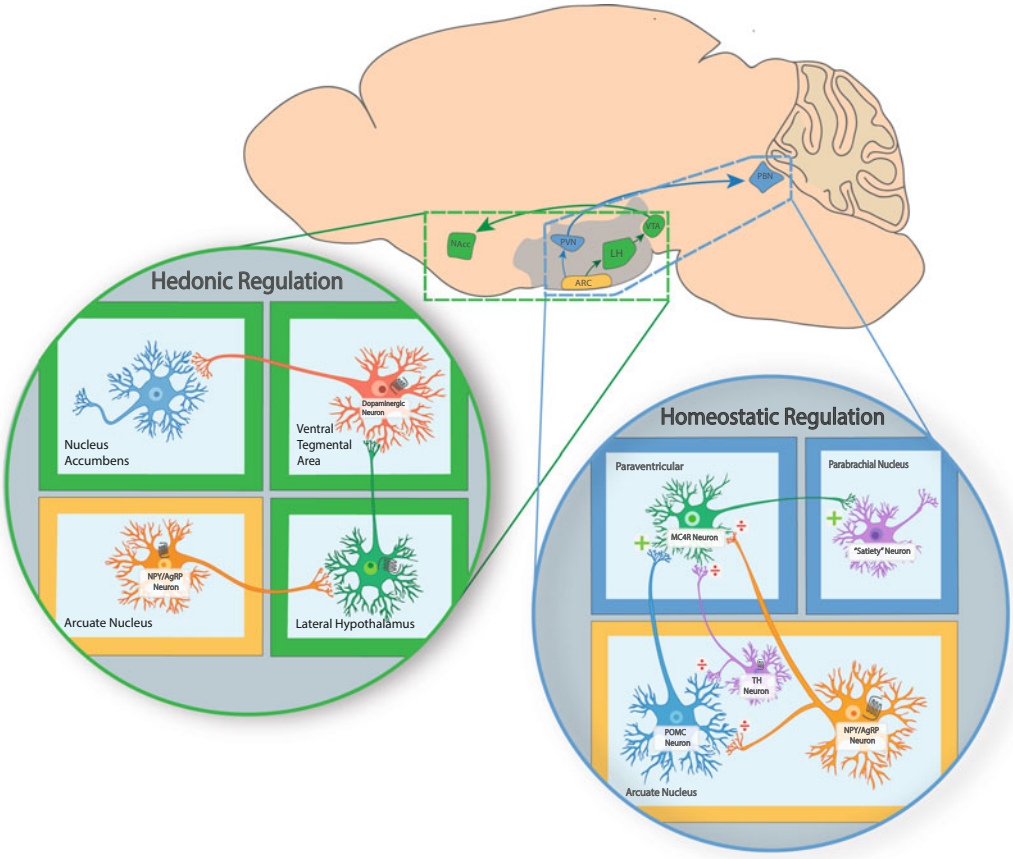
Role of Ghrelin in Stress and Anxiety

Studies have shown that ghrelin is secreted in response to acute stressors, such as fasting, physical restraint, and psychological and social stress, possibly to counter anxiety and depression. Administration of ghrelin induced antidepressant-like and anxiolytic-like responses in mice during acute stress tests compared to untreated mice. Conversely, GhrR KO mice displayed more anxiogenic-like behavior when exposed to the same stress compared to WT mice.

Both epinephrine and norepinephrine along with other β-adrenergic receptor agonists are some of the most potent stimulators of ghrelin secretion, indicating an important role of stress in the regulation of the ghrelin system. When GhrR KO and WT mice were subjugated to acute restraint stress, KO mice were more anxious during the following behavioral tests but had an attenuated corticosterone response compared to WT mice, indicating a dysfunctional glucocorticoid response in the absence of ghrelin. Additionally, when mice were subjugated to chronic social defeat stress, a paradigm that induces a depressive-like phenotype, plasma ghrelin levels were elevated, resulting in long-lasting increase in food intake and body weight (Wittekind and Kluge 2015).

Role of Ghrelin in Memory and Neuroprotection

The GhrR plays a role in enhancing synaptic plasticity and hippocampal neurogenesis. It has been shown that the GhrR is expressed in CA3



Ghrelin, Physiological Roles and Clinical Relevance of, Fig. 2 Ghrelin and the GhrR are involved in hedonic and homeostatic regulation of appetite. The homeostatic regulation of appetite is partially framed with a blue color: Activation of GhrR on the orexigenic NPY/AgRP neurons in the arcuate nucleus (ARC) inhibits the satiety-inducing network, which consists of POMC neuron stimulation of MC4R neurons in the paraventricular nucleus (PVN) that in turn stimulates "satiety" neurons in the parabrachial nucleus (PBN) in the brainstem. TH neurons in the ARC inhibits POMC and MC4R neurons and indirectly activates NPY/AgRP neurons (not illustrated). The hedonic regulation of appetite is marked with green: GhrR activation of NPY/AgRP neurons projects to the lateral hypothalamus (LH) that in turn stimulates the mesolimbic reward system by activating dopaminergic neurons in the ventral tegmental area (VTA). These in turn activate neurons in the nucleus accumbens (NAc). The receptors on the neurons symbolize the 7TM G-protein-coupled ghrelin receptor, GhrR

and CA1 hippocampal neurons, and its activation promotes dendritic spine synapse formation and long-term potentiation. Peripheral administration of ghrelin to rats has been demonstrated to improve spatial memory compared to controls. Additionally, it has been shown that repeated peripheral ghrelin administration stimulates neurogenesis in the adult mouse hippocampus.

Huntington's disease (HD) is a neurodegenerative disease that also causes metabolic disturbances such as weight loss and muscle wasting. Using a mouse model of HD, it was found that in the late stage of HD, mice had reduced circulating ghrelin levels as well as downregulation of the GhrR in the hypothalamus and an attenuated response to peripheral ghrelin administration compared to WT mice (Rudenko et al. 2019). However, the response to ghrelin was not dysfunctional, while the mice were still pre-symptomatic and chronic peripheral administration of ghrelin was able to increase lean body mass while decreasing energy expenditure and fat

utilization during the early stage of HD (Rudenko et al. 2019).

There is increasing evidence that the ghrelin system is impaired in Parkinson's disease (PD), as patients with PD have reduced plasma ghrelin levels and a diminished pre-prandial peak response and post-prandial ghrelin suppression compared to healthy controls. The degeneration of DA neurons in the substantia nigra pars compacta (SNc) leads to PD, and this population of neurons also expresses the GhrR (Yanagi et al. 2018). Studies have demonstrated that peripheral administration of ghrelin can protect against neurodegeneration and decrease SNc DA neuron loss in rodent models of PD.

Effects of Ghrelin on the Autonomic Nervous System

While there is not consistent evidence that the GhrR is expressed in white adipose tissue, it has been demonstrated that central ghrelin administration increases food intake and adiposity in rodents. This is at least in part mediated via altered sympathetic activity, as demonstrated by an abolished effect on body weight when ghrelin is administered to β-adrenergic receptor KO rodents (Theander-Carrillo et al. 2006).

The Current Understanding of the Spatial Separation Between Ghrelin and the GhrR in the Brain

It is apparent that ghrelin has the ability to regulate GH release, appetite, stress, and body weight when administered directly into specific brain areas or the lateral ventricle and that neurons in various brain regions express the GhrR and respond to ghrelin. It has also been demonstrated that peripheral ghrelin is able to directly or indirectly activate central targets. However, evidence has shown that ghrelin produced in the periphery has a limited ability to permeate the blood-brain barrier to reach extrahypothalamic regions, such as the VTA (Edwards and Abizaid 2017). Therefore, one of the most persistent unanswered questions in the research of central ghrelin functions is the function of GhrRs in brain regions that are not readily accessible to circulating ghrelin. Studies in rodents and humans indicate that ghrelin reaches the hypothalamus via the afferent fibers of the vagal nerve. Blocking of the vagal afferent pathway attenuated ghrelin-induced food intake, and following the administration of peripheral ghrelin, vagal afferents that travel to the NTS increased norepinephrine in the ARC. However, several other studies have suggested that ghrelin may also reach the ARC directly via the fenestrated capillaries or tanocytes in the median eminence (Edwards and Abizaid 2017).

The formation of heterodimers and the high constitutive activity of the GhrR point to a ghrelin-independent function that may explain the expression of the GhrR in brain areas not accessible to peripheral ghrelin. The G protein α-subunits activated following ghrelin binding to the GhrR are varied and influenced by many factors such as cell type, tissue, and heterodimer partner (Edwards and Abizaid 2017). Heterodimerization is the interaction of two receptors in a heteromeric complex. Heterodimerization between GPCRs can modify the strength and/or nature of downstream signaling pathways. Evidence indicates that the GhrR can homodimerize with itself or heterodimerize with other GPCRs, including dopamine receptors 1 and 2 (D1R, D2R), serotonin 2C receptor (5-HT_{2c}), melanocortin 3 receptor (MC3-R), and somatostatin receptor 5 (SST5) in order to modulate the downstream signaling of these receptors (Hedegaard and Holst 2020). For example, D1R has been shown to form heterodimers with the GhrR in hippocampal cells, and the heterodimer changes the signaling pathway of the D1R from Gαs-coupling to $G\alpha_q$-coupling. This modification in signaling pathway results in an increase in early markers of synaptic plasticity, suggesting that the D1R-GhrR heterodimer plays a role in memory formation in the hippocampus (Hedegaard and Holst 2020). Interestingly, beta-amyloid deposits, which are a characteristic of AD, have been shown to disrupt the formation of D1R-GhrR heterodimers in the human brain. This points to a local disruption of GhrR signaling in the pathophysiology of this type of dementia.

Role of Ghrelin in Gastric Motility

The GhrR is sparsely expressed in peripheral tissues compared to the brain, but receptor

expression has been identified in the GI tract and pancreas. In the periphery, ghrelin specifically regulates gastric motility and glucose metabolism. Pharmacological doses of ghrelin increase gastric tone and gastric emptying in rodents and humans. Ghrelin exerts its effect on gastric motility both directly on the enteric nerves of the GI tract and indirectly via central modulation of autonomic nerve activity. Ghrelin signaling via afferent vagal fibers projects to the NTS and the dorsal motor nucleus in the brain stem, which causes the release of acetylcholine and substance P from efferent vagal fibers resulting in contraction of gastric smooth muscle (Peeters 2013).

Role of Ghrelin in Glucose Metabolism

Peripheral ghrelin administration increases blood glucose, lowers insulin levels, and decreases insulin sensitivity in rodents and humans (Müller et al. 2015). In isolated rat pancreatic islet cell cultures, ghrelin suppressed insulin release, while a blockade of the GhrR increased cytosolic calcium (Ca^{2+}) in β-cells and increased glucose-stimulated insulin secretion. Furthermore, the inhibitory effects of ghrelin on insulin secretion and Ca^{2+} release were absent when β-cells were treated with an antisense oligonucleotide for the $G\alpha_{i2}$-subunit of the GhrR, indicating that in β-cells, the GhrR mediates suppression of insulin release via the $G\alpha_i$ pathway. Additionally, evidence shows that GhrR heterodimerization is important in modulating insulin secretion as the heterodimer formation of the GhrR with somatostatin receptor 5 is required to initiate the $G\alpha_i$ signaling pathway (Hedegaard and Holst 2020).

While ghrelin KO and GhrR KO mice showed no difference in phenotype compared to WT littermates under basal conditions, mice with KO of either ghrelin, the GhrR, or GOAT develop fatal hypoglycemia during prolonged caloric restriction. This has led to the hypothesis that ghrelin acts as a survival hormone that maintains glucose levels during starvation. In rodents, it has been shown that ghrelin levels increase during caloric restriction, and the associated increase in GH prevents fatal hypoglycemia (Mani and Zigman 2017).

Pharmacological Intervention

Clinical Findings of Ghrelin's Effect on Growth Hormone

A missense mutation that abolishes the constitutive activity of the GhrR has been found to result in short stature, pointing to a role of GhrR signaling in normal growth in humans (Yanagi et al. 2018). Due to their potency in stimulating somatotroph cells, synthetic GhrR agonists are in clinical use for diagnosing GH deficiency.

Clinical Findings of Ghrelin's Effect on Appetite and Body Weight

Plasma levels of ghrelin increase shortly before a meal, with the lowest values post-prandially. Clinical studies show that an administration of ghrelin increases energy intake, and long-term administration has been reported to cause an increase in the sense of appetite (Yanagi et al. 2018). Despite the appetite-stimulating effect of ghrelin in humans, clinical studies with GhrR agonists do not consistently lead to increased adiposity. A number of studies have investigated weight changes after long-term administration of ghrelin analogs and found they tend to cause a slight increase in body weight in patients with chronic illness, as well as in normal-weight individuals. Studies that report on body composition have found that the increased weight is caused by an increase in lean body mass (Garin et al. 2013).

Total ghrelin plasma levels are inversely correlated with nutritional status, such that obese individuals have lower levels and lean individuals have higher levels (Müller et al. 2015). Total ghrelin increases after diet- or exercise-induced weight loss. Additionally, ghrelin decreases after bariatric surgery, especially after sleeve gastrectomy. This difference in plasma levels between the two causes of weight loss is hypothesized to be an important contributing factor to the relative stability of the weight loss achieved after bariatric surgery (Svane et al. 2019).

Clinical Findings of Ghrelin's Effect on Anxiety and Alcohol Dependence

In clinical studies, reports on the relation between physiological and pharmacological levels of

ghrelin to anxiety have not been consistent. One study found that a majority of patients with malignancy-related cachexia preferred ghrelin to placebo, which could indicate a positive effect on well-being. In summary, more research is needed in order to understand if ghrelin influences mood and anxiety in humans.

Several clinical trials and rodent studies have investigated ghrelin levels in relation to alcohol dependence. Ghrelin infusion increases alcohol craving compared to placebo and has been shown to significantly increase the frequency of alcohol self-administration in humans. Significant correlation has been found between plasma ghrelin and mesolimbic activation in response to alcohol cues in individuals with alcohol dependence. A GhrR inverse agonist has recently been tested as a potential treatment for alcohol dependence in a phase I trial, with an acceptable safety profile and a promising finding of decreased alcohol craving at the highest dosage (Lee et al. 2020).

Clinical Findings of Ghrelin's Effect on Neuroprotection

There is evidence that ghrelin activity is dysfunctional in brain areas involved in memory formation in Alzheimer's disease (AD). Patients with AD have unaltered levels of plasma ghrelin. However, expression of the GhrR has been shown to increase in proportion to the pathognomonic accumulation of beta-amyloid deposits in the hippocampus, and amyloid beta impairs ghrelin signaling.!!Expression of the GhrR in human inferior temporal lobe is significantly lower in diseased tissue than in control specimen from non-demented individuals. In a mouse model of AD, peripheral administration of a synthetic GhrR agonist reduced beta-amyloid accumulation and inflammation. However, one multi-center randomized clinical trial has tested the same drug in more than 400 patients with AD and, disappointingly, found no effect on disease progression after 1 year of treatment (Sevigny et al. 2008).

Clinical Findings of Ghrelin's Effect on the Autonomic Nervous System

Ghrelin decreases sympathetic and increases parasympathetic activity, possibly by acting on GhrRs in the hypothalamus and the nucleus tractus solitarius (NTS), thereby causing beneficial effects on the cardiovascular system. Ghrelin administration decreases blood pressure and heart rate in healthy individuals, and several studies found that ghrelin increases ventricular contractility (Garin et al. 2013). However, this last finding is inconsistent in the literature. There are reports that the GhrR is expressed in myocardial tissues and blood vessels, but these findings are not consistent. Therefore, the impact of ghrelin on the cardiovascular system is currently perceived as being centrally mediated. In patients with chronic heart disease, 3 weeks of ghrelin treatment improved contraction of the left ventricle and physical performance. In contrast, GhrR antagonism may have a potential negative effect on the autonomic regulation of the heart and vasculature. Preclinical data show that antagonism of the GhrR causes increase in blood pressure and heart rate, and more research in the cardiac safety profile of GhrR antagonists is warranted.

Clinical Findings of Ghrelin's Effect on Gastric Motility

In clinical trials, ghrelin increases gastric emptying in healthy volunteers as well as in patients with neurogenic gastroparesis. Two recently published systematic meta-analyses have documented that parenteral administration of ghrelin mimetics improves gastric emptying in patients with neurogenic gastroparesis and in a mixed population of patients receiving pro-motility agents. There is a concern for the increase in plasma glucose when treating patients with diabetic gastroparesis with ghrelin mimetics, but overall, the potential benefits of treatment have led one of the GhrR agonist, relamorelin, being accepted for fast track designation for diabetic gastroparesis by the FDA in 2017.

Clinical Findings of Ghrelin's Effect on Glucose Metabolism

In order to assess the effect of ghrelin itself on blood glucose in humans, one study investigated the effect of ghrelin infusion in individuals with GH deficiency. In these individuals, there was no significant effect on plasma glucose by ghrelin. However, they

did find that ghrelin induced peripheral insulin resistance measured during a hyperinsulinemic euglycemic clamp (Vestergaard et al. 2017).

GhrR Antagonism

An inverse agonist for the GhrR that is able to eliminate its high constitutive activity has been highly sought after as a potential anti-obesity agent. In 2003, a known low-potency GhrR antagonist, [D-Arg1,D-Phe5,D-Trp7,9,Leu11]-substance P (SPA), was found to be a high-potency inverse agonist of the receptor. Truncation analysis of this compound showed that the inverse agonist property is located in the C-terminal pentapeptide, and mutational analysis of the GhrR binding sites showed that, in contrast to ghrelin, the inverse agonist binds to an intracellular part of the receptor (Holst et al. 2003).

Liver-expressed antimicrobial peptide 2 (LEAP2) was recently found to be the endogenous antagonist for GhrR (Ge et al. 2018). LEAP2 is a 40-amino-acid-long peptide with two disulfide bridges that is primarily secreted by cells in the small intestine and liver. LEAP2 has been shown to be both an inverse agonist of the GhrR and a competitive antagonist to ghrelin at the GhrR (M'Kadmi et al. 2019). Whole-cell patch-clamp recording on mouse hypothalamus showed that ghrelin depolarizes NPY neurons and that this is inhibited by LEAP2, which further hyperpolarizes the neuronal membrane, likely due to a decrease in the constitutive activity of the GhrR (Mani et al. 2019). LEAP2 and the N-terminal part of LEAP2 have been found to inhibit both ghrelin's orexigenic effect and the stimulation of GH release (Ge et al. 2018; M'Kadmi et al. 2019). The development of LEAP2 analogs that are able to diminish the constitutive activity of the GhrR could be a potential therapeutic anti-obesity target in the future. A recent study examined the plasma levels of LEAP2 compared to ghrelin in different nutritional states and found that LEAP2 has an opposite pattern of secretion to ghrelin in that it increases post-prandially in obese individuals and positively correlates with BMI and fat mass in both mice and humans. LEAP2 plasma levels were found to decrease during 24 h fasting and increased in response to an oral glucose load and after streptozotocin-induced diabetes mellitus in mice. It was also shown that gastric bypass and gastric sleeve surgery decreased circulating LEAP2 levels in a follow-up period of up to 2 years (Mani et al. 2019). More studies are needed to confirm the regulation of LEAP2 in obesity.

Synonyms

Asthma controllers; Corticosteroids; Glucocorticoid agonists; Steroids

Definition

Both external and internal stress cause the release of glucocorticoids (cortisol) from the zona fasciculata of the adrenal gland. Heightened levels of glucocorticoids result in muscle catabolism, which causes the release of amino acids which can be used by the liver to enhance glucose synthesis (gluconeogenesis). Another key function of glucocorticoids, particularly in acute and chronic disease, is the downregulation of inflammation and immune responses that occur in response to exogenous infections or other stimuli. This aspect of glucocorticoid function has been utilized clinically for over 70 years, and topical and systemic glucocorticoids are the most effective anti-inflammatory agents used to treat most immunoinflammatory diseases.

Regulation of Inflammation

Many chronic diseases such as bronchial asthma are driven by excess activation of inflammatory and immune responses. Each disease will have precise inflammatory and immune features associated with their site of inflammation, but they all require infiltrating immune and inflammatory cells to be recruited and both infiltrating and tissue resident cells to be activated. In asthma, airway structural cells are also important inflammatory cells. Chronic inflammatory diseases feature

enhanced mediator expression including cytokines, chemokines, growth factors, enzymes, receptors, and adhesion molecules often under the control of the pro-inflammatory transcription factor nuclear factor-κB (NF-κB). For example, asthma is characterized by exaggerated NF-κB activation in immune and structural cells such as airway epithelial cells, and upregulation of NF-κB in these cells drives the abnormal inflammatory gene profile observed in bronchial asthma (Adcock and Mumby 2017; Wadhwa et al. 2019). Recent advances in high-throughput and genome-wide technologies have revealed unforeseen complexities in both inflammatory gene expression and how glucocorticoids regulate this expression. Many of these insights are summarized in the sections below.

Mechanism of Gene Induction by NF-κB

Virtually all of the stimuli that drive asthma or asthma exacerbations can enhance NF-κB activity including allergen, pollution, and rhinovirus exposures. Cytokines, such as tumor necrosis factor-α (TNFα), interleukin (IL)-1β, and key asthma cytokines such as IL-13, also activate NF-κB within airway cells. Importantly, NF-κB is also a key target for glucocorticoid actions (Adcock and Mumby 2017). There is ubiquitous expression of NF-κB in immune and inflammatory cells and it alone can induce the expression of numerous inflammatory and immune genes although its actions are often amplified by cooperation/interaction with cell- and signal-specific transcription factors such as CAAT/enhancer-binding protein (C/EBP)α and interferon response factor (IRF)-1 (Taniguchi and Karin 2018). Within a resting inflammatory cell, NF-κB is localized in the cytoplasm in an inactive state by interaction with an inhibitor protein I-κBα. Stimulation of the inflammatory cells activates a receptor-driven phosphorylation cascade that leads to IκBα phosphorylation and dissociation of IκBα from NF-κB. Released activated NF-κB is then able to translocate into the nucleus where it binds to specific *regulatory regions* of DNA within the promoters of NF-κB-responsive inflammatory genes (Taniguchi and Karin 2018). However, it is important to note that other transcription factors such as activator protein (AP)-1 and members of the signal transducers and activators of the transcription (STAT) family are also important in regulating inflammation in airway cells under various stimuli (Adcock and Mumby 2017).

The several meters of DNA within each nucleus are carefully packaged around basic histone proteins, which form a structure relatively inaccessible to the enzyme RNA polymerase II that stimulates the formation of mRNA. This chromatin structure is described as "closed" and is generally linked with limited gene expression. Heightened inflammatory gene expression following NF-κB activation is linked to enzymatic modification of these basic histones, which results in an alteration in local and also more widespread chromatin structure (Miranda et al. 2013; Pope and Medzhitov 2018; Vandewalle et al. 2018). Activated NF-κB that is bound to DNA recruits transcriptional coactivator complexes such as CREB-binding protein (CBP) and p300/CBP-associated factor (PCAF), which possess intrinsic histone acetyltransferase (HAT) activity. Acetylation of the σ-group on lysine residues within the N-terminal tail of histones close to the site of NF-κB DNA binding generates a "mark" or "tag" (Miranda et al. 2013; Pope and Medzhitov 2018; Vandewalle et al. 2018).

This tag results in mutually opposing charges on DNA and histones, which, together with the ability of coactivator enzymes and chromatin remodeling complexes being able to recognize this tag, promotes a more relaxed local DNA structure that enables the further recruitment of RNA polymerase II and other components of the basal transcriptional machinery. Inflammatory stimuli including NF-κB activating cytokines such as TNFα and IL-1β are able to enhance histone acetylation in a time- and concentration-dependent manner. The precise sequence of the NF-κB DNA-binding sequence in each inflammatory gene tends to differ, as does the chromatin

status in different cell types. NF-κB may also interact with other transcription factors in a cell-specific manner. As a result, the composition and time course of the NF-κB-induced transcriptomic profile varies with the precise cell and stimulus examined. Recent data using RNA sequencing have identified a range of time courses for NF-κB-directed gene expression, and interestingly a similar number of genes are also repressed by NF-κB (Miranda et al. 2013; Oh et al. 2017; Pope and Medzhitov 2018; Vandewalle et al. 2018).

Suppression of gene expression has been linked to a reversal of this process under the action of histone deacetylases (HDACs). Deacetylation of acetylated histones removes the charge differences between DNA and histones which results in enhanced winding of DNA around histone residues. Thus, we end with a dense chromatin structure, which produces a barrier to transcription factor access to their binding sites and suppression of inflammatory gene expression (Adcock and Mumby 2017; Wadhwa et al. 2019).

Mechanisms of Glucocorticoid Functions

Dexamethasone-induced transcriptomic profiles vary considerably across cell types and only a few genes are regulated across many cells. This indicates that identifying a key set of glucocorticoid-induced anti-inflammatory genes and mechanisms will be probably cell-specific (Adcock and Mumby 2017).

Gene Induction

Glucocorticoids generally mediate their effects by binding to a cytoplasmic glucocorticoid receptor (GR) present in virtually all cells. The unliganded GR is retained within the cytoplasm in an inactive complex containing two heat shock protein (HSP) 90 proteins. Hsp90 binding to GR blocks the nuclear localization signal within the GR preventing its activation. Glucocorticoids are lipophilic molecules that freely diffuse across the plasma membrane to enable binding to the cytoplasmic GR. Ligand binding alters the structure of GR complex with dissociation of HSP90 allowing activated GR to translocate into the nucleus. Within the nucleus, activated GR seeks out and binds specific DNA sequences (GREs, GGTACAnnnTGTTCT) as a homodimer and interacts with coactivator complexes. Classical GREs consist of inverted repeats of hexameric half sites separated by a sequence of three base pairs. GR can also transactivate genes by binding to a GRE half site as a monomer by binding to other transcription factors through tethering or by binding to composite elements (Miranda et al. 2013; Oh et al. 2017).

Recent research has highlighted the diversity in the sequence of GREs and how this affects the overall strength of the transcriptional response acting in a manner synonymous with ligand binding to GR. Furthermore, cryptic GREs are found within NF-κB- and AP-1-binding sites, and GR has been found to occupy AP-1 response elements in the absence of AP-1 to influence its activity (Miranda et al. 2013; Oh et al. 2017). In addition, RNA sequencing identified that GR can also repress gene expression by binding to inverted repeat GR-binding sequences (IR-GBS) following recruitment of corepressors such as HDACs (Vandewalle et al. 2018).

Inflammatory Gene Suppression by Glucocorticoids

Glucocorticoids can either directly modulate the expression of genes by GR acting as a transcription factor in a similar way to that described above for NF-κB with the target genes identified by the upstream GREs in a process known as transactivation. Initial studies suggested that the activated GR *directly* upregulated between 10 and 100 genes depending upon the cell type studied including the expression of anti-inflammatory proteins, such as annexin-1, DUSP1, IL-10, and the inhibitor of NF-κB, IκB-α (Table 1) (Adcock and Mumby 2017; Ronchetti et al. 2018). Again, RNA sequencing analysis has greatly amplified the number of GR-regulated genes that are

Glucocorticoids, Table 1 Glucocorticoid-sensitive genes

Increased transcription	Decreased transcription
Lipocortin-1/annexin-1 (phospholipase A_2 inhibitor)	Cytokines (IL-1, 2, 3, 4, 5, 6, 9, 11, 12, 13, 16, 17, 18, TNFα, GM-CSF, SCF)
β-Adrenoceptor	Chemokines (IL-8, RANTES, MIP-1α, MCP-1, MCP-3, MCP-4, eotaxin)
Secretory leukocyte inhibitory protein (SLPI)	Inducible nitric oxide synthase (iNOS)
Clara cell protein (CC10, phospholipase A_2 inhibitor)	Inducible cyclooxygenase (COX-2)
IL-1 receptor antagonist	Cytoplasmic phospholipase A_2 (cPLA $_2$)
IL-1R2 (decoy receptor)	Endothelin-1
IκBα (inhibitor of NF-κB)	NK_1-receptors, NK_2-receptors
CD163 (scavenger receptor)	Adhesion molecules (ICAM-1, E-selectin)

upregulated to differing extents and over distinct time courses and identified genes that are repressed following direct GR-DNA interaction (Miranda et al. 2013; Oh et al. 2017; Van Moortel et al. 2020; Vandewalle et al. 2018).

Alternatively, activated GR may downregulate inflammatory gene expression driven by NF-κB following protein-protein interaction with activated NF-κB within the nucleus or while DNA associated known as transrepression. This may occur through a process known as tethering with NF-κB and GR interacting while on DNA. However, the concept of tethering as a mechanism for suppression of NF-κB function does not occur in all cases. Bulk RNA sequencing and chromatin-binding analysis in mouse bone marrow-derived macrophages stimulated with LPS prior to exposure to dexamethasone to mimic the clinical situation gave a similar anti-inflammatory transcriptomic profile as dexamethasone pretreatment. Chromatin occupancy of GR did not predict dexamethasone suppression of gene expression rather GR-induced suppressors of NF-κB and AP-1 chromatin interaction (Adcock and Mumby 2017; Miranda et al. 2013; Oh et al. 2017). However, although representing a simplification, it is likely that many of the anti-inflammatory effects of glucocorticoids in suppressing inflammation occur via transrepression while glucocorticoid side effects, such as osteoporosis, cataracts, skin fragility, and hypothalamic-preoptic-adrenal axis suppression, may reflect transactivation by GR (Wadhwa et al. 2019).

Transcription factors including GR and NF-κB regulate transcription through altered chromatin modifications, DNA unwinding, and local recruitment of basal transcriptional complexes including RNA polymerase II. GR interacts with coactivator proteins such as CBP, PCAF, and steroid receptor coactivator-1 (SRC-1), which all are able to promote HAT activity. How do we explain how GR or NF-κB interacts with its specific DNA-binding site when DNA is compacted? For GR, this may result from GR binding to a GRE whose residues face outward from the compacted DNA-chromatin structure. GRE interaction may modify the local chromatin structure, further enabling GR access to other GREs (Adcock and Mumby 2017; Miranda et al. 2013; Oh et al. 2017; Vandewalle et al. 2018).

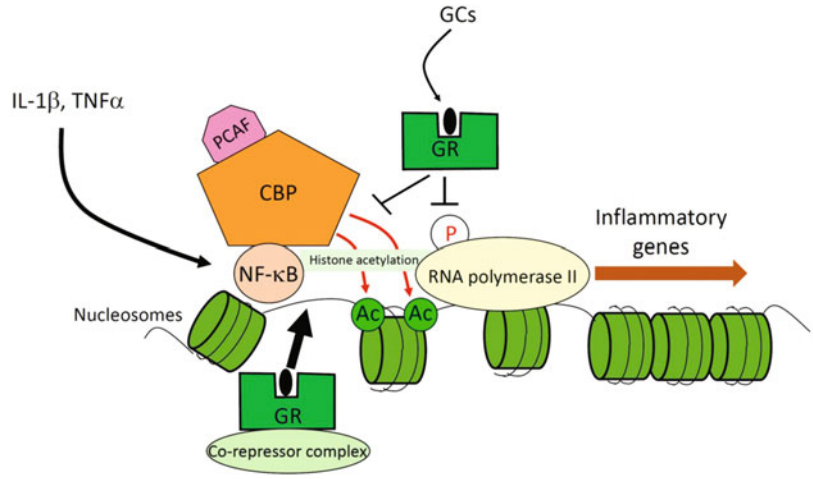
GR only remains bound to DNA for a short time (<10 s) and so it must utilize a "hit-and-run" mechanism of action. Activated GR tracks along DNA until it encounters an accessible GRE, it is quickly ejected, which allows replacement by another GR or by regulatory HAT-containing factors that enhance gene transcription. This has also been implicated in GR feedback mechanisms and subsequent GR proteasomal degradation (Adcock and Mumby 2017; Miranda et al. 2013; Oh et al. 2017; Vandewalle et al. 2018).

Although glucocorticoids are very efficient at inducing gene transcription, their main major anti-inflammatory effects are through repression of inflammatory and immune genes. This is due mainly via and interaction between the activated GR and pro-inflammatory transcription factors including NF-κB and AP-1 (a heterodimer of Fos and Jun proteins). The precise interplay

between these pro-inflammatory transcription factors and GR differs between immune and structural, which may reflect different NF-κB/transcription factor/coactivator complexes activated by differing stimuli between the cell types and the distinct inflammatory gene and chromatin profiles within the cells (Adcock and Mumby 2017; Vandewalle et al. 2018; Wadhwa et al. 2019). Thus, the synthetic glucocorticoid dexamethasone attenuates NF-κB-enhanced histone acetylation in lung epithelial cells and macrophages following stimulation with IL-1β. This is due to a combination of direct inhibition of NF-κB-associated HAT activity and by active recruitment of HDAC-containing corepressor complexes (Fig. 1). The overall effect is a localized loss of pro-inflammatory transcription factor function linked to histone deacetylation and chromatin remodeling resulting in suppression of inflammatory gene expression (Adcock and Mumby 2017; Vandewalle et al. 2018; Wadhwa et al. 2019).

Other Mechanisms of GR Regulation of Inflammation

Inflammatory gene expression is also regulated by mitogen-activated protein kinases (MAPKs) and their ability to activate pro-inflammatory transcription factors. MAPK pathways are also targets for glucocorticoid actions. The expression of cyclooxygenase-2 (COX-2), an important pro-inflammatory gene, is repressed by glucocorticoids acting to reduce COX-2 mRNA stability downstream of suppressing p38 MAP kinase activity. This effect is driven by the upregulation of p38 MAPK phosphatase (MKP-1) with a subsequent dephosphorylation of active phospho-p38 MAPK. Furthermore, activated GR prevents c-Jun phosphorylation and AP-1 activation by attenuating the Jun N-terminal kinase (JNK) signaling cascade. Glucocorticoids also prevent the activity of other JNK-stimulated transcription factors such as ETS-like kinase 1 (Elk-1) and activating transcription factor 2 (ATF-2). This effect



Glucocorticoids, Fig. 1 How glucocorticoids switch off inflammatory genes. Inflammatory genes are activated by inflammatory stimuli, such as interleukin (IL)-1β or tumor necrosis factor (TNF)α, resulting in activation of the transcription factor nuclear factor κB (NF-κB). NF-κB translocates to the nucleus and binds to specific κB recognition sites and also to *transcriptional coactivators*, such as CREB-binding protein (CBP) or p300/CBP-activating factor (PCAF), which have intrinsic *histone* acetyltransferase (HAT) activity. This results in acetylation of lysines in *histone* proteins, alteration in the charge between histones and DNA resulting in chromatin remodeling and recruitment of *RNA polymerase II* resulting in enhanced inflammatory gene expression. Binding of glucocorticoids (GCs) to glucocorticoid receptors (GR) results in their activation, nuclear translocation, and interaction with *corepressor* proteins to inhibit NF-κB-associated gene expression. Activated GR is also able to recruit corepressor proteins including *histone* deacetylases (HDAC) to the NF-κB complex further enabling suppression of inflammatory genes. GR may also affect the phosphorylation of *RNA polymerase II* to block inflammatory gene expression or directly induce repressors of NF-κB activation

is mutual since JNK attenuates GR function by direct phosphorylation (Adcock and Mumby 2017; Vandewalle et al. 2018; Wadhwa et al. 2019).

The construction of a GR dimerization-deficient mutant mice in which the ability of GR to form homodimers and bind DNA has provided insights into glucocorticoid actions. These mice were initially thought to show a complete separation of GR DNA binding (transactivation) from transrepression since dexamethasone suppressed AP-1- and NF-κB-mediated inflammation with a reduced ability to induce cortisol suppression and T-cell apoptosis (Adcock and Mumby 2017). These early data indicated that the development of glucocorticoids with a greater therapeutic window is possible if DNA binding was responsible for the detrimental side effects of glucocorticoids. However, the separation of transactivation from transrepression in these mice is not complete and that these mice also suffer glucocorticoid-induced side effects (Rogliani et al. 2020; Ronchetti et al. 2018; Van Moortel et al. 2020).

Nongenomic Actions of Glucocorticoids

The GR may also act rapidly within minutes through nongenomic actions that do not require transcription or protein synthesis. These actions include glucocorticoid effects on membrane lipids, changing their physicochemical properties and the presence of a membrane-bound GR, either related or unrelated to the classical GR (Panettieri et al. 2019). A recent report has indicated that one of these unrelated receptors may be the adhesion G-protein-coupled receptor G3 (ADGRG3; also known as GPR97) (Ping et al. 2021). Glucocorticoids have very rapid effects on intracellular calcium ([Ca2+]i) levels, but whether calcium levels are up- or downregulated depend upon the target cell type. For example, short-term (<20 min) treatment of airway smooth muscle (ASM) cells with dexamethasone reduced contraction and enhanced the bronchodilator effects of β_2-agonists. This effect may be a result of nonspecific interactions of dexamethasone with the cell membrane (Panettieri et al. 2019). Furthermore, the effect of dexamethasone on phosphorylation of the cell surface caveolin-1 protein also occurs rapidly (within 2 min), but in this case, it probably reflects the existence of a membrane-localized GR (Panettieri et al. 2019; Vandewalle et al. 2018).

An additional nongenomic action of GR results from GR translocation into mitochondria where it can rapidly regulate cellular metabolism and apoptosis via direct effects on mitochondrial membrane potential and the release of proapoptotic factors such as cytochrome C for example. These effects of mitochondrial GR probably vary according to cell type with the proapoptotic action of glucocorticoids being more important in the treatment of lymphoproliferative disorders (Kokkinopoulou and Moutsatsou 2021).

Clinical Use (Including Side Effects)

A wide variety of immune and inflammatory diseases have been treated with glucocorticoids for the past 70 years since their beneficial effects were first discovered in the treatment of rheumatoid arthritis. In asthma, glucocorticoids have been the mainstay of therapy since the recognition of the critical role of airway inflammation in driving the disease even in patients with mild asthma. Indeed, inhaled glucocorticoids are the first-line anti-inflammatory treatment in adults and children with persistent asthma, the most common chronic inflammatory disease of the airway (Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

Inhaled glucocorticoids have profound suppressive effects on most airway cells particularly on infiltrating mast cells, macrophages, and T-lymphocytes. Glucocorticoids drive differentiation of monocytes/macrophages toward an anti-inflammatory phenotype and regulate granulocyte trafficking. They reduce the expression of selectins on neutrophils, and of integrin receptors on endothelial cells, to prevent extravasation. This effect is amplified by the ability of glucocorticoids to upregulate annexin-1 (Anxa1), thereby reducing migration but counteracted by the fact that glucocorticoids protect them from apoptosis, which helps the fight against infections. In contrast, eosinophils and basophils undergo apoptosis in response to glucocorticoids (Rogliani et al.

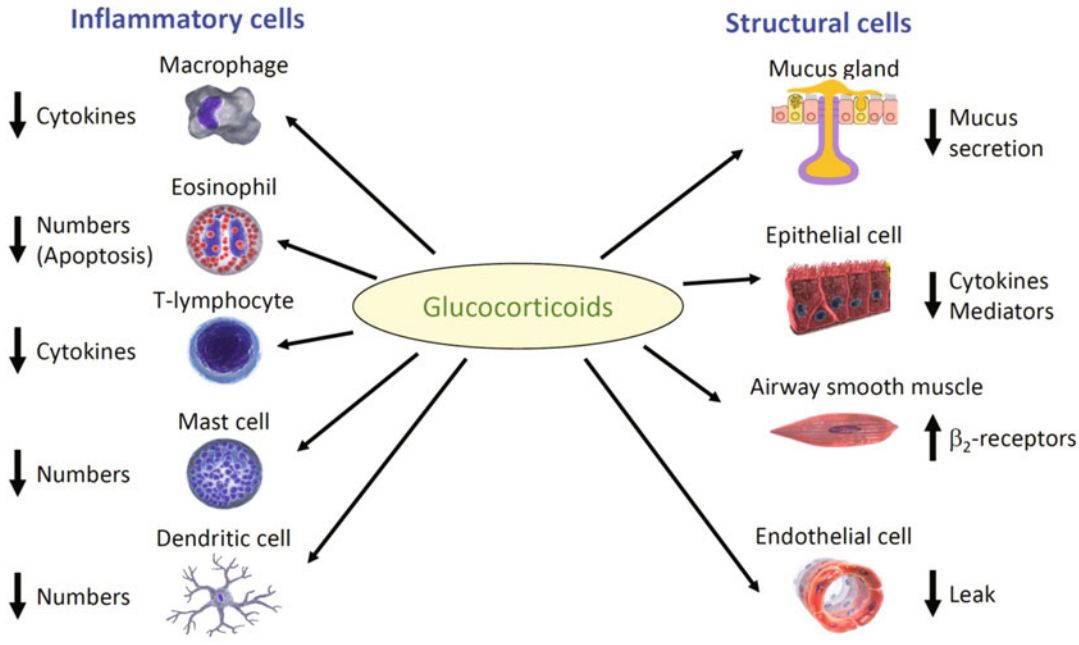
2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

Furthermore, glucocorticoids have important effects on airway remodeling by reversing the shedding of epithelial cells and the goblet-cell hyperplasia and reducing airway smooth hypertrophy, which are characteristic features of asthma (Fig. 2). Inhaled glucocorticoids also reduce airway hyperresponsiveness in asthmatic adults and children probably indirectly by reducing airway inflammation (Adcock and Mumby 2017; Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

Combination Therapy in Asthma

Asthma guidelines indicate that rather than increasing the dose of inhaled glucocorticoid when a subject loses control of their asthma, the addition of a long-acting β_2-agonist should be considered. Indeed, the new Global Initiative for Asthma (GINA) guidelines (https://ginasthma.org/) suggest that a combination of inhaled glucocorticoid with a fast-acting, long-duration β2-agonist should be preferentially used as needed for mild and moderate asthmatics. The rationale being that (i) long-acting β_2-agonists can enhance GR activation and inflammatory gene suppression without affecting the side-effect profile and that (ii) inhaled glucocorticoids can prevent downregulation of β_2-agonist efficacy. Thus, a fast-acting, long-duration β_2-agonists in combination with an inhaled glucocorticoid will provide immediate relief when a patient feels that they require additional help while delivering a sufficient anti-inflammatory dose to control further deterioration in disease (Adcock and Mumby 2017; Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

Glucocorticoids, particularly when delivered in combination with a fast-acting, long-duration β_2-agonist, are extremely effective in controlling asthma. They are similarly effective in many other chronic immune or inflammatory diseases. However, a small proportion of patients with a



Glucocorticoids, Fig. 2 Cellular effect of glucocorticoids. Glucocorticoids can affect the activation of most resident and infiltrating cells with the airway suppressing either cell number or mediator release or both. In addition, glucocorticoids are able to decrease vascular permeability (leak) within the airways that causes edema and increases the expression of β_2-receptors in smooth muscle cells

chronic immune or inflammatory disease including asthma do not respond well to high doses of topical or even systemic or oral glucocorticoids. A relative insensitivity or resistance to the beneficial effects of glucocorticoid therapy is across most chronic inflammatory and immune diseases such as inflammatory bowel disease, atopic dermatitis, and rheumatoid arthritis. These patients with a relative glucocorticoid insensitivity constitute ~5% of severe asthmatics, with greater numbers in other diseases, and present considerable management problems. Absolute glucocorticoid resistance is extremely rare and often reflects genetic mutations in GR and is associated with an abnormal hypothalamic-pituitary-adrenal (HPA) axis (Adcock and Mumby 2017; Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

However, relative insensitivity is part of a spectrum with asthmatic patients with relative resistance seen in patients who require high doses of inhaled and oral glucocorticoids (glucocorticoid-dependent asthma). A number of mechanisms have been proposed to account for this relative glucocorticoid insensitivity including defective GR nuclear translation and/or association with transcriptional cofactors or repressors, elevated inflammation driven by p38 MAPK, STAT, IL-17, and AP-1 pathways, oxidative stress, and infections. Recently, the expression of a long non-coding RNA (lncRNA) GAS5, which binds to the DNA-binding domain of GR, was found to be upregulated was found to be upregulated in patients with severe asthma as well as children with glucocorticoid-resistant inflammatory bowel disease (Adcock and Mumby 2017; Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

The detrimental side effects seen with high-dose glucocorticoid therapy prevent the use of ever- increasing doses of glucocorticoids in these subjects. However, the advent of antibodies directed against Th2 targets such as IL-5 and IL-4Rα is providing an alternative therapeutic approach for some of these patients with T2-high asthma, but no similar treatments are available in severe asthmatics whose disease is not driven by T2 mechanisms.

Glucocorticoid-Induced Adverse Effects

Topical or inhaled glucocorticoids in the case of asthma have few side effects and these depend upon the dose, the frequency of administration, and the delivery system used. The most common side-effects, which affects one-third of asthmatics on inhaled glucocorticoids, is dysphonia or hoarseness. Oropharyngeal candidiasis or thrush is seen in some elderly patients when the drug is taken more often than twice daily. There were initial concerns that children taking inhaled glucocorticoids were at risk of growth suppression or stunting, but this has not proved to be an issue even in children treated with higher doses of inhaled glucocorticoids for a long period since they "catch up" by the age of 18. Skin thinning, telangiectasia, and bruising are classic side effects of glucocorticoids, and elderly asthmatic patients on inhaled glucocorticoids are more susceptible to skin bruising. In addition, long-term therapy of COPD patients with inhaled glucocorticoids may increase the susceptibility to opportunistic infections (Adcock and Mumby 2017; Rogliani et al. 2020; Ronchetti et al. 2018; Vandewalle et al. 2018; Wadhwa et al. 2019).

The use of oral glucocorticoids in the treatment of severe asthmatics, however, presents a far greater risk of adverse side effects. Of major importance is the hypothalamic-pituitary-adrenal axis, which is suppressed by glucocorticoids resulting in reduced release of cortisol by the adrenal glands. The impact on the adrenocorticotrophic hormone (ACTH) system gives rise to profound withdrawal symptoms after discontinuation and is a major clinical problem with patients on high-dose oral or systemic glucocorticoids. The degree of suppression depends upon the dose, duration, frequency, and timing of glucocorticoid administration. Prolonged treatment with 5 mg prednisone equivalent per day is generally linked with a low risk of adverse effects, while >10 mg/day is associated with a high frequency of adverse glucocorticoid side effects (Adcock and Mumby 2017; Bourdin et al. 2020).

Oral glucocorticoid therapy also causes osteoporosis with an increased risk of vertebral and rib fractures, particularly in the elderly, and results from effects of glucocorticoids on

phospho-calcium metabolism and a subsequent reduction in bone mineral density and mass. However, there is no evidence that long-term treatment with inhaled glucocorticoids increases the risk of bone fractures. Mechanistically, glucocorticoids act to impair osteoblast proliferation and reduce their ability to produce bone matrix proteins, while high doses cause osteocyte apoptosis. In GRdim/dim mice, skeletal side effects of glucocorticoids remain suggesting that these events are mediated through glucocorticoid receptor transrepression. Long-term glucocorticoid use is also associated with reduced muscle mass and strength that contributes to the increased numbers of falls seen in these patients (Adcock and Mumby 2017; Bourdin et al. 2020).

Furthermore, high-dose oral steroids affect the growth hormone system leading to growth impairment as well as having a major impact on behavioral changes in children. Glucocorticoid-induced diabetes and glucose fluctuations occur in patients due to effects on carbohydrate metabolism leading to insulin resistance. In addition, long-term treatment with oral glucocorticoids increases the risk of posterior subcapsular cataracts; this may be a problem in some patients taking inhaled glucocorticoids (Adcock and Mumby 2017; Bourdin et al. 2020).

Approaches for Reducing Glucocorticoid-Induced Side Effects

Due to the presence of adverse side effects observed particularly with oral glucocorticoids and occasionally in patients on high doses of inhaled glucocorticoids with a high degree of systemic absorption, researchers have strived to obtain safer glucocorticoids for inhalation and oral administration. As described above, a major mechanism of the anti-inflammatory effect of glucocorticoids is *trans*repression, while many endocrine and metabolic effects of glucocorticoids are mediated by *trans*activation. This has resulted in a search for novel glucocorticoids that selectively *trans*repress without significant *trans*activation, thereby reducing the risk of systemic side effects (Wadhwa et al. 2019).

Several compounds with either a steroidal or nonsteroidal structure have been developed that bind to GR which possess dissociated properties although none have reached the clinic (Van Moortel et al. 2020). In a Phase II study, 12 weeks treatment of rheumatoid arthritis patients with fosdagrocorat attenuated disease activity to a similar extent as prednisolone (10 mg daily) but with reduced impairment of glycemic control, a side effect known to be driven by transactivation (Buttgereit et al. 2019). In addition, a recent chemical systems biology approach has been used to generate GR ligands with distinct muscle-sparing effects and reduced mitochondrial potential while retaining an anti-inflammatory function both in vitro and in vivo, although these need to be tested in humans (Bruno et al. 2021). Of interest, deflazacort, a glucocorticoid developed in 1986, appears to possess dissociated qualities in patients with a number of chronic inflammatory diseases since it has a similar anti-inflammatory profile as prednisolone and hydrocortisone but with a much reduced impact on the ACTH/HPA axis, osteoporosis, glycaemia, and growth impairment in children. No studies have been performed to address the molecular mechanisms of deflazacort actions in key cells to determine the reasons for these effects (Joseph et al. 2019). Further studies are needed with these and similar steroids in patients with severe asthma who currently require high-dose oral glucocorticoid therapy.

Other approaches that have been used to reduce glucocorticoid side effects are linked rro the glucocorticoid ligand to an antibody or drug to provide targeted delivery to a specific cell type using, for example, anti-CD163 to target activated macrophages or glucagon-like peptide-1 (GLP1). The latter being developed for metabolic disease (Uchinuma et al. 2020). Encapsulation of glucocorticoids within liposomes has also been proposed for targeted delivery to inflamed tissues in rheumatoid arthritis, Crohn's disease, and atherosclerosis (Vandewalle et al. 2018).

Despite the huge amount of work undertaken in examining the molecular mechanisms of glucocorticoids, there are still major gaps that need to be addressed with respect to mechanisms in cells and tissues from patients with disease. Currently, the data suggest that there is the potential to

develop novel nonsteroidal anti-inflammatory treatments, which mimic the anti-inflammatory actions of glucocorticoids independent of GR (Panettieri et al. 2019; Vandewalle et al. 2018). It has proved difficult to develop effective inhibitors of NF-κB or to specific HATs that are linked to NF-κB activation, but selective bromodomain mimics such as RVX000222 have been produced that show benefit in phase II clinical studies in chronic kidney disease, cardiovascular disease, and chronic metabolic diseases (Wadhwa et al. 2019). Glucocorticoids target NF-κB, and this is an obvious target as a novel anti-inflammatory approach. Initial studies using small molecule inhibitors of IkB kinase-2 (IKK2), which is an upstream kinase that activates NF-κB, were developed but failed to take into consideration the complex feedback control processes that regulate IKK2. Other approaches that target NF-κB such as proteasome inhibitors have some success in clinical trials (Adcock and Mumby 2017; Taniguchi and Karin 2018). Other treatments that may have therapeutic potential as glucocorticoid-sparing agents include kinase inhibitors such as those directed against p38 MAP kinase and Janus kinases (Wadhwa et al. 2019). The clinical benefit of monoclonal antibody therapy in selected patients with severe asthma highlights the potential for novel therapeutic agents when the disease driver mechanisms have been elucidated and a good biomarker developed (Chung and Adcock 2019).

School of Life and Health Sciences, Aston University, Birmingham, UK

Synonyms

Antihyperglycaemics; Blood glucose-lowering drugs; Hypoglycaemic agents; Insulin secretagogues

Definition

This section is focused on glucose-lowering drugs other than insulin that are used in the treatment of hyperglycemia in type 2 (non-insulin-dependent) diabetes mellitus and occasionally as adjuncts to insulin in the treatment of type 1 (insulin-dependent) diabetes mellitus. They are used in conjunction with non-pharmacological interventions involving diet, exercise, and health education. Insulin therapy is essential for all type 1 patients and is often used to treat more advanced stages of type 2 diabetes. Type 2 diabetes accounts for more than 85% of all cases of diabetes. The classes of glucose-lowering drugs other than insulin are the biguanide metformin, sulphonylureas, prandial insulin releasers (also termed meglitinides), dipeptidyl peptidase-4 (DPP-4) inhibitors (also termed gliptins), glucagon-like peptide-1 receptor agonists (GLP-1RAs), sodium-glucose co-transporter-2 (SGLT-2) inhibitors, thiazolidinediones (TZDs), and α-glucosidase inhibitors. Pramlintide, bromocriptine, and colesevelam are also approved in some countries for glucose-lowering in type 2 diabetes (Table 1) (Bailey 2015; Tahrani et al. 2016).

Mechanism of Action

Type 2 diabetes is a heterogeneous and progressive endocrine disorder involving hyperglycemia and widespread metabolic disturbances. Key pathogenic factors are insulin resistance (impaired insulin action) and defective function of the insulin-secreting β-cells in the pancreatic islets of Langerhans. Obesity aggravates the pathogenic process alongside many other contributing factors including excess glucagon secretion, an impaired incretin effect, and abnormalities of the gluco-regulatory functions of adipose tissue, liver, kidney, and the central nervous system (DeFronzo et al. 2015). Hence a variety of differently acting glucose-lowering agents has emerged with capability to address different pathogenic factors. The present classes of glucose-lowering medicines other than insulin offer a variety of actions that can improve the effects of insulin, increase insulin secretion, suppress glucagon secretion, mimic incretin hormones, increase urinary glucose elimination, slow the rate of intestinal carbohydrate digestion, or slow gastric emptying.

Biguanide

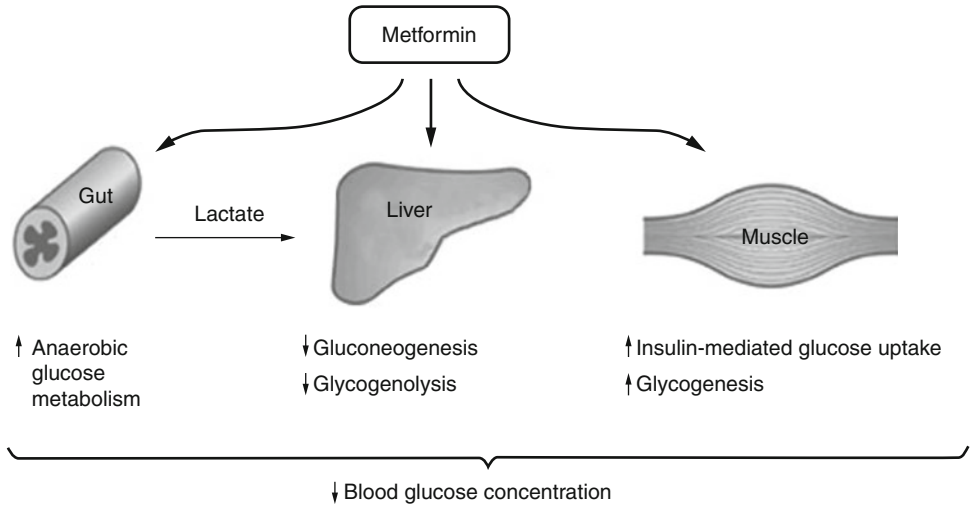
Metformin is now the only compound in this class in most countries: other biguanides, namely, phenformin and buformin have been discontinued.

Glucose-Lowering Drugs Other than Insulin, Table 1 Classes of glucose-lowering drugs other than insulin and their main mechanisms of action

Class	Examples[a]	Main mechanism of action	Route
Biguanide	Metformin	Counter insulin resistance	Oral
Sulphonylureas	Chlorpropamide, glibenclamide[b] gliclazide, glimepiride glipizide tolbutamide	Stimulate insulin secretion (typically 6–24 h)	Oral
Prandial insulin releasers (meglitinides)	Repaglinide, nateglinide	Stimulate insulin secretion (rapid and short acting <6 h)	Oral
DPP-4 inhibitors (gliptins)	Sitagliptin Vildagliptin Saxagliptin Linagliptin Alogliptin	Inhibit DPP-4[c]: enhance prandial insulin secretion	Oral
Glucagon-like peptide-1 receptor agonists (GLP-1RAs)	Exenatide Liraglutide Lixisenatide, Dulaglutide Semaglutide	Mimic GLP-1[d]: enhance prandial insulin secretion	SC injection[e]
Sodium-glucose cotransporter-2 inhibitors (SGLT-2 inhibitors)	Canagliflozin Dapagliflozin Empagliflozin Ertugliflozin Sotagliflozin[f]	Increase glucose elimination in the urine	Oral
Thiazolidinediones (TZDs)	Pioglitazone, Rosiglitazone[g]	Improve insulin action via PPARγ agonism[h]	Oral
α-Glucosidase inhibitors	Acarbose Miglitol, Voglibose	Slow rate of carbohydrate digestion	Oral
Amylin analogue	Pramlintide	Suppress glucagon secretion and slow gastric emptying	SC injection[e]
Dopamine agonist	Bromocriptine	Improve circadian glycemic control	Oral
Bile sequestrant	Colesevelam	Alter release of incretin hormones	Oral

[a]Availability of agents and prescribing information vary between countries
[b]Glibenclamide is called glyburide in some countries
[c]Dipeptidyl peptidase-4
[d]Glucagon-like peptide-1
[e]Subcutaneous injection
[f]Sotagliflozin is a dual inhibitor of SGLT-2 and SGLT-1
[g]Rosiglitazone has been withdrawn in many countries
[h]PPARγ, peroxisome proliferator-activated receptor-γ

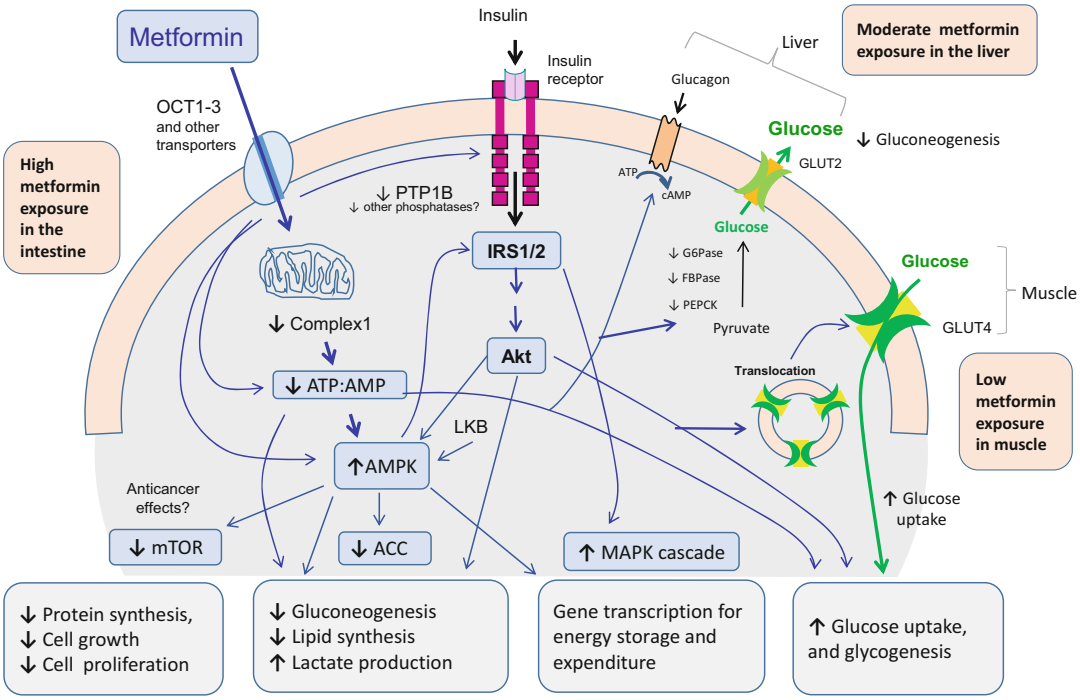
Metformin was introduced in the late 1950s and is now the preferred initial pharmacological glucose-lowering therapy in most guidelines for the treatment of hyperglycemia in type 2 diabetes. This reflects its antihyperglycemic efficacy without weight gain, negligible risk of hypoglycemia, reduced long-term cardiovascular risk, low cost, and a mode of action that counters insulin resistance. The metabolic effects of metformin are produced by effects on the intestine, liver, and muscle (Fig. 1). At a cellular level, metformin exerts several different effects depending on the drug concentration within the tissue and the metabolic pathways operative within that tissue. Some of these effects are independent of insulin, and some are dependent on insulin, but the blood glucose-lowering efficacy of metformin requires a presence of insulin. The drug does not stimulate insulin release and is often associated with a small decrease in basal insulin concentrations in hyperinsulinemic patients (Metformin Special Issue 2017).



Glucose-Lowering Drugs Other than Insulin, Fig. 1 The glucose-lowering effect of metformin involves increased anaerobic glucose metabolism by the intestine, suppression of glucose production by the liver and increased glucose uptake by muscle. ↑, increase; ↓ decrease

Metformin enters cells via organic cation transporters (OCT1-3), the plasma membrane monoamine transporter (PMAT), and other transporters (Fig. 2). Very high concentrations of metformin that accumulate in enterocytes increase anaerobic glucose metabolism by suppression of the respiratory chain at complex I, reducing ATP availability and giving rise to increased lactate production. This lactate is recycled to glucose by the liver, thus increasing glucose turnover. Metformin can also interfere with mitochondrial function by reducing the mitochondrial glycerophosphate dehydrogenase (mGPD) shuttle. Depletion of ATP raises ADP and AMP and activates AMP-activated protein kinase (AMPK): metformin can also enhance LKB-mediated activation of AMPK. Increased activity of AMPK decreases the activity of acetyl-CoA carboxylase, reducing lipogenesis and allowing increased fatty acid oxidation. Activation of AMPK also inhibits the mammalian target of rapamycin mTOR, and high concentrations of metformin may additionally exert a direct inhibitory effect on mTOR. Suppression of mIOR reduces cell growth and division and could contribute to reduced neoplasm in the intestine. It is likely that high concentrations of metformin in the intestinal lumen alter the microbiome, but such effects are unclear at this time. There is also evidence that metformin can increase secretion of glucagon-like peptide-1 and peptide YY from enteroendocrine L-cells.

Metformin reduces hepatic gluconeogenesis and glycogenolysis. The concentration (and accordingly the activity) of metformin achieved in the liver is less than in enterocytes. Gluconeogenesis is reduced through effects on three key enzymes: raised AMP in hepatocytes reduces the activity of fructose-1,6-bisphosphatase, while increased activity of AMPK reduces expression of phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase. Metformin also appears to reduce the effectiveness of glucagon in the liver, possibly related to a decrease in the ATP:AMP ratio, reducing glucagon-stimulated adenylate cyclase activity. In consequence, reduced cAMP could further reduce expression of gluconeogenic enzymes. It is noted that the collective effect of these mechanisms produces only a modest reduction of gluconeogenesis (typically 10–30%) which is not sufficient to allow interprandial blood glucose concentrations to fall into hypoglycemia. Metformin has been shown to acutely reduce hepatic glucose output, and there is some evidence that this involves a decrease in the rate of glucagon-induced glycogenolysis. Metformin has also been reported to promote some



Glucose-Lowering Drugs Other than Insulin, Fig. 2 The cellular mechanisms of action of metformin vary with drug exposure and metabolic pathways in individual tissues. Metformin reduces ATP production by suppression of the mitochondrial respiratory chain at complex 1, increases activity of AMPK, reduces activity of mTOR, and alters the expression and activity of key enzymes affecting hepatic glucose production and glucose uptake by muscle. ↑, increase; ↓ decrease. ACC, acetyl-CoA carboxylase; Akt, protein kinase B; AMPK, adenosine monophosphate-activated protein kinase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FBPase, fructose-1,6-bisphosphatase; G6Pase, glucose-6-phosphatase; GLUT, glucose transporter isoform; GPD, glycerophosphate dehydrogenase; IRS, insulin receptor substrate; IR-TKA, insulin receptor tyrosine kinase activity; LKB, serine/threonine kinase 11; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; OCT, organic cation transporter; PEPCK, phosphoenolpyruvate carboxykinase; PTP-1B, protein tyrosine phosphatase-1B

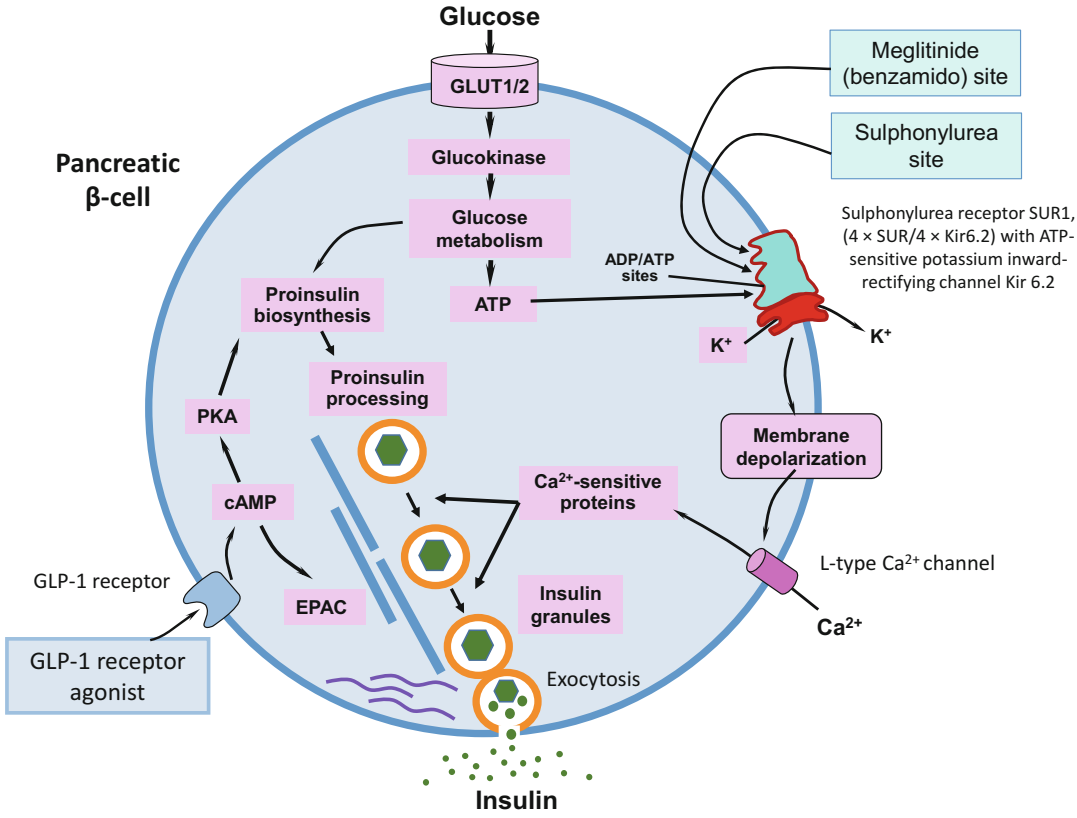
actions of insulin in the liver, partly by reducing the activity of protein-tyrosine phosphatases that dephosphorylate (and so deactivate) the tyrosine kinase activity of the insulin receptor. Increased activity of several post-receptor steps of insulin action has been associated with metformin exposure to the liver, including increased activation of insulin receptor substrates and downstream signaling intermediates, but mechanisms have not been determined.

In muscle, metformin increases glucose uptake by enhancing translocation of insulin-sensitive glucose transporters (GLUT4) into the plasma membrane partly via pathways involving AMPK, c-Jun N-terminal kinase, and Akt. Concentrations of metformin in the muscle, which are lower than in liver, do not preclude an increase in glucose oxidation and promote glycogenesis.

Further effects of metformin have been reported, although their cellular and molecular mechanisms have not been fully delineated. These include reduced platelet aggregation, altered fibrin that assists clot dispersal, increased endothelium-mediated vasodilatation, reduced atherogenesis, improved cardiac contractility, reduced neoplasms (see comments on mTOR), reduced androgen production in polycystic ovarian syndrome, and general antiaging effects.

Sulphonylureas

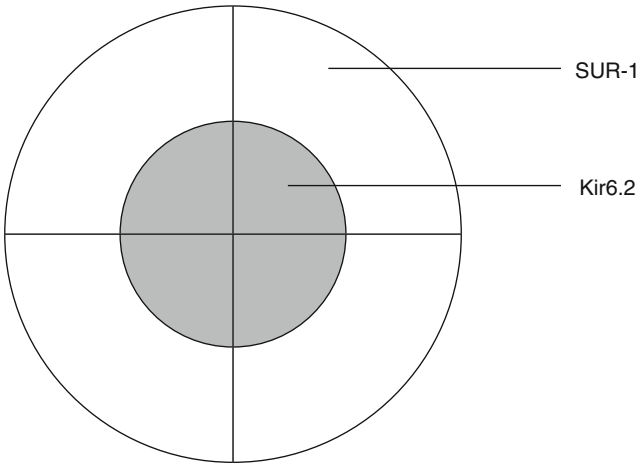
The first sulphonylureas were introduced in the 1950s (Lebovitz and Melander 2015). They



Glucose-Lowering Drugs Other than Insulin, Fig. 3 Sulphonylureas stimulate insulin release by pancreatic β-cells. They bind to the sulphonylurea receptor-1 (SUR-1), which closes the Kir6.2 (ATP-sensitive) potassium channel. This promotes local depolarization, voltage-dependent calcium influx, and activation of calcium-sensitive proteins that control exocytotic release of insulin. EPAC, exchange protein activated by cAMP; GLP-1, glucagon-like peptide-1; GLUT, glucose transporter isoform; PKA, cAMP-dependent protein kinase A

stimulate insulin secretion by a direct effect on pancreatic β-cells. The insulin then increases glucose uptake and metabolism by muscle and reduces glucose output by the liver (insulin, ► insulin receptor). Sulphonylureas enter the β-cell and bind to a site at the cytosolic face of the sulphonylurea receptor-1 (SUR-1). SUR-1 forms part of a transmembranal complex that makes up the ATP-sensitive Kir6.2 potassium efflux channel (K-ATP channel). The binding of a sulphonylurea to SUR-1 produces a conformational change that closes the K-ATP channel, favoring local depolarization of the plasma membrane. This opens local voltage-dependent L-type calcium channels, which increase calcium influx and raise the cytosolic free calcium concentration. In turn, this activates calcium-dependent signaling proteins controlling the contractile activities of microtubules and microfilaments that mediate exocytosis of insulin granules. Preformed insulin granules adjacent to the plasma membrane are released first (first-phase insulin release). Newly formed granules contribute to the secretory pool within 1 h of continued stimulation. Increased insulin release is sustained as long as drug stimulation is maintained, provided the β-cells are functionally competent (Fig. 3).

The SUR–Kir6.2 complex is a non-covalently bonded octamer (4 × SUR/4 × Kir6.2), with a central pore-forming Kir6.2 channel (Fig. 4). SUR molecules are members of the ATP-binding cassette proteins (ABC proteins). Each SUR-1 molecule comprises 17 transmembrane domains, 2 cytosolic nucleotide-binding domains, and



Glucose-Lowering Drugs Other than Insulin, Fig. 4 Octameric structure (4 × SUR/4 × Kir6.2) of the SUR–Kir6.2 complex

cytosolic-binding domains for a sulphonylurea, a benzamido compound, and other ligands. The Kir6.2 channel also has cytosolic binding regions, including one for ADP/ATP. Sulphonylureas bind to the sulphonylurea site with high affinity (e.g., *Ki* for glibenclamide in the low nanomolar range), being dependent on a "U" shape to the ligand with 5.5 Å between the hydrophobic rings.

By closing K-ATP channels, sulphonylureas induce insulin release by activating a step along the normal pathway of glucose-induced insulin secretion. Activation of insulin secretion is therefore independent of glucose, provided there is sufficient glucose metabolism to stimulate proinsulin biosynthesis and service the energy requirements for the cellular processing and exocytosis of insulin. Hence sulphonylureas can stimulate insulin secretion at low glucose concentrations, creating the risk of hypoglycemia. Sulphonylureas will also increase the amount of insulin secreted at any level of stimulation by glucose, subject to adequate β-cell function. Additionally, sulphonylureas may potentiate insulin release that is stimulated by glucose and other nutrients. This may involve SUR molecules located within the membranes of insulin granules and activation of certain isoforms of protein kinase C.

Although the main therapeutic effect of sulphonylureas is increased insulin secretion, there are reports that these drugs exert weak extra-pancreatic effects. The latter effects include suppression of hepatic gluconeogenesis, possibly by suppression of a kinase which leads to increased formation of fructose-2, 6-bisphosphate. This stimulates phosphofructokinase and suppresses fructose-1, 6-bisphosphatase, thereby increasing glycolytic flux and suppressing gluconeogenic flux. Sulphonylureas might also enhance insulin-stimulated glucose transport by increasing translocation of GLUT4 glucose transporters to the plasma membrane in adipocytes and muscle. However, these effects appear to require supra-therapeutic concentrations of sulphonylureas and are probably not therapeutically relevant. Sulphonylureas have been reported to reduce the hepatic extraction of insulin and to act on pancreatic α-cells to transiently stimulate and then suppress glucagon secretion.

Prandial Insulin Releasers (Meglitinides)

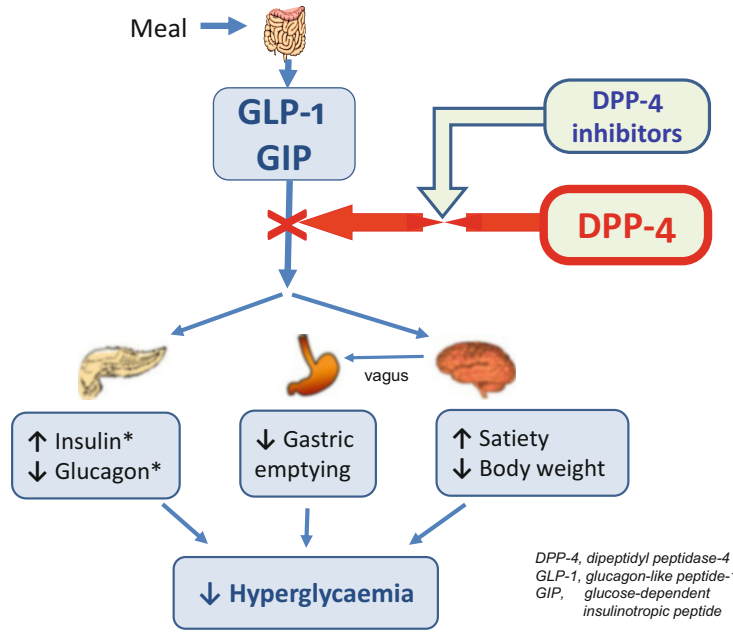
This class comprises the meglitinide analogue repaglinide (introduced in 1998) and the structurally related D-phenylalanine analogue nateglinide (introduced in 2001) (Lebovitz and Melander 2015). These agents have a benzamido group that binds to a site on SUR-1 that is distinct from the sulphonylurea site but is probably in close proximity and capable of binding interference. Some sulphonylureas also have a benzamido moiety (e.g., glibenclamide, glimepiride, glipizide), but the binding affinity for the sulphonylurea site has a higher affinity. Binding of repaglinide or nateglinide to the benzamido site closes the K-ATP channel and induces insulin secretion via the same pathway described for sulphonylureas (Fig. 3).

Repaglinide and nateglinide are rapidly absorbed; their binding durations to SUR-1 are much shorter than sulphonylurea binding, and their hepatic metabolism and subsequent elimination are faster. Consequently, repaglinide and nateglinide are faster-acting and shorter-acting insulin releasers than sulphonylureas. They can be taken immediately before a meal and quickly stimulate insulin secretion to coincide approximately with the period of meal digestion, hence their categorization as "prandial insulin releasers."

Dipeptidyl Peptidase-4 Inhibitors

Dipeptidyl peptidase-4 (DPP-4) inhibitors (also termed gliptins) selectively inhibit the cell surface and extracellular enzyme DPP-4 (EC 3.4.14.5) which inactivates the incretin hormones glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP, also termed gastric inhibitory peptide). GLP-1 (from enteroendocrine L-cells) and GIP (from enteroendocine K-cells) are normally released in response to a meal and act on the pancreatic islets directly and via neural pathways to potentiate nutrient-induced insulin secretion. GLP-1 also reduces glucagon secretion in a glucose-dependent manner. Accordingly, DPP-4 inhibitors enhance the incretin effect by slowing the degradation of endogenous GLP-1 and GIP, thereby enhancing the potentiation of nutrient-induced insulin secretion and further suppressing glucagon secretion. These effects lower blood glucose concentrations, especially after a meal (Fig. 5). The first DPP-4 inhibitor, sitagliptin, became available in 2007 (Deacon 2019).

DPP-4 cleaves the dipeptides X-alanine or X-proline from the N-terminus. In addition to GLP-1 and GIP, there are many other circulating substrates for DPP-4 including neuropeptide Y (NPY), peptide YY (PYY), gastrin-releasing polypeptide (GRP), substance P, insulin-like growth factor-1 (IGF-1), vasostatin-1, and several chemokines. Thus, DPP-4 inhibitors have the potential to influence the hunger-satiety system, gastrointestinal motility, growth, vascular reactivity, and immune mechanisms, although reports of any clinically significant adverse effects have been rare. DPP-4 is also the T-cell activation molecule CD26, but its role in immune regulation appears to be unaffected by the DPP-4 inhibitors used in the treatment of type 2 diabetes. DPP-4 is closely related to DPP-8, DPP-9, fibroblast activation protein-α, and quiescent cell proline dipeptidase, but DPP-4 inhibitors are sufficiently



Glucose-Lowering Drugs Other than Insulin, Fig. 5 Dipeptidyl peptidase-4 (DPP-4) inhibitors prevent the enzymatic degradation of incretin hormones GLP-1 and GIP by DPP-4. * Glucose-dependent effects. GLP-1, glucagon-like peptide-1; GIP, glucose-dependent insulinotropic peptide

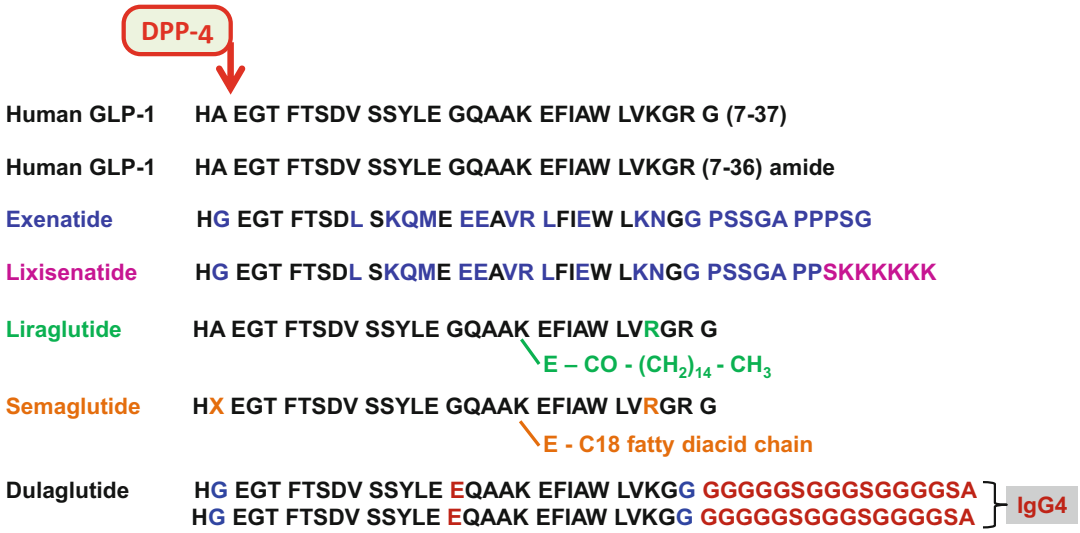
selective for DPP-4 that this has not been problematic for clinical use.

In clinical studies, DPP-4 inhibition has almost completely inhibited the peptidase function of DPP-4 for 12–20 h and has increased active circulating concentrations of endogenous GLP-1 and GIP by twofold to threefold. This was associated with increased glucose-induced insulin secretion and suppression of glucagon secretion, but since incretin hormones are not effective at low glucose concentrations, there is little risk of hypoglycemia. DPP-4 inhibitors do not cause weight gain and may assist modest weight loss, although they are not associated with measurable changes in satiety or gastric emptying as seen with high concentrations of exogenous GLP-1.

Glucagon-like Peptide-1 Receptor Agonists

Glucagon-like peptide-1 receptor agonists (GLP-1RAs), sometimes referred to as incretin mimetics, are analogues of the incretin hormone glucagon-like peptide-1 (GLP-1). Because GLP-1 is rapidly degraded by DPP-4, native GLP-1 is not suitable for routine clinical purposes, so GLP-1RAs have modified amino acid sequences and formulation features that protect against degradation by DPP-4 (Fig. 6). The first GLP-1RA, exenatide, was introduced in 2005. It is a synthetic form of exendin-4, a peptide discovered in the saliva of a lizard from Arizona – the Gila monster (*Heloderma suspectum*) (Drucker 2018).

As peptides, GLP-1RAs are administered by subcutaneous injection, although an oral formulation of one GLP-1RA (semaglutide) is advanced in development. Therapeutic doses of GLP-1RAs typically achieve more than ten times the concentration of active endogenous GLP-1, substantially boosting the normal incretin effect with enhanced potentiation of nutrient-induced insulin secretion and suppression of glucagon secretion. Additionally, GLP-1RAs delay gastric emptying and exert a satiety effect. Collectively these actions reduce prandial blood glucose excursions and improve basal glycemic control with negligible risk of hypoglycemia, and they also assist a reduction in body weight. Although GIP makes an important contribution alongside GLP-1 to generate the normal incretin effect, the insulin-releasing effect of GIP becomes considerably reduced in type 2 diabetes, which has favored use of GLP-1 (rather than GIP) as a therapeutic template. There is also mounting evidence that GLP-1RAs produce beneficial effects on the vasculature to reduce atherosclerotic cardiovascular disease, and preliminary evidence suggests these agents may reduce albuminuria in diabetes patients. Further effects of



Glucose-Lowering Drugs Other than Insulin, Fig. 6 Amino acid sequences of GLP-1 receptor agonists. DPP-4, dipeptidyl peptidase-4; IgG4, immunoglobulin-4; X, aminoisobutyric acid

GLP-1RAs to improve cognitive function and bone mineral density have also been reported.

Most evidence relating to the cellular mechanism of action of GLP-1 and GLP-1RAs derives from their effect on pancreatic β-cells, where they bind to a G protein-coupled receptor. Binding to the receptor brings about a conformational change that activates the $G\alpha_s$ subunit which in turn activates adenylate cyclase to produce cAMP from ATP. The increased cytosolic concentration of cAMP activates cAMP-dependent protein kinase A (PKA) and the exchange protein activated by cAMP (EPAC). PKA improves insulin biosynthesis by increasing the rate of transcription of the insulin gene and decreasing the rate of breakdown of insulin mRNA and may also promote distal steps in the pathway of insulin granule exocytosis. Transcriptional effects that are independent of PKA have also been reported. EPAC activates ryanodine receptors to liberate calcium from intracellular stores, raise cytosolic calcium, and activate early steps in the exocytotic pathway.

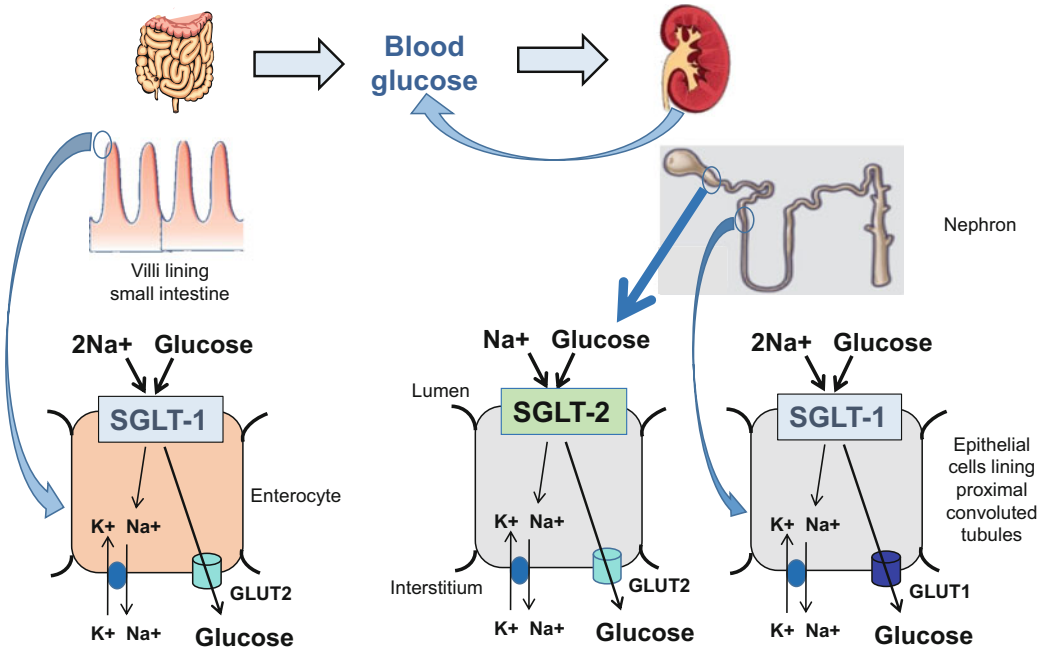
In addition to amplifying nutrient-stimulated insulin release, animal studies and in vitro studies have indicated that GLP-1RAs can increase β-cell mass through increased neogenesis and proliferation, as well as reduced apoptosis, although effects have varied considerably between models. In vitro and animal studies indicate that GLP-1 can initiate neogenesis of β-cells, possibly from exocrine ductal cells and by transdifferentiation of other islet endocrine cells. GLP-1 can also promote proliferation of existing β-cells in part via PKA and PDX-1, but mechanisms are unclear. Moreover, it is uncertain whether GLP-1RAs can instigate these effects to preserve β-cell mass in advancing stages of human type 2 diabetes when β-cell numbers and functional capacity are already significantly compromised.

Mechanisms through which GLP-1RAs suppress glucagon secretion appear to include a direct effect on islet α-cells as well as an inhibitory effect of somatostatin released from islet δ-cells in response to a direct effect of GLP-1RAs and via vago-vagal pathways. Central effects of GLP-1RAs to promote satiety are mediated partly via vagal afferents triggered by GLP-1RAs in the intestinal mucosa and portal circulation. However, some circulating GLP-1RAs may be able to cross the blood-brain barrier. GLP-1 receptors are located in many regions of the brain including the limbic system and lateral hypothalamus, but it has been difficult to distinguish effects mediated by GLP-1 and GLP-1RAs entering from the circulation compared with GLP-1 that is generated by many central neurons.

Sodium-Glucose Cotransporter-2 Inhibitors

Sodium-glucose cotransporter-2 (SGLT-2) inhibitors, sometimes termed flozins, were introduced in 2013 as agents to lower blood glucose by eliminating excess glucose in the urine. The template for these agents was the glucoside phlorizin which was isolated from the bark of apple trees and has long been known to cause glucosuria (Tahrani et al. 2013).

SGLT-2 (SLC5A2) is one of several members of the sodium substrate symporter family. It is located in the apical (luminal) membrane of epithelial cells lining the first segment of the proximal tubules of the kidney where it is responsible for the reuptake of about 90% of the glucose filtered into the tubule at the glomerulus. Glucose passing further along the tubule is taken up by SGLT-1 (SLC5A1) located in apical membranes along the third segment of the proximal tubules. SGLT-2 is a low-affinity high-capacity cotransporter with a 1:1 stoichiometry of sodium to glucose, whereas SGLT-1 is a high-affinity low-capacity cotransporter with a sodium to glucose stoichiometry of 2:1. Both cotransporters are secondary active, being driven by the Na+/K+-ATPase pump in the basolateral membrane. Glucose taken into the tubular cells by these transporters moves out across the basolateral membrane via the facilitative transporters GLUT1 and GLUT2 (Fig. 7). SGLT-2 inhibitors act through competitive inhibition, and although they are highly selective for SGLT-2, some of these agents can also exert a weak inhibitory effect at SGLT-1. Circulating concentrations are insufficient for an effect on renal SGLT-1, but oral dosing of agents with the strongest inhibitory effect on SGLT-1 (sotagliflozin and canagliflozin) can achieve concentrations in the upper small intestine that interfere with glucose absorption by SGLT-1. Deferring glucose absorption to more distal regions of the intestine helps to



Glucose-Lowering Drugs Other than Insulin, Fig. 7 Sodium-glucose cotransporter-2 (SGLT-2) inhibitors act mainly by competitive inhibition of SGLT-2 cotransporters in the renal proximal tubules. Members of the class that can also exert an inhibitory effect on SGLT-1 cotransporters can reduce glucose uptake in the upper intestinal tract

reduce prandial blood glucose excursions and deliver more glucose to ileal L-cells resulting in increased release of GLP-1 and peptide YY, which further assist blood glucose lowering.

With regard to the treatment of type 2 diabetes, a key feature of the mechanism of action of SGLT-2 inhibition is that it is independent of insulin, i.e., it will lower plasma glucose concentrations irrespective of insulin resistance or hypoinsulinemia provided there are adequate basal levels of endogenous insulin to sustain life. Indeed, some SGLT-2 inhibitors can be used as an adjunct to insulin in type 1 diabetes, and their mechanism of action is complementary to that of other glucose-lowering therapies with which they can be combined in the treatment of type 2 diabetes.

In individuals with a good to moderate glomerular filtration rate (eg GFR >60 ml/min/1.73m^2) and substantial hyperglycemia (e.g., an average daily plasma glucose concentration exceeding >150 mg/dl), an SGLT-2 inhibitor can create a glucosuria of 30–100 g glucose/day. The loss of calories associated with the glucosuria is typically associated with weight loss. A reduction in blood pressure is also commonly noted in patients receiving an SGLT-2 inhibitor: this is attributed at least in part to a reduction in plasma volume due to the osmotic diuresis of glucosuria.

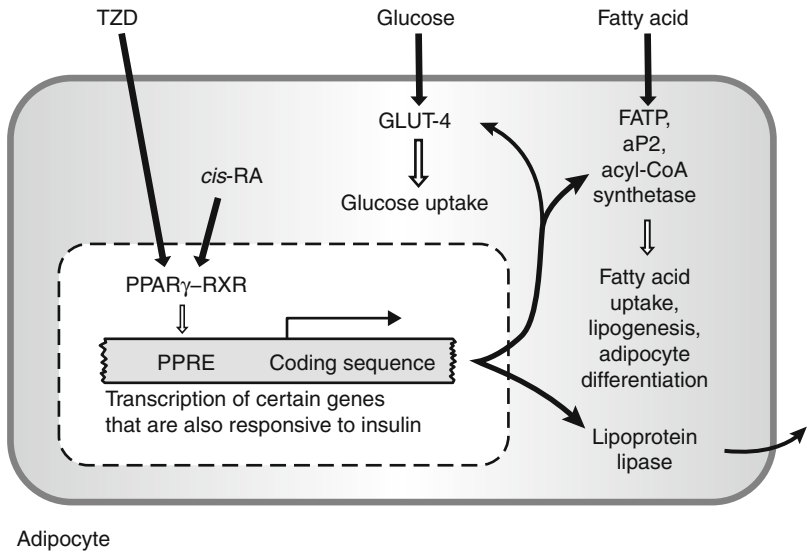
Recent studies have noted that SGLT-2 inhibitors reduce the onset and progression of heart failure which is likely to reflect a lowering of body weight and blood pressure, although several other mechanisms have been indicated that are independent of glucose lowering. These include inhibition of the cardiac sodium-hydrogen exchanger which increases mitochondrial calcium, adjustments to electrolyte balance and hemodynamics, a reduction in uric acid, and increased production of ketones. SGLT-2 inhibition also reduces albuminuria and, in the long-term, slows the rate of decline in GFR. This is explained in part by the retention of additional sodium in the tubules during SGLT-2 inhibition which is sensed by the macula densa to increase juxtaglomerular feedback, constricting afferent

glomerular arterioles and reducing intraglomerular pressure.

Thiazolidinediones

Two thiazolidinediones (TZDs), pioglitazone and rosiglitazone, were introduced in 1999: pioglitazone remains available in most countries, but rosiglitazone was withdrawn in Europe and many other countries in 2010. The use of rosiglitazone was restricted in the USA for 2010–2015, and it has received little use thereafter. Another TZD, troglitazone was briefly introduced and withdrawn. TZDs improve insulin sensitivity, and their principal mechanism of action is stimulation of the nuclear receptor peroxisome proliferator-activated receptor-γ (PPARγ). PPARγ (PPARs) is a member of the nuclear receptor superfamily for retinoid, steroid, and thyroid hormones. PPARγ exists as a heterodimer with the retinoid X receptor (RXR). Binding of a TZD to PPARγ together with binding of *cis*-retinoic acid to the RXR moiety produces a conformational change that prompts dissociation of corepressors. The activated heterodimer then binds to the peroxisome proliferator response element (PPRE), which is a sequence (AGGTCAXAGGTCA) located in the promoter region of the responsive genes. Recruitment of co-activators including PGC-1 and assembly of the RNA polymerase complex follows, initiating transcription (Fig. 8). Many of the responsive genes are also activated by insulin or encode for proteins that enhance actions of insulin, hence the ability of TZDs to improve insulin sensitivity (Cariou et al. 2012).

PPARγ is strongly expressed in adipocytes, and stimulation by TZDs promotes adipogenesis, predominantly in preadipocytes from subcutaneous depots. Increased transcription of transporters and enzymes involved in fatty acid uptake, and lipogenesis increases the deposition of lipid in these adipocytes (Table 2). This appears to facilitate a reduction in hyperglycemia by reducing circulating concentrations of nonesterified (free) fatty acids and triglycerides. The consequent effect on the glucose-fatty acid (Randle) cycle is to reduce the availability of fatty acids as an energy source, thereby favoring the utilization of glucose. Additionally, TZDs increase transcription of GLUT-4 glucose transporters that facilitate



Glucose-Lowering Drugs Other than Insulin, Fig. 8 Thiazolidinediones stimulate the PPARγ moiety of the PPARγ–RXR nuclear receptor complex, which then binds to a response element, leading to transcription of certain genes some of which are also responsive to insulin. These facilitate increased uptake of fatty acids, lipogenesis and adipogenesis. PPARγ, peroxisome proliferator-activated receptor-γ; RXR, retinoid X receptor; PPRE, peroxisome proliferator response element; TZD, thiazolidinedione; *cis*-RA, *cis*-retinoic acid; GLUT-4, glucose transporter isoform-4; FATP, fatty acid transporter protein; aP2, adipocyte fatty acid-binding protein

Glucose-Lowering Drugs Other than Insulin, Table 2 Tissue expression, ligands, genes activated, and biological actions of the peroxisome proliferator-activated receptor-γ (PPARγ)

Tissue expression	Mainly white and brown adipose tissue; weak expression in liver, muscle, gut, macrophages, pancreatic β-cells and hemopoietic tissues
Natural ligands	Certain unsaturated fatty acids and prostaglandin metabolites
Synthetic ligands	Thiazolidinediones and some non-steroidal anti-inflammatory drugs
Genes activated	Lipoprotein lipase; fatty acid transporter protein; adipocyte fatty acid binding protein; acyl-CoA synthetase; malic enzyme; GLUT-4 glucose transporter; phosphoenolpyruvate carboxykinase
Biological actions	Adipocyte differentiation; fatty acid uptake; lipogenesis; glucose uptake; other effects on nutrient metabolism which lower hepatic glucose production

glucose uptake. Reducing circulating free fatty acid concentrations reduces ectopic fat which in turn reduces the production of lipid metabolites, which would suppress early postreceptor steps in the insulin-signaling pathway. TZDs may further improve insulin signaling by increasing production of the adipocyte hormone adiponectin, decreasing production of the adipocyte cytokine tumor necrosis factor-α (TNFα), and decreasing production of the adipocyte hormone resistin (and possibly leptin), which have been implicated in the pathogenesis of insulin resistance.

There is weak expression of PPARγ in the liver, muscle, and other tissues, enabling TZDs to support the effects of insulin in these tissues, notably reduced glucose production by the liver and increased glucose uptake by muscle.

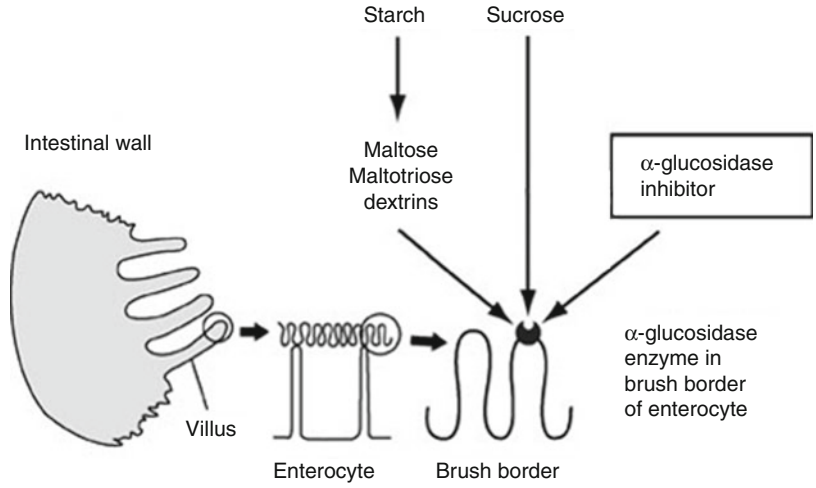
α-Glucosidase Inhibitors

The first member of this class, acarbose, was introduced in the early 1990s. α-Glucosidase inhibitors slow the intestinal process of carbohydrate digestion by competitive inhibition of the activity of α-glucosidase enzymes located in the brush border of the enterocytes (Fig. 9). Acarbose also causes a modest inhibition of pancreatic α-amylase activity. The principal α-Glucosidase enzymes are glucoamylase, sucrase, maltase, and dextrinase. The inhibitors bind to these enzymes with much higher affinity than their natural disaccharide and oligosaccharide substrates. Hence, when bound to the inhibitor, the enzyme fails to cleave the disaccharides and oligosaccharides into their absorbable monosaccharides. The available α-glucosidase inhibitors, acarbose, miglitol, and voglibose, show different binding affinities for the enzymes, giving them different activity profiles. For example, the affinity profile of acarbose is glycoamylase > sucrase > maltase > dextrinase. Miglitol is a more potent inhibitor of sucrase, and voglibose of other α-glucosidases (Lebovitz 2004).

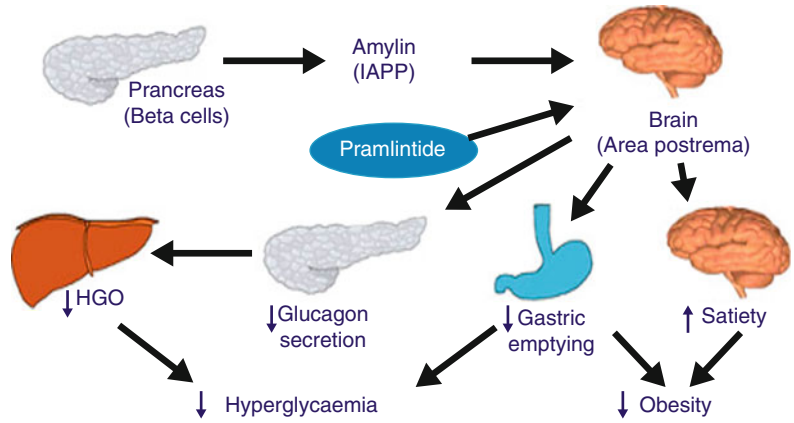
When α-glucosidase activity is inhibited, carbohydrate digestion is prolonged and takes place further along the intestinal tract. This in turn delays and spreads the period of glucose absorption, which reduces the extent of the postprandial rise in blood glucose concentrations. The effectiveness of α-glucosidase inhibitors is dependent on the consumption of a meal rich in complex carbohydrate.

Pramlintide

Pramlintide was introduced in the USA in 2005 as an adjunct to insulin therapy. It is a soluble analogue of the islet hormone amylin (islet amyloid polypeptide, IAPP) that is normally co-secreted from the pancreatic β-cells with insulin and C-peptide in response to nutrient stimuli. Paradoxically, amylin has been a suspect in the demise of β-cells in type 2 diabetes due to its accumulation and polymerization to form insoluble fibrils in the islets. However, normal amylin secretion appears to contribute to glucose homeostasis. Amylin acts centrally, via receptors in the area postrema (where there is no blood-brain barrier), dorsal raphe, and nucleus accumbens. The central effects induce satiety and initiate a vagally mediated suppression of prandial glucagon secretion and a slowing of gastric emptying (Fig. 10). In type 1 diabetes and advanced stages of type 2 diabetes, there is a lack or substantial reduction of amylin. Thus this non-aggregating analogue of amylin can be used to complement insulin therapy in type 1 and advanced type 2 diabetic patients (Messer and Green 2009).



Glucose-Lowering Drugs Other than Insulin, Fig. 9 α-Glucosidase inhibitors slow the rate of intestinal carbohydrate digestion by competitive inhibition of α-glucosidase enzymes in the brush border of enterocytes. The α-glucosidase inhibitors have a higher affinity for the α-glucosidase enzymes than the natural disaccharide and oligosaccharide substrates.



Glucose-Lowering Drugs Other than Insulin, Fig. 10 Mechanisms of action of the amylin analogue pramlintide

The structure of pramlintide (Fig. 11) differs from human amylin by the substitution of three residues with proline residues, retaining biological potency but preventing self-aggregation. Pramlintide is administered by subcutaneous injection and always as an adjunct to insulin therapy. Since pramlintide requires a more acidic pH than insulin, it has to be given as a separate injection to insulin, usually just before the main meals. The suppression of glucagon secretion and to a lesser extent the slowing of gastric emptying are the main immediate actions of pramlintide that reduce blood glucose. The satiety effect is typically associated with a long-term reduction of food intake and body weight: reduced adiposity in obese type 2 diabetes generally improves metabolic control. It is advised to reduce the mealtime insulin dose during initiation of pramlintide therapy to reduce the risk of interprandial hypoglycemia. Antibodies to pramlintide have been identified in some patients although these do not appear to affect biological activity.

Bromocriptine

Bromocriptine is a dopamine D2 receptor agonist that is well established as a treatment for Parkinson's disease and pituitary tumors. In 2009, a low-dose rapid release formulation was approved for glucose lowering in type 2 diabetes, based on studies showing improved glucose tolerance without increased insulin. It is suggested

Glucose-Lowering Drugs Other than Insulin, Fig. 11 Structure of human amylin and its soluble analogue pramlintide

that increased dopaminergic activity in the morning assists the normal circadian role of the hypothalamus in glucoregulation, particularly to reduce sympathetic activity and suppress hepatic glucose production. Bromocriptine is reported to improve the blood lipid profile and reduce cardiovascular risk (Raskin and Cincotta 2016).

Colesevelam

Colesevelam is a bile acid sequestrant that acquired an additional approval in 2008 to improve glycemic control in type 2 diabetes. The glucose-lowering effect is modest, and the mechanism is uncertain. There is evidence that when bile acids are carried by colesevelam to more distal regions along the intestine, they interact with the bile acid receptor-1 (TGR5) on enteroendocrine L-cells in the ileum and colon to promote GLP-1 secretion and thereby increase the incretin effect. Also, by reducing the enterohepatic circulation of bile acids, colesevelam reduces the activity the farnesoid X receptor (FXR), which could affect hepatic glucose metabolism (Beysen et al. 2012).

Clinical Use

Type 2 (non-insulin-dependent) diabetes typically emerges in middle or later life. Unlike type 1 diabetes in which there is total loss of pancreatic β-cells and a critical need for exogenous insulin administration, type 2 diabetes is associated with a continued presence of β-cells and continued insulin production. However, insulin resistance often develops as a prelude to type 2 diabetes and creates a demand for a compensatory increase in insulin secretion. Eventually, the β-cells are unable to produce sufficient extra insulin to overcome the insulin resistance. This results in impaired insulin-mediated glucose uptake by the muscle, failure of insulin to suppress hepatic glucose production, and consequently hyperglycemia. Pancreatic β-cells of type 2 diabetic patients become increasingly sluggish in their responsiveness to raised glucose concentrations, and eventually β-cell function becomes severely impaired, leading to a state of hypoinsulinemia and greater hyperglycemia. Obesogenic disturbances and other contributing factors mentioned earlier (in the section "Mechanism of Action") collectively conspire to create metabolic abnormalities in most body tissues. The toxic effects of hyperglycemia on the functional integrity of small blood vessels and nerves result in the long-term microvascular and neuropathic complications of diabetes (retinopathy, nephropathy, and neuropathy). The additional effects of dyslipidemia, hypertension, and other cardiovascular risks associated with insulin resistance are largely responsible for the long-term cardiovascular complications of type 2 diabetes (DeFronzo et al. 2015).

Achieving and maintaining blood glucose concentrations close to normal reduce the morbidity and premature mortality of the long-term complications of type 2 diabetes. Treatment begins with non-pharmacological measures (diet, exercise, and healthy living), and some patients can achieve remission, but the typical scenario of a gradual deterioration in glycemic control eventually requires add-on pharmacological therapy for the majority of patients. This is usually started with one oral glucose-lowering agent. Most guidelines and consensus reports favor metformin as the initial agent because it offers glucose-lowering efficacy without overswings into hypoglycemia, does not cause weight gain, counters insulin resistance, reduces long-term risk of cardiovascular complications, and may reduce risk of some neoplasms (Davies et al. 2018; Buse et al. 2019).

In some treatment algorithms, a sulphonylurea or a prandial insulin releaser is favored as the first oral glucose-lowering agent if substantial β-cell failure is suspected. A prandial insulin releaser would be preferred for individuals with either mainly postprandial hyperglycemia or irregular meal patterns which would predispose to interprandial hypoglycemia if taking a sulphonylurea. A sulphonylurea or prandial insulin releaser is often recommended as a complementary add-on to metformin as the disease progresses, although add-on therapy with a DPP-4 inhibitor has been adopted widely as a strategy for continued avoidance of hypoglycemia and weight gain. Recent guidance has suggested that add-on therapy to metformin should take particular account of the presence of cardiovascular and renal complications or very high risk of these complications, favoring use of a GLP-1RA or SGLT-2 inhibitor (Davies et al. 2018; Buse et al. 2019). The use of TZDs has receded since the emergence of the DPP-4 inhibitors, GLP-1RAs, and SGLT-2 inhibitors, largely due to the regulatory issues with

Glucose-Lowering Drugs Other than Insulin, Table 3 Main exclusions, adverse events, and precautionary monitoring required for clinical use of glucose-lowering drugs other than insulin

Class[a]	Main exclusions	Main adverse events	Monitoring[b]
Metformin	Renal or liver disease; any predisposition to hypoxia	Gastro intestinal upsets; risk of lactic acidosis if severely impaired renal function	GFR, creatinine, Hb, or Vit B12[b]
Sulphonylureas	Severe liver or renal disease[c]	Hypoglycemia	–[b]
Prandial insulin releasers (meglitinides)	Severe liver or renal disease[c]	Hypoglycemia[d]	–[b]
DPP-4 inhibitors (gliptins)	Caution if history of acute pancreatitis	Possible increased risk of pancreatitis	–[b]
Glucagon-like peptide-1 receptor agonists (GLP-1RAs)	Caution if history of acute pancreatitis	Initial nausea, possible increased risk of pancreatitis	–[b]
Sodium-glucose cotransporter-2 inhibitors (SGLT-2 inhibitors)	Poor renal function	Genital mycotic infection, dehydration, euglycemic ketoacidosis	GFR[b]
Thiazolidinediones (TZDs)	Heart failure; liver disease	Edema, anemia, heart failure, bone fractures	LFT[b]
α-Glucosidase inhibitors	Chronic intestinal disease	Gastrointestinal upsets	LFT[b,e]
Pramlintide	Gastroparesis	Hypoglycemia, nausea	–[b]
Bromocriptine	Hypertension, significant cardiovascular disease	Nausea; dizziness	Blood pressure[b]
Colesevelam	Intestinal disease or obstruction, biliary obstruction	Gastrointestinal upsets, increased triglyceride	LFT[b]

GFR, glomerular filtration rate; Hb, hemoglobin; Vit B12, vitamin B12; LFT, liver function test

[a]The dosage of each antidiabetic drug should be increased until either the target level of glycemia is achieved or the last dosage increment produces no additional effect

[b]Appropriate monitoring of glycemic control may involve self-measurement or laboratory measurement of fasting or random blood/plasma glucose, interstitial glucose monitoring, glycated hemoglobin (HbA1c) or fructosamine (glycated albumin)

[c]Depending upon pathways of metabolism and elimination of individual members of the class

[d]Prandial insulin releasers are less likely to produce severe or prolonged episodes of hypoglycemia than sulphonylureas

[e]Liver function should be checked in patients on high dose acarbose

rosiglitazone, weight gain, and concerns about possible edema and risk of heart failure for some patients. However, pioglitazone can be used in impaired renal function. The use of α-glucosidase inhibitors is more common in Asia and can be helpful if the diet is high in complex carbohydrate, but glucose-lowering efficacy may be modest and predominantly restricted to postprandial periods.

Insulin therapy in type 2 diabetes tends to be reserved until combinations of two or sometimes three differently acting classes of agents are no longer effective (insulin, ▶ insulin receptor). Insulin may be used earlier if hyperglycemia is extensive or patients are symptomatic, and rapid disease progression to require insulin may prompt enquiry to exclude late onset type 1 diabetes. Metformin is usually retained with insulin in type 2 diabetes: other oral glucose-lowering agents as well as GLP-1RAs may be indicated together with insulin to address concerns about weight, cardio-renal complications, or insulin dose.

It is noted that not all agents are available in all countries, and indications for use may vary between countries and between localities. Pramlintide, bromocriptine, and colesevelam have limited availability as glucose-lowering agents and are not approved treatments for type 2 diabetes in Europe. There are further agents used for glucose-lowering in parts of Asia, the Middle East, Africa, and South America that are not considered in the present account.

Precautions associated with the use of glucose-lowering agents, including restrictions in patients with chronic kidney disease, cardiovascular, and other morbidities, are itemized in the summary of product characteristics (also termed product label) for each agent, and may vary between formularies in different countries. The main limitations and cautions for use of glucose-lowering drugs are listed in Table 3.

Glycine Receptors

Gustavo Moraga-Cid and Luis G. Aguayo
Department of Physiology, Faculty of Biological Sciences, Universidad de Concepción, Concepción, Chile

Synonyms

Glycine-gated chloride channel; Inhibitory glycine receptor; Strychnine-sensitive glycine receptor

Definition

Glycine receptors (GlyRs) are from the family of ligand-gated pentameric ion channels (pLGICs) which also includes inhibitory gamma-aminobutyric acid receptors ($GABA_AR$) and excitatory nicotinic acetylcholine (nAChR) and 5-hydroxytryptamine receptors ($5\text{-}HT_3R$) (Burgos et al. 2016; Lynch et al. 2017a; Zeilhofer et al. 2018). The binding of the neurotransmitter glycine to the alpha (α) receptor subunit opens a chloride-permeable ion channel, allowing rapid hyperpolarization of the membrane potential and control of neuronal excitability in a millisecond time course. This effect is blocked by nanomolar concentrations of strychnine. Each α GlyR subunit consists of a large extracellular N-terminal domain (ECD) which contains the orthosteric binding site, four membrane-spanning helices (M1–M4; TMD) where the TM2 helices from each subunit contribute to shape the central pore, and a large intracellular domain (ICD) connecting the TM3 and TM4 (Fig. 1a). Adding to the receptor complexity, GlyRs are protein complexes composed of α- and β-subunits. Molecular cloning studies have identified four isoforms of the α-subunits (α1–4) and one β-subunit. The four α-subunits show a high degree of amino acid sequence identity but differ in their developmental regulation and regional expression, as well as in their biophysical properties. GlyRs have important physiological/pharmacological roles throughout the entire nervous system, contributing to the control of muscle tone, respiration, motor coordination, sensory processing, and higher brain functions. Impaired GlyR function underlies many neurological diseases, including hyperekplexia, chronic pain, autism, epilepsy, and spectrum disorders. Therefore, there is an active search for subunit selective allosteric modulators that can alter the course of these diseases (Burgos et al. 2016; Lynch et al. 2017b).

Basic Characteristics

Glycinergic Synapses

Besides the expression in the spinal cord and brainstem, synaptic GlyRs are also expressed in other areas such as the neocortex, amygdala, nucleus accumbens, and retina (Ogino and Hirata 2016; Muñoz et al. 2018). In these regions, functional GlyRs are pentameric complexes which are formed by five α-subunits (homomeric) or by a mixture of α- and β-subunits with a 2α:3β stoichiometry (Fig. 1b). During CNS development, GlyRs are predominantly expressed as heteromeric α2β conformations but then later switch to α1β in the adult state. However, α2 remains at rather high levels into adulthood in the cerebral cortex and striatum. The α3 subunit is also expressed as a heteropentamer in the adult CNS, but its expression is restricted mainly to the dorsal horn layer of the spinal cord. In humans, functional GlyRs containing the α4 subunit cannot be expressed because a premature stop codon is present within the fourth membrane-spanning domain (for this reason α4 is often considered as a pseudogene in humans) (Ogino and Hirata 2016; Patrizio et al. 2017). In contrast to the α-subunits, the β-subunit alone cannot form functional receptors. However, the β-subunit is essential for postsynaptic organization of the GlyRs via their interaction with the scaffold protein gephyrin. Therefore, whereas the heteropentameric GlyRs are accumulated at the postsynaptic sites, it is believed that homomeric GlyRs are mainly distributed in the extrasynaptic area or presynaptic terminal (Patrizio et al. 2017). These

extrasynaptic GlyRs are activated by local glycine (or taurine) producing glycinergic currents that contribute to the tonic regulation of neuronal excitability. This tonic current response is likely controlled by the biosynthesis of glycine that is catalyzed by the enzyme serine hydroxymethyltransferase from the precursor serine. Glycine is incorporated into synaptic vesicles by the vesicular inhibitory amino acid transporter (VIAAT). Since VIAAT also mediates the uptake of GABA, a combined inhibitory glycinergic/GABAergic synapse frequently occurs. Glycinergic neurotransmission is terminated by clearance of glycine from the extracellular space, which is achieved by two high-affinity sodium-dependent glycine transporter subtypes: glycine transporter 1 (GlyT1) and glycine transporter 2 (GlyT2). While GlyT1 is predominantly expressed in astrocytes (controlling the allosteric modulation of NMDARs by glycine), GlyT2 is expressed in glycine-releasing neurons in the spinal cord and in the brain stem where it drives the reuptake of glycine into presynaptic terminals. It is feasible that the discovery of new potent and selective reuptake inhibitors of glycine might provide compounds with interesting pharmacological properties that affect GlyRs (Erdem et al. 2019).

Excitatory Role of GlyRs in Immature Neurons

Contrary to the role of GlyRs in the mature CNS, the activation of GlyRs in immature neurons induces depolarizing responses (at this stage the chloride gradient is reversed to that of mature neurons) which elicit the excitation of the neuronal network (Lynch 2009). The inverted chloride gradient during this developmental phase is originated by action of the Na^{+}-K^{+}-$_2Cl^{-}$ cotransporter (NKCC1) that transports chloride ions inwardly. During early development of the CNS, the activity of KCC2 increases thereby establishing a low intracellular chloride concentration. Thus, KCC2 activity is necessary for glycinergic synapse maturation. Indeed, deletion of KCC2 impaired cluster formation of α1 subunits and gephyrin in cultured spinal neurons. On the other hand, cluster formation composed by α2 subunits was not affected by KCC2 knockdown (Schwale et al. 2016).

Glycine Receptor Structure-Function Relationship

The architecture of GlyRs has been confirmed by recent high-resolution structures using

cryoelectron microscopy (cryo-EM) and X-ray crystallography. The studies have provided atomistic models for open and closed states. To date, structures for human α3 GlyR and zebra fish α1 GlyR subunits have been solved (Du et al. 2015; Huang et al. 2017). Functional GlyRs adopt a pentameric cylinder-shape assembly in which the five subunits are arranged around a central fivefold axis (Fig. 1b,c). The data show that the structural features and the amino acid identity of the ECD and the TMDs of the different GlyRs subunits are highly conserved. The ECD adopts a barrel-like structure formed by β-strands (β1–β10) accompanied by two α-helices at the N-terminal. The glycine binding site is located between two neighboring subunits and is formed by three loops (A, B, C) of the principal subunit (+) along with three β-strands (D, E, F) from the complementary subunit (−). In addition, residues R65, T204, Y202, S129, F159, and P207 interact with glycine. The TMD consists of four amphipathic α-helices (TM1–4), where TM2 helices form the channel pore while TM4s are located on the external face corresponding to the region that interacts with lipid components of the neuronal membrane. On the other hand, the large ICD connecting the TM3 and TM4 is the least conserved domain in length and amino acid composition among the GlyR subunits. Unfortunately, all the structural data available on GlyRs to date has been obtained from ion channels lacking an important portion of the ICD (Du et al. 2015; Huang et al. 2017).

With regard to the structure-function relationship, it has historically been thought that GlyRs transition between three discrete global conformational states: (1) **resting**, a non-conductive conformation unbound to the agonist; (2) **active**, a conductive state bound to the agonist; and (3) **desensitized**, a non-conductive conformation bound to the agonist. However, more recent structural and functional studies have proposed that the activation of GlyRs (a process known as gating) occurs through numerous intermediate states, with a conformational sequence moving from the ECD to the TMD during gating. These experimental and structural data have suggested that the gating process is mainly determined by the ECD and TMDs. Binding of the agonist to the orthosteric site triggers a rapid isomerization that results in a transient structural rearrangement of the TM2 and TM3 leading to the opening of a transmembrane pore that allows the diffusion of anions. If the binding of the agonist is prolonged, the channel adopts a closed-state conformation (distinct from the agonist-unbound state) or desensitized state. Clearance of the agonist from the synaptic cleft causes the receptor to return to the inactive-closed configuration (Du et al. 2015; Huang et al. 2017). However, despite significant advances, the mechanisms underlying the gating process in pLGICs are not fully understood. Structural data from the cryo-EM reconstruction of GlyRs in complex with glycine captured an open channel configuration with an active pore configuration larger than those obtained in complex with strychnine (a competitive antagonist of GlyR) or with glycine and ivermectin (an allosteric modulator of GlyR) (Du et al. 2015; Huang et al. 2017). These structures also differ from open configurations obtained from other members of the pLGICs family. Thus, the structural changes occurring during the gating process are still a matter of debate.

In this context, the contribution of the ICD to the gating process is also a debatable issue, especially considering the lack of structural data. For instance, studies showing that the inclusion of the GlyRs α1 ICD into the bacterial GLIC receptor (which does not have an ICD) did not produce noticeable functional changes in the proton-activated currents of this receptor (Jansen et al. 2008; Goyal et al. 2011). Nevertheless, functional evidence (based on site-directed mutagenesis) showed that the desensitization of α1 GlyRs is influenced by lysine residues located in the ICD. Moreover, a short splicing variant of the α3 GlyR, α3K, shows a faster desensitization compared with the α3LGlyR wild type. In addition, mutagenesis performed on arginine residues within the ICD of α1 GlyRs showed a contribution to ion channel conductance (Carland et al. 2009). Thus, key questions regarding the functional and structural relevance of the ICD in the context of functional GlyRs remain to be solved.

Interaction of GlyRs with Intracellular Proteins

Compared with GABAergic synapses, glycinergic-mediated neurotransmission has restricted molecular variants and fewer subunit combinations to influence the neurotransmitter content, channel kinetics, and pharmacology at both pre- and postsynaptic levels. Nonetheless, glycinergic synapses show neuroplasticity that is achieved by the interaction with anchoring proteins which have been described as essential for the synaptic localization of the receptor. At inhibitory synapses, gephyrin is the major scaffold protein for the transient immobilization of GlyRs, as well as $GABA_A$Rs. Mutagenesis and electrophysiological experiments have shown that the ICD of the GlyR β-subunit contains critical residues for the functional interaction with gephyrin (Tyagarajan and Fritschy 2014). Additional to the components of the postsynaptic protein scaffold, other interacting proteins have been identified, including collybistin, profiling, Gβγ heterodimer, the vesicular trafficking factor SEC8, and the ubiquitination protein HUWE. It is likely that these components contribute to distinct levels of synaptic plasticity.

Physiological Consequences of Impaired Glycinergic Function

Glycinergic malfunction is associated mainly with motor disorders. Hyperekplexia (startle disease, stiff baby syndrome), a rare neurological disorder characterized by neonatal hypertonia and exaggerated startle responses, is caused by hereditary mutations that disrupt the functioning of inhibitory glycinergic synapses in neuromotor pathways of the spinal cord and brainstem (Bode and Lynch 2014). So far at least 51 mutations in the α1 subunit and 18 in the β-subunit have been described. Mutations in the α1 subunit include **(a)** single nucleotide exchange, **(b)** nonsense mutation, and **(c)** large deletion. These mutations can be inherited in both an autosomal dominant and recessive fashion. Autosomal dominant mutations, which cannot be rescued by a wild-type allele, produce deleterious effects in glycinergic neurotransmission though different molecular mechanisms: **(a)** spontaneous activation (e.g., Y128C, Q226E, V280M, and R414H) which can displace the chloride equilibrium potential to more positive values leading to a further reduction in the inhibitory efficacy; **(b)** impaired channel gating where mutant GlyRs carrying the mutation R271Q or R271L showed a reduced channel conductance; **(c)** increased sensitization rate (e.g., P250T mutation reduces glycine-activated current amplitudes and induces fast desensitization); and **(d)** reduced cell surface expression (e.g., S231R, I244N, R252H, R392H). All these mutations exhibited low cell surface expression and reduced glycine sensitivity. In addition to hyperekplexia, altered glycinergic neurotransmission is also associated with inflammatory chronic pain (Harvey et al. 2004). The proposed mechanism of α3 GlyR-dependent pain sensitization involves the loss of glycinergic inhibition following the activation of neuronal EP2 receptors (EP2-R) by prostaglandin E2 (PGE2). EP2-R stimulation increases cAMP and subsequently promotes the PKA-dependent phosphorylation of the α3 GlyR at the S346 residue within the ICD, decreasing the amplitude of glycinergic currents. This loss of inhibitory control enhances the excitability of dorsal horn excitatory neurons, leading to the development and maintenance of chronic pain (Harvey et al. 2004). Recently, compelling evidence have shown that mutations affecting the function of α2 containing GlyRs are related to the occurrence of autism disorders (Zhang et al. 2017).

Allosteric Pharmacological Modulation

The function of GlyRs is modulated by several compounds having distinct chemical entities. Unfortunately, these ligands do not show specificity and can modulate α1, α2, and α3 containing GlyRs with similar potencies. Moreover, many of these modulators can also affect the function of related receptors such as $GABA_AR$ or $5HT_3R$. The spectrum of these modulators includes bivalent cations, general anesthetics, cannabinoids, tropeines, colchicine, ginkgolic acids,

ivermectins, synthetic neurosteroids, and n-alcohols. Mutagenesis, electrophysiological, and structural studies have proposed that the effect of many of these modulators is mediated by residues located mainly in the TMD (S267) and TM3 (A288, A296) that form an intrasubunit cavity able to accommodate compounds of different chemical characteristics (Burgos et al. 2016). Thus, mutations of these residues reduced the potentiation of glycine-evoked currents by ethanol, propofol, isoflurane, alphaxolone, THC, and cannabidiol (CBD). On the other hand, more recent studies have suggested that the ICD also has an important role on the sensitivity of GlyRs to these modulators. For example, electrophysiological studies using chimeric receptors with and without ICDs showed that the ICD is essential for the modulation of GlyRs by ethanol, propofol, and CDB. Mutagenesis and electrophysiological studies have also shown that residues in the ICD are critical for the effects of ethanol (α1 GlyRs 385KK386), propofol (α1 GlyRs F380), and the propofol derivative 2,6-DTBP (α3 GlyRs F388) (Yévenes and Zeilhofer 2011). Interestingly, KI mice having this 385KK386 mutation were less sensitive to ethanol-induced sedation and drank more ethanol that their WT counterpart (Muñoz et al. 2019).

More recently, the study of α3 GlyRs structure with a novel class of tricyclic sulfonamides (AM-1488) described a novel allosteric site (Huang et al. 2017). Interestingly, the compound was able to reduce allodynia in mice with spared nerve injury-induced neuropathic pain. Therefore, even though the pharmacology of GlyRs has surely advanced in the last decade, there are no pharmacological drugs available for treatment of glycinergic failures.

G-Protein-Coupled Receptors

Nina Wettschureck
Department of Pharmacology, Max Planck Institute for Heart and Lung Research, Bad Nauheim, Germany

Definition

G-protein-coupled receptors (GPCRs) are a large family of heptahelical membrane proteins able to translate the binding of extracellular molecules into modulation of intracellular signaling pathways. This process involves in most cases activation of heterotrimeric G-proteins, but may also occur in a G-protein-independent manner.

Basic Characteristics

GPCRs are the largest family of transmembrane receptors in eukaryotes. Due to their typical seven transmembrane structure, they are also known as seven-(pass)-transmembrane domain receptors, 7TM receptors, heptahelical receptors, or serpentine receptors. GPCRs mediate cellular responses to a wide variety of signals, including neurotransmitters, hormones, local mediators, metabolic or olfactory cues, and light (Rosenbaum et al. 2009). The human genome encodes about 800 GPCRs, the majority of them sensory (olfaction, vision, taste) receptors. The approximately 360 nonsensory GPCRs have central roles in cell-cell communication in all organ systems, and constitute a highly successful group of drug targets. However, for more than 100 nonsensory GPCR, endogenous ligand and function are still unknown, so-called orphan GPCRs (Ngo et al. 2016; Wise et al. 2004).

Structure and Function

All GPCRs consist of an extracellular N-terminus, followed by seven transmembrane (7-TM) α-helices (TM-1 to TM-7) connected by three intracellular (IL1 to IL3) and three extracellular loops (EL1 to EL3), and finally an intracellular C-

terminus, which in some GPCR contains an eighth helical region termed helix 8 (Fig. 1a). The N-terminus is in many GPCRs glycosylated, and the C-terminus is often tethered to the plasma membrane by a lipid modification. The GPCR arranges itself into a tertiary structure resembling a barrel, with the seven transmembrane helices forming a cavity within the plasma membrane (Fig. 1b). This cavity serves in many GPCRs as the ligand-binding domain and is often covered by EL2. Ligands may also bind elsewhere, especially in case of bulkier ligands (e.g., proteins or large peptides), which instead interact with the extracellular loops, or, as illustrated by the class C metabotropic glutamate receptors, the large N-terminal tail (see also Fig. 3) (Culhane et al. 2015).

Regardless of where ligand binding occurs, the consequence is a change in the relative orientation of the TM helices, for example, an outward movement of transmembrane helices TM5 and TM6 (Rasmussen et al. 2011; Weis and Kobilka 2018), resulting in a wider intracellular surface and better accessibility of residues crucial for signal transduction. This conformational change allows the GPCR to act as a guanine nucleotide exchange factor (GEF) towards the heterotrimeric G-protein, i.e., it facilitates the release of GDP from and consecutive binding of GTP to the G-protein α subunit (Fig. 2a). After successful GDP/GTP exchange, α and β/γ subunit of the heterotrimeric G-protein dissociate and are free to interact with their respective downstream effectors. β/γ subunits regulate ion channels such as G protein-gated inward rectifier channels or calcium channels, other potential β/γ effectors are phospholipase C (PLC) β isoforms and adenylyl cyclases (AC) (Wettschureck and Offermanns 2005). Responses elicited by the α subunit depend on the type of G-protein: activation of $G\alpha_s$ results in activation of AC and consecutive cAMP-dependent PKA activation, activation of $G\alpha_{i/o}$ inhibits AC activity, stimulation of $G\alpha_{q/11}$ induces phospholipase C β-dependent calcium mobilization and PKC activation, and $G\alpha_{12/13}$ finally mediates RhoGEF-dependent activation of RhoA (Fig. 3b) (Wettschureck and Offermanns 2005). G-protein activation is terminated by the intrinsic GTPase activity, which returns the G-protein into the inactive, GDP-bound state. Intrinsic GTPase activity is slow, but can be greatly enhanced by RGS proteins. In addition to signaling cascades controlled by heterotrimeric G-protein activation, GPCRs may signal independently of G-protein, for example, through β-arrestins (Shukla et al. 2011).

GPCR activation itself is not only terminated by disappearance of the ligand, but also by the process of densitization. The main underlying mechanism is GPCR phosphorylation by G protein-coupled receptors kinases (GRKs) and other kinases, resulting in β-arrestin recruitment. β-arrestin binding results in uncoupling of the G-protein α subunit from the receptor and clathrin-mediated internalization of the receptor (Shukla et al. 2011). In addition, also

Structure					

G-Protein-Coupled Receptors, Fig. 3 Human GPCRs: classification and characteristics. Classes D & E not listed, since not present in vertebrates. VNO, vomeronasal receptors for pheromones. *Numbers in brackets refer to orphan receptors for which an endogenous ligand has been proposed in at least one publication. Ligands (or in the case of adhesion GPCRs, the proteolytic cleavage site) are indicated in red.VN, vomeronasal pheromone receptors (for details, see https://www.guidetopharmacology.org/GRAC/ReceptorFamiliesForward?type=GPCR).

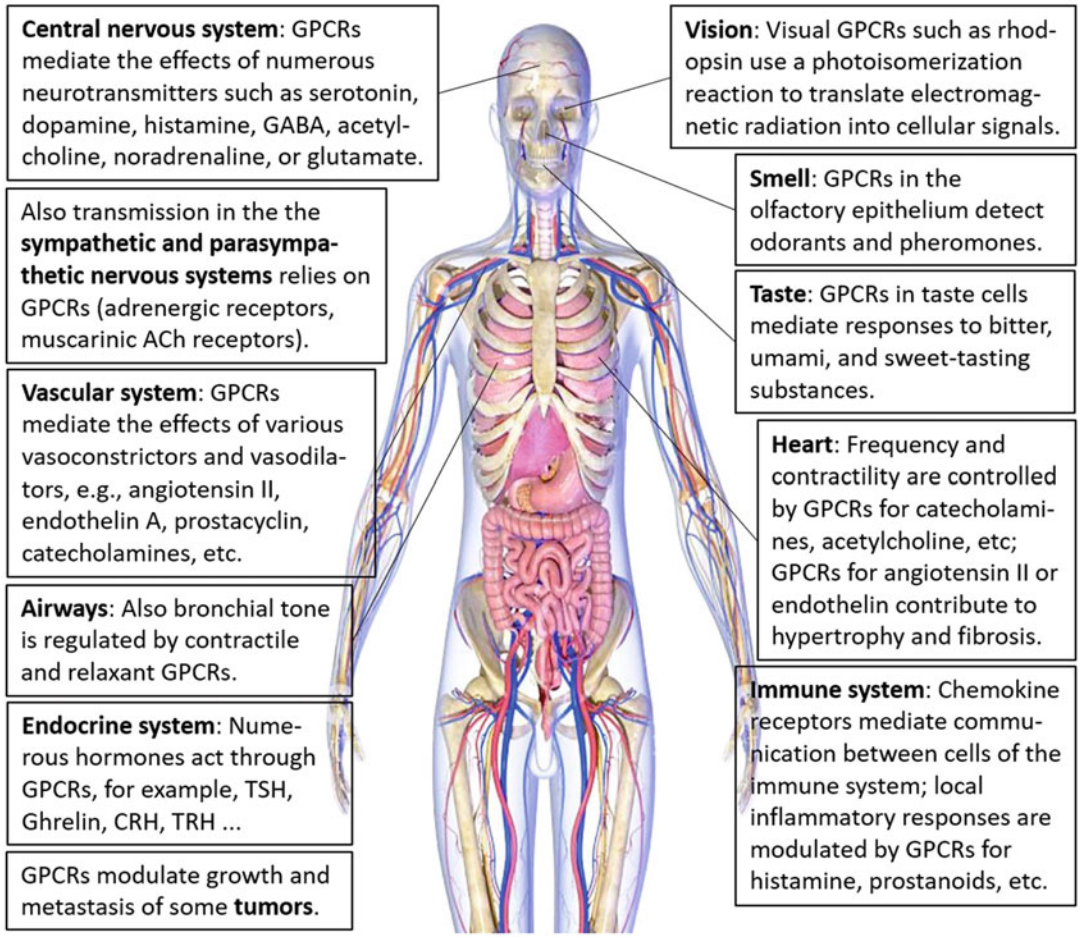
β-arrestin-independent internalization may occur. This process is not only observed in ligand-activated GPCR (homologous densitization), but can also affect nonactivated receptors (heterologous desensitization).

Classification

Based on sequence homology and functional similarity, different classification systems have been proposed for GPCRs, for example, the A-F system (A: Rhodopsin-like, B Secretin receptor family, C: Metabotropic glutamate/pheromone; D Fungal mating pheromone receptors, E: Cyclic AMP receptors, F: Frizzled/Smoothened) or the GRAFS system (Glutamate, Rhodopsin, *Adhesion*, Frizzled/Taste2, Secretin) (Bjarnadóttir et al. 2006). Figure 3 summarizes main features of GPCR classes.

Dimerization

Numerous co-immunoprecipitation studies using tagged receptors indicated that GPCRs can form homo- or heterodimers, and it was suggested that dimerization may affect both signaling and trafficking (Gurevich and Gurevich 2008; Milligan 2009). While for most class A receptors the functional relevance of dimerization is unclear, there is no doubt that class C receptors exist and function as stable dimers: metabotropic glutamate receptors (mGluR) and the calcium-sensing receptor (CASR) form homodimers, whereas $GABA_B$ and sweet and umami taste receptors are



G-Protein-Coupled Receptors, Fig. 4 Physiological functions of GPCRs (selection)

G-Protein-Coupled Receptors, Table 1 Data are based on Sriram and Insel (2018) and https://www.guidetopharmacology.org/. Some drugs have effects on multiple targets (including various GCPRs), but not all these interactions are necessarily of therapeutic relevance. In these cases, the respective drug is only listed for those GPCRs whose modulation is most likely underlying the therapeutic effect. For example, estradiol is an agonist at the G-protein-coupled estrogen receptor GPER1, but its main action is mediated via nuclear estrogen receptors; Estradiol is therefore not listed for GPER1

Receptor	Mode of action	Clinical use (example)	Approved drug (example)
Cardiovascular system			
Adenosine A1 receptor	Agonist	Supraventricular tachycardia	Adenosine
Adenosine A2a receptor	Agonist	Diagnostic agent	Regadenoson
Adrenoceptor alpha 1A, 1B, 1D	Antagonist	Arterial hypertension	Prazosin, Doxazosin, Terazosin, . . .
Adrenoceptor alpha 1A, 2A	Agonist	Nasal congestion	Oxymetazoline
Adrenoceptor Beta 1	Antagonist	Hypertension, angina pectoris, arrhythmia, . . .	Atenolol, Carvedilol, Metoprolol, . . .
Bradykinin receptor B2	Antagonist	Hereditary angioedema	Icatibant
Angiotensin II receptor AT1A	Antagonist	Hypertension	Candesartan, Irbesartan, Losartan, . . .
Arginine vasopressin receptor 2	Agonist	Central diabetes insipidus	Vasopressin, Desmopressin
Arginine vasopressin receptor 1A, 2	Antagonist	Euvolemic/hypervolemic hyponatremia	Conivaptan
Dopamine receptors D1-D5	Agonist	Shock syndrome, kidney failure	Dopamine
Endothelin receptor type A, ETA	Antagonist	Pulmonary arterial hypertension	Ambrisentan, Macitentan
Endothelin receptor type B, ETB	Antagonist	Pulmonary arterial hypertension	Bosentan
Prostaglandin I2 receptor	Agonist	Art. hypertension, scleroderma, Raynaud's	Iloprost, Treprostinil
Proteinase-activated receptor 1, PAR1	Antagonist	Prevention of platelet activation	Vorapaxar
Purinergic receptor P2Y12	Antagonist	Prevention of platelet activation	Ticagrelor
Endocrine/metabolic system			
Calcitonin receptor	Agonist	Osteoporosis	Calcitonin
Calcium sensing receptor	Agonist	Sec. hyperparathyreoidism	Etelcalcetide
Cholecystokinin B receptor, CCK_2	Agonist	Diagnostic agent	Pentagastrin
Corticotropin releasing hormone receptor 1	Agonist	Diagnostic agent	Corticorelin ovine triflutate
Follicle stimulating hormone receptor	Agonist	Fertility medicine	Follitropin alfa
Glucagon like peptide 1 receptor	Agonist	Type 2 diabetes	Lixisenalide, Exendin-4, Semaglutide, . . .
Glucagon like peptide 2 receptor	Agonist	Short bowel syndrome	Teduglutide
Glucagon receptor	Agonist	Severe hypoglycemia, diagnostic agent	Glucagon
Gonadotropin releasing hormone receptor	Antagonist	Hormone-sensitive cancers	Abarelix, Cetrorelix, Elagolix, . . .
Gonadotropin releasing hormone receptor	Agonist	Hormone-sensitive cancers	Leuprolide, Buserelin, Goserelin, . . .
Growth hormone releasing hormone receptor	Agonist	Diagnostic agent	Tesamorelin, Sermorelin
Hydroxycarboxylic acid receptor HCA2	Agonist	Hyperlipidemia	Acipimox, Nicotinic acid

(continued)

G-Protein-Coupled Receptors, Table 1 (continued)

Receptor	Mode of action	Clinical use (example)	Approved drug (example)
Luteinizing hormone/ Choriogonadotropin receptor	Agonist	Female infertility	Choriogonadotropin alfa
Melanocortin receptors 2	Agonist	Diagnostic agent	Corticotropin
Oxytocin receptor	Agonist	Labor induction	Oxytocin
Parathyroid hormone receptor 1	Agonist	Osteoporosis	Teriparatide
Secretin receptor	Agonist	Diagnostic agent	Secretin
Somatostatin receptors 1, 2, 3, 5	Agonist	Cushing's disease	Pasireotide
Somatostatin receptors 2,5	Agonist	Acromegaly, neuroendocrine tumors	Lanreotide
Gastrointestinal system			
Histamine H2 receptor	Antagonist	Peptic ulcer	Ranitidine, Cimetidine, Famotidine
Histamine H2 receptor	Agonist	Diagnostic agent	Betazole
Prostaglandin E receptor 3	Agonist	Gastrointestinal ulceration	Misoprostol
Immune system			
C-C motif chemokine receptor 5	Antagonist	HIV infection	Maraviroc
C-X-C motif chemokine receptor 4	Antagonist	Stem cell mobilization	Plerixafor
Histamine H1 receptor	Antagonist	Allergies	Cetirizine, Clemastine, Desloratadine, . . .
Sphingosine-1-phosphate receptor 1 + 5	Agonist	Multiple sclerosis	Fingolimod, Siponimod
Central nervous system			
5-Hydroxytryptamine (serotonin) receptor 1A	Agonist	Depressive disorder	Vilazodone
5-Hydroxytryptamine (serotonin) receptor 1B, 1D	Agonist	Migraine	Frovatriptan, Naratriptan, Elatriptan, . . .
5-Hydroxytryptamine (serotonin) receptor 2A	Antagonist	Schizophrenia, bipolar disorder	Asenapine*, Risperidone*, Sertindole*,. . ..
5-Hydroxytryptamine (serotonin) receptor 4	Agonist	Motility-related gastrointestinal disorders	Cisapride
5-Hydroxytryptamine (serotonin) receptors 2B, 2C	Agonist/ antagonist	Migraine, cluster headaches	Methysergide
Adrenoceptor alpha 2A, 2B, 2C	Agonist	Sedation in ICU setting	Dexmedetomidine
Cannabinoid receptors 1 + 2	Agonist	Antiemetic, analgesic	Nabilone
Dopamine receptor D2	Agonist	Parkinson's disease	Ropinirole*
Dopamine receptor D2	Antagonist	Schizophrenia	Risperidone*
Dopamine receptor D3	Agonist	Parkinson's disease	Ropinirole*
Gamma-Aminobutyric acid type B receptor 1 + 2	Agonist	Spasticity in multiple sclerosis	Baclofen
Histamine H3 receptor	Antagonist	Narcolepsy	Pitolisant
Hypocretin (Orexin) receptor 1 + 2	Antagonist	Insomnia	Suvorexant
Melatonin receptors 1A, 1B	Agonist	Insomnia	Ramelteon, Agomelatine, Tasimelteon
Muscarinic acetylcholine receptor M1	Antagonist	Parkinson's disease	Biperiden
Opioid receptor μ	Agonist	Pain management	Fentanyl, Alfentanil, Sufentanil
Opioid receptors μ, κ, δ	Antagonist	Opioid/alcohol dependence	Naltrexone

G-Protein-Coupled Receptors, Table 1 (continued)

Receptor	Mode of action	Clinical use (example)	Approved drug (example)
Pulmonary system			
Adenosine A1 receptors A2A, A2B	Antagonist	Reversible airway obstruction	Theophylline
Adrenoceptor Beta 2	Agonist	Airway constriction, premature labor	Orciprenaline, Salbutamol, Salmeterol, . . .
Cysteinyl leukotriene receptor 1	Antagonist	Airway constriction	Zafirlukast, Montelukast
Muscarinic acetylcholine receptor M3	Antagonist	Chronic obstructive pulmonary disease	Tiotropium, Ipratropium
Other systems			
Adrenoceptor alpha 2A, 2C	Agonist	Elevated intraocular pressure	Apraclonidine
Adrenoceptor Beta 3	Agonist	Overactive bladder	Mirabegron
Muscarinic acetylchonine receptors M1, M2, M3	Antagonist	Gastrointestinal spasms, enuresis, hyperhidrosis	Propantheline
Prostaglandin E receptor 1	Agonist	Erectile dysfunction	Alprostadil
Prostaglandin E receptor 2	Agonist	Induction of labor/abortion	Dinoprostone
Prostaglandin F receptor	Agonist	Elevated intraocular pressure	Latanoprost
Smoothened, frizzled class receptor	Antagonist	Advanced basal cell carcinoma	Sonidegib

PAM Positive allosteric modulator. *Effects on other GPCRs contribute to therapeutic effect

obligatory heterodimers (Gurevich and Gurevich 2008; Milligan 2009). Dimerization of class C receptors is mediated by distinct structural features, for example, by the very large N-terminus containing a Venus flytrap motif (VFM), which mediates both ligand binding and dimerization of N termini. Additionally, mGluRs and CASR contain a cystein-rich domain (CRD) between VTF and heptahelical domain, which allows formation of disulfide bonds within the homodimer (Gurevich and Gurevich 2008).

Physiological Functions

GPCRs are involved in a wide variety of physiological processes. Some examples of their physiological roles include are shown in Fig. 4.

Pharmacological Modulation

In its simplest form, receptor theory proposes that a given GPCR can exist in two functionally distinct states, the inactive (R) and the active (R*) state. In the absence of ligands, most receptors are in the R state, but may spontaneously assume the R* conformation. This basal equilibrium between R and R* defines the basal (constitutive) activity of the receptor. GPCR ligands are classified according to their effect on basal activity of the receptor:

- Full agonists stabilize R* and elicit maximum signaling at the interrogated pathway.
- Partial agonists shift the balance towards R* without reaching maximum efficacy.
- Inverse agonists shift the balance towards R, i.e., they inhibit basal receptor activity.
- Neutral antagonists have no effect on receptor activity, but may block agonist effects.

Of note, a given GPCR may couple to different effector pathways, for example, different families of heterotrimeric G-proteins and/or arrestin. A specific ligand at this GPCR may exert the same effect, for example, full agonism, at all effector pathways, or it may have differential effects, for example, enhancing G-protein signaling while reducing β-arrestin signaling. Such ligand-dependent selectivity for certain signal transduction

pathways is referred to as "functional selectivity" or "biased signaling" (Smith et al. 2018).

Drugs

The unique combination of diversity and specificity within the GPCR family, together with the fact that they are readily targetable by exogenous agonists and antagonists, has made GPCRs a most successful group of drug targets (Wise et al. 2004): Approximately, 34% of all Food and Drug Administration (FDA) approved drugs target this family. Table 1 gives an overview of GPCRs targeted by approved drugs.

Cytokines; Differentiation factors; Mitogens

Definition

Growth factors are relatively small and stable soluble polypeptides that mediate short-range cell-to-cell interactions. Growth factors and their cognate receptors, which often harbor enzymatic activity, function in the framework of modules regulating various cellular processes, such as proliferation, differentiation, and migration. These modules are evolutionarily conserved, and in many cases their primary developmental function is the determination of cell lineage through heterotypic cellular interactions. Many growth factors are versatile, promoting appropriate biological outcomes of several cell lineages, while others are more limited in scope. Growth factor expression is highly regulated, such that excessive growth factor activity is often associated with pathogenic hyper-proliferation (e.g., cancer, fibrosis, and psoriasis).

Historical Perspective

One of the first lines of evidence that led to the discovery of soluble growth factors (GFs) emerged from studies performed in the 1950s, in the laboratory of Victor Hamburger, by two fellows, Rita Levi-Montalcini and Stanley Cohen (Escudier et al. 2007). When studying mechanisms enabling limb innervation in chick embryos, they grafted a lump of a mouse sarcoma onto an embryo and observed a more extensive attraction of nerve fibers to the lump. They later found that snake venom and the murine submaxillary gland secrete a similarly active "nerve-stimulating factor," which instigated the isolation of the first two GFs: nerve growth factor (NGF) and epidermal growth factor (EGF). Two decades later, Cohen and Todaro reported that cells infected by the feline sarcoma virus lost their ability to bind EGF (Todaro et al. 1976). This observation led to the isolation from a murine sarcoma of two "transforming growth factors," TGF-α and TGF-β (Roberts et al. 1982). Subsequent studies revealed that not only virally transformed cells but also chemically transformed cells, as well as cells derived from human tumors, often secrete GFs, which are responsible for self-stimulation (autocrine) of growth. In support of autocrine theories, Waterfield and colleagues reported in 1983 that the transforming gene of the simian sarcoma virus is structurally related to the platelet-derived growth factor (PDGF) (Waterfield et al. 1983). In 1984 Waterfield provided yet another link between GFs and cancer: partial sequencing of the EGF-receptor (EGFR/ERBB1) uncovered homology to another oncogene, the *erbB* gene of the avian erythroblastosis virus (Downward et al. 1984).

Around the same time, recombinant DNA technology was about to transform biology. Scientists led by Paul Berg, Stanley Cohen, and Herbert Boyer devised a way to splice together different pieces of DNA using restriction enzymes. The benefits of gene technology were soon realized through the industrial production of recombinant GFs, such as human somatostatin and insulin, in the late 1970s. Human insulin (Humulin), made by a young biotechnology company, Genentech, was approved for clinical use in 1982. Subsequent molecular cloning of EGFR by Ullrich and colleagues (Ullrich et al. 1984) boosted the understanding of the intracellular mechanisms of GF action: like EGFR, the majority of GF receptors are single-pass transmembrane proteins harboring an intracellular tyrosine kinase domain (Yarden and Ullrich 1988) or a serine/threonine kinase in the case of TGF-β receptors. A similarly important development impacted our current understanding at the tissue level: similar to

their roles in embryogenesis, GFs are the short-range mediators of the interplay between tumors and both the extracellular matrix (Lee et al. 1984) and stromal, non-cancer cells, such as myofibroblasts, macrophages, and endothelial cells. This cross talk underlies processes fundamental to development and tumor progression, such as sprouting of blood vessels (Folkman 1971) and local inflammatory responses.

Concerted Actions of Growth Factors: Wound Healing as an Example

GFs are involved in progenitor cell migration and proliferation during embryogenesis, and they regulate various processes in adults, such as mammary gland development, inflammation, and wound healing (Werner and Antsiferova 2016). Skin injury and vascular damage instigate local blood clotting and inflammation. While the clot comprises mainly fibrin and fibronectin, it also acts as a pool of GFs essential for wound repair. Different cell types originating from the circulation and adjacent unaffected tissues are attracted to the wound. Like in wounds, malignant tumors often deposit an extracellular matrix and attract lymphoid and other cell types by means of GFs like EGF, which act as chemo-attractants. In addition, the GFs promote proliferation and migration of epithelial cells, thus allowing re-epithelialization of the injured body site. Importantly, re-epithelialization within the wound is tightly controlled, and the process is terminated when the new epidermis fully covers the wound. In contrast, unlimited epithelial cell growth characterizes carcinomas and other tumors, often due to the self-production of GFs or mutations preventing negative feedback of GF action. Wound healing involves loss of keratinocyte cell-to-cell contacts, enhanced migration, and secretion of matrix-degrading proteases. A spectrum of similar processes, collectively called epithelial-mesenchymal transition (EMT), repeatedly occurs during development and in tumor progression, such as in the course of metastasis (Terry et al. 2017). EMT, along with matrix deposition and degradation, is regulated by GFs, especially factors belonging to the TGF-beta family. The family includes activin, a crucial regulator of wound healing, scar formation, fibrosis, and the susceptibility to skin tumorigenesis (Antsiferova and Werner 2012).

Growth Factor Families

GFs are classified according to their structure and the family of receptors they activate. Whereas the definition of GFs may broadly apply also to lymphokines (e.g., interleukins; ILs) and cytokine-like members of the tumor necrosis factor (TNF) family, here we will consider only GFs that bind to receptors harboring kinase activities, either receptor tyrosine kinases (RTKs) or serine/threonine kinase receptors. GFs bind with such receptors with high affinity (in the low nanomolar range) and specificity, and they may be accordingly classified as ligands of a specific receptor subfamily (Blume-Jensen and Hunter 2001). For example, growth factors comprising an epidermal growth factor (EGF) motif bind to the ERBB subgroup of RTKs (also called type I RTKs). We will use this classification to elaborate on the shared mechanism of action of growth factors. Table 1 lists the major families of GFs acting by means of stimulating RTKs. In similarity to the EGF family, the fibroblast growth factor (FGF) family contains at least 22 distinct members and the TGFβ family comprises 35 known members, which fall into several subfamilies. Likewise, the neurotrophin family contains four members.

Biochemical Mechanisms Activated by Growth Factors

Cells of most if not all major tissue types are targets of GFs that mediate their effects by means of receptors with intrinsic tyrosine kinase activity. These receptors have an extracellular ligand-binding domain and an intracellular tyrosine-kinase domain responsible for transducing the mitogenic signal. Ligand binding induces the formation of receptor dimers or oligomers (Schlessinger and Ullrich 1992), and molecular interactions between adjacent cytoplasmic domains lead to activation of kinase function.

Growth Factors, Table 1 The major families of growth factors able to stimulate receptor tyrosine kinases. Listed are the major families of growth factors and the respective RTKs they bind with. The table also identifies the major biological functions of the respective ligands and receptor complexes

Growth factor family	Receptors	Major physiological functions
Epidermal growth factor (EGF) family and the neuregulin (NRG) family (altogether, 11 molecules: EGF, TGF-α, epiregulin, amphiregulin, HB-EGF, betacellulin, epigen), NRG1, NRG2, NRG3 and NRG4	ERBB family ERBB1 (EGFR), ERBB2 (Neu, HER2), ERBB3/HER3 and ERBB4/HER4	Morphogenesis, maintenance and proliferation of epithelial, mesenchymal and nerve tissues
Fibroblast growth factor (FGF) family (altogether, 22 members; FGF1 through FGF10 bind with RTKs) FGFs require heparan sulfate chains to activate their receptors	FGFRs Four members that form seven different receptors through alternative mRNA splicing	Proliferation of many cell types, embryo patterning and organogenesis, bone development, and angiogenesis
Platelets derived growth factors (PDGFs) Five different isoforms consisting of homo- and heterodimers of A- and B-polypeptide chains, and homodimers of C- and D-polypeptide chains	PDGFRs Comprising PDGFR-alpha and PDGFR-beta.	Embryonic development, particularly formation of the kidney, blood vessels, and various mesenchymal tissues. Proliferation of connective tissues, glial and smooth muscle cells
Hepatocyte growth factors (HGFs) The ligands are heterodimers of A and B subunits linked by a disulfide bond	MET family There are three receptors: MET, SEA, and RON	Motogenesis, morphogenesis, angiogenesis myogenesis, and embryonic development
Glial cell line derived neurotrophic factor (GDNF) family In addition to GDNF, the family includes neurturin (NRTN), artemin (ARTN), and persephin (PSPN)	RET RET is an RTK recruited by one of four co-receptors, called GFRs. Alternative mRNA splicing results in three isoforms of RET	Required for enteric neuron development, kidney development, and spermatogenesis
VEGF family There are four members in mammals (VEGF-A, -B, -C, and -D), and PGF (placenta growth factor). A viral gene encodes VEGF-E	VEGFR family There are three RTKs that bind with VEGFs (VEGFR-1, −2, and − 3). VEGFs also binds to receptor neuropilins	Formation and maintenance of the vasculature, including de novo establishment of the circulatory system in embryos and sprouting of existing blood vessels
Angiopoietin family There are four angiopoietin proteins (1 through 4).	TIE family Angiopoietin proteins 1 through 4 serve as ligands of Tie-2 receptors. TIE-1 heterodimerizes with TIE-2	Crucial for vessel stabilization
Stem cell factor (SCF or KIT-ligand) Due to mRNA splicing, there are soluble and membrane forms of SCF	c-KIT/SCFR	Hematopoiesis, gametogenesis, and melanogenesis
Nerve growth factor (NGF) family There are four members: NGF, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3) and NT-4.	TRK family The family comprises three RTKs: TRK-A, -B, and -C NGF also binds the p75NTR which forms a heterodimer with TRK-A	The neurotrophins promote neurite outgrowth and neural cell survival. The family is involved in synaptogenesis and synaptic transmission
Ephrins There are five ephrin A and three ephrin B ligands, all are membrane bound (insoluble)	EPH family receptors There are 14 RTK members: nine EphAs and five EphBs	Patterning the developing hindbrain, axon pathfinding, angiogenesis, and long-term potentiation Rhombomeres, axon pathfinding, and guiding neural crest cell migration

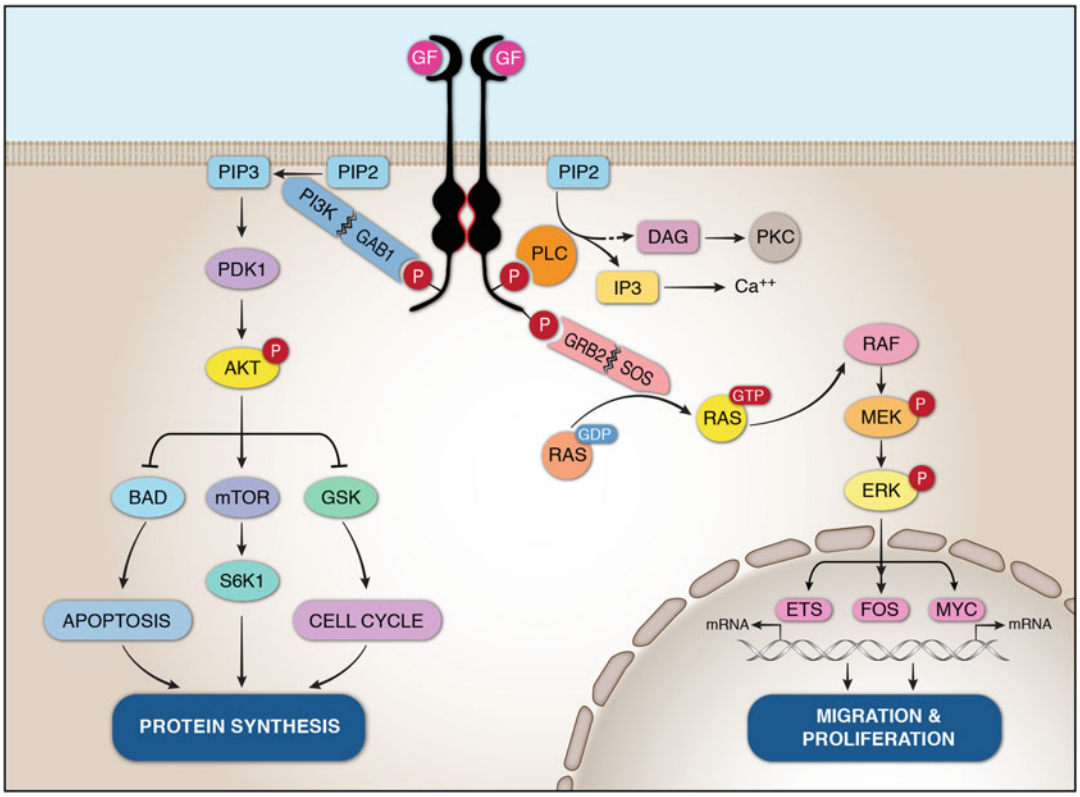
The tyrosine kinase domain is the most conserved and is absolutely required for receptor signaling. Mutation of a single lysine in the ATP (adenosine triphosphate) binding site, which destroys the ability of the receptor to phosphorylate tyrosine residues, completely inactivates biological function (Yarden and Ullrich 1988). The receptor itself is often the major tyrosine-phosphorylated species observed after stimulation with a ligand.

Formation of a signaling complex at the plasma membrane: Tyrosine phosphorylation modulates kinase activity and affects the ability of RTKs to interact with substrates. Conformational changes are relayed across the plasma membrane and orient the kinase domains of two receptors to promote auto- and transphosphorylation of key tyrosines within the kinase's activation loop (Kovacs et al. 2015). This shifts the loop in a manner that releases its autoinhibitory effect. Once activated, the kinase transfers phosphate groups to tyrosine residues of its own, as well as to nearby substrate proteins. Phosphorylated tyrosine residues of RTKs function as docking sites for a wide range of proteins. These proteins include phospholipase C (PLC-g), phosphatidylinositol 3′ kinase (PI3K), RAS guanosine triphosphatase (GTPase) activating protein (GAP), and SRC family tyrosine kinases (Pawson and Scott 1997). These molecules contain non-catalytic domains called SRC homology (SH) regions 2 and 3. SH2 domains bind preferentially to tyrosine-phosphorylated proteins while SH3 domains may promote binding to membranes or the cytoskeleton. Phosphatases like DEP1 and ubiquitin ligases (e.g., CBL) are recruited to the receptor either directly or through adaptor proteins (e.g., SHC and GRB2) with multiple docking sites. Thus, a large multi-protein signaling complex is assembled at the membrane (see Fig. 1).

Phosphoinositol signals and AKT activation: Though the outcome of signaling events initiated by receptors within a family is distinct, some common themes have emerged. Activation of the phospholipid PI3K pathway may be achieved by binding of the regulatory p85 subunit to an activated RTK or through the activation of the small GTP-binding protein RAS. On activation, PI3K induces the formation of phosphatidylinositol (3,4,5)-phosphate (PIP_3), which serves as a docking site for proteins containing phospholipid-binding domains (e.g., PH domains), including protein kinase B and AKT (Luo et al. 2003). Recruitment of AKT to the membrane enables its phosphorylation on two stimulatory residues. PTEN and INPP4B are phosphatases that abolish AKT activation and act as tumor suppressors. AKT has a large number of substrates that regulate mainly survival and metabolism. One example is the proapoptotic protein BAD, which is inhibited following phosphorylation by AKT. BAD induces permeabilization of the mitochondrial membrane to enable the release of cytochrome C. The latter is involved in the generation of a protein complex known as the apoptosome, which cleaves pro-caspases to generate the active form of caspase-9.

Mitogen-activated protein kinase (MAPK) and other pathways: The ERK pathway is a multiple layer kinase cascade, in which the most distal MAPK elements are activated following tyrosine/threonine phosphorylation (Seger and Krebs 1995). In the ERK1/2 kinase pathway, the binding of a ligand to an RTK enables autophosphorylation and recruitment of adaptors like GRB2 and SHC. The adaptors mediate recruitment of a GTP/GDP exchange protein, SOS, which loads GTP onto RAS. Active, GTP-loaded RAS molecules stimulate RAF kinases, which instigates the cascade leading to MEK (MAPK kinase) and then to ERK activation. Active ERK molecules translocate to the nucleus to stimulate multiple transcription programs essential for cell cycle progression and cell migration. The phospholipase C-gamma-protein kinase C (PKC) pathway is instigated on recruitment of PLC-gamma to ligand-bound receptors. The activated enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to form 2 second messengers, diacylglycerol (DAG), and inositol 1,4,5-triphosphate (IP_3). The binding of IP_3 to receptors on the membrane of the endoplasmic reticulum leads to Ca^{2+} release. Free cytosolic calcium ions, together with DAG, activate members of the protein kinase C (PKC) family, resulting in the phosphorylation of various effector proteins. In addition, cytosolic Ca^{2+} activates the calcium/calmodulin-dependent protein kinases and specific phosphatases.

Signal downregulation by means of endocytosis: Concomitant with the activation of



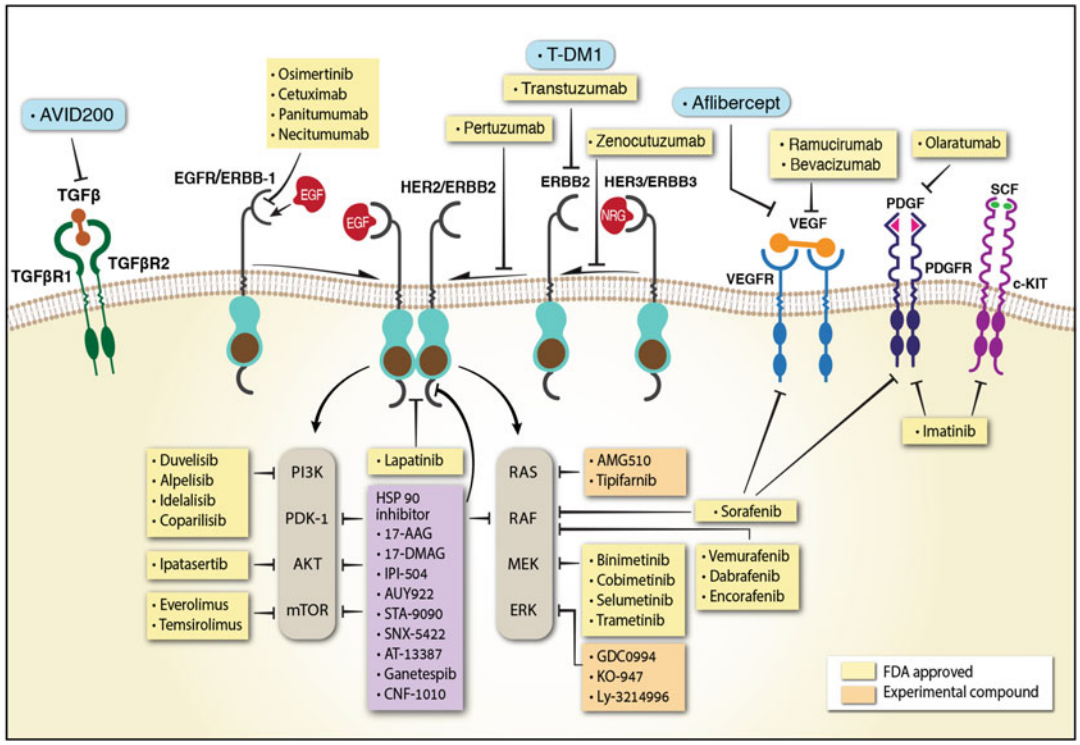
Growth Factors, Fig. 1 Growth factor-induced signal transduction pathways. The binding of growth factors (GFs) to their cognate receptors initiates the activation of intracellular signaling pathways, culminating in the nucleus. Demonstrated here are three of the best-understood pathways: (i) the pathway involving RAS and the MAPK cascade, which activates multiple transcription factors (e.g., ETS, FOS, and MYC) and regulates cell proliferation and migration; (ii) the PI3K/AKT pathway, which modulates the activity of enzymes involved in the control of apoptosis (e.g., BAD) and metabolism (e.g., mTOR, GSK); and (iii) PLC-gamma, through intrinsic SH2 domains, binds with specific phosphotyrosines located in the C-terminal tails of specific RTKs. This facilitates efficient tyrosine transphosphorylation by the RTK. Both tyrosine phosphorylation and membrane translocation of PLC-gamma, through binding of its PH domain to PtdIns (3,4,5)P3, are essential for complete activation of the catalytic activity. Note that several signaling pathways are activated by binding of non-catalytic adaptor molecules (e.g., GRB2 and GAB1), which bind specific phosphorylated tyrosine residues of the receptor, thereby stimulating the first enzyme in a linear cascade of enzymatic reactions

signaling pathways, multiple mechanisms are set in motion to regulate and eventually attenuate signaling by activated growth factor receptors. As in the case of EGFR and other RTKs, receptor internalization coupled to degradation is considered the most immediate and effective process that attenuates signaling by removing receptors from the cell surface and targeting them for degradation in lysosomes (Mosesson et al. 2008). Phosphorylated receptors are tagged by conjugation of a 76-amino-acid-long molecule called ubiquitin; tagging is performed by a three-step enzymatic pathway culminating in a ubiquitin ligase called CBL, which recognizes both the substrate receptor and the ubiquitin donor, an E2 ubiquitin-conjugating enzyme. A series of ubiquitin-binding endocytic adaptors subsequently recognize the ubiquitylated receptor and target it to regions of the plasma membrane called clathrin-coated pits. The latter invaginate to form a clathrin-coated neck that progressively moves inward, eventually generating a coated vesicle. This tiny vesicle shuttles to a vesicular compartment called the early endosome. Through acidification of the endosome's lumen, some ligand-receptor complexes are dissociated, leading to recycling to the plasma membrane,

while other complexes remain intact. The latter are handed to the subsequent sorting compartment, the multivesicular body, where hydrolases are accumulated. It is in this compartment and the subsequent one, the lysosome, where degradation of the receptor is completed. Receptor activation also causes the recruitment of a number of other attenuators, such as tyrosine phosphatases, like the density-enhanced phosphatase-1 (DEP1), which dephosphorylates EGFR, as well as other RTKs, GTPase-activating enzymes (e.g., GAP, which activates Ras' GTPase activity), and other negative regulators. These proteins inhibit the signaling cascade at multiple levels, thus realizing negative feedback loops, which help tuning and regulating the effect of GFs.

Drugs Targeting Growth Factors and Downstream Signaling Pathways

Several of the most formidable human diseases are characterized by aberrant signaling downstream of GFs and their cognate receptors, and thus these are constantly being pursued as targets for pharmacological intervention (Fig. 2). The ability of growth factors to stimulate cell proliferation and survival, for example, may help



Growth Factors, Fig. 2 Drugs blocking growth factor-induced pathways of signal transduction. The signaling cascades set in motion by growth factors can be blocked by pharmacological interventions at different levels. Monoclonal antibodies can specifically bind to growth factors (e.g., bevacizumab) or to the extracellular domain of their cognate receptors (e.g., cetuximab). Tyrosine kinase inhibitors, on the other hand, are small molecules that traverse the plasma membrane and block kinase domain activation. Some of them are specific to certain RTKs, like osimertinib and erlotinib, which are EGFR blockers, while others inhibit the activity of multiple kinases (e.g., lapatinib or sorafenib). Several drugs block enzymes downstream of the receptors, such as drugs targeting individual effectors of the MAPK pathway or the PI3K/AKT pathway. An additional site for pharmacological intervention is the chaperone protein HSP90, which is essential for the stabilization of many components of various signaling cascades (e.g., HER2, RAF1, PDK1, and AKT). Inhibition of HSP90 enhances degradation of its client proteins, leading to downregulation of the respective signals. See Table 2 for a complete list of drugs that have already been approved for clinical use

Growth Factors, Table 2 List of clinically approved antibodies and small-molecule kinase inhibitors targeting growth factor signaling. Note that names ending with "mab" refer to antibodies, whereas names ending with "nib" refer to kinase inhibitors. Drugs are arranged according to the timing of their first approval for clinical application. Also listed are respective major clinical indications. The abbreviations used are epidermal growth factor (EGF), transforming growth factor-b (TGF-b), neuregulin (NRG), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), vascular endothelial growth factor (VEGF), nerve growth factor (NGF), rearranged during transfection (RET), tyrosine kinase receptor in endothelial cells (TIE), mammalian target of rapamycin (mTOR), anaplastic lymphoma kinase (ALK), breast tumor kinase (BRK), ephrins (EPH), breakpoint cluster region- Abelson (BCR-ABL), cyclin-dependent kinase (CDK), insulin-like growth factor (IGF), Janus kinase (JAK), mitogen-activated protein kinases (MAPK), extracellular signal-regulated kinase (MEK/MAPK), tropomyosin receptor kinase (TRK), tyrosine kinase with immunoglobulin and EGF homology domains (Tie2), insulin receptor precursor (InsR), hepatocyte growth factor receptor (HGFR or c-MET)

Protein target	Name (trade name)	Year of first approval	Company	Condition	Remarks
PDGF	Becaplermin (Regranex)	1997	Ortho-McNeil Pharmaceutical	Treatment of lower extremity diabetic neuropathic ulcers	Available as a topical gel
HER2	Trastuzumab (Herceptin and Biosimilars)	1998	Genentech	Breast cancer, gastric and gastroesophageal junction cancer	Indicated in combination with chemotherapy for patients with tumors overexpressing HER2
PDGFRA, ABL, c-KIT	Imatinib mesylate (Gleevec)	2001	Novartis	Philadelphia chromosome positive chronic myelogenous leukemia (Ph+ CML), Ph+ acute lymphoblastic leukemia (Ph+ ALL), GIST, chronic eosinophilic leukemia (CEL)	
EGFR	Gefitinib (Iressa)	2003	AstraZeneca	Non-small cell lung cancer (NSCLC)	Resistance conferred by the T790M mutation and additional mechanisms
EGFR	Erlotinib hydrochloride (Tarceva)	2004	OSI	NSCLC and pancreatic cancer	Resistance conferred by the T790M mutation and additional mechanisms
EGFR	Cetuximab (Erbitux)	2004	ImClone	Colorectal cancer, squamous cell cancer of head and neck and small cell lung cancer (SCLC)	Applied in combination with chemotherapy. KRAS mutations confer resistance of colorectal tumors
VEGF-A	Bevacizumab (Avastin and biosimilars)	2004	Genentech	Multiple cancers: Ovarian and cervical cancer, colon, rectum, lung, glioblastoma, and renal cancer	Administered in combination with chemotherapy

(continued)

Growth Factors, Table 2 (continued)

Protein target	Name (trade name)	Year of first approval	Company	Condition	Remarks
VEGFR1/2/3, PDGFR, RAF, KIT, FLT3, and RET	Sorafenib (Nexavar)	2005	Bayer	Kidney cancer and certain type of thyroid cancer	EMT might confer resistance
EGFR	Panitumumab (Vectibix)	2006	Amgen	Colorectal cancer with wild-type KRAS	Applied in combination with chemotherapy. KRAS mutations confer resistance of colorectal tumors
PDGFR, VEGFR1/2/3, KIT, FLT3, CSF-1R, and RET	Sunitinib (Sutent)	2006	Pfizer	Renal cell cancer, gastrointestinal stromal tumors (GIST), pancreatic and neuroendocrine tumors	KIT mutations might confer resistance
VEGF-A	Lucentis (ranibizumab)	2006	Genentech	Macular degeneration	
EGFR and HER2	Lapatinib ditosylate (Tykerb)	2007	GSK	Canakinumab (Ilaris)	ER activation might confer resistance
VEGFR1/2/3, PDGFR, FGFR1/3, KIT, and FMS	Pazopanib (Votrient)	2009	GSK	Renal cell cancer, soft tissue sarcoma, gastrointestinal stromal tumors	
mTOR	Everolimus (Afinitor)	2009	Novartis	Some pancreatic cancers, kidney cancer, HER2+ breast cancer and neuroendocrine tumors	
ALK, MET, and ROS	Crizotinib (Xalkori)	2011	Pfizer	ALK-positive NSCLC	ALK mutations might confer resistance
VEGFRs, EGFR, RET, BRK, TIE2, EphRs, and SRC	Vandetanib (Caprelsa)	2011	IPR Pharms	Medullary thyroid cancer	
BRAF	Vemurafenib (Zelboraf)	2011	Daiichi-Sankyo and Genentech	Certain types of blood cancer and melanoma	
JAK	Ruxolitinib (Jakafi)	2011	Novartis	Myelofibrosis	
HER2	Pertuzumab (Perjeta)	2012	Genentech	Breast cancer	Inhibits heterodimer formation by HER2.Applied in combination with trastuzumab and chemotherapy
VEGF-A, VEGF-B, and PGF	Aflibercept (Zaltrap)	2012	Regeneron	Colorectal cancer	A recombinant decoy, combined with chemotherapy

enhancing tissue healing and reduce organ damage in diseases of different origins. Recombinant forms of growth factors are currently being tested for potential usefulness in a variety of clinical settings, such as hepatitis, cirrhosis, renal fibrosis, multiple sclerosis, amyotrophic lateral sclerosis, and myocardial ischemia. Recombinant PDGF, for example, is currently employed as a drug (becaplermin) to facilitate the healing of diabetic ulcers (see Table 2). GFs may also be used for the production of artificial tissues, e.g., for skin replacements and bone and connective tissue reconstruction. In contrast, blocking the actions of specific GFs can help reduce uncontrolled cell proliferation, a characteristic of cancer (and also of diabetic retinopathy and vascular stenosis). Drugs in clinical use include small-molecule tyrosine kinase inhibitors (TKIs) and anti-receptor or anti-ligand monoclonal antibodies (mAbs). TKIs penetrate the plasma membrane and interact with the ATP-binding site of the receptor, thus preventing kinase activation. The EGFR's kinase inhibitors gefitinib and erlotinib, for instance, are both approved for a subset of non-small cell lung cancer (NSCLC) patients. Another example is the broad-spectrum inhibitor, sorafenib, targeting both VEGFR and PDGFR, as well as the RAF kinase, which has been approved for the treatment of renal cancer. In contrast to TKIs, anti-receptor monoclonal antibodies (mAbs) bind to the extracellular domain of the receptor and exert inhibition of cell proliferation by several mechanisms (Carvalho et al. 2016). Trastuzumab, which targets HER2/ERBB2, is approved for the treatment of metastasizing breast cancer and is thought to stimulate an immune response against the tumor and to induce receptor internalization. Examples of other mAbs include cetuximab (approved for colorectal and head and neck cancers) and panitumumab (approved for colorectal cancer), which are directed against EGFR and may act also by inhibiting ligand binding. Pertuzumab is another antibody targeting HER2/ERBB2 by inhibiting receptor dimerization. Some of the mAbs are directed against the ligands, rather than the receptors. For example, bevacizumab targets VEGF and inhibits angiogenesis. This mAb has been approved for the treatment of multiple cancers, as well as macular degeneration (Ferrara et al. 2004). Drugs that inhibit the signaling cascades downstream of the receptor at different levels (e.g., inhibitors of the MAPK or the PI3K/AKT pathways) have also been developed. Likewise, chaperone proteins like HSP90, which are essential for the stability and function of many receptors, effectors, and transcription factors, can also be targeted by specific inhibitors (e.g., 17-AAG, 17-DMGA), thus enhancing the degradation of their client proteins. The successful clinical application of RTK-based therapeutics in the last two decades has instigated further research aimed at generating the next generation drugs. Thus, antisense RNAs and aptamers and decoy receptors are being tested for their ability to reduce GF signaling.

Definition

Guanylyl cyclases (GC) are a family of enzymes (EC 4.6.1.2) that catalyze the formation of the

second messenger cyclic GMP (cGMP) from guanosine triphosphate (GTP). GCs are subdivided into NO-sensitive GCs and transmembrane GCs stimulated by peptide hormones (Koesling et al. 2016; Kuhn 2016).

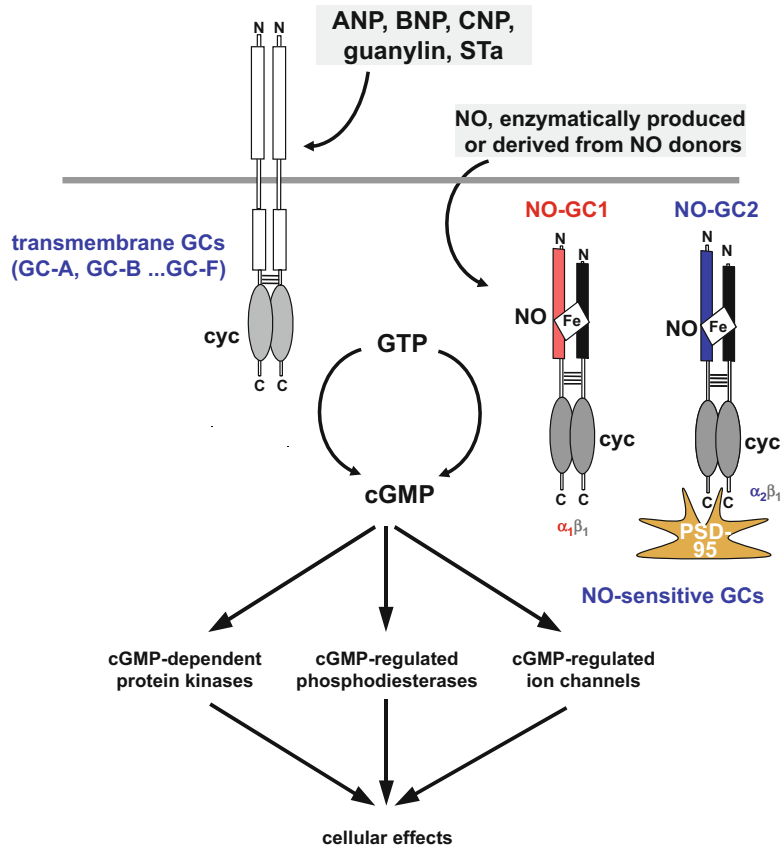
Basic Characteristics

Activation of GCs leads to an increase of the intracellular messenger molecule cGMP. Three different groups of cGMP effector molecules mediate the transduction of the cGMP-signal: cGMP-activated protein kinases, cGMP-regulated phosphodiesterases, and cGMP-gated ion channels, see Fig. 1. The cGMP increases are terminated by cGMP-degrading phosphodiesterases that reduce cGMP levels. cGMP executes established functions in smooth muscle relaxation, inhibition of platelet aggregation, retinal phototransduction, and alteration of synaptic transmission. Moreover, cGMP is involved in regulation of the water/electrolyte balance as well as in bone metabolism, exhibits antifibrotic properties, has been proposed to participate in cell growth/proliferation, and modifies the renin/angiotensin and the immune system.

According to their structural features and their regulation, GCs are grouped into NO-sensitive and transmembrane guanylyl cyclases.

NO-Sensitive GCs

NO-sensitive GCs (NO-GCs) represent the most important effectors for the signaling molecule NO, which is synthesized by NO synthases in a Ca^{2+}-dependent manner. NO-GCs contain a prosthetic heme group, acting as the binding site for NO. Formation of the NO–heme complex leads to a conformational change, resulting in an increase of up to 200-fold in catalytic activity of the enzymes (Koesling et al. 2016). The NO-releasing organic nitrates (see below)



Guanylyl Cyclase, Fig. 1 cGMP-signaling. Shown are the two groups of cGMP-forming guanylyl cyclases (transmembrane and NO-sensitive GCs) and the three effectors, which mediate the cGMP effects (see text for further explanation). *ANP* A-type natriuretic peptide, *BNP* B-type natriuretic peptide, *CNP* C-type natriuretic peptide, *Sta* heat-stable enterotoxin of *Escherichia coli, PSD-95* postsynaptic density protein 95

commonly used in the therapy of coronary heart disease exert their effects via the stimulation of these enzymes.

NO-GCs consist of two subunits, α and β, and two isoforms of the enzyme have been identified: the ubiquitous *NO-GC1* isoform ($\alpha_1\beta_1$) and the less broadly distributed *NO-GC2* isoform ($\alpha_2\beta_1$). Overall, the NO-GC subunits can be divided into four domains: the N-terminal domain, a Per/Arnt/Sim (PAS)-like domain, a coiled-coil domain, and a C-terminal catalytic domain (Koesling et al. 2016). In the N-terminal domain, the homology between the α_1 and α_2 subunit is quite low; the respective region in the β_1 subunit is responsible for heme binding and shares homology to the so-called HNOX (Heme Nitric Oxide/OXygen binding) domains. The cyclase catalytic domains are conserved among the subunits, in the transmembrane GCs as well as in the adenylyl cyclases (see below). The structure of NO-GC under stimulated and nonstimulated conditions has been elucidated and suggests a model of activation, which requires a bidirectional flow of information between the heme containing sensor domain and the catalytic module (Kang et al. 2019).

Both NO-GC isoforms show indistinguishable regulatory properties but may well differ in subcellular distribution as the α_2 subunit of *NO-GC2* is able to interact with PDZ domains and has been shown to be associated with the postsynaptic adapter protein PDS95.

NO-GCs occur in relatively high concentration in vascular smooth muscle cells and platelets as well as in lung, kidney, and brain. The NO-induced increase in cGMP causes smooth muscle relaxation and inhibition of platelet aggregation. Aside from the cardiovascular system, the NO/cGMP cascade has an important function in the nervous system, where it participates in synaptic plasticity, i.e., the use-dependent change in efficiency of synaptic transmission.

The phenotypes of knockout mice deficient in the β_1 or either one of the α subunits of NO-GC support and expand our current understanding of NO/cGMP signaling. The complete NO-GC knock out mice ($\beta_1^{-/-}$), which are completely devoid of NO-GC, show a greatly reduced life expectancy and die of fatal gastrointestinal symptoms. In these mice, NO-induced relaxation is totally abolished as is NO-induced inhibition of platelet aggregation. The mice show a pronounced increase in blood pressure underlining the important role of NO in blood pressure regulation.

The *NO-GC1* ($\alpha_1^{-/-}$)- or *NO-GC2* ($\alpha_2^{-/-}$)-deficient mice with a lack of the respective isoform allow to study the individual role of the GC isoforms (Koesling et al. 2016). Concerning distribution tissues, the isoforms occur in brain in similar amounts; in all other tissues tested, *NO-GC1* represents the major isoform. In aortic smooth muscle cells, *NO-GC2*, representing only 6% of the total GC content in WT, is sufficient to induce complete relaxation albeit with a reduced potency of NO. The results show that in smooth muscle cells, (I) *NO-GC2* can functionally substitute for *NO-GC1* and that (II) a minor cGMP increase induces relaxation. Studies on synaptic plasticity in the visual cortex and hippocampus revealed an involvement of both GC isoforms in long-term potentiation (LTP) suggesting the occurrence of two NO/cGMP-mediated signals that have to work in concert for the induction of LTP. Further studies with the isoform-specific KOs revealed a presynaptic and postsynaptic localization of *NO-GC1* and *NO-GC2,* respectively, in hippocampal glutamatergic neurons. Facilitation of the neurotransmitter release and an increase of postsynaptic responsiveness were assigned to *NO-GC1* and *NO-GC2*, respectively; in both cases, HCN channels were identified as cGMP targets.

Besides NO, other NO-GC-activating substances have been reported: Carbon monoxide (CO) known to bind to heme groups with high affinity activates the enzyme only marginally (three- to fivefold). YC-1 ([3-(5′-hydroxymethyl-2′-furyl)-1-benzyl indazole]) represents the prototype of new GC-stimulating compounds, the NO-sensitizers (the so-called "GC stimulators"). YC-1 causes a tenfold activation of NO-GCs. Pharmacologically more interesting, YC-1 increases GC's sensitivity toward NO and CO suggesting potential beneficial effects of YC-1 by increasing the responsiveness of NO-GCs toward physiologically occurring NO. Thus,

YC-1 exemplifies a new class of drugs with potential use in the treatment of cardiovascular diseases and YC-1-related compounds with a higher affinity for NO-GCs have been developed (see below; "Drugs Acting on NO-Sensitive GCs"). In addition to these NO-sensitizers, a second class of compounds, the NO-heme-mimetics (the so-called "GC activators") that activate NO-GCs independently of NO by replacing and mimicking the conformation of the activated NO–heme group (cinaciguat, ataciguat) have been identified. The high potency of these NO-heme-mimetics in vivo led to the postulate of a highly responsive oxidized state of NO-GCs occurring under pathophysiological situations such as oxidative stress.

Transmembrane GCs

Transmembrane GCs belong to the group of receptor-linked enzymes with one membrane-spanning region that form homodimers (Kuhn 2016). All of these GCs share a characteristic structural arrangement of an extracellular ligand-binding domain coupled to a conserved intracellular region comprising a kinase homology domain and the cyclase catalytic domain at the C-terminus. As the extracellular ligand-binding domains differ among the isoforms, the transmembrane GCs are activated by different peptide hormones and accordingly, the GCs activated by natriuretic peptides are also referred to as natriuretic peptide receptors (NPRs). The guanylyl cyclase A (*GC-A, NPR-A*) isoform acts as the receptor for the natriuretic peptides ANP and BNP, two primarily cardiac hormones that are involved in the regulation of blood pressure as well as in water and electrolyte balance. ANP- and BNP-induced cGMP increases mediate physiological effects such as smooth muscle relaxation, modulation of endothelial permeability, inhibition of aldosterone secretion in the adrenal cortex, and salt and water excretion in the kidney. During chronic pressure or volume overload, the increased ANP and BNP levels exert local antiproliferative and antifibrotic effects in cardiac cells.

Another GC isoform, *GC-B* (or *NPR-B*), present in fibroblasts, chondrocytes, brain, lung, vascular smooth muscle, and uterus displays the highest affinity for the C-type natriuretic peptide (CNP). CNP is, e.g., produced by vascular endothelial cells and in an autocrine/paracrine fashion exhibits a fundamental role in the regulation of blood flow (Moyes and Hobbs 2019). CNP attenuates cardiac fibrosis and stimulates growth of long bones. Another form of NPRs, *NPR-C*, lacks the GC catalytic domain and contains only a very short intracellular C-terminal region. This receptor has been regarded as a clearance receptor involved in the internalization and degradation of the natriuretic peptides. However, a recently identified role for CNP in angiogenesis and vascular remodeling was found to proceed via *NPR-C*/Gi coupling (Bubb et al. 2019). It will be interesting to see whether CNP-induced *NPR-C* activation represents a general principle and acts as the underlying mechanism of other biological effects as well.

In contrast to other GC isoforms with a broader distribution, GC-C (guanylin receptor) is mainly restricted to the intestinal epithelium. GC-C is activated by the two endogenous peptides, guanylin and uroguanylin, secreted by the epithelium of the intestine, and the heat-stable enterotoxins of bacterial origin causing diarrhea (Rappaport and Waldman 2018). Activation of GC-C causes phosphorylation of the cystic fibrosis transmembrane regulator (CFTR) via the cGMP-activated protein kinases II (PKGII). This leads to the transepithelial secretion of chloride and bicarbonate ions, inhibition of sodium absorption by the sodium/hydrogen exchanger 3 and as a result to a net flux of ions and water into the lumen. In addition to the regulation of fluid secretion, recent research indicates participation of the GC-C/cGMP in various additional aspects of intestinal homeostasis and functions (epithelial proliferation, responses to DNA damage, intestinal barrier integrity, microbiome composition, epithelial-mesenchymal cross-talk, and colorectal cancer prevention) (Rappaport and Waldman 2018). Because of this wide variety of tasks, dysregulation of the signaling cascade has been implicated in the pathogenesis of intestinal motility disorders, in inflammatory bowel disease, and colorectal cancer. Accordingly, GC-C ligands have been developed to allow reconstitution or

enhancement of cGMP signals (see below; "GC-C Ligands").

Further, GC isoforms GC-D (pseudogene in humans), GC-E, and GC-F are restricted to sensory cells. GC-D is only expressed in a subset of olfactory neurons; GC-E and GC-F are exclusively found in the retina. Regulation of these GC isoforms by proteins that interact with the intracellular cGMP-forming domain has been demonstrated and the cGMP-forming activity does not appear to be controlled by the receptor domain.

Drugs

Drugs Acting on NO-Sensitive GCs

NO-Releasing Compounds

Clinically, the organic nitrates (glyceryl trinitrate, isosorbide dinitrate, isosorbide mononitrate, pentaerythrityltetranitrate) are typically used in the treatment of coronary heart disease. They exert their main therapeutic effect by activating NO-GC via NO (Münzel et al. 2014). Altogether, nitrate-induced vasodilation is more pronounced in veins than in arteries; the marked venorelaxation reduces central venous pressure, which, in turn, reduces pre- and cardiac workload thereby relieving symptoms of acute angina pectoris. In addition, the nitrates dilate the coronary arteries and arterioles.

In general, nitrates are nowadays preferentially used to treat or to prevent acute episodes of angina, for this purpose, sublingual and spray formulations of glyceryl trinitrate are preferred to avoid a pronounced first-pass metabolism. This way, a therapeutic blood level of glyceryl trinitrate is rapidly achieved and the antianginal effect occurs within minutes. However, the drug's duration is very short (15–30 min). Similarly, sublingual application of isosorbide dinitrate can be used that has a slightly delayed onset of activity but its duration ($\leq$1 h) is more sustained.

In the past, long-acting nitrates have been used chronically to provide long-term prophylaxis against episodes of angina in patients with frequent angina attacks. Due to lack of positive results on survival in clinical studies, the use of long-acting nitrates has dropped markedly. Long-acting nitrate therapy is only considered if initial therapy with a beta-blocker or a non-dihydropyridine calcium channel blocker is contraindicated, poorly tolerated, or insufficient in controlling angina symptoms (Knuuti et al. 2019). For a long-lasting drug effect, long-acting nitrate formulations (glyceryl trinitrate, isosorbide dinitrate, isosorbide mononitrate, or pentaerythrityltetranitrate) are applied orally at dosages sufficient to provide effective plasma levels after first-pass degradation. Another option to administer glyceryl trinitrate takes advantage of transdermal absorption from slow release preparations.

None of the nitrates releases NO spontaneously, instead they undergo a complex enzymatic bioactivation that either yields NO or bioactive S-nitrosothiols. Two main pathways of biotransformation have been postulated for glyceryl trinitrate/pentaerythrityltetranitrate and isosorbide dinitrate/isosorbide mononitrate, respectively (Münzel et al. 2014). An activity decline of the metabolizing enzymes contributes to the phenomena of nitrate tolerance (see below) but is without a major therapeutically relevant impact.

The major problem of long-term nitrate-based prophylaxis of angina is the loss of drug efficacy. The continuous application of nitrates for more than a few hours leads to the development of nitrate tolerance. Conceivably, tolerance is not caused by a single event but can be attributed to several factors, e.g., it occurs at the level of the drug-metabolizing enzymes and is partially due to an increase in the production of NO-scavenging superoxide ion. In addition, higher cGMP levels have been shown to be counteracted by cGMP-induced activation of phosphodiesterase 5 appearing as desensitization of the NO/cGMP signaling pathway. Moreover, counter-regulatory mechanisms like an increase of sympathetic tone and a rise in activity of the renin/angiotensin system are likely to contribute to the development of tolerance. However, since the marked attenuation of the nitrate effect is rapidly reversible upon discontinuation of the drug, development of tolerance can be controlled by allowing a "nitrate-free" period of about 10–14 h (usually at night) within 24 h.

Molsidomine represents another option for a long-term NO-releasing compound. The former notion that this compound does not induce tolerance and therefore should be used in the "nitrate-free" interval has been left. Molsidomine features a similar pharmacological profile as the organic nitrates. As a pro-drug, it is bioactivated in the liver and yields SIN-1 that decomposes spontaneously in a two-step reaction. In the first step, SIN-1 undergoes a base-catalyzed ring opening to form SIN-1A. This in turn yields NO and the stable metabolite SIN-1C. As the onset of action of molsidomine is comparatively slow, it is not used to acutely treat angina episodes.

The acute adverse effects of the organic nitrates as well as molsidomine are directly related to their therapeutic vasodilation as they can cause orthostatic hypotension, tachycardia, and throbbing headache.

NO-GC Sensitizers and NO-Heme-Mimetics (~ciguat)

The finding of new compounds that stimulate NO-GCs, the sensitizers and the NO-heme mimetics, led to the development of a variety of therapeutically applicable substances (Sandner 2018). After considerable testing of the compounds in animal disease models, they were subjected to clinical testing. In patients with pulmonary arterial hypertension and chronic thromboembolic pulmonary hypertension, the NO-sensitizer *Riociguat* improved hemodynamic parameters and exercise capacity in two phase III studies. Accordingly, *Riociguat* was the first NO-GC sensitizer to be approved for these two states of pulmonary hypertension. Several other NO-GC sensitizers are in preclinical and clinical testing for the treatment of various diseases like endothelial and vascular dysfunction, congestive heart failure, arterial hypertension, kidney diseases, fibrosis, inflammation, and others (Sandner 2018).

Compared to NO-GC sensitizers, the development of heme-mimetics yielded less compounds and their characterization is less advanced. In patients with acute decompensated heart failure, the heme-mimetic *Cinaciguat* improved cardiopulmonary hemodynamics. Yet, *Cinaciguat* caused hypotensive events and the study was terminated. So far, no NO-heme-mimentic is approved or in late stage of development (Sandner 2018).

Drugs Acting on Receptor-Linked GCs

GC-A Ligands

In theory, GC-A ligands, which increase the salt and water excretion, should reduce blood volume and lower blood pressure. *Nesiritide*, human recombinant BNP, was the first member of this new class of drugs approved for the intravenous treatment of acutely decompensated congestive heart failure. The outcome of the treatment with *Nesiritide* to relieve symptoms of decompensated heart failure was negative and the treatment is not recommended (O'Connor et al. 2011). In addition, the use of a synthetic analog of human ANP, *Carperitide*, in heart failure was associated with an increase of mortality (Matsue et al. 2015).

Elevating Natriuretic Peptides

Besides attempts to directly supply natriuretic hormones, e.g., the recombinant form of BNP, there are pharmacological approaches to elevate the concentration of natriuretic peptides by inhibiting their degradation by the neutral endopeptidase. Of special interest were dual-function inhibitors that do not only block the natriuretic peptide-degrading neutral endopeptidase to increase natriuretic peptides but also the angiotensin-converting enzyme (ACE), thereby causing an additional decrease of angiotensin II (Mangiafico et al. 2013). The best characterized of these also called "vasopeptidase inhibitors," omapatrilat, was shown to lower blood pressure in clinical trials; however, because of the occurrence of angioedema, omapatrilat has not been approved. By substituting the ACE inhibitory component (risk of angioedema) by an angiotensin receptor (AT_1) blocker lacking angioedema-inducing properties, the problem of a higher incidence of angioedema has been resolved. *Sacubitril* as inhibitor of the neutral endopeptidase (the so-called neprilysin) increases the concentration of natriuretic peptides, bradykinin and adrenomedullinin (McMurray et al.

2014). *Sacubitril* applied in a fixed combination with *Valsartan* (angiotensin receptor blocker) improved symptoms of heart failure when tested against (a sub-maximal dose of) *Enalapril* alone.

GC-C Ligands

Because of the importance of the GC-C/cGMP signaling cascade in various function of the gastrointestinal system, oral ligands for the receptor domain are of great interest (Rappaport and Waldman 2018). Available synthetic ligands are *Linaclotide,* an analog of the heat-stable enterotoxin, and *plecanatide*, an analog of the GC-C ligand uroguanylin. Both ligands are approved for the treatment of chronic idiopathic constipation and irritable bowel syndrome with constipation. Another uroguanylin analog, *Dolcanatide*, showed positive results when tested in rodent models of intestinal inflammation. If findings suggest that colorectal cancer arises in a microenvironment of GC-C ligand deficiency, oral GC-C ligands may emerge as a possibility to restore GC-C/cGMP signaling and prevent cancer.

HCN Channels

M. Biel, V. Hammelmann and S. Fenske
Center for Drug Research, Department of Pharmacy, Ludwig-Maximilians University, Munich, Germany

Definition

Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are activated by membrane hyperpolarization. Cyclic nucleotides enhance HCN channel activity by affecting the voltage dependence of channel activation (Biel et al. 2009).

Basic Characteristics

A cation current that slowly activates upon membrane hyperpolarization was detected in a variety of excitable cells including neurons and cardiac pacemaker cells in the late 1970s and early 1980s. This current is inwardly directed at the physiological resting membrane potentials of most cells and is carried by Na^+ and K^+ ions and, hence, depolarizes the cell membrane. Additionally, cyclic adenosine monophosphate (cAMP) was found to facilitate current activation in a direct, PKA-independent manner. Because of these unique biophysical properties, this current was termed funny current (I_f) in the heart or hyperpolarization-activated current (I_h) in the brain.

HCN channels represent the molecular correlate of the I_h/I_f current. Structurally, these channels belong to the large superfamily of pore-loop cation channels (Yu et al. 2005). In mammals, the HCN channel family comprises four members (HCN1–4) that share approximately 60% sequence identity to each other. When expressed in heterologous systems, all four HCN channel subtypes generate currents displaying the typical features of native I_h/I_f: (1) activation by membrane hyperpolarization, (2) permeation of Na^+ and K^+ with a permeability ratio P_{Na}/P_K of approximately 0.2, (3) a positive shift in voltage dependence of channel activation by direct binding of cAMP, and (4) channel blockade by extracellular Cs^+ concurred with relative insensitivity to Ba^{2+}. HCN1–4 mainly differ from each other with regard to their speed of activation and deactivation and the extent in which they are modulated by cAMP. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage dependence of activation to a more positive membrane potential and thereby facilitate voltage-dependent channel activation. Unlike HCN2 and HCN4, whose activation curves are shifted by approximately +15 mV by cAMP,

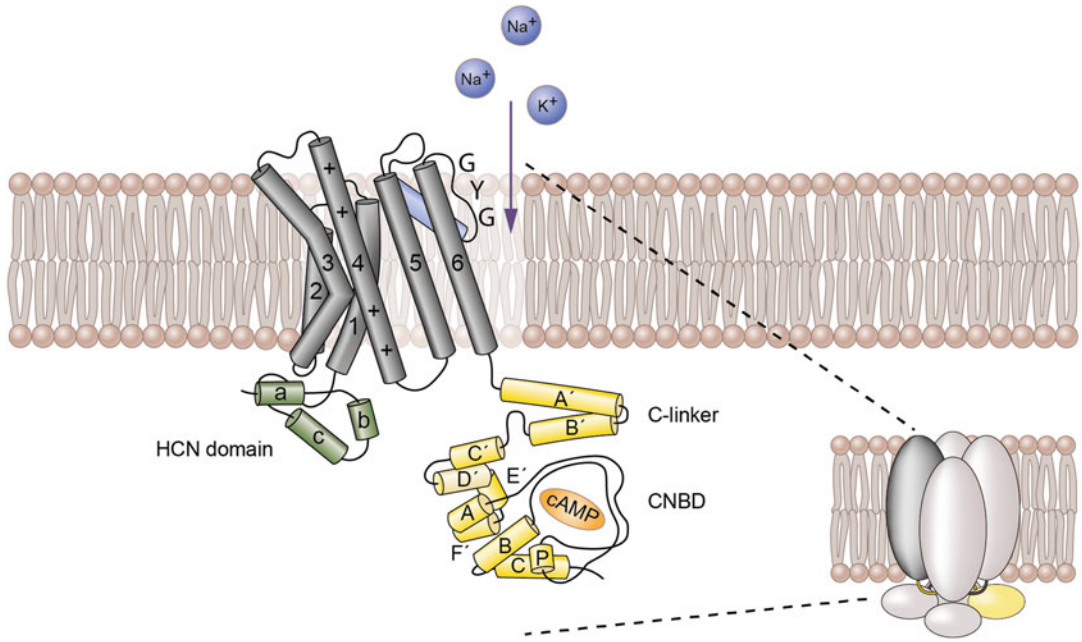
HCN1 and HCN3 are only weakly affected by cAMP.

HCN channels are protein complexes consisting of four subunits that are arranged around a centrally located pore. The proposed structure of a single subunit and a HCN channel tetramer is shown in Fig. 1. The ion channel core comprises six α-helical transmembrane segments (S1–S6) and the ion-conducting pore-loop between the S5 and S6 segment. The pore-loop contains a glycine-tyrosine-glycine (GYG) motif that is responsible for K^+ selectivity in several subtypes of potassium channels. Albeit in the presence of this motif, HCN channels also conduct Na^+. The voltage-sensing domain of HCN channels (S1–S4) contains a positively charged S4 helix containing nine regularly spaced arginine or lysine residues at every third position. Transition metal ion fluorescence resonance energy transfer (tmFRET) has shown that the S4 segment undergoes a substantial (~10 Å) downward movement in response to membrane hyperpolarization (Dai et al. 2019). The resulting conformational change in the channel protein is allosterically coupled by the channel domains to the opening of the ion-conducting pore. In the carboxy-terminus, HCN channels contain a cyclic nucleotide-binding domain (CNBD) that is highly conserved to CNBDs of CNG channels, cAMP-dependent protein kinases, cGMP-dependent protein kinases, and cAMP-guanine nucleotide exchange factors. The CNBD fulfills the role of an auto-inhibitory channel domain. In the absence of cAMP, the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel core and thereby shifts the activation curve to more hyperpolarizing

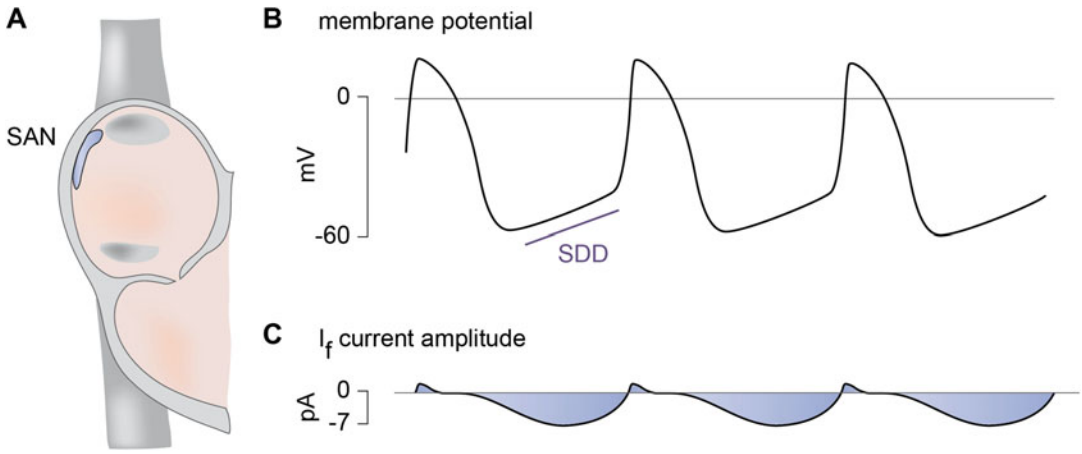


HCN Channels, Fig. 1 Topology of a single HCN channel subunit and an HCN channel tetramer (inset). The channel transmembrane domain (gray) consists of six α-helical segments (S1–S6). Helices S1–S4 serve as the voltage-sensing domain including the voltage sensor (S4) carrying charged arginine or lysine residues regularly spaced at every third position. Helices S5, S6, and the pore helix (purple) form the ion-conducting channel pore. The pore contains the glycine-tyrosine-glycine (GYG) motif that represents the selectivity filter. The C-terminus (yellow) contains the C-linker, composed of six α-helices (A′–F′), and the cyclic nucleotide-binding domain (CNBD), composed of three α-helices (A–C) and a β-roll between helix A and B. Cyclic adenosine monophosphate (cAMP) is bound to the CNBD. The amino-terminal HCN domain (green) consists of three α-helices (HCNa-HCNc). (Figure is courtesy of S. Fenske)

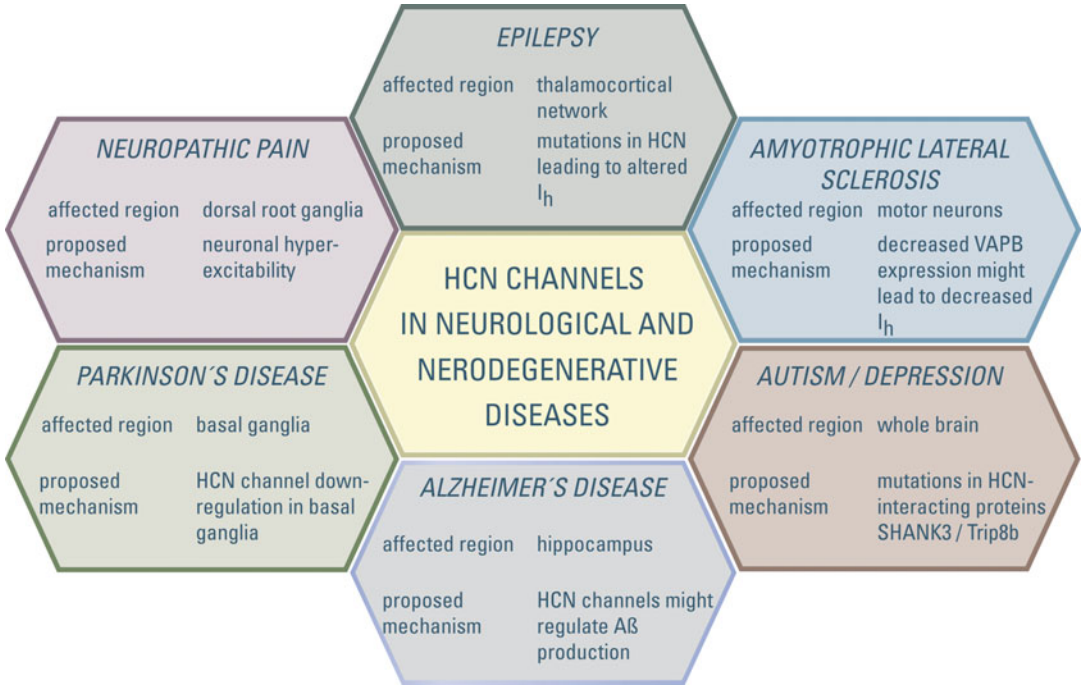
voltages. Binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal gating. Mutating two amino acids in the CNBD of the HCN channel (mHCN2: R591E, T592A) is sufficient to abolish cAMP-binding and cAMP-dependent modulation of I_h (Hammelmann et al. 2019). The amino-terminal HCN domain consists of three α-helices and is unique to HCN channels. Recent evidence suggests that this domain is involved in integration of ligand and voltage gating.

The best-characterized function of I_f is its contribution to the slow diastolic depolarization (SDD) phase in sinoatrial node (SAN) pacemaker cells of the heart (Fig. 2). I_f is activated during membrane hyperpolarization leading to an inward Na^+ current that slowly depolarizes the plasma membrane until it reaches the threshold to fire an action potential. The rhythmic action potentials generated in this way propagate through the conducting systems of the heart and trigger myocardial contraction. The autonomic regulation of I_f and its specific impact on the SDD are still a matter of debate. I_f has been suggested to play a pivotal role in heart rate (HR) acceleration mediated by the sympathetic nervous system, as I_f increases upon binding of cAMP to HCN channels. However, there is strong evidence from human channelopathies and genetically engineered mouse models that suggest HCN channels are not needed for principal heart rate acceleration by the sympathetic nervous system. HCN channels rather set the intrinsic heart rate, blunt the parasympathetic response of the sinoatrial node, and thereby protect the heart from destabilizing influences of the parasympathetic nervous system.

In the brain, I_h fulfills diverse functions: it modulates neuronal excitability as well as the rhythmic activity of spontaneously spiking neurons ("neuronal pacemaking"). Additionally, I_h is one of the critical quantities keeping the resting membrane potential stable and tuned as well as modulating dendritic integration and synaptic transmission. In the brain, HCN channels are tightly regulated by the cytoplasmic auxiliary subunit tetratricopeptide repeat-containing Rab8b-interacting protein (TRIP8b) that interacts with the CNBD and the last three amino acids of the C-terminus. Binding of TRIP8b to the HCN



HCN Channels, Fig. 2 **I_f contributes to the slow diastolic depolarization phase in sinoatrial node pacemaker cells.** (**a**) Scheme of the heart depicting the location of the sinoatrial node (SAN) in the right atrium. (**b**) Specialized pacemaker cells within the SAN generate spontaneous action potentials due to their ability to slowly depolarize (*SDD* slow diastolic depolarization) until the threshold to fire an AP is reached. (**c**) The I_f inward cation current, carried mainly by HCN4 channels, contributes to the SDD and, hence, is important for cardiac pacemaking. (Figure is courtesy of S. Fenske)



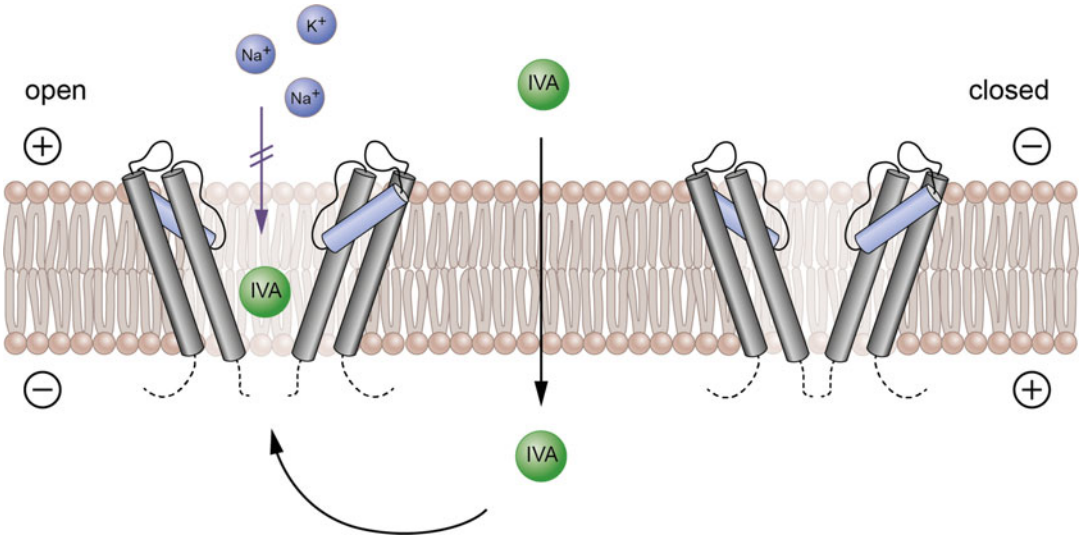
HCN Channels, Fig. 3 Potential use of HCN channel modulators in neurological diseases. HCN channels play a major role in diverse neurological diseases. The neurological disease, the corresponding affected region, and the proposed mechanisms are listed

channel increases cell surface protein expression and thereby the density of I_h. Recent studies showed that deletion of TRIP8b promotes antidepressant behavior in mice. I_h plays an important role in shaping firing properties of neuronal circuits that control motor function, sleep and wakefulness, learning and memory, and somatic sensation. In recent years, HCN channel dysfunction has become associated with pathophysiological states in a variety of neuronal pathways such as epilepsy, neuropathic pain, autism, and neurodegenerative disorders including Parkinson's disease, Alzheimer's disease, or amyotrophic lateral sclerosis (Fig. 3).

Drugs

The only blocker of HCN channel, which is currently used in clinics, is the drug ivabradine. It is approved for the treatment of stable, symptomatic chronic heart failure and stable angina pectoris in patients who are on maximally tolerated doses of beta-blockers or have a contraindication to beta-blocker use (e.g. asthma or obstructive pulmonary disease) (Prescribing Information CORLANOR® 2019).

Studies with heterologously expressed HCN channels indicate that ivabradine preferentially blocks the HCN4 channel, which is highly enriched in pacemaker cells of the SA node (Fig. 4). Ivabradine is able to diffuse into SAN cells where it has free access to the binding site in the inner vestibule of the HCN channel only when channels are in the open state. Hence, the inhibition is use-dependent, and the heart rate reduction with ivabradine is greater when the initial heart rate is high and lower when the initial heart rate is low. In clinical terms, this



HCN Channels, Fig. 4 Use-dependent block of HCN channels by ivabradine. Left, HCN channel in the open conformation at hyperpolarized membrane potential. The S5, S6, and pore helix of two HCN subunits are depicted representing the ion-conducting pore. For clarity transmembrane segments S1–S4, the C-terminus, and HCN domain were omitted. Ivabradine passively diffuses through the cell membrane, enters the open channel, binds within the inner cavity of the channel, and thereby blocks the ion-conducting pore. Right, HCN channel in the closed conformation at depolarized membrane potential. Ivabradine is not able to bind to the closed channel. Hence, it blocks HCN channels in a use-dependent way being more effective at higher heart rates, while its action declines during bradycardia. (Figure is courtesy of S. Fenske)

means that the risk of pronounced bradycardia with ivabradine is lower compared to beta-blockers and non-dihydropyridine calcium channel blockers. At recommended doses, heart rate reduction is approximately ten beats per minute.

Electrophysiological studies in SAN cells isolated from several species have demonstrated that, at therapeutic doses, ivabradine does not act on any other cardiac ion currents (I_K, $I_{Ca,L}$, or $I_{Ca,T}$). Therefore, ivabradine has no effect on cardiac repolarization, on heart muscle function (contraction and relaxation), and on heart and coronary artery adaptation to exercise. Since HCN channels are not expressed in vascular smooth muscle, there are no side effects on the peripheral resistance and blood pressure.

Following oral administration, peak plasma concentrations are reached in approximately 1 h under fasting conditions. Food intake extends absorption by approximately 1 h. Because of pronounced first-pass elimination in the gut and liver, the oral bioavailability is approximately 40%. Ivabradine is metabolized in the liver and intestines by CYP3A4-mediated oxidation. Hence, coadministration of drugs and substances that affect CYP3A4 metabolism (e.g. verapamil, diltiazem, amiodarone, grapefruit juice) should be avoided.

The most common adverse reactions of ivabradine are bradycardia and atrial fibrillation. In addition, ivabradine also blocks HCN channels in photoreceptors and other neurons in the retina. There, the I_h current is involved in the processing of retinal response to bright light stimuli. Via this mechanism of action ivabradine is thought to cause medication-induced perception of phosphenes. Phosphenes are luminous phenomena described as a transiently enhanced brightness in a limited area of the visual field, image

decomposition (stroboscopic or kaleidoscopic effects), or multiple images.

Over the last years, several attempts have been made to develop subtype-specific HCN channel blockers. For example, HCN4-specific blockers would be beneficial for cardiological indications, while HCN1/2-specific blockers would be useful to target neurological or psychiatric disorders. However, a major unsolved problem in the development of such blockers is the very high structural similarity of the four HCN channel types. Recent progress made in determining high-resolution structures of HCN channels may facilitate in the future the specific design of novel classes of compounds tailored to specific HCN channel types.

Definition

Chronic heart failure is defined by the presence of typical symptoms and clinical signs, including dyspnea, edema, and fatigue, which are related to reduced cardiac output or elevated filling pressure and caused by structural or functional alterations of the heart (Ponikowski et al. 2016). The diagnosis of heart failure relies on clinical signs and symptoms, echocardiography, and the detection of the biomarker NT-proBNP (see "Natriuretic Peptides"). Normal levels of NT-proBNP largely exclude heart failure. For the pathophysiological understanding and therapy of heart failure it is necessary to distinguish whether systolic or diastolic function is predominantly disturbed. According to left ventricular ejection fraction (LVEF) which is an echocardiographic measure of systolic function, heart failure is classified as heart failure with reduced ejection fraction (HFrEF, LVEF $<$ 40%), mid-range ejection fraction (HFmEF, LVEF 40–49%) or preserved ejection fraction (HFpEF, LVEF $\geq$ 50%) (Table 1) (Ponikowski et al. 2016). Today, HFpEF is considered to account for approximately 50% of heart failure cases (Gladden et al. 2018).

Heart Failure, Table 1 Classification of heart failure

	HFrEF	HFmEF	HFpEF
Criteria	Symptoms and signs		
	LVEF < 40%	LVEF 40–49%	LVEF ≥ 50%
	Elevated natriuretic peptides[a]	1. Elevated natriuretic peptides 2. Relevant structural heart disease or diastolic dysfunction	

HFrEF heart failure with reduced ejection fraction, *HFmEF* heart failure with mid-range ejection fraction, *HFpEF* heart failure with preserved ejection fraction, *LVEF* left ventricular ejection fraction

[a]Elevated natriuretic peptides are frequently observed but not required to diagnose HFrEF according to ESC guidelines (Ponikowski et al. 2016)

In addition, heart failure can be categorized by the New York Heart Association (NYHA) functional classification, ranging from patients showing structural changes without symptoms (NYHA class I) to patients with mild (II), moderate (III), or severe symptoms (IV).

Cases in which the myocardium is directly affected, for example, in ischemia or by gene mutations, are also referred to as cardiomyopathy. However, valve defects, arrhythmia, pericardial effusion and others may cause heart failure as well.

Basic Mechanisms

Heart Failure with Reduced Ejection Fraction

Arterial hypertension and coronary artery disease are the most common reasons for HFrEF (Burchfield et al. 2013). In hypertension, cardiac myocytes respond to increased afterload with hypertrophic growth. While this mechanism is in short term adaptive to cope with elevated wall stress, in long term myocyte growth leads to disproportional wall thickness, capillary rarefaction, and chronic ischemia (Oka et al. 2014). In coronary artery disease, acute or chronic ischemia due to hypoperfusion induces cardiac myocyte necrosis and scarring of the ventricular wall while the remaining cardiac myocytes have to compensate workload. In cases of persistently elevated wall stress, adaptive remodeling may turn into a decompensated state. Ischemia impairs contractile function, drives cardiac myocyte loss, and ends up in chamber dilatation. Increased chamber diameters in turn increase wall stress which again fuels cardiac myocyte hypertrophy and myocardial ischemia (Burchfield et al. 2013).

Cardiac myocyte hypertrophic growth is a complex process involving sarcomere reassembly, protein synthesis and degradation, electrical and metabolic remodeling (Schiattarella and Hill 2015; Burchfield et al. 2013). As part of this process cardiac myocytes undergo profound transcriptional reprogramming including re-expression of the fetal myosin heavy chain isoform and natriuretic peptides (Schiattarella and Hill 2015; Gilsbach et al. 2018). Altered expression and phosphorylation of calcium handling proteins impairs contractility and causes pro-arrhythmogenic action potential prolongation and calcium leakage (Burchfield et al. 2013).

Crosstalk between cardiac myocytes and non-myocytes is crucial for the cardiac remodeling process. Macrophages accumulate in failing heart tissue. Though resident macrophages mostly perish after acute myocardial infarction the pool is rapidly expanding by invasion of spleen-derived monocytes and local macrophage proliferation (Honold and Nahrendorf 2018). In the early phase after myocardial injury, macrophages promote infarct healing by pursuing phagocytosis and secretion of factors that stimulate fibroblast proliferation and activity and thereby facilitate stable scar development. However, sustained activation of fibroblasts in the chronic phase by profibrotic factors derived from macrophages, for example, tumor necrosis factor, leads to excessive collagen production, interstitial fibrosis, and myocardial stiffening (Honold and Nahrendorf 2018; Frangogiannis 2017).

Heart Failure with Preserved or Mid-Range Ejection Fraction

More than HFrEF, heart failure with preserved ejection fraction is considered as a syndrome including multiple other organ systems. HFpEF is frequently accompanied by other disorders including arterial hypertension, diabetes, renal dysfunction, pulmonary disease, sleep disorders, or anemia. Female, aged, and obese individuals are at higher risk to develop HFpEF (Mentz et al.

2014). Due to its multifaceted nature there is no standard experimental model for HFpEF (Valero-Munoz et al. 2017). However, it is a widely accepted concept that cardiac and non-cardiac comorbidities bidirectionally impact each other (Mentz et al. 2014; Gladden et al. 2018). Mechanistically, it has been proposed that multimorbidity promotes a systemic inflammatory state with high levels of pro-inflammatory cytokines, endothelial cell activation, and attraction of circulating immune cells to the heart tissue (Paulus and Tschope 2013). Endothelial cell activation is associated with increased reactive oxygen species production and reduced nitric oxide (NO) bioavailability. Lack of endothelial cell-derived NO impairs the production of cyclic guanosine monophosphate (cGMP) in cardiac myocytes and thereby promotes cardiac myocyte hypertrophy and diastolic dysfunction (Paulus and Tschope 2013).

Heart failure with mid-range ejection fraction has been newly introduced to the classification in the 2016 revision of the European Society of Cardiology guidelines to acknowledge the gap of evidence for patients with left ventricular ejection fraction of 40–49% (Ponikowski et al. 2016). It remains unclear whether these patients represent a separate collective or a transition area between HFpEF and HFrEF and what is the underlying pathophysiology.

Neuroendocrine Activation

Chronic heart failure is accompanied by an activation of the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS). In the initial phase, this is a compensatory mechanism to increase cardiac output and sustain organ perfusion. However, in long term sympathetic drive and RAAS activation promote adverse cardiac remodeling and failure.

Adrenergic activation increases vascular tone via activation of α_1-adrenergic receptors (Lymperopoulos et al. 2013). In the heart, adrenaline acts predominantly on β_1-adrenergic receptors to improve cardiac inotropy and relaxation through phosphorylation of L-type calcium channels, ryanodine receptors, and phospholamban. As a consequence, adrenergic stimulation increases energy and oxygen demand. Sustained adrenergic activation drives the risk for ventricular arrhythmia and leads to cardiac myocyte hypertrophy and interstitial fibrosis (Engelhardt et al. 2004; Lymperopoulos et al. 2013). Adrenergic stimulation, hypotension, and low sodium levels are key drivers for the release of renin from the kidney. Renin mediates the cleavage of circulating angiotensinogen to angiotensin I, which is then converted to angiotensin II by the angiotensin-converting enzyme (Lother et al. 2015). Angiotensin II mediates its effect on the heart and the vasculature through activation of angiotensin II type 1 receptors (AT_1). Angiotensin II is vasoconstrictory and increases blood pressure but independently promotes cardiac myocyte hypertrophy and fibroblast activation (Karnik et al. 2015; Hein et al. 1997). In addition to its direct effects of the heart, angiotensin II increases the production of aldosterone in the adrenal gland (Lother et al. 2015). While the physiological role of aldosterone is to regulate salt and water homeostasis in the kidney, it acts detrimentally on the cardiovascular system by activating the mineralocorticoid receptor in different cell types (Lother and Hein 2016; Cole and Young 2017).

Natriuretic Peptides

In response to increased wall stress the expression of natriuretic peptides type A and B (ANP, BNP) is increased in heart failure. Natriuretic peptide precursor B is secreted and the N-terminal fragment (NT-proBNP) is cleaved. While NT-proBNP can be used as a biomarker, active BNP binds to the extracellular domain of the natriuretic peptide receptor A, a membrane-bound guanylate cyclase, that facilitates the production of intracellular cGMP (Kuhn 2016). cGMP is vasodilatory and thereby increases renal blood flow and diuresis and lowering blood pressure. In the heart, cGMP signaling has beneficial effects by inhibiting hypertrophy, inflammation, and fibrosis (Kuhn 2016; Braunwald 2015). Together with other

peptides, including angiotensin II, natriuretic peptides are degraded by the endopeptidase neprilysin (Braunwald 2015).

Pharmacological Intervention

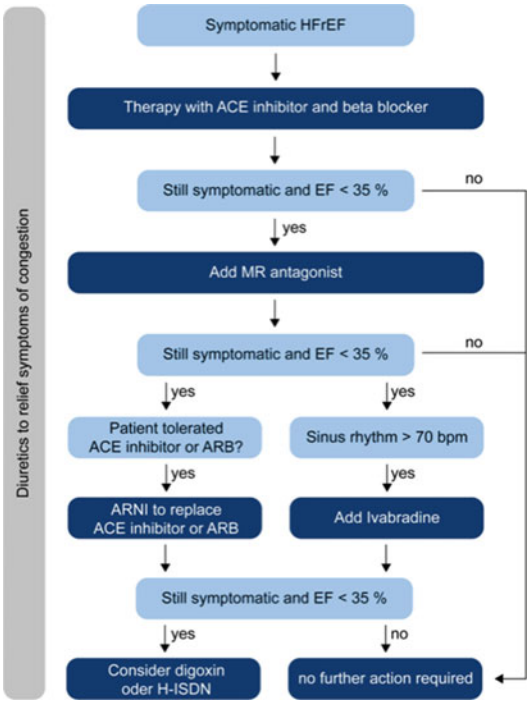
The current guideline recommends initial treatment of HFrEF patients to receive a diuretic (to relieve congestion), an ACE inhibitor (or angiotensin receptor blocker, ARB) plus a beta-blocker (BB). RAAS inhibitors, beta-blockers, and MRAs have been shown to improve survival of patients with HFrEF (Ponikowski et al. 2016). For HFpEF, no pharmacological treatment has shown to lower mortality of patients yet (Ponikowski et al. 2016) (Fig. 1).

Diuretics

In order to reduce congestive symptoms, diuretics are recommended in HFrEF. Diuresis lowers body fluid retention and thus reduces edema, breathlessness, and other related symptoms. The effects of diuretics of mortality of heart failure have not been studied in randomized clinical trials. If renal function is normal or medium impaired (eGFR > 30 mL/min/1.73 m^2), thiazide diuretics, for example, hydrochlorothiazide or chlorthalidone, may be used. With stronger impairment of renal function, loop diuretics (e.g., furosemide, torasemide) are recommended. Typical side effects are hypokalemia, hyponatremia, hypovolemia, renal dysfunction, hypotension, or hyperuricemia.

Beta Blockers (BB)

In HFrEF, the sympathetic system is activated to compensate for the loss of contractile function and elevated catecholamine levels are associated with increased mortality (Cohn et al. 1984). However, it took three decades until the protective effect of BB in HFrEF were shown in clinical trials in 1999 (CIBIS-II and MERIT-HF trials) (Ponikowski et al. 2016). Bisoprolol, carvedilol, metoprolol, and nebivolol were shown to reduce mortality and morbidity in HFrEF patients. This effect was even observed in the presence of an ACEI. Thus, ACEI and BB act synergistically and should be given together. It is essential that BB therapy starts with a very low dose to prevent acute decompensation of heart failure, and BB doses should be gradually up-titrated to the maximum recommended or tolerated dose. Contraindications for BB (second- or third-degree AV block, critical limb ischemia, asthma) should be observed. Typical side effects are bardykardia, hypotension, AV block, and bronchoconstriction.



Heart Failure, Fig. 1 Pharmacological treatment of heart failure with reduced ejection fraction. Treatment algorithm for patients with symptomatic heart failure with reduced ejection fraction according to present ESC guidelines. (Modified from Ponikowski et al. 2016). ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor; EF, ejection fraction; HFrEF, heart failure with reduced ejection fraction; H-ISDN, hydralazine-isosorbide dinitrate; MR, mineralocorticoid receptor

ACE Inhibitors

ACEI are the first drugs which have been proven in clinical trials to increase survival of HFrEF patients (enalapril; CONSENUS trial, 1987 (Ponikowski et al. 2016)). They improve heart

failure symptoms, increase exercise capacity, and lower the risk of hospitalization. ACEI prevent the generation of angiotensin II and thus reduce systemic effects of RAAS activation in HFrEF, lowering afterload, reducing blood pressure, and inhibiting cardiovascular remodeling and hypertrophy (Lother and Hein 2016). Several ACEI can be prescribed to treat HFrEF. Frequently used ACEI are ramipril, enalapril, and lisinopril. Contraindications which prevent use of ACEI are angioedema, bilateral renal artery stenosis, or pregnancy. Typical side effects are hyperkalemia, renal dysfunction, hypotension, and cough. If cough does not resolve, the patient may be switched to an ARB.

Angiotensin Receptor Blockers (ARB)

Several blockers of the G-protein-coupled angiotensin II type 1 (AT_1) receptor (ARB) are available, including candesartan, valsartan, and losartan. They inhibit the vasoconstrictory action of angiotensin II in the vasculature and in cells of the heart to attenuate cardiac remodeling due to RAAS activation. The evidence of reduction of mortality of HFrEF patients is stronger for ACEI than for ARBs (Ponikowski et al. 2016). Thus, ARBs are recommended for patients who do not tolerate an ACEI. Contraindications and side effects are similar to ACEI with the exception of cough which is typically associated with ACEI-induced accumulation of bradykinin. Due to increased risk for hyperkalemia, the combination of ACEI with ARBs is no longer recommended (Ponikowski et al. 2016).

Angiotensin and Neprilysin Inhibitors

Inhibition of neprilysin prevents the degradation of natriuretic peptides and thereby enhances their beneficial effects in heart failure. However, neprilysin inhibition may increase the levels of other vasoactive peptides, for example, angiotensin II, endothelin-1, and bradykinin, which partially counteracts the beneficial effect (Braunwald 2015). As a consequence, a combination drug consisting of the angiotensin receptor blocker valsartan and the neprilysin inhibitor sacubitril has been developed. In the PARADIGM-HF trial, sacubitril-valsartan significantly reduced the rate of death from cardiovascular causes or first hospitalization for heart failure in HFrEF patients when compared to an ACE inhibitor (McMurray et al. 2014). Subsequently, sacubitril-valsartan was evaluated in patients with HFpEF, but did not reduce the rate of hospitalizations for heart failure or cardiovascular mortality (Solomon et al. 2019). Interestingly, subgroup analysis revealed a potential benefit of sacubitril-valsartan in women with HFpEF (Solomon et al. 2019**;** O'Connor and deFilippi 2019). Various differences in the pathophysiology of HFpEF between males and females have been described (Beale et al. 2018), but at present the underlying reasons for that finding remain speculative.

Mineralocorticoid Receptor Antagonists

Mineralocorticoid receptors (MR) belong to the family of ligand-activated nuclear transcription factors. MR is expressed in different cell types of the cardiovascular system, including cardiac myocytes, endothelial cells, and immune cells (Lother and Hein 2016; Lother et al. 2015; Cole and Young 2017). MR activation in heart failure drives cardiac myocyte hypertrophy, inflammation, and extracellular matrix deposition. In addition, MR takes a pivotal role in the translation of cardiovascular risk factors into cardiac disease (Lother and Hein 2016).

The use of the steroid-based competitive MR antagonists spironolactone or eplerenone improved mortality and reduced mortality of patients with mild to severe HFrEF in large randomized trials (Pitt et al. 1999, 2003; Zannad et al. 2011). In HFpEF, the TOPCAT trial spironolactone did not significantly reduce cardiovascular mortality (Pitt et al. 2014). However, significant discrepancies in event rates, responses to spironolactone, and in the reported use versus metabolite concentrations of spironolactone severely compromise the validity of the study (de Denus et al. 2017). Another phase III trial on spironolactone in HFpEF is ongoing (SPIRIT-HF, EudraCT 2017-000697-11).

Ivabradine

Ivabradine is a HCN channel inhibitor. Reduction of the pacemaker current (I_f) delays f spontaneous depolarization in sinoatrial node myocytes and

thereby decreases heart rate in sinus rhythm (Bois et al. 1996). High heart rate is considered to drive the pathophysiology of heart failure, potentially due to altered calcium cycling and a mismatch of increased oxygen consumption but decreased coronary perfusion time (Grande et al. 2018). In a phase III clinical trial, ivabradine improved the outcome of patients with reduced ejection fraction, mostly driven by a reduced hospitalization rate (Swedberg et al. 2012).

Additional Drugs

In case the HFrEF patients are still symptomatic with the combination of these drugs, hydralazine and isosorbide dinitrate or digitalis glycosides are additional options. Recently, inhibitors of the sodium/glucose transporter 2 (SGLT2) have shown beneficial effects in patients with HFrEF. SGLT2 is the main glucose transporter mediating glucose reabsorption from kidney tubules. SGLT2 inhibitors, for example, dapagliflozin and empagliflozin, are approved for treatment of type II diabetes. By preventing renal glucose reabsorption, they reduce blood glucose levels. In a recent trial, dapagliflozin significantly reduced cardiovascular mortality in HFrEF patients with NYHA II-IV even independent of diabetes (McMurray et al. 2019). The mechanism of action has not been uncovered (Packer 2020) and SGLT2 inhibitors have not been included in clinical treatment guidelines for HFrEF yet.

Conclusion

Pharmacological inhibition of neuroendocrine activation of the adrenergic and renin-angiotensin-aldosterone systems is well established to reduce morbidity and mortality of patients with HFrEF. The underlying molecular mechanisms of HFrEF involve multiple signaling events at the cardiac myocyte cell surface, intracellular pathways (Schmid et al. 2015) as well as long-term transcriptional adaptations (Gilsbach et al. 2018). In contrast, further studies are required to uncover the molecular pathophysiology of HFpEF and to develop clinical treatments which improve prognosis of HFpEF.

Synonyms

Granulocyte colony-stimulating factor (G-CSF), filgrastim, pegfilgrastim and lenograstim; Granulocyte macrophage colony-stimulating factor (GM-CSF), molgramostim and sargramostim; HGFs; EPO, recombinant erythropoietin, epoetin and darbepoetin alfa; Interleukin 11 (IL-11)

Definition

Hematopoietic growth factors (HGFs) are a specific type of cytokines that regulate hematopoiesis, which is a process related to the production of blood cells in the bone marrow. More specifically, HGFs directly stimulate the proliferation, differentiation, and maturation of bone marrow cells, originating functional blood cells (Silva et al. 2019; Pérez-Ruixo 2019; Walsh 2013; Groopman et al. 1989).

HGFs molecules are proteins and peptides produced through DNA recombinant techniques and used in the management of diseases related to blood and bone marrow. Food and Drug

Administration (FDA) and European Medicines Agency (EMA) approved several HGFs for clinical use (Table 1), which include recombinant erythropoietin or epoietin (EPO) and darbepoetin alfa, granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF), and interleukin 11 (IL-11) (Silva et al. 2019; Pérez-Ruixo 2019; Walsh 2013; Kaushansky 2006).

Erythropoietin (EPO)

EPO is mainly synthetized in the kidneys, being released in response to tissue hypoxia, that is, when the blood oxygen level is low. Nonetheless, it was detected that the liver and brain also produce EPO (Silva et al. 2019; Pérez-Ruixo 2019; Walsh 2013; Elliott et al. 2008).

Mechanism of Action

EPO stimulates and regulates erythropoiesis, which is the body's mechanism of producing red blood cells. The result of this process is an increase of differentiated red blood cells in the bloodstream (Silva et al. 2019; Pérez-Ruixo 2019; Walsh 2013). Briefly, EPO binds directly to the red blood cells surface receptors, originating their conformational change, which brings the Janus family tyrosine protein kinase 2 (JAK2) to

IL-11 (interleukin-11) or oprelvekin	Avoidance of thrombocytopenia and need of platelet transfusions after chemotherapy treatments	Silva et al. 2019; Walsh 2013; Lipiäinen et al. 2015

the vicinities and originates its phosphorylation, promotes the phosphorylation of tyrosine residues in the EPO receptor cytoplasm, and activates signaling molecules. This mechanism induces the proliferation and differentiation of red blood cells precursors while avoids their apoptosis (Elliott et al. 2008).

Clinical Use

Epoetin, which is the recombinant form of human erythropoietin, is used to manage anemia caused by different disorders, reducing or avoiding the patient's need for blood transfusions. For example, to treat patients with chronic renal failure, who had myelosuppressive chemotherapy, undergoing bone marrow transplantation, and on antiretroviral therapy or hepatitis C infection. There are five different subtypes of epoetin clinically available, which include the epoetins alfa, beta, theta and zeta, and darbepoetin alfa. Among these, epoetin alfa was first approved, although this subtype of epoetin show several side effects, such as hypertension and other cardiovascular events, thromboembolism, seizures, stroke, tumor return or development, and anemia (Silva et al. 2019; Walsh 2013; (FDA), F.a.D.A. 2017a). Darbepoetin alfa was also approved for the same clinical applications, showing the same side effects ((FDA), F.a.D.A. 2017b). Epoetin beta and epoetin theta were further approved to treat similar conditions. The most common side effects observed for epoetin beta are hypertension, headache, and thromboembolic events (Silva et al. 2019; (EMA), E.M.A. 2015c, 2012; (FDA), F.a.D.A. 2018a), while epoetin theta can also cause skin reactions, joint pain, and influenza-like symptoms in addition to these effects ((EMA), E.M.A. 2009a, b). Latter, epoetin biosimilars that include the subtypes alfa and zeta were approved for the same therapeutic indications as the reference epoetin alfa. In addition, these biosimilars have also been used to support surgeries in anemic patients, avoiding the need for blood transfusions. Regarding side effects, epoetin biosimilars show the same as the reference epoetin. Although the use of these biosimilars is more cost-effective than the reference medicines, some clinicians are uncertain about its real effectiveness and prefer to prescribe the reference epoietin (Santos et al. 2019).

Granulocyte Colony-Stimulating Factor (G-CSF) and Granulocyte Macrophage Colony-Stimulating Factor (GM-CSF)

G-CSF and GM-CSF are blood cell growth factors responsible for the proliferation, differentiation, and maturation of white blood cells from hematopoietic stem cells (Silva et al. 2019; Walsh 2013).

Mechanism of Action

Bone marrow stromal cells, macrophages, and fibroblasts generate G-CSF, which regulates the proliferation and maturation of neutrophils, induces the proliferation and migration of endothelial cells, and participates in the differentiation of other hematopoietic cells (Silva et al. 2019; Walsh 2013). G-CSF stimulates the neutrophils production, upon binding to the receptors expressed on the surface of myeloid progenitor cells, changing their conformation, and triggering several signaling pathways, such as JAK/STAT, PI3K/AKT, and MAPK/ERK. Besides, G-CSF improves the phagocytic activity of neutrophils, avoiding infections, and the neutrophils recovery after chemotherapy-induced neutropenia (Dwivedi and Greis 2017).

Endothelial cells, fibroblasts, macrophages, and T-lymphocytes produce GM-CSF, which binds to the respective cells receptors and stimulates the JAK2, STAT1, and STAT3 signaling transduction pathways that promote the proliferation of neutrophils, and other hematopoietic cells, such as macrophages, eosinophils, erythrocytes, and megakaryocytes (Silva et al. 2019; Walsh 2013; Chen et al. 2006).

Clinical Use

G-CSF and GM-CSF have been widely used in the treatment of neutropenic patients, although they also show effectiveness against some infectious diseases, cancer, and in the recovery of patients undergoing bone marrow transplants. The recombinant forms of G-CSF under clinical use are called filgrastim and lenograstim, while the recombinant forms of GM-CSF are called molgramostim and sargramostim (Silva et al.

2019; Pérez-Ruixo 2019; Walsh 2013). Among these, filgrastim was the first approved to reduce neutropenia related to different conditions, including in patients undergoing myelosupressive chemotherapy (except in chronic myeloid leukemia and myelodysplastic syndrome) and myeloablative chemotherapy; patients with idiopathic, congenital, or cyclic neutropenia; and patients with hematopoietic syndrome of acute radiation syndrome (i.e., patients acutely exposed to myelosupressive radiation). To improve the pharmacokinetics of filgrastim, pegfilgrastim and lipegfilgrastim were approved for the same therapeutic indications. These medicines contain as active substance a filgrastim molecule linked to a polyethylene glycol (PEG) molecule, which improves its half-life, reducing the number of administrations per patient. The most common side effects associated to filgrastim and derivatives are bone and muscle pain, nausea, fever, rash, headache, cough, difficulty breathing, and nose bleeding. Due to the expiration of patents, several biosimilars were approved for the same therapeutic indications as the references filgrastim and pegfilgrastim. Nonetheless, some of these biosimilars were withdrawn (Silva et al. 2019; Walsh 2013). Furthermore, filgrastim has been granted with two orphan designations for the management of amyotrophic lateral sclerosis ((EMA), E.M.A. 2015a) and spinal cord injury ((EMA), E.M.A. 2015b).

Regarding GM-CSF, molgramostim was granted with the orphan designation to treat the acute respiratory distress syndrome, which is a lung disorder that originates insufficient oxygen supply from the lungs into the blood ((EMA), E.M.A. 2016). In contrast, sargramostim is indicated to improve neutropenia recovery and avoid infections after induction chemotherapy in acute myelogenous leukemia, autologous transplantation of peripheral blood progenitor cells, autologous and allogenic bone marrow transplantation for myeloid reconstitution, bone marrow transplantation failure or engraftment delay, and to decrease the death of patients with hematopoietic syndrome of acute radiation syndrome. Sargramostim is well tolerated by most patients. Some of the reported side effects include pain, thrombosis, hepatic dysfunction, hypotension, arrhythmia, syncope, and eosinophilia ((FDA), F.a.D.A. 2017c, 2018b).

Interleukin-11 (IL-11)

IL-11 is a cytokine that belongs to the interleukins group, which are cytokines that regulate cells growth, and the inflammatory and immune responses within the body (Silva et al. 2019; Walsh 2013).

Mechanism of Action

IL-11 is a thrombopoietic growth factor that stimulates thrombopoiesis by inducing the proliferation of hematopoietic stem cells and megakaryocyte progenitor cells. This process results in an increase in platelets production (Silva et al. 2019; Walsh 2013).

Clinical Use

Oprelvekin, which is the recombinant IL-11, is used to avoid severe thrombocytopenia and the need of platelets transfusion in patients submitted to chemotherapy treatments. Oprelvekin is well-tolerated by patients, although some side effects were reported, including arrhythmia, edema, dyspnea, and oral yeast infections (e.g., moniliasis) (Silva et al. 2019; Lipiäinen et al. 2015).

Definition

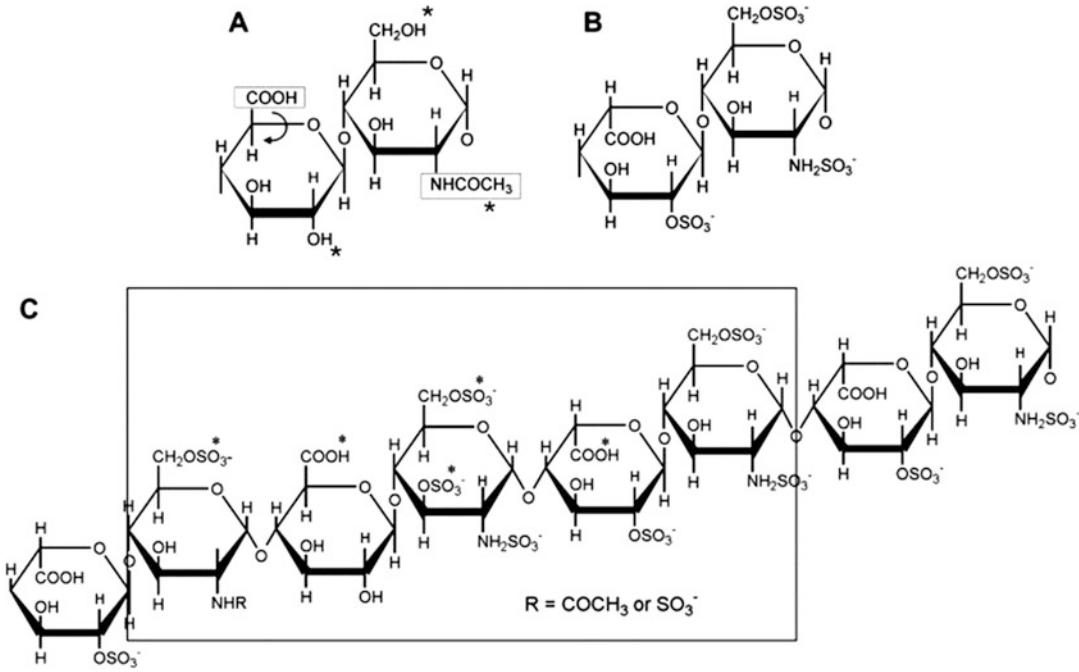
Heparin is a naturally occurring sulfated polysaccharide, and as such it is composed of many sugar units or saccharides. It has a long history being first marketed as a pharmaceutical product in the USA in 1939. It is still used in the prevention and treatment of coagulation disorders. It is an anticoagulant, inhibiting the clotting of blood collected into a tube, and an antithrombotic, inhibiting the formation of clots in blood vessels in the body (Mulloy et al. 2016).

Structure and Origin

The structure of heparin is complex. It is a completely linear molecule resembling a long chain (unlike many other polysaccharides which

may be branched). It is made up of alternating glucosamine and uronic acid monosaccharide units, heavily substituted with sulfates attached to the nitrogen in the glucosamine, and oxygen in the glucosamines and the uronic acids (N- and O-sulfates, respectively). A minor proportion of the glucosamines carry an acetyl group on their nitrogen, and these are N-acetylglucosamines (Fig. 1a, b). The biosynthetic process by which the heparin polysaccharide is elaborated is summarized in Fig. 1a. This process does not yield an absolutely regular polysaccharide but introduces sequence heterogeneity. This means that most heparin chains are different from each other in their structural details, including in the unusual but important modifications that give rise to the pentasaccharide sequence in heparin that has high affinity for antithrombin (see below). This sequence is very important for heparin's anticoagulant activity.

Heparin is a member of the glycosaminoglycan (GAG) family of polysaccharides, all of which contain an amino sugar (a glucosamine, or a galactosamine) alternating with either a uronic acid or galactose. Like other GAGs, heparin is synthesized in the cell attached to a protein core to form a proteoglycan: the heparin proteoglycan is called serglycin (Fig. 2). Unlike other GAGs that are found on the cell surface or outside of cells in their surrounding extracellular matrix of proteins and polysaccharides, heparin occurs inside the cell, in the granules of mast cells. Mast cells are one of the many cell types that make up the body's immune system. When first synthesized

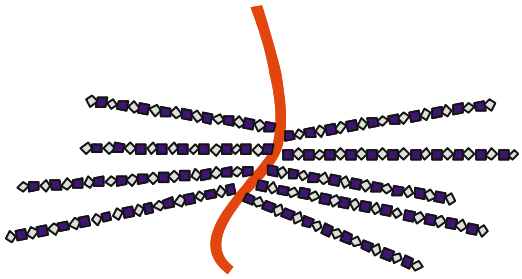


Heparin and Related Drugs, Fig. 1 Heparin substructures and biosynthesis. (**a**) The second most common repeat disaccharide unit in heparin: β-D-glucuronic acid and N-acetyl α-D-glucosamine, often abbreviated to GlcA-GlcNAc. In the biosynthesis of heparin, the GlcA-GlcNAc disaccharide is polymerized from a protein linked oligosaccharide, after which post-polymerization enzymes remove most *N*-acetylation, add sulfates (where indicated by asterisks), and epimerize the glucuronic acid to iduronic acid. (**b**) The main repeating unit of heparin is a disaccharide: α-L-iduronic acid *O*-sulfated at the 2-position and α-D-glucosamine *N*-sulfated at the 2-position and *O*-sulfated at the 6-position: often abbreviated to IdoA2S-GlcNS6S. This highly sulfated disaccharide sequence makes up more than 70% of heparin. All the monosaccharide residues in heparin are 1–4 linked. (**c**) The octasaccharide sequence in heparin with high affinity for antithrombin. The core pentasaccharide is outlined. Asterisks indicate some essential structural features for the interaction with antithrombin. (Reproduced with permission from Mulloy et al. (2010))

the heparin chains on serglycin range in size from 60 to 100 kilo Daltons (kDa). However, the heparin chains are subject to partial enzymatic digestion in the mast cells of the tissue of origin, resulting in free heparin chains that range in molecular weights from 5 to 20 kDa. The enzyme performing this function is called heparanase (Gong et al. 2003).

Heparin is extracted from tissues such as porcine (pig) or bovine (cow) intestinal mucosa that are rich in mast cells. The manufacturing process involves digestion of mucosa with proteolytic enzymes to remove protein; the heparin chains are then captured onto an ion exchange resin. Purification and bleaching and then final finishing and drying follow (van der Meer et al. 2017). The API product is either heparin sodium or heparin calcium and has an average molecular weight of around 16,000 g/mole.

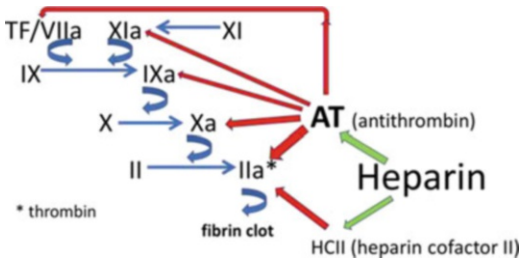
In some parts of the world, such as Europe and the USA, heparin for clinical use comes only from porcine intestinal mucosa (at the time of writing). Heparin from bovine intestinal mucosa is available in some other areas, and in the past bovine lung heparin was used. Heparins from these different sources vary systematically in their composition. They contain the same disaccharide units as are described above but in different proportions, which vary according to both the species and the tissue of origin. Other animals, such as sheep, have also been explored as sources of heparin.



Heparin and Related Drugs, Fig. 2 A cartoon representation of the intracellular PG serglycin, bearing closely packed heparin chains, on a peptide core. The protein chain is shown as a red ribbon, and GAG chains are depicted as symbols: blue squares represent GlcNS6S (or GlcNAc) and open lozenges represent uronic acid, usually IdoA2S but with minor proportions of IdoA and GlcA. (Reproduced from Pomin and Mulloy (2018))

Mechanism of Action

The coagulation cascade (for a simplified diagram, see Fig. 3) depends on a stacked set of serine proteases, each of which cleaves the inactive pro-enzyme which is next in the cascade into an active form. This culminates in the cleavage of fibrinogen to fibrin by thrombin (also known as factor IIa) to form the clot itself. This enzyme cascade acts as an amplification mechanism so that a small initial stimulus can lead to a substantial clotting response. Control of the coagulation system is complex, and the naturally occurring plasma protein antithrombin (a serpin, or *ser*ine *p*rotease *in*hibitor) can inhibit the process at several stages (Fig. 3). When heparin binds to antithrombin, through its high-affinity pentasaccharide sequence (Fig. 1c), the conformation of antithrombin is altered so that its affinity for its targets, principally factors IIa and Xa, is increased several thousand fold. Antithrombin interacts with the target enzyme to form a covalent, inactive complex. While antithrombin is consumed by this process, heparin dissociates from the complex and is free to bind to another antithrombin molecule. It is this catalytic action that makes heparin such a



Heparin and Related Drugs, Fig. 3 A much simplified representation of the coagulation cascade, in which serine proteases cleave pro-enzymes to give active serine protease coagulation factors. Factor IX is converted to active factor IXa in two ways, by the complex of tissue factor (TF) and factor VIIa and by factor XIa. Factor IXa cleaves factor X to Xa, and Xa cleaves factor II (prothrombin) to IIa (thrombin). IIa goes on to cleave fibrinogen to fibrin, which is incorporated into the blood clot along with platelets. Heparin potentiates the inhibitory activity of AT (which inhibits active coagulation factors throughout the cascade) and HCII (which inhibits only thrombin). Blue arrows signify activation by cleavage; red arrows signify inhibition; green arrows signify potentiation of inhibition. Figure reproduced by kind courtesy of Dr. Elaine Gray

powerful anticoagulant, as long as the antithrombin concentration is not depleted.

In order to potentiate the inhibition of factor Xa by antithrombin, a heparin molecule must include a copy of the high-affinity pentasaccharide (Fig. 1c); this is the only structural requirement. This means very small heparin fragments can be active against factor Xa, and indeed a synthetic heparin mimetic, fondaparinux, closely modelled on the pentasaccharide has been developed and is currently in clinical use (Zhang et al. 2019). Inhibition of factor IIa, however, needs not only a copy of the pentasaccharide but an additional length of heparin of at least 13 monosaccharide residues attached at the non-reducing side of the pentasaccharide (the left side in Fig. 1c). This adds up to a minimum molecular weight of 5400 g/mole, assuming a molecular weight of 600 g/mole per repeating disaccharide.

Additional Anticoagulant Mechanisms of Action

A second serpin present in the circulation in lower concentrations than antithrombin is called heparin cofactor II (HCII). Heparin can potentiate the action of HCII against factor IIa (HCII is not active against factor Xa). There is no specific sequence in heparin that has high affinity for HCII, and many other sulfated polysaccharides can also enhance its activity. Dermatan sulfate (DS), another GAG, can activate HCII; as DS is a component of the network of proteins and polysaccharides comprising the extracellular matrix that underlies the endothelial cells of the blood vessel wall, it may be exposed when a blood vessel wall is injured. When this occurs DS can act like heparin and potentiate the inhibition of factor IIa by HCII.

Low Molecular Weight Heparins: Mechanisms of Action

It is possible, by a process of controlled, partial depolymerization, to make lower molecular weight heparin that has reduced anti-IIa activity and a high ratio of anti-Xa to anti-IIa activity. This is because the anti-IIa activity of heparin is restricted to molecules with a molecular weight of above about 5000 g/mole. Several proprietary versions of low molecular weight heparin (LMWH) are in clinical use (e.g., tinzaparin, enoxaparin, dalteparin), each with its characteristic molecular weight distribution and activity profile. The average molecular weights of LMWHs are less than half that of unfractionated heparin (UFH). These products have improved absorption and bioavailability as compared with UFH; they are removed less quickly from the body's circulation. They also have fewer adverse side effects as their smaller size reduces nonspecific reactions with plasma proteins. As a result, depending on the medical condition being treated, LMWHs may be preferred over UFH, for example, to prevent thrombosis during surgical procedures.

Units of Activity of Heparin

Heparin is a polydisperse, heterogeneous polysaccharide in which not every molecule contains a copy of the high-affinity pentasaccharide motif necessary for antithrombin binding. This means some heparin samples are more effective as anticoagulants than others. As a consequence, heparin is administered to patients in doses defined by units of activity rather than by weight. Activity may be measured by several methods, including assays that depend on the measurement of plasma clotting times, but the values that appear on the labels of heparin products are derived from assays in which purified antithrombin acts on purified factor Xa or IIa as appropriate. Activity is measured relative to a heparin standard reference material. The International Standard for Unfractionated Heparin and the International Standard for Low Molecular Weight Heparin, established by the World Health Organization, are the primary global standards, and activity values determined against these reference materials are expressed in International Units (IU) (Mulloy et al. 2010).

Clinical Uses of Heparin

Heparin has been approved by the drug-regulating authorities for use in the prevention and treatment of venous thromboembolism, which is a blood clot that begins in a vein. There are two types of

venous thromboembolism: deep vein thrombosis (DVT) and pulmonary embolism. The first is a clot deep in a vein, usually in a leg but can occur in an arm or other veins, whereas the latter occurs when a clot detaches from the vein wall and travels to the lung where it stops part of, or all of, the blood supply. Commonly surgery, immobilization, or cancer triggers this condition, and it can lead to stroke and other cardiovascular disorders, both of which may be life threatening. Where a risk of thrombosis can be foreseen, for example, when surgery is planned, heparin (often LMWH) can be administered in advance to prevent clotting. Patients are generally treated with an anticoagulant, commonly heparin, very soon after DVT diagnosis is confirmed with the objectives of preventing an extension of the clot and pulmonary embolism (Gresele et al. 2012).

Heparin is also used to treat cardiac conditions like heart attacks (acute myocardial infarction) or unstable angina, where the heart, due to poor blood flow and narrowing of the coronary arteries, does not receive sufficient oxygen. Heparin is given following diagnosis, and during and after surgery to widen an artery by inserting a stent. The aim being to reduce the possibility of the stent triggering the formation of a thrombus or clot. Other agents like aspirin are used in combination with heparin to limit thrombosis in such settings.

Heparin is often administered to patients in hospital via a drip into a vein, the solution in the bag being pumped into the patient's vein at a controlled rate. This is called intravenous infusion. It can also (especially for LMWH) be given by an injection under the skin (subcutaneous injection), but then the anticoagulant effect is not seen until 1 or 2 h after administration. In contrast, when given intravenously an immediate anticoagulant effect is seen. Heparin cannot be given orally.

Some forms of open heart surgery require the circulation and oxygenation of blood outside of the body; this cardiopulmonary bypass process involves exposing blood to foreign surfaces in the heart-lung machine and then recirculating it throughout the body. When a patient's blood is exposed to surfaces that differ from the walls of blood vessels, this triggers an inflammatory response comprising the initiation of protein cascades of the immune system and the activation of platelets and leukocytes (white blood cells) with their release of inflammatory mediators. The result is a state of heightened coagulation. The management of patients on extracorporeal life support has only been possible because of the use of anticoagulants to prevent thrombus formation within the circuitry and in the patient's vasculature. Heparin is the usual anticoagulant. Managing the balance between anticoagulation and clotting is particularly challenging for patients on extracorporeal life support, and heparin has the advantages of a short half-life and the possibility of reversing, or neutralizing, its effects by the addition of a peptide called protamine.

These days extracorporeal circuitry coated in heparin is increasingly being used during cardiopulmonary bypass surgery, with circuitry in which the heparin is covalently bonded to the surface being preferred. The discovery of the critical pentasaccharide sequence for antithrombin binding prompted the covalent immobilization of partially depolymerized heparin chains by their reducing termini as a way of retaining heparin's bioactivity. This technology has now been used to covalently coat heparin onto not only cardiopulmonary bypass equipment but also vascular stents, vascular grafts, and hemodialysis catheters. In this way the possibility of thrombosis and inflammation triggered by the device is reduced (Biran and Pond 2017).

Heparin Clearance from the Circulation

Heparin is cleared from the circulation by a combination of saturable and non-saturable mechanisms. The saturable mechanism is due to the binding of heparin to cell surfaces, while the non-saturable mechanism is due to renal excretion. Both UFH and LMWH are primarily cleared from the circulation by the liver, through attachment to the HARE (Hyaluronic Acid Receptor for Endocytosis) receptor. UFH has a half-life of about 1 h in the circulation, but LMWH has a longer circulatory half-life of 2–6 h, having lower affinity than UFH for the receptor (Harris et al. 2009). The renal route of clearance is more

significant for LMWH than for UFH (Johansen and Balchen 2013).

Heparin Neutralizing Agents

The risk of bleeding is a potential side effect of heparin treatment. Heparin treatment is a balance between the prevention of thrombotic events and the triggering of excessive bleeding. Generally elderly patients and patients with poor renal function have a higher risk of bleeding following anticoagulant therapy. Patients undergoing cardiac surgery and interventions that require the use of extracorporeal circuitry need to have any excess heparin in their bloodstreams neutralized to prevent postoperative bleeding. Linear positively charged molecules, such as the arginine-rich protamine peptide, can bind to heparin and neutralize its bioactivity. This property is used in the clinic to remove excess heparin. Protamine neutralizes heparin very rapidly acting within 5 min following its administration, which in a cardiac operating room is usually by an intravenous 10–15 min infusion. Protamine is less effective at neutralizing LMWH, with an efficacy of around 60%, and protamine does not neutralize fondaparinux, the synthetic analogue of heparin modelled on the pentasaccharide sequence of heparin that binds antithrombin. Excessive bleeding following fondaparinux use may be partially corrected by injections of factor VIIa, but there is no specific antidote yet.

In order to optimize protamine doses for each patient, the quantity of anticoagulant active heparin in a patient's blood must be measured. This is usually done using the clotting-time assays, activated partial thromboplastin time (aPTT), and anti-factor Xa assays, with the latter being particularly important for monitoring the amounts of LMWH in plasma. The reliability of these assays for estimating the anticoagulant response is greater for LMWH than for UFH. The reasons being heparin can more readily bind to the surfaces of endothelial cells effectively taking it out of plasma, and it can also readily bind certain proteins that may be present in plasma that have heparin-neutralizing properties, including platelet factor 4 (PF4), histones, histidine-rich glycoprotein, and others. The limitations of the clotting-time assays are why research is being undertaken to find alternative assays that can reliably estimate the quantities of heparin and LMWH in plasma and blood (Ourri and Vial 2019).

Non-bleeding Side Effects of Heparin Treatment

Non-bleeding side effects of heparin treatment arise because heparin binds to proteins other than antithrombin and factors involved in coagulation. Possibly the best known side effect is immune heparin-induced thrombocytopenia (HIT). It is relatively uncommon, with a reported incidence of 0.2% to 5% of patients who are exposed to UFH developing this complication. There are two types of HIT. Type I HIT is a transient fall in platelet numbers which is probably caused by heparin-activating platelets; it generally resolves without complications. Type II HIT can be life threatening, and it is caused when heparin forms complexes with PF4, a protein released from activated platelets. These complexes can trigger the body's immune system to produce antibodies that recognize and bind to the heparin-PF4 complexes, further increasing their size. These large immune complexes bind to platelets causing platelet activation and a cascade of events that can lead to the massive generation of thrombin, the formation of blood clots, and thromboembolism. Associated with this is a fall in platelet numbers. The likelihood of HIT occurring following the use of LMWH is much lower than when UFH is used. This is because the size of the initial UFH-PF4 complexes is generally larger than complexes of LMWH and PF4, and larger complexes more effectively trigger the immune response and antibody production. If HIT is suspected, heparin treatment must be stopped and an alternative anticoagulant used to prevent clot formation in the capillaries (Alban 2012; Gupta et al. 2015).

The most common side effect of long-term heparin use is osteoporosis, but if heparin is used on a short-term basis to treat acute thromboembolism, osteoporosis does not occur. Osteoporosis is a bone disease associated with a low bone mass, fragile bones, and an increased risk of fractures. The mechanisms contributing to heparin's effects

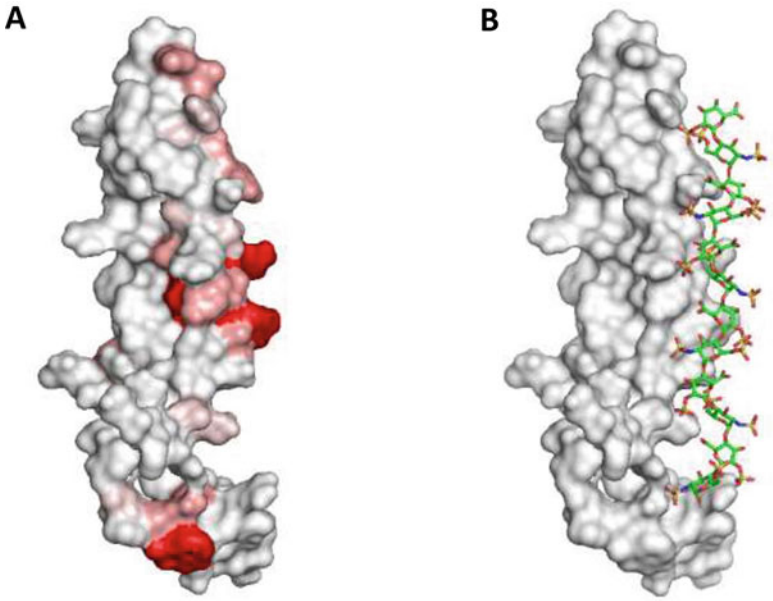
on bone density are not well understood, but it is believed that the binding of heparin to a protein (called osteoprotegerin) that regulates bone density is a key contributing factor. Heparin binding prevents this protein from inhibiting bone resorption, and this results in increased rates of bone resorption compared to bone formation, which leads to osteoporosis. LMWHs do not bind osteoprotegerin so well, and so their use has less of an adverse effect on bone densities than that of UFH (Signorelli et al. 2019).

Heparin Contamination

In 2007–2008, some patients suffered a severe adverse reaction to heparin involving loss of blood pressure, nausea, and shortness of breath; there were some fatalities. These events were linked with specific heparin batches that were contaminated with an unusual compound, oversulfated chondroitin sulfate (OSCS). Though chondroitin sulfate itself is a naturally occurring and harmless GAG, OSCS is made by a chemical treatment to increase its sulfate content and its ability to inhibit plasma clotting. Pharmacopoeial specifications for heparin have been improved worldwide to ensure that events of this type do not happen again (see, e.g., Szajek et al. 2016).

Other Heparin-Protein Interactions

The number of proteins that bind heparin is unknown but amounts to over 400 (Ori et al. 2011). Heparin, as the most highly negatively charged biopolymer found in nature, can be expected to interact with positively charged molecules or to an area of positive charge on the surface of a protein. As heparin has a regular repeating structure with a linear conformation, the spacing and orientation of charges on the protein surface can affect the affinity of any interaction. Structurally, heparin resembles heparan sulfate, a GAG found on the surface of cells that modulates the actions of soluble protein mediators like growth factors, morphogens, cytokines, and chemokines. Heparin similarly binds to proteins in all these categories in addition to the coagulation factors and their inhibitors. The size and the nature of the heparin binding site on proteins varies according to the protein's structure. Some of these binding sites are extended and comprise amino acids that are widely separated in the protein's amino acid sequence (Fig. 4), while others are compact. Extended binding sites interact with longer heparin chains, while compact sites may require only a pentasaccharide or hexasaccharide. The biological consequences of heparin binding



Heparin and Related Drugs, Fig. 4 (**a**) A surface view of the protein sclerostin, in which residues are colored according to the perturbation of nuclear magnetic resonance (NMR) signals induced by heparin binding. (**b**) A representative view of a heparin fragment docked by molecular modelling techniques onto its binding site on the surface of sclerostin. Heparin is shown in a stick representation colored by atom type: carbon is green, oxygen red, nitrogen blue, and hydrogen white. (Reproduced from Veverka et al. (2009))

these proteins are many, and they vary depending on the protein bound and its function. Despite being a topic of current research, it is known these consequences include blocking an enzyme's activity, regulating the binding of growth factors to their cell surface receptors, regulating white blood cell migration, and inhibiting some viral infections. Heparin binding to sclerostin as shown in Fig. 4 was found to release sclerostin into the culture medium from the cell layer, presumably by blocking it from associating with the heparan sulfate chains of cell surface proteoglycans (Veverka et al. 2009). Sclerostin is an inhibitor of bone formation that plays a role in skeletal development; sclerostin inhibitors are being developed for use in the treatment of postmenopausal osteoporosis.

The diversity of heparin's activities is the stimulus for current research to make molecules by synthetic chemistry that resemble aspects of heparin's structure and which display particular subsets of heparin's activities. The goal being to develop synthetic heparin-like molecules as drugs for diseases like cancer or inflammation (Mohamed and Coombe 2017). Although we have known about heparin for over a century, there remains more to be understood about how this complex molecule can be used to benefit our lives.

Definition

HTS is a translational research technology used for identifying effectors (compounds, peptides, and biologics) that modulate target-specific biochemical or cell-based assays. In the context of small molecule drug discovery, HTS involves performing assays in the presence of large collections of compounds. The compounds identified from HTS are referred to as "hits" once the actives are reconfirmed for activity and specificity in downstream assays. The method uses automation for dispensing compounds and assay reagents and for reading detection signals. Advances in automation, liquid handing, and signal detection, as well as large data computing and analysis, have greatly facilitated screening of mid- to large (10^3 – $>10^6$) compound collections in HTS. Depending upon the type of robotic instrumentation available, high-throughput screening can yield up to 40,000 data points per day, whereas ultrahigh-throughput screens (uHTS) can generate 10^5 to 10^6 data points daily. High content screening (HCS) uses automated microscopy to capture images and quantify changes in cells exposed to compound collections. In contrast to the wet bench HTS- or HCS-based approaches to identifying hits, theoretical in silico methods are also used for screening virtual compound databases to identify compounds that dock into computational models of protein binding or interaction sites based on theoretical models or on actual X-ray

diffraction-based models. The compounds identified from HTS/HCS or virtual screenings are tested for activity (potency and efficacy) and selectivity using counterscreens and orthogonal assays. Compounds that show sub-micromolar potency against a target and exhibit reasonable selectivity serve as probes or chemical tools for mechanism of action studies. The probes can also serve as starting points for optimization of hits to chemical leads that have the potential of being developed into marketed drugs.

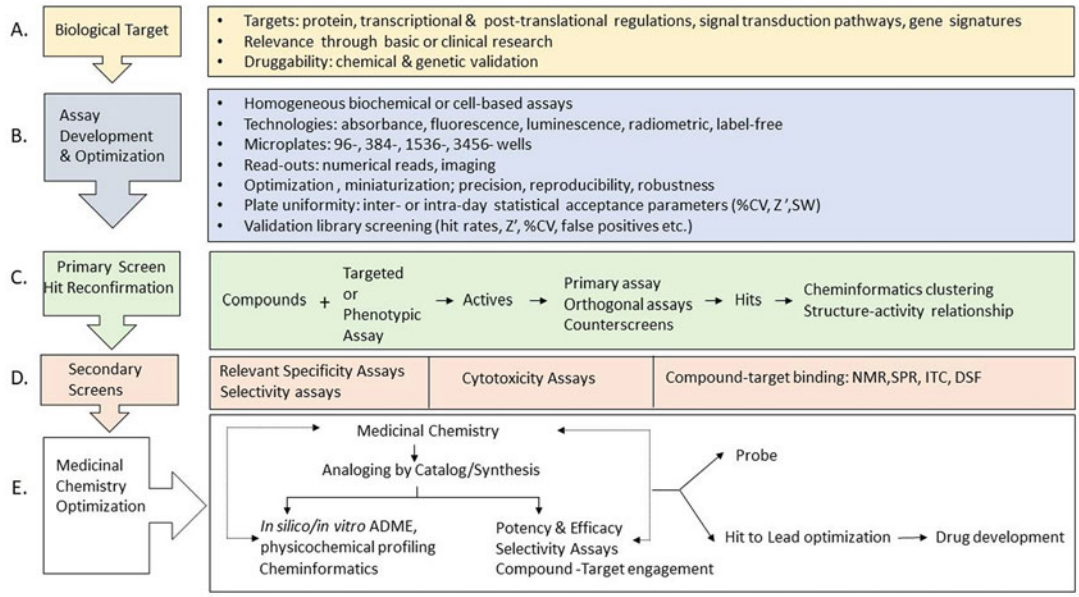
Description

Any screening campaign, medium-, high-, ultrahigh-throughput starts with identification of a biological target and a quantifiable assay. The optimized assay is first validated against a small test set of compounds which may be a focused or bioactive collection or a small diversity compound set representative of most of the scaffolds in larger library sets. Data from the validation screen is useful to evaluate statistical parameters in the presence of compounds, determine hit rates, and validate the assay workflow. The following steps are involved to execute the screening campaign (Fig. 1).

Target Identification and Validation. The process of translational research starts with identification of a biological target such as an enzyme, protein, receptor, regulatory DNA or RNA sequence, a signaling pathway effector, or modulator/adaptor macromolecules through basic research or via clinical observations. The unequivocal role of target in disease or a phenotype is first validated either (a) chemically (Wyatt et al. 2011), using available peptides, antisense oligonucleotides, aptamers, compounds, and antibodies, and/or (b) genetically, via knockouts, knockins, or knockdown experiments using gene-editing tools (e.g., clustered regularly interspaced short palindromic repeats, CRISPR-Cas9 editing, CRISPR interference) and RNA interference or microRNAs. A target is of therapeutic value or "druggable" once a dose-dependent relationship between target function and biological phenotype in homeostasis or pathogenesis is established. Alternatively, a genetic variant that directly correlates to a clinical condition can also serve as a validated target for developing therapeutics. Data integration and extraction from high-throughput genomics, transcriptomics, proteomics, and other such "omics" databases can also support target identification and validation efforts (Roy and Chaguturu 2017).

Targeted and Phenotypic Assays. Identifying an assay that best represents target biology and function is a critical success factor for HTS (Roy 2018). Assays are conceptualized and executed exploiting some known aspect of target function, like enzymatic activity or interaction with another protein or DNA or RNA sequences or post-transcriptional regulation. When target function is unclear, biophysical assays are set up to screen for compounds that directly bind to the target. Several of the target functions can be set up using purified components in biochemical assays, where reaction components are well defined. Targeted biochemical screens, or the reverse chemical genetic screens, help to identify compounds that modulate function of the target either by binding directly to the protein or nucleic acid or to interaction interfaces between the reactants. The hits from targeted screens require cellular validation.

Several of the target functions can also be analyzed in the context of their cellular environments. In such cell-based assays, the target activity can be tracked using engineered cells, stably or transiently expressing reporters like luciferase, green fluorescent proteins (GFP) or its variants under the nucleic acid regulatory elements or as protein fusions or via in-cell enzyme assays (e.g., caspases), or target-dependent toxicity assays. Assays using whole organisms, primary cells, or cancer cell lines are utilized for executing phenotypic screens. In phenotypic screens or the classical forward chemical genetic screens, whole organisms or cells are treated with chemical collections in microplate formats. Deconvolution of compound mechanism of action in phenotypic screens is more complex, as screening will identify cell-permeable compounds that through various specific or non-specific interactions within



High-Throughput Screening (HTS) Technology, Fig. 1 Schematic showing high-throughput screening workflow. (**a**) The relevance of biological target in therapeutics is validated chemically and/or genetically. (**b**) Biochemical and cell-based assays are established for primary screening of large compound libraries. The assays are optimized and miniaturized for screening in low-volume high-density microplates. Once the assay meets statistical acceptance parameters, it is validated in a small screen using test set of compounds (up to 10,000 compounds). (**c**) The assay is used to screen large compound libraries at single concentration, and primary screen actives are reconfirmed for dose-depending activity. The actives are also tested in parallel against assay platform-dependent counterscreens to eliminate assay interference compounds. Various orthogonal assays are used to confirm target-specific activity. Cheminformatics analysis is performed to flag promiscuous actives, chemical liabilities, and structure-activity-based clustering. A few synthetically tractable chemical series are selected by medicinal chemists. The compounds and their analogs are purchased as fresh powders from commercial vendors. (**d**) The purity and structural integrity of fresh powders is evaluated, and compounds that are >95% pure are tested in a series of assays that profile the compounds for potency, efficacy, selectivity, and direct binding. (**e**) The physicochemical properties of hits as well as their in vitro and in silico ADME (adsorption, metabolism, and excretion) are evaluated along with compound potency, selectivity and toxicity. The ultimate goal is to identify compounds that can serve as probes or chemical tools or serve as starting points in hit to lead drug development programs

cells will cause changes in cell morphology, spatial regulation, and viability. Phenotypic screens also can help in the identification of prodrugs or compounds that show activity after chemical transformations within the cells. Signaling pathways are queried in cells expressing reporter coding sequences under the control of target promoter or regulatory sequences. The reporter proteins include firefly and renilla luciferase, β-galactosidase, secreted alkaline phosphatase, green fluorescent proteins, and β-lactamase. Unmodified whole cells and organisms that are commonly used for screening range from bacteria, algae, fungi or mammalian cells, multicellular vertebrate organisms like Zebrafish, *Xenopus laevis*, drosophila, and *Caenorhabditis elegans*.

A large number of cell-based screens have used two-dimensional (2D) cultures of immortalized primary or cancer cell lines or induced pluripotent stem cell (iPSC)-derived normal or patient cell lines. While the throughput of screening large compound libraries in cell lines in 2D monolayer formats is high and convenient, more relevant preclinical information (Vincent et al. 2015) is obtained from testing compound activity in three-dimensional (3D) single-cell or multicellular co-cultures or organoids. Organoid cultures capture structural and functional interactions

between relevant cell populations and with extracellular matrices in solid tumors. While in some organoids some cellular subtypes do not exactly recapitulate normal levels and patterns of gene expression profiles, migration, and layering, the use of the 3D models is a significant technological advancement in drug discovery. Organs-on-a-chip microfluidic models derived from human origin cells are available for the livers, pancreas and prostate glands, brains, and kidneys and are predicted to serve as more relevant alternatives to rodent models. Advances in organoids (Rossi et al. 2018) that completely recapitulate human organ cellular complexity and function will be invaluable for allowing more direct translation of compound behavior in clinical trials.

Homogeneous versus heterogeneous assay formats. Whenever possible, a primary homogeneous assay that is simple (mix and read, up to two steps), precise, robust, and amenable to automated handling is used to execute large compound screens. Depending upon target complexity, biology, and availability of reagents, heterogeneous formats like ELISA (enzyme-linked immunosorbent assay) or radiofiltration assays involving multiple steps of reagent additions or removals or washing cycles can also be optimized for primary screening. Heterogeneous formats limit batch sizes of screening plates and are generally more prone to plate-to-plate and screening batch-wise variability, which ultimately complicates global data analysis and hit identification of primary screen. While a homogeneous assay is desirable for screening large compound libraries, secondary assays for activity reconfirmation, specificity, and selectivity for small numbers of hits can be both homogeneous and heterogeneous formats.

Assay Detection Technologies

Assays for HTS are developed using platform technologies based on optical properties, like absorbance, fluorescence, and luminescence (Inglese et al. 2007). Absorbance-based or colorimetric assays exhibit small signal dynamic range but are easy to set up. Fluorescence assays exploit the intrinsic light absorption and emission characteristics of proteins or fluorophores (fluorescein, Texas Red, Pacific Blue, Rhodamine, etc.) at two distinct wavelengths. All fluorescence measurements require external light source for activation. Upon absorption of light at specific wavelength, the assays can use fluorescence intensity, for direct emission measurements, or measure emissions from energy transfer between donor and short-lived fluorophore acceptors or to quenchers (Förster resonance energy transfer (FRET)). The more specialized FRET assays like time-resolved FRET (TR-FRET) or HTRF ((homogeneous time-resolved fluorescence) assays are based on the use of long emission fluorophores as donor and acceptors as well an integrated time delay between initial excitation and final fluorescence measurement. The fluorescence polarization/anisotropy (FP/FA) assays are based on selective excitation of fluorophore absorption vectors that are parallel to the electric vector of incident linearly polarized light. Low polarization values are obtained when fluorophores on small rapidly rotating probes (small molecules or peptides or nucleic acids) orient randomly. When the fluorophore-tagged probes bind to a large protein, high polarization values are obtained due to slower rotation in the plane of polarized light. All fluorescence formats are very sensitive and show high dynamic range. Majority of fluorescence formats are applicable to both biochemical and cell-based assays.

Luminescence-based assays are based on quantification of photons emitted after chemical (chemiluminescence) or enzymatic (bioluminescence) reactions between the luciferase enzymes and photon-emitting substrates (Fan and Wood 2007). Luminescence detections do not require a light source for excitation and use a photomultiplier tube that proportionately converts the photons to electrons. HTS assays are based on luciferase enzyme from *Photinus pyralis* (firefly luciferase) which catalyzes luciferin substrate in the presence of ATP. Bioluminescence assays also use *Renilla* (*R. reniformis*) luciferase or secreted *Gaussia* luciferase, both of which use coelenterazine as substrate. The activity of aequorin enzyme from *Aequorea victoria* is

calcium sensitive and is used extensively in calcium channel assays. Luciferase assays for biochemical and cell-based assays are configurable in various ways to evaluate target-related activity. Some of the formats used include genetic reporter constructs expressing luciferase under target promoters or regulatory untranslated regions of mRNA, or protein-luciferase fusions, adding luciferase enzyme and substrate to quantify ATP levels of kinase reactions and within cells. A wide variety of luciferin tagged substrates for protease, assays are available to set up biochemical assays that are sensitive to ATP concentrations in purified luciferase enzymatic reactions. A number of novel formats integrate both luminescence and fluorescence for developing protein-protein interactions or for multiplexing different readouts. These include BRET or bioluminescence resonance energy transfer assays (Machleidt et al. 2015) for protein-protein interactions in which energy transfers occur from bioluminescence donor to a fluorescence acceptor.

Many assay formats are used in more restricted niche due to requirement for specialized detection systems or due to expense-related and biohazard issues. For example, radiometric assays, despite their high sensitivity, are not used extensively for primary screening due to the biohazard nature of radioactivity-based assays. Screening for various targets is executed based on Scintillation Proximity Assays (SPA) in which radioactive decay of β-particles released from ^{3}H. ^{14}C, ^{33}P, and ^{125}I isotopes is used to generate light via scintillant material in microbeads or coated on the wells of flash plates. Label-free assays measure changes in native proteins or cells based on biophysical principles and do not require modified proteins, fluorescent tags, or reporter expression constructs. The label-free detection systems require specialized instrumentation and assay plates. Label-free systems based on optics are employed for primary screening and for orthogonal hit confirmation, e.g., Optical/resonant waveguide Grating (OWG) technologies (Corning Epic® EnSpire label-free module and SRU Biosystems BIND®) and surface plasmon resonance (SPR). In another form of label-free technology, measuring changes in electrical impedance across the interdigitated microelectrodes is used for quantifying compound modulated changes in cell growth, migrations, and invasion. In recent years high-throughput screening is also being performed using advanced Mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy technologies (Dahlin et al. 2018).

All platform technologies have their pros and cons and can contribute toward artifactual activities resulting in false positives and negatives. Compound interference arises from intrinsic absorbance, fluorescence, aggregation, redox activity, or direct binding of the compound to reporter or to the recombinant protein tags (Nickel chelate-Histidine (His), glutathione S-transferase (GST), maltose-binding protein (MBP) tags used for affinity purification). To minimize assay false positives, the HTS workflow also incorporates additional downstream assays during hit reconfirmation. These include (1) orthogonal assays, which use a platform technology distinct from that used in the primary screen to confirm compound activity against a target, and (2) counterscreen assays that help deprioritize compounds interfering with primary assay signal detection. Sometimes, compounds that exhibit assay interference can also be true positives if they show activity in a physiologically relevant secondary assay.

Assay Microplates. The assays are performed in polystyrene multiwell microplates that vary in the total number of wells (96-, 384-, 1536-, or 3456-wells) and in their well volumes (5ul–100ul). The footprint and tolerances of standard microplates manufactured by commercial vendors conform to microplate dimension standards established by the Society for Biomolecular Screening (SBS, American National Standards Institute (ANSI 1-2004)). Primary screening of large compound libraries in high-density plates using small reagent volumes is both cost- and time-effective. Assay performance is significantly affected by microplate color as microplates can contribute to inner filter effects by absorbing light. UV transparent plates are used for signal detection at wavelengths <320 nm, while standard clear microplates are used for absorbance assays in visual spectrum; black plates reduce background

signals for fluorescence intensity and polarization, and the white plates are used for TR-FRET and luminescence-based assays. AlphaScreen™ technology (Perkin Elmer Inc.) utilizes gray plates for reducing cross-talk and background. The clear bottom plates used for HCS permit image capture from bottom of the plate. Based on their ability to bind nucleic acids and proteins, microplate surfaces can be non-binding, low to high binding to facilitate setting up of different assay formats. Cell-based assays require lidded plates that are untreated for suspension cell growth or treated with agents that enhance attachment of adherent cells (cell culture-treated plates, poly-D lysine plates, etc.). A large number of ultralow attachment hydrophilic surfaces and geometries are currently available to promote formation of spheroids in three-dimensional assay systems. More specialized assays incorporate use of modified 96-well or 384-well plates. In radiometric scintillation proximity assays, flash plates are coated with scintillant material. Label-free assays like xCELLigence (Roche Applied Science) may have microelectrodes integrated on the bottom of cell culture plates.

Assay Optimization. In routine HTS campaigns, as an example, a screening campaign of 1000 plates may be divided into batches of 50–100 plates/day each, depending upon the assay. The datasets from all 1000 plates must show high degree of uniformity from plate to plate, and on day to day basis, as signal variability creates issues in hit identification. Both biochemical and cell-based assays are optimized for signal and uniformity, signal dynamic range, signal to background ratios, and batch consistency. Various parameters like reagent stability, reagent concentrations, buffer components (salts, reducing agents, and detergents), temperature, order of addition, preincubation time, dispense volumes, incubation times, read times, positive and negative controls, and DMSO sensitivity are defined for all types of assays. The cell lines used for assay development are authenticated via short tandem repeat (STR) PCR analysis, routinely screened for mycoplasma, preferably grown in the absence of general antibiotics (penicillin/streptomycin) in media and tested for the assay response in relation to DMSO concentration, passage number in culture, number of cells per well, and growth kinetics in multiwall plates. Cell-based assays that require transient transfections or transductions to express reporter constructs have to be validated for batch-wise transfection efficiencies and baseline drifts. Assay variability using cell lines expressing recombinant reporter constructs or proteins is greatly reduced by using well-characterized stable cell lines derived from a single high-expressing cell clone.

Once the assay is optimized on a small scale, all steps in assay setup are transitioned to robotic handling for improving efficiency and throughput of screening. For any new assay, experiments addressing plate uniformity are performed using reagent amounts or cell numbers or inhibitor/activators that give low, medium, and high signals with any platform technology. In its most extensive format, raw values and distribution of signals across three plates run within a day and over 3 days are evaluated for signal drifts, for variability, and for row-wise/column-wise edge effects. When assays are transferred from one lab to another, two-plate, 2-day formats for plate uniformity assessment are used. Assay conditions are defined for generating three types of signals on a plate: (1) "Max," highest value of a read out, using high enzyme concentration or higher cell numbers per well; (2) "Mid," ~50% of Max signal; and (3) "Min" (<80% of Max signal) which are performed at concentrations of enzyme or cell numbers giving moderate and low signals. The Mid and Min signals can also be obtained by adding different inhibitor or substrate concentrations to the reactions or to cells ((Roy and Mir 2017) Fig. 2). The assay robustness and variability are defined by a number of statistical parameters: the absolute value of the signal, coefficient of variability (CV<20%), signal windows (SW>2), midpoint signal shifts (>2), and Z' ratios (between 0.5 and 1). The Z' factor ($Z' = 1 - (3SD_{Max} + 3SD_{Min})/|Mean_{Max-} Mean_{Min}|$) is key parameter that measures the signal spread (standard deviation, SD) around the positive and negative controls as well as the window of separation between the two controls. In screening plates, the Z' score is defined in terms of positive

High-Throughput Screening (HTS) Technology, Fig. 2 Representative example of assay optimization parameters. (**a**) A two-plate assay was set up over 3 days, and inter-plate and intra-plate reads were evaluated statistically to study signal drifts and variability. The millipolarization counts from a protein-RNA fluorescence polarization assay show tight separation of counts at max, mid, and min signals in all plates across all 3 days. (**b**) The table shows assay robustness and variability data from the plate uniformity assay including signal values, means, standard deviations, and CVs. (**c**) The Z' scores and signal window calculations are shown. The assay meets the statistical acceptance parameters for optimized assay: coefficient of variability (CV<20%), signal windows (SW>2), midpoint signal shifts (>2), and Z' ratios (between 0.5 and 1)

and negative controls on each assay plate. The Z' score of >0.5 is acceptable for cell-based assays; the acceptable scores generally lie between 0.7 and 0.9 for biochemical screens. Z' values are evaluated not only during assay development and optimization but are used throughout the HTS campaign. Genomic screens with siRNAs are noisier, and additional statistical evaluation parameters are used to define assay readiness.

An assay that meets all statistical acceptance criterions is ready for screening compounds (small molecule/natural products/fragment screens) or siRNAs (genomic screens) or antibodies (biologics screens) or peptides (peptide screens). Screening large collections efficiently with high precision and fidelity requires use of reliable, well-calibrated robotic/automated instrumentation.

HTS Laboratory Instrumentation. In addition to basic research equipment (balances, incubators, shakers, pH meters, centrifuges, biosafety cabinets), the resources of a typical HTS laboratory include (a) screening collections, compound management and handling (b) automated liquid handling robotics, and (c) multimodal plate readers (Jones et al. 2004). In addition to this, HTS programs require large data storage and processing abilities. The HTS labs also have dedicated spaces and equipment for aseptic mammalian cell culture and/or for handling infectious disease organisms. Screenings with more infectious BSL3 organisms require more specialized enclosed spaces that harbor all screening equipment.

Screening Collections. Compound libraries are an important resource for screening centers, all of which maintain medium to large compound collections. Majority of the compounds are purchased from commercial vendors, e.g., ChemDiv, Inc. (San Diego, CA), ChemBridge Corp (San

Diego, CA), Life Chemicals Inc. (CT, US), and Prestwick (Illkirch, France), but each center may have varying numbers of proprietary or legacy compounds, which may include natural products, metabolites, synthesis intermediates, focused compound collections, etc. Compound collections include small organic molecules containing diverse chemical scaffolds that range in size from <300 Da (fragments), small molecules (300–500 Da) or macrocycles, and natural products (>1000 Da). Small or high molecular weight natural products and metabolites isolated from plants, microbes (soil, marine), and other living organisms are also attractive candidates for drug discovery and often utilized in screenings. Peptides, siRNAs, biologics, and CRISPR libraries are also employed in identifying mechanism or genomic sequences that will modulate a target identified through basic or clinical research. Library collections are characterized via computational selection tools or filters. These include Lipinski's rule of five (Ro5) which selects drug-like and potentially bioavailable compounds that are <500 Da, <5 hydrogen (H) bonds donors (NH &OH groups), <10 H-bond acceptors (N + O), with octanol-water partition coefficient, ClogP<5. The rule of three (Ro3) for fragment library selection identifies compounds <300 Da, <3 H-bond donors, <3 H-bond acceptors, ClogP≤3. At least 275 rules have evolved over the last two decades that identify compound liabilities from screening datasets (Bruns and Watson 2012), and several filters like rapid elimination of swill (REOS), Lilly Rules, and PAINS filters are employed to flag or exclude compounds that show promiscuous chemical reactivity, oxidizing/reducing agents, intercalators, large lipophilic molecules, heavy metals, or synthetically challenging scaffolds. Compound libraries also include a drug-repurposing collection, which includes FDA-approved drugs, used for screens directed toward identifying novel indications for marketed drugs. Since safety and human clinical trial data is already available, the FDA-approved drugs can be developed quickly if shown to be efficacious against a novel target both in vitro and in vivo. Over the last decade, the use of compounds tagged with DNA barcodes (DNA-encoded chemical libraries, DECLs) has evolved for use in screens that can be conducted in single tubes (Franzini et al. 2014). The DECLs are still not readily accessible, and their success in hit identification will become evident over the next few years.

Compound Storage and Management. The compounds in HTS collections are stored as liquid stocks or as solids (powders). For primary screens, compounds are solvated in 100% dimethyl sulfoxide (DMSO) as vast majority of small organic molecules are soluble in DMSO at 10 mM. Some labs also store pre-weighed amounts of solid powders in barcoded vials at various temperatures (room temperature, refrigerated, or −20 °C, depending upon the collections). The solids are generally used for verification of hit structures, for reconfirmation of activity, or for secondary assays. The solvated compounds are stored, sealed, and frozen in polypropylene (PP) or cycloolefin microplates at −20 °C, flushed with nitrogen to reduce humidity and minimize DMSO hydration. The automated plate sealing systems (e.g., Agilent PlateLoc TM Thermal microplate sealer) can also flush nitrogen prior to heat sealing the microplates containing compounds. Various automated compound storage and retrieval systems are available commercially with software that also tracks frequency of freeze-thaws. DMSO is hygroscopic, and compound-processing protocols that include repeated freeze-thaws, plate unsealing, and compound transfers facilitate slow hydration of DMSO, which, in turn, reduces solubility of some compounds causing them to eventually crash out of solution. HTS labs are also equipped with multi-wall plate sonicators like Covaris L8 for homogeneous compound plate preparation. Covaris L8 uses high-frequency, ultrasonic acoustic energy to resuspend compounds prior to transfer. In addition to using DMSO as a solvent, occasionally, ethanol, methanol, acetonitrile, or other solvents are also used for solvating natural products. Peptides tend to require different solvents based on

their net charge and size. All compound libraries are managed through inventory databases containing information on barcodes, plate ID, unique compound identification numbers, batch information, molecular weight, chemical formula, structure SMILES (simplified molecular-input line-entry system), salt form, and vendor catalog number (Vendor ID) or internal synthesis notebook ID, enantiomer forms, etc. While primary screens are performed using HTS library stocks that undergo repeated freeze-thaws, the hits from HTS are further reconfirmed from less utilized HTS stocks or freshly dissolved compound powders that are first analyzed for structural integrity and purity.

Compound Dispensing. Daughter plates that contain compound stocks are stored in 384-well or 1536-well plate formats in DMSO. Compound transfers are performed via either contact tip-based methods or non-contact transfers acoustically. Robotic platforms with mechanical arms and tip-heads are utilized for transfer of small volumes of compounds to the assay plates. Tip-based transfers are made via air displacement disposable tips (250 nl or higher) or via fixed positive displacement tips (25 nl or higher) or stainless steel pre-calibrated pin tools (2–5 nl). Depending upon the stock volumes and the concentration of compound screened in the final assay volume, intermediate concentration plates may be required for compound transfers. Reusing plastic tips or pin tools requires washes between transfer to prevent cross-contamination or carryover of compounds. Non-contact acoustic transfer systems (Labcyte Inc., EDC Biosystems™) use sound energy to transfer volumes as low as 1 to 2.5 nanoliter directly from stock plates to assay plates without any cross-contamination, or any need for intermediate plate dilutions or tips. Acoustic transfers are especially convenient for setting up combination screens where two drugs of interest can be transferred from single-source well to a single destination test well with ease. Some screening labs also use piezo actuator-based technologies that allow electrical to mechanical energy conversions which can create 0.1 nl to 1 nl transfers.

Screening Formats. In vast majority of screens, a single compound is screened per well of the microplate, which requires screens of hundreds of microplates to screen large compound/peptide collections. Appropriate vehicle controls are always included in each assay plate during screenings. Generally, large compound collections are screened at a single concentration (e.g., 1 uM or 10 uM) for time- and cost-effectiveness. In quantitative HTS (qHTS) mode, compound libraries are screened at six to eight concentrations to enable hit selection based on their dose-responsiveness, shapes of curves, and approximate IC50 values. In drug repurposing-focused screens, the FDA-approved collection of drugs or known bioactives are screened alone at very low concentrations (1uM–2.5 uM) or may be screened in the presence of a known standard of care in drug combination screens to identify synergistic combinations. Synthetic lethality screens (Huang et al. 2020) can be set up using an FDA-approved or chemotoxic compound that at low concentrations is non-lethal to cells but, in combination with a hit from siRNA screen, identifies a protein product and eventually another drug, which sensitizes a tumor to the drug, thus identifying a novel chemotherapy combination.

Bulk Reagent Dispensing. The reagents are dispensed into assay plates before or after the compound transfers, depending upon the assay design. Generally for biochemical screens, the compounds and vehicle controls or known positive controls are first transferred from HTS stock plates ("daughter plates") into the assay plates. For cell-based screens, the cells are first plated and allowed to attach to the plates before the compounds are dispensed. For most assays, the dispensing volumes of cells, media, proteins, substrates, and buffer into the wells of 96-, 384- or 1536-well plates in a screening batch range between 2.5 ul and 120 ul. Bulk volume dispensing is conducted with either automated pipetting platforms that use plastic or stainless steel tips attached to 384- or 1536-well heads that move in

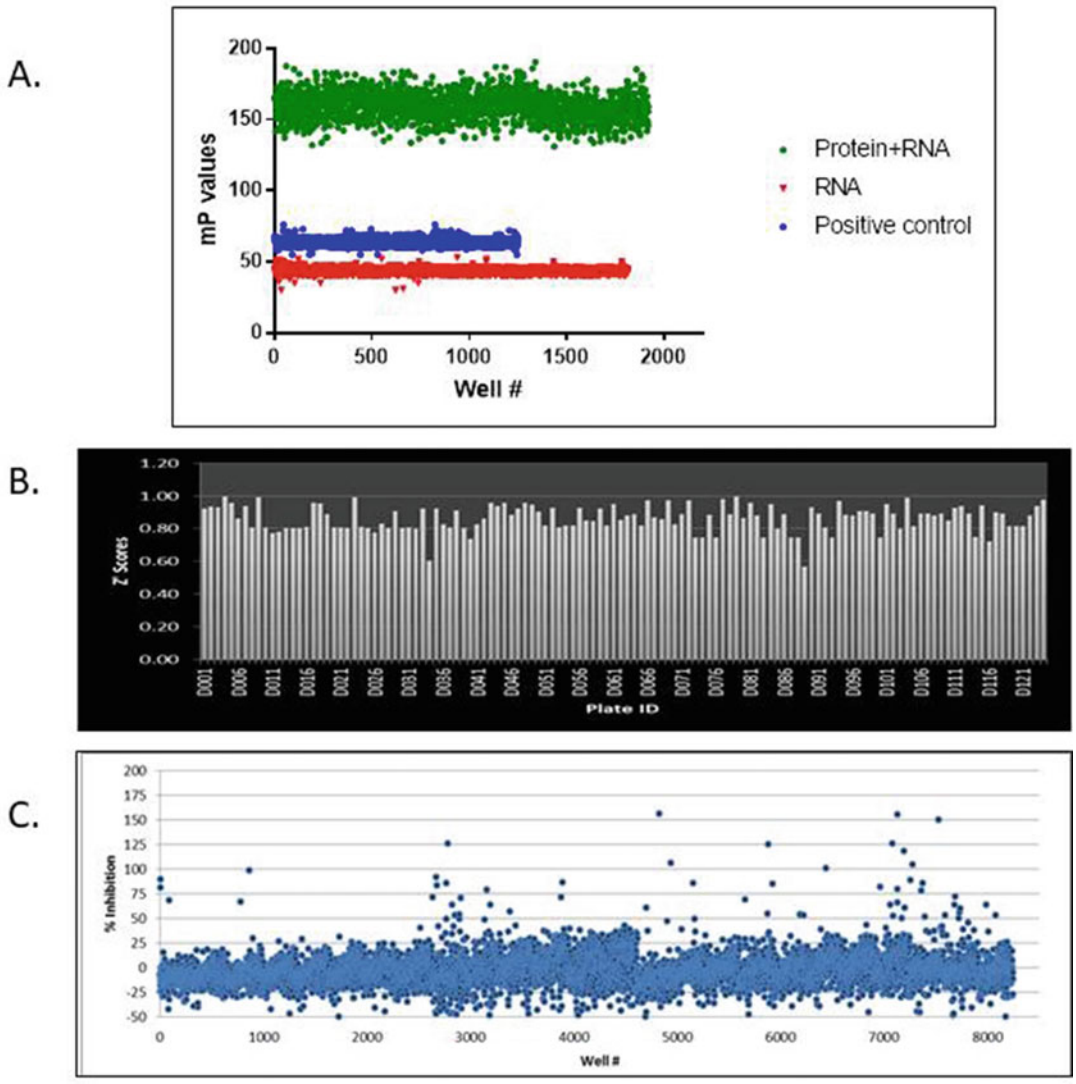
x-, y-, and z-axes with a robotic arm across all pipetting positions on instrument deck. Reagent dispensing is also performed with more affordable peristaltic pump-based dispensers containing multichannel tubing cassette assembly, which are calibrated for dispensing variable volumes. In a typical plate map for screening, each 384-well assay plate may contain 16 wells each of negative and positive controls in the first two columns of assay plate. Compounds are transferred to the remaining wells of the plate (columns 2–24). The control wells are also backfilled with 100% DMSO to ensure the same final percent of DMSO in all the wells of the plate.

Plate Readers. The plates containing compounds and assay components are incubated under defined optimal conditions, and the signals are read on multimodal plate readers that are capable of reading all available assay technologies. The microplate readers are equipped with plate stackers that can harbor up to 100 microplates that are inserted in defined sequence inside the plate reader to quantify absorbance-, fluorescence-, or luminescence-based detection technologies through use of monochromators and/or filter sets of specific wavelengths. The plate readers also capture the assay plate barcodes and store raw data of all the plates for quality control management. Rapid decaying signals are captured one well at a time using reagent injectors in plate readers that inject the detection reagent just before a well is read. Specialized modules in plate readers facilitate reading of AlphaScreen counts or TR-FRET or HTRF-based assays. Specialized drug discovery systems like Functional Drug Screening System (FDSS, Hamamatsu) allow fast kinetic measurement and analysis of fluorescent and luminescence signals in all wells of 384- or 1536-well microplate in millisecond intervals without time lags using highly sensitive camera. The RT-PCR systems are utilized in capturing qRT-PCR profiles of selected primers to evaluate changes in gene expression induced by compound exposure or to capture protein unfolding in presence of compounds for direct compound binding screens using differential scanning fluorimetry. Although not widespread in practice, a small number of HTS laboratories also use highly specialized screening formats like automated flow cytometry, mass spectrometry, and NMR for primary screening.

The readouts of phenotypic screens include direct reads from absorbance, fluorescence, or luminescence or imaging-based high content screening (HCS). The images of all the wells in clear bottom plates containing cells and compounds are captured with automated microscopy either directly or after fixing and immunostaining. The automated confocal microscopic platforms provide resolution at subcellular level and can quantify spatial and temporal signals from fluorescent reporter proteins, fluorescently labeled antibodies, and stains. Imaging readouts include quantification of cell morphology, cell number, nuclei, cell membrane changes, apoptosis, translocations within cells, neuronal or vascular outgrowths, cell migrations, cell differentiation, etc.

Data Analysis

The raw data from 10^3 to 10^6 wells is transferred from plate readers or imagers to assay and compound databases like IDBS ActivityBase or in-house databases. Large compound screens are performed at $n = 1$ and are therefore not statistically reliable. The data is susceptible to compound purity, stability, solubility, and intrinsic spectral properties. Issues with physicochemical properties of compounds can result in identification of false positives due to aggregation or assay interference. Despite extensive optimization, assays in 1536-well or 384-well plates can sometimes show edge effects, row- or column-dependent patterns in HTS workflows. The data analysis for entire screening campaign is analyzed using a variety of excel or informatics tools. The readouts from the positive and negative controls per plate are utilized for evaluating the quality control of the screen (Fig. 3). The plates that show unacceptable Z' scores or show row- or column-wise issues can be rejected and rescreened if time and cost permit. As a general guideline, hits are identified as compounds that inhibit or activate an assay at plate median plus/minus 3 standard deviations. Depending upon the hit rates, the hit selection



High-Throughput Screening (HTS) Technology, Fig. 3 Data analysis from a representative primary screen. (**a**) Scattergram showing uniform distribution of high (protein + RNA) and low (RNA only) control signals across all the plates. (**b**) Distribution of Z' scores across assay plates. An average of 0.8 ± 0.02 was obtained showing acceptable separation of controls. (**c**) Scattergram of percent inhibition across the primary screen. Primary screen actives are identified as compounds that inhibit the assay at plate median plus three standard deviations

criterion can also be changed accordingly. Most targeted biochemical screens show very low hit rates (<1%), whereas cell-based or phenotypic screens can show anywhere between 0.5 and 4% hit rates. Cheminformatics analysis is used again to flag compounds with PAINS (Pan Assay Interference Compounds) or reactive groups, chelators, and covalent binders. The hits from a screen are also evaluated for their promiscuous activity against other targets or specific targets using internal screening databases or using the publicly available PubChem database (Wang et al. 2017). Depending on the number of hits from a screen, hits can be clustered based on substructure similarity at this stage or after the hits from $n = 1$ screen is reconfirmed for

concentration-dependent activity experiment. Imaging data management for phenotypic screens requires large data storage clusters and development of analysis algorithms (CellProfiler https://cellprofiler.org) to analyze multiparametric high content information.

Hit Reconfirmation. Compound attrition is an essential step in viable hit identification in both academic and pharmaceutical settings. The hits from primary screen are reconfirmed in dose-response studies using compound aliquots cherry-picked from in-house library DMSO or powder stocks. The reconfirmation assay is the primary screening assay that is run in parallel with counterscreen to remove assay interference compounds or cytotoxicity assays in relevant cell lines to eliminate non-specific toxics or with an orthogonal assay to confirm compound activity against the target of interest. The hits that are dose-responsive and show higher potency in target-specific screen are analyzed further for structure-activity relationships by cheminformatics analysis (Shun et al. 2011). The clusters are analyzed by medicinal chemists for exploring SAR using minimal scaffold analysis, and some clusters are prioritized for further analysis by medicinal chemists based on their amenability to chemical optimization. At this stage, the hits are also examined for their promiscuity or activity against other targets using internal databases or public databases like PubChem (https://pubchem.ncbi.nlm.nih.gov/). The compounds of interest are repurchased in larger amounts as fresh powders of high purity (>95% purity) for reconfirmation and further profiling. A limited number of compounds may be synthesized by medicinal chemists if they look interesting but are not available from commercial vendor sources.

Hit Profiling. A number of biochemical and cell-based assays are used to define biological potency and selectivity and physicochemical properties of compounds (Arrowsmith et al. 2015). In addition to activity and potency in the primary assay, the hits are evaluated for toxicity in relevant cell lines and activity in 3D models, quantifying target-relevant signaling pathway proteins. Other orthogonal assay schemes also include several biophysical approaches to show direct binding of the compound to the target of interest. Depending upon availability of resources, the direct binding of hits to targets is performed using Surface Plasmon Resonance (SPR), Differential Scanning Fluorimetry (DSF), Isothermal Titration Calorimetry (ITC), or Nuclear Magnetic Resonance (NMR) assays. Identification of targets of hits from phenotypic assays is complex and utilizes various techniques to establish target engagement. The binding of the hit compounds to cellular targets in intact cell or in cell lysates is performed via Cellular Thermal Shift Assay (CETSA). The proteins stabilized by compound binding at increasingly high temperatures are detected by immunodetection or via activity assay. The more complete profile of targets stabilized by compounds in CETSA is obtained via mass spectrometry. Alternative methodologies that are used in combination with mass spectrometry to establish hit-target interactions include affinity elution of proteins from compounds immobilized on solid-phase resins pull-down experiments, or use of protein arrays. Compound profiling also includes in silico or in vitro profiling of compounds for their physicochemical properties like structure, aqueous solubility, protein binding, microsome stability, and other ADME/pharmacokinetic profiling in vitro or in silico screens. The selectivity, specificity, and ADME profiles form the basis of identifying probes that can be used for chemical genetics or provide starting points for a more involved and cost-intensive drug development programs. The hits that bind the target non-covalently show high potency (<0.1 uM biochemical and ~up to 1 uM cell based); selective (>50–100-fold) and quantitative modulation of a specific biological target are very useful in defining the mechanism of action.

Pharmacological Relevance

HTS as a standardized translational research exploratory platform evolved largely in pharmaceutical sector as an approach toward identifying

starting compounds for drug discovery programs. The National Institutes of Health (NIH) funded initiative Molecular Libraries Probe Production Centers Network (MLPCN), and the NIH Molecular Libraries Program (MLP) brought the technology to academic screening centers by providing protocols, guidelines, novel compound collections, screening methods, as well as funding mechanisms to expand the scope of basic research. The MLP successfully identified ~375 high-quality probes against diverse therapeutic targets (Schreiber et al. 2015). Several of these probes are currently being advanced for late-stage drug discovery programs. There are several notable examples of hits from HTS that were developed ultimately to marketed drugs (Macarron et al. 2011). High-throughput targeted or phenotypic screening has also resulted in the discovery of several first-in-class drugs (Eder et al. 2014). HTS, hit identification and probe, and lead development are a constantly evolving technology that serves to impact our understanding of basic biology and therapeutic development to treat various conditions in pathology and progression of human diseases.

Hippo Pathway

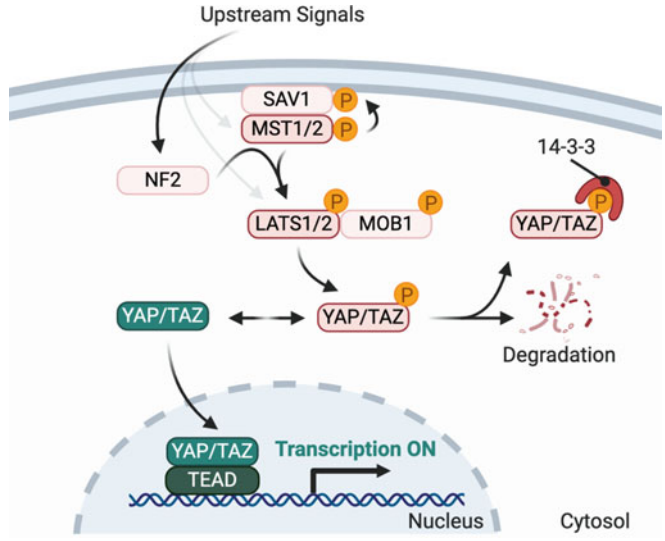
Jeffrey K. Holden[1] and James J. Crawford[2]
[1]Department of Early Discovery Biochemistry, Genentech, Inc, San Francisco, CA, USA
[2]Department of Discovery Chemistry, Genentech, Inc, South San Francisco, CA, USA

Definition

The Hippo pathway is a highly conserved signaling pathway that regulates multiple cellular and developmental processes within metazoans. It is composed of a kinase cassette, Yes-associated protein (YAP), and WW-domain-containing transcription regulator 1 (WWTR1; or TAZ). YAP and TAZ are paralogs that function, separately, as transcriptional co-activators upon binding to the transcriptional enhanced associate domain (TEAD) family of proteins and TEAD's cognate DNA binding sites. Formation of a YAP/TAZ-TEAD complex in the nucleus can activate transcription of genes involved in cell fate, growth, proliferation, and survival. The kinase cassette functions as a switch to regulate YAP/TAZ activity. When the kinase cassette is active, YAP/TAZ activity is suppressed via phosphorylation. In contrast, when the kinase cassette is inactive, YAP/TAZ can translocate into the nucleus, bind TEAD, and induce target gene transcription. This pathway gets its atypical name from the *Drosophila melanogaster* kinase Hippo as initial deletion studies of Hippo in *D. melanogaster* led to an overgrowth phenotype. Aberrant Hippo signaling has been linked to a range of different cancers, therefore tight control of the Hippo pathway is critical due to the important role of the Hippo pathway in development and tumorigenesis.

Basic Characteristics

The Hippo pathway regulates the activity and cellular localization of transcriptional co-activators YAP and TAZ to control organ size, tissue homeostasis, and cell growth. Unlike most conventional cell signaling pathways, Hippo activity is not controlled by a dedicated ligand-receptor pairing but is instead regulated by multiple mechanisms including – but not limited to – the cell microenvironment, cell polarity, metabolic pathways, and extracellular growth factors. When the Hippo kinase cassette is activated, transcriptional co-activators YAP and TAZ are localized to the cytosol, where they bind to 14-3-3 proteins or are degraded by the proteasome (Fig. 1) (Ma et al.



Hippo Pathway, Fig. 1 Key components of the Hippo pathway in mammalian cells

2019). In contrast, when the kinase cassette is inactive, YAP/TAZ can translocate into the cell nucleus, bind TEAD, and induce a transcriptional response (Fig. 1). Genes activated for transcription by YAP/TAZ are involved in cell survival, migration, and proliferation, such as *BIRC5*, *CTGF*, and *Cyr61*.

Key Hippo pathway components were first identified in *Drosophila melanogaster* via genetic mosaic screens (Pocaterra et al. 2020). Deletion of the kinase genes for Hippo and Warts resulted in an overgrowth phenotype (Wu et al. 2003) thought to be visually reminiscent of a hippopotamus, hence the colorful pathway name. While the gene names of Hippo pathway components between *D. melanogaster* and mammals are quite different, both the domain composition and functional roles of each protein is conserved (Table 1). *D. melanogaster* has thus served as a useful model system for identifying and characterizing components of the Hippo pathway.

Hippo Pathway, Table 1 Hippo pathway components and functional homology shared between mammals and *D. melanogaster*

Mammalian gene	Fly gene (*D. melanogaster*)	Role in Hippo pathway
NF2	Merlin	Binds and localizes LATS1/2 to the plasma membrane
MST1/2	Hippo	Phosphorylate LATS1/2
Sav1/WW45	Salvador	Scaffold for MST1/2
LATS1/2	Warts	Phosphorylate YAP/TAZ
MOBKL1A/B or Mob1	Mats	Adaptor protein for LATS1/2
YAP, TAZ	Yorkie	Nuclear localization activates transcription in presence of TEAD
TEAD1, TEAD2, TEAD3, TEAD4	Scalloped	Co-transcriptional activator for YAP/TAZ

Hippo Pathway Activation-Inactivation

The upstream signals that regulate the Hippo pathway are diverse and not fully characterized. Activity of the Hippo kinase cassette can be affected by hormonal signaling through GPCRs, cellular stress, phosphatases such as the STRIPAK complex, and cell biological properties like cell-cell contact, cell polarity, and sheer stress (Ma et al. 2019). As an inverse pathway, it is able to integrate and convert multiple biochemical, cellular, and mechanical cues into a transcriptional response. This requires the kinase cassette to be activated in order to turn off transcription, and the kinase cassette to be inactivated for transcription to be turned on.

Hippo Kinase Cassette

The Hippo kinase cassette is composed of tumor suppressor kinases MST1/2 and LATS1/2, along with their respective accessory proteins SAV1 and MOB1. Activation of the kinase cassette is initiated by NF2, which functions as a scaffold by binding the LATS1/2-MOB1 complex and delivering it to the membrane bound MST1/2-SAV1 complex (Manning et al. 2020). Following autophosphorylation of MST1/2, the LATS1/2–MOB1 can be phosphorylated by MST1/2. Other kinases, such as MAP 4K and TAO kinases, can also activate LATS1/2 via phosphorylation (Meng et al. 2015). Importantly, LATS1/2 phosphorylation enables it to function as a kinase for YAP/TAZ; whose kinase activity is promoted through interactions with the angiomotin family of proteins (Mana-Capelli and McCollum 2018). Both YAP and TAZ contain WW domains that bind the PPxY motif of LATS1/2, where P is a proline, Y is a tyrosine, and x is any residue. The YAP WW and LATS1/2 PPxY interaction is essential for YAP/TAZ phosphorylation. Based on gene deletion studies, LATS1/2 and MOB1 are also indispensable for YAP/TAZ phosphorylation (Bae et al. 2016; Plouffe et al. 2016). Therefore, maintaining a functional kinase cassette and accessory proteins is imperative for controlling YAP/TAZ activity.

YAP/TAZ

YAP and TAZ serve as the terminal effectors of the Hippo pathway. These are paralogs that share 46% sequence identity and activate similar pro-growth transcription profiles (Pocaterra et al. 2020). While YAP and TAZ are essential for development, they lack a DNA binding domain and require the transcriptional enhanced associate domain (TEAD) family of proteins to activate transcription.

Transcriptional activation requires YAP/TAZ to translocate into the nucleus and form a transcriptional complex with TEAD. Under normal physiological conditions, TEAD is exclusively located within the nucleus, whereas YAP/TAZ cellular localization is regulated by the Hippo kinase cassette. LATS1/2 mediated phosphorylation of YAP/TAZ occurs at the consensus HxRxxS motifs on YAP/TAZ where H is histidine, R is arginine, S is serine, and x is any amino acid. Phosphorylation of YAP at S127 or TAZ at S89 enables binding to 14-3-3 (Callus et al. 2019). Phosphorylation of YAP also triggers subsequent phosphorylation by casein kinase 1δ/ε at the YAP-encoded phosphodegron, which in turn serves as a substrate for $SCF^{\beta\text{-}TrCP}E3$ ligase-induced degradation.

At the molecular level, regulation of YAP/TAZ activity is accomplished through modulating gene expression, ubiquitin directed proteasome degradation, increased nuclear YAP/TAZ export rates, YAP/TAZ phosphorylation, and binding to 14-3-3 in the cytosol (Pocaterra et al. 2020). Together, these mechanisms serve to regulate YAP/TAZ nuclear levels, retain YAP/TAZ to the cytosol, and limit the pro-growth transcription profile induced by nuclear YAP/TAZ-TEAD complex formation. Although the full range of YAP/TAZ binding partners has not yet been elucidated, it appears their roles are likely both context- and tissue-dependent (Callus et al. 2019).

TEAD

The TEAD family protein Scalloped was first characterized in *Drosophila* to promote wing development and control organ size (Zhang et al. 2008). Unlike *Drosophila* whose genome encodes for one TEAD protein, mammals have four distinct TEAD genes whose translated protein sequences (TEAD1, TEAD2, TEAD3, and TEAD4) share a high sequence identity. Each TEAD protein is composed of an N-terminal DNA binding domain, a C-terminal YAP binding domain, and a proline-rich sequence between the two domains (Holden and Cunningham 2018). The TEAD DNA binding domain is highly conserved across all TEADs and is composed of a helix-turn-helix homeodomain fold that directs TEAD towards the muscle-specific cytidine-adenosine-thymidine (MCAT) consensus sequence (Holden and Cunningham 2018). Despite high sequence homology shared between human TEAD1–4, the individual TEAD proteins are differentially expressed in a tissue- and development-dependent manner. A clear understanding of how TEAD1–4 interact and complement one another in a physiological setting remains unknown.

Crystal structures and binding studies have enabled a detailed mapping of critical interactions between YAP/TAZ-TEAD (Holden and Cunningham 2018; Bokhovchuk et al. 2020). In short, YAP/TAZ are able to wrap around a highly conserved surface on TEAD to form a heterodimer complex. The YAP binding domain of TEAD is posttranslationally modified by a palmitate group with the lipid tail extending into a conserved hydrophobic pocket. This palmitoylation is required for TEAD activity and stability. While YAP/TAZ are the best-known coactivators and regulators of TEAD transcriptional activity, the vestigial-like protein family (VGLL) and p160s also interact with TEAD to function – in part – as competitive YAP/TAZ antagonists (Callus et al. 2019). On a similar note, YAP has also been shown to have a TEAD-independent role in intestinal Wnt inhibition (Li et al. 2020).

Genetic Dysregulation of the Hippo Pathway

Gene fusions that promote tumorigenesis have also been identified within the Hippo pathway. Notably, epithelioid hemangioendotheliomas

(EHEs) result from a TAZ-CAMTA1 gene fusion that is constitutively expressed and can no longer be regulated by the Hippo pathway. YAP can also be fused to transcription factor E3 resulting in EHE. In lung cancer, gene fusions to TAZ, NF2, and LATS1/2 have also been identified and correlated to poor overall survival (Meng et al. 2016). A missense mutation that ablates the TEAD-YAP interaction and results in the human disease Sveinsson's chorioretinal atrophy – also referred to as helicoid peripapillary chorioretinal degeneration, atropia areata, or circumpapillary dysgenesis – a progressive degenerative disease of the eye has also been identified on TEAD1 at the TEAD-YAP interface.

Pathophysiology and Therapeutic Potential

There is increasing interest in harnessing the therapeutic potential of compounds that modulate the Hippo pathway to affect YAP/TAZ mediated transcription. Modulation of the pathway's activity is envisioned for two disparate approaches: (1) limiting cell growth in various cancers with aberrant YAP/TAZ induced transcription and (2) inactivating the Hippo kinase cassette to promote cell growth for tissue repair and wound healing.

Suppressing YAP/TAZ transcriptional activation in cancers represents a significant therapeutic opportunity. While both proteins are critical in early development and tumorigenesis, their activity is expendable in most adult tissues. This indicates that YAP/TAZ antagonists could be tolerated and a viable therapeutic target. Although there are multiple hypothesized benefits of deactivating YAP/TAZ activity in the context of cancer, directly inhibiting the transcription profile induced by YAP/TAZ is challenging. Viable inhibition of YAP/TAZ activity will require a therapeutic that can either (1) prevent YAP/TAZ from entering the nucleus or (2) modulate the YAP/TAZ interaction with TEAD. These two general strategies represent potential therapeutic avenues for modulating YAP/TAZ activity and the discovery of new anticancer therapeutics.

Due to the pro-growth and pro-survival transcription profile induced by YAP/TAZ, it might also be possible to leverage this to accelerate wound healing and tissue repair mechanisms. In wounded *in vitro* cultured cells, YAP is activated and thus able to translocate into the nucleus and induce transcription of its target genes (Meng et al. 2016), enabling cell migration and proliferation at the site of the wound. The cellular response to injury also requires the Hippo pathway to be suppressed for the repair mechanisms to be enabled. In short, therapeutic control of YAP/TAZ localization represents an exciting opportunity to advance healing of damaged tissues.

Genetic disruption of core Hippo pathway components and subsequent YAP translocation into the nucleus leads to sustained liver growth and cancer, such pathway inhibition enhances regenerative capacity *in vivo* and an MST1/2 inhibitor has been shown to augment liver and intestinal repair in mice (Hong et al. 2019; Fan et al. 2016). In addition, YAP-deficient mice have an impaired intestinal regenerative response in a colitis model and conditional deletion of TAZ in a bleomycin-induced lung injury model reduced AEC1 regeneration during recovery, leading to increased alveolar destruction and fibrosis (Sun et al. 2019). Further, deletion of SAV1 in mouse hearts resulted in enhanced cardiomyocyte regeneration, reduced fibrosis, and recovery of pumping function after myocardial infarction (Leach et al. 2017). In short, dysregulation of canonical Hippo signaling can have effects on cell and tissue development, and may contribute to the pathology of many diseases.

Pharmacological Intervention

In the context of cancer, sustained inhibition of the core kinase cassette members is problematic as NF2, Mst1/2, and LATS1/2 are tumor suppressors. Most reports thus far have focused on targeting the Hippo pathway via the transcriptional co-activators YAP/TAZ and TEAD. While YAP/TAZ are known to be mostly intrinsically disordered proteins that lack binding pockets for ligands, one YAP ligand – verteporfin – has been reported. Statins have also been evidenced to inhibit YAP nuclear translocation by inducing YAP phosphorylation (Bae et al. 2016); however,

the precise molecular mechanisms and thus the utility of both verteporfin and statins as physiological tools remains unproven. Despite the many challenges associated with targeting YAP/TAZ transcriptional activity in cancer or wound healing, multiple groups have identified molecules that lower YAP/TAZ activity. Interestingly, the vast majority of the small molecules reported thus far bind to the TEAD palmitoylation site. This lipidated pocket site is hydrophobic and seems to accommodate a range of small hydrophobic molecules that have been shown to lower target gene transcription in vitro (Crawford et al. 2018). Recent evidence indicates some of these molecules function as a surrogate for palmitoylation to affect TEAD protein levels and induce a dominant-negative phenotype (Holden et al. 2020). Overall, targeting TEAD to affect YAP/TAZ transcription presents an interesting opportunity for the development of new anticancer therapeutics.

Taken together, modulation of the Hippo kinase cassette activity, YAP/TAZ localization, and YAP/TAZ targeted gene transcription play an indisputable role in both development and tumorigenesis. It appears certain that the identification of tool compounds capable of altering YAP/TAZ activity will remain of high interest. Therefore, advances leading to physiological control of nuclear YAP/TAZ activity will enable important discoveries of the Hippo pathway, clinically relevant processes, and the identification of therapeutics for a range of diseases.

Histamine Receptors

Natalia C. Fernández and Federico Monczor
Laboratorio de Transducción de Señales y Diseño de Fármacos, ININFA – Instituto de Investigaciones Farmacológicas – UBA-CONICET, Buenos Aires, Argentina

Synonyms

Histaminergic receptors

Definition

Histamine receptors are transmembrane proteins that bind to the endogenous ligand histamine and activate a sequence of intracellular events ("Transmembrane Signalling") that lead to all the cellular and physiological responses attributed to histamine. They are part of the histaminergic system ("Histaminergic System").

Basic Characteristics

Classification

Four subtypes of histamine receptors have been described in the literature, namely, H_1, H_2, H_3, and H_4 receptors. This classification is based on their sequential discovery by either pharmacological characterization or molecular identification (Alexander et al. 2019).

Expression and Function

H_1 Receptor

Histamine H_1 receptor is widely expressed throughout the body. It is found mostly in the smooth muscle of the airways and blood vessels, endothelium, and cells of the immune system such as dendritic cells, monocytes, neutrophils, and T and B cells. Here, activation of H_1 receptor mediates most actions of histamine related to allergy, asthma, and inflammation (▶ "Inflammation") including bronchoconstriction, mucus secretion, mucosal edema, pruritus, pain, increased vascular permeability, hypotension, flushing, and tachycardia. Most of the clinical relevance of antihistamines rely on the treatment of these allergic/anaphylactic and asthmatic physiological reactions (▶ "Bronchial Asthma"). High levels of H_1 receptors are also found in neurons in several brain regions involved in neuroendocrine, behavioral, and nutritional regulation, such as the cortex, hypothalamus, thalamus, septum, hippocampus, brain stem, and olfactory bulb where it controls the sleep-wake cycle ("Sleep"), food intake, aggressive behavior, memory, and learning. Apart from these systems, the H_1 receptor is also expressed in chondrocytes, hepatocytes, and in the heart where its function is less clear (Panula et al. 2015).

H_2 Receptor

The **H_2 receptor** is predominantly expressed in mucosa parietal cells where it mediates gastric acid secretion. In order to block histamine action at this level, H_2 receptor antagonists have been widely used for the treatment of duodenal and gastric ulcers until they were replaced by proton pump inhibitors ("Proton Pump Inhibitors and Acid Pump Antagonists"). Strong expression of H_2 receptor is also found in almost all brain areas in both neurons and astrocytes and, more modestly, in cells of the immune system such as neutrophils, eosinophils, monocytes, macrophages, dendritic cells, and T and B cells. In addition, H_2 receptor can be found in the heart, chondrocytes, smooth muscle, and endothelial and epithelial cells. Here, activation of the H_2 receptor results in hypotension, bronchoconstriction, flushing,

increased vascular permeability, and tachycardia (Panula et al. 2015).

H_3 Receptor

The **H_3 receptor** is mainly expressed in the central nervous system where it functions as autoreceptor in histaminergic neurons, regulating the synthesis and release of histamine and as a heteroreceptor regulating transmission by GABA, glutamate, and biogenic amines, such as acetylcholine, serotonin, noradrenaline, and dopamine. By doing so, the H_3 receptor is involved in the regulation of the sleep-wake cycle ("Sleep"), cognition and attention, circadian rhythms, homeostasis, arousal, appetite, satiety, and energy expenditure. The H_3 receptor also modulates histamine release from mast cells (Panula et al. 2015).

H_4 Receptor

The last histamine receptor to have been discovered is the **H_4 receptor**. Although it is mainly expressed in bone marrow, it can also be also detected in peripheral hematopoietic cells, the spleen, and the thymus, where it regulates the maturation and differentiation of blasts and the chemotaxis of blood cells. It appears to be an important mediator of inflammation, and its expression is also upregulated by inflammatory stimuli. Therefore, its expression pattern is complicated because it changes in response to the state of the cell. Despite these limitations and considerations, evidence of H_4 receptor expression can be found in the lung, small intestine, colon, heart, liver, brain, skeletal muscle, gastrointestinal tract, and epidermal tissue (Panula et al. 2015).

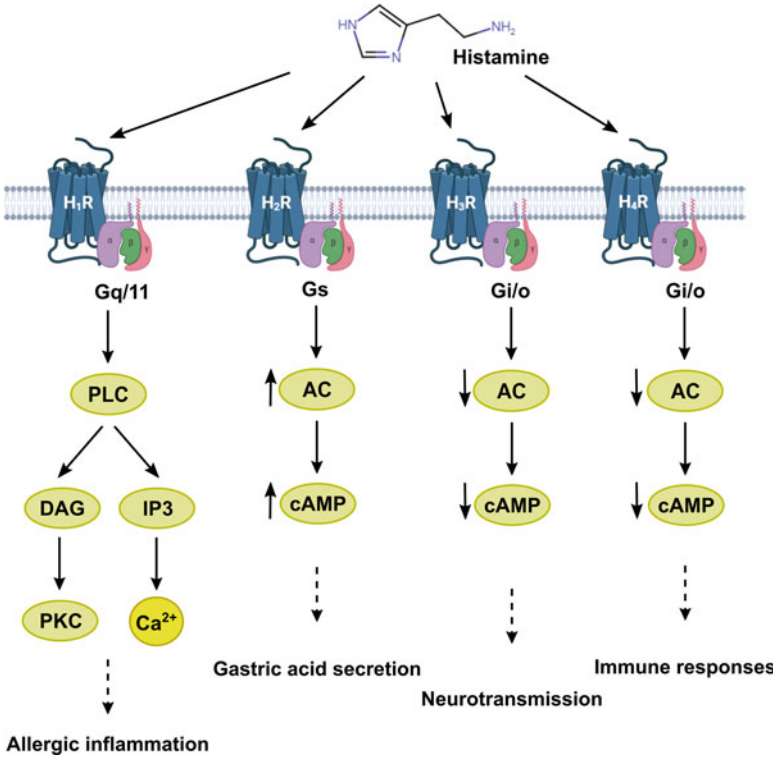
Structure and Signaling

Histamine receptors belong to the superfamily of G protein-coupled receptors (▶ "G-Protein-Coupled Receptors") which are structurally characterized by an amino-terminal extracellular domain, a carboxy-terminal intracellular domain, and seven transmembrane-spanning helices connected by three intracellular loops and three extracellular loops. Functionally, when activated, these receptors signal through coupling to heterotrimeric G -protein and lead to the modulation of cytoplasmic second messengers (Fig. 1).

H_1 Receptor

The **H_1 receptor** human gene (HRH1, 126.16 kb, 3 exons) is located in chromosome 3p25.3. The protein contains 487 amino acids and there are described 20 single nucleotide polymorphisms: 2 of them are relatively common, while some act as predictors of therapeutic efficacy or are associated with the severity of antihistamines' side effects. Crystallographic studies showed that ligands bind deeply in the binding pocket defined by transmembrane helices 3, 5, and 6. Specifically, it has been proposed the interaction of the $Asp107^{3.32}$ with the protonated amine group of histamine that would be conserved among all histamine receptors subtypes (Shimamura et al. 2011).

In most systems, the H_1 receptor is coupled to Gq/11 protein, and its stimulation leads to phospholipase C (PLC) activation, with a consequent increase in diacylglycerol (DAG) that activates protein kinase C (PKC) (▶ "Protein Kinase C"), a serine-threonine kinase that phosphorylates different downstream effectors, and inositol-1,4,5-trisphosphate (IP_3) that stimulates the IP_3 receptor ("IP_3 Receptor") triggering calcium mobilization that binds calmodulin (▶ "Ca^{2+}-Binding Proteins"). One of the main PKC targets is the NF-kB (▶ "NF-κB, Molecular Target") transcription factor which is tightly related to inflammation. In the central nervous system, both calmodulin and PKC modulate, among others, potassium voltage-gated type 7 (Kv7) channels (▶ "Voltage-Gated K^+ Channels") resulting in depolarization and increased nociception (Obara et al. 2020). Human H_1 receptor presents high levels of spontaneous activation ("Constitutively Active Receptor States"). Receptors exist in at least two states: an inactive state and an active state which triggers a response. Under basal conditions, the equilibrium between these two states largely favors the inactive state. Agonists normally bind with higher affinity to the active form of the receptor and modify the equilibrium increasing the proportion



Histamine Receptors, Fig. 1 Main signal transduction mechanisms of histamine receptors and the major physiological processes they regulate

of receptors in the active state. Sometimes, however, under basal conditions, there is enough proportion of the receptor in the active state to produce an appreciable response in the absence of agonist. In this situation the receptor is termed to have constitutive or spontaneous activity) in the absence of an agonist, and many drugs considered to act only by blocking the receptor are actually inverse agonists of this signaling pathway as they reduce the spontaneous basal activity of the receptor. Although coupling to Gq/11 is the canonical signaling mechanism of H_1 receptor, it may also signal through small G proteins Rac and RhoA (► "Small GTPases") or through Gi/o increasing nitric oxide production and cGMP levels. In some cellular systems, it may also stimulate cAMP production by adenylyl cyclase (► "Adenylyl Cyclases") (Monczor and Fernandez 2016).

H_2 Receptor

The **H_2 receptor** was first cloned in 1991. Its gene is located in chromosome 5q35.2 and spans over 28.31 kb. The gene has an open reading frame of 1194 bp including 3 exons and codifies for a 359 amino acid polypeptide. Several polymorphisms have been described. Although there is no direct structural information of this receptor, based on mutagenesis data and homology modelling (► "Molecular Modelling"), it was inferred that histamine binds with a different orientation compared to H_1 receptor (Panula et al. 2015).

In humans, H_2 receptor stimulates adenylyl cyclase-mediated cAMP production by coupling to G proteins. Elevated cAMP, in turn, activates the serine-threonine kinase dependent of cAMP (PKA) which can phosphorylate several targets as Ca^{2+}-activated potassium channels (K_{Ca}), ligand-gated α-AMPA receptors, modulating its activity (Obara et al. 2020).

Histamine H_2 receptor displays high constitutive activity ("Constitutive Activity") toward cAMP production, and many ligands used in clinical practice actually behave as inverse agonists for this signaling pathway. Alternatively, in many

cellular systems, though not in all, the H_2 receptor can also couple to Gq/11 proteins, resulting in inositol-1,4,5-trisphosphate formation and increasing cytosolic calcium levels. Some functions of the H_2 receptor are mediated by modulation of signaling cascades associated with tyrosine kinase receptors such as the extracellular signal-regulated kinase (ERK1/2) and phosphoinositide 3-kinase pathways. H_2 receptors may also inhibit the generation of reactive oxygen species (ROS) by NADPH oxidase (► "NADPH Oxidase") inhibition (Monczor and Fernandez 2016).

H_3 Receptor

The **H_3 receptor** was firstly described on a pharmacology basis in 1983, but due to its poor sequence homology (~20%) with respect to H_1 and H_2 receptors, it was cloned in 1999. The gene covers 5.31 kb, is located in chromosome 20q13.33, and codifies for a polypeptide of 445 amino acids. Alternative splicing has been described for the H_3 receptor producing multiple receptor isoforms that could account for its pharmacological heterogeneity. Several genetic polymorphisms have been identified which may additionally confer pharmacological heterogeneity (Panula et al. 2015).

The H_3 receptor is coupled to Gi/o. Receptor activation results in inhibition of cAMP production and stimulation of PI3K-mediated phosphorylation of protein kinase B (PKB/Akt) via Gi β- and γ-subunits. After that, the downstream signaling pathway may depend on the cellular context. For example, receptor activation may inhibit voltage-gated Ca^{2+} channels (► "Voltage-Dependent Ca^{2+} Channels") in the heart and brain, stimulate G -protein-coupled inwardly rectifying potassium (Kir) channels (► "Inward Rectifier Potassium Channels"), and inhibit the Na^+/H^+ exchange transporter located in the plasmatic membrane of sympathetic nerve endings. Activation of PKB may inactivate neuronal GSK3 and activate MAPK/ERK as a neuroprotective mechanism for inflammation (Obara et al. 2020). The agonist-independent activity of the receptor leads to inhibition of cAMP production and increases arachidonic acid release.

H_4 Receptor

The **H_4 receptor** was the last histamine receptor to be discovered. Its gene was mapped at chromosome 18q11.2 and covers 19.33 kb containing 3 exons and 2 large introns. The open reading frame is of 1172 bp and encodes for 390 amino acid protein. Also, several polymorphisms have been described and at least two truncated isoforms were confirmed. Stimulation of the human H_4 receptor diminishes cAMP and increases Ca^{2+} mobilization from intracellular stores by Gi/o coupling and activation. Although H_4 receptor signaling pathways are thought to be similar to the described for the H_3 receptor, they are still being explored. Human H_4 receptors exhibit high constitutive activity ("Constitutive Activity") diminishing cAMP levels in transfected systems, but this observation was not reproduced in naive systems (Panula et al. 2015).

Drugs

H_1 Receptor Ligands

Those ligands that bind the H_1 receptor and block histamine function are important actors in the pharmacology of inflammation, typically used to treat different allergic and inflammatory-related conditions such as anaphylactic shock and allergic rhinitis and conjunctivitis. They are usually known as antihistamines and are among the most widely prescribed and over-the-counter-sold drugs in the world (Arrowsmith 2012). Most, if not all, of these compounds are now defined as inverse agonists possessing negative efficacy ("Inverse Agonism" and ► "Drug–Receptor Interaction"). Moreover, some of them were described as possessing pluridimensional efficacy, specifically activating different signaling pathways. Whether their pharmacological utility depends on this has to be established (Monczor and Fernandez 2016).

First-generation antihistamines massively marketed since the 1950s (e.g., mepyramine, diphenhydramine, and chlorpheniramine, among

the most common) are poorly selective ligands that also have significant affinity for cholinergic, alpha-adrenergic, dopaminergic, and serotonergic receptors. Chemically first-generation antihistamines include aminoalkyl ethers, ethylenediamines, piperazines, propylamines, phenothiazines, and dibenzocycloheptenes. Their major disadvantage is that they are able to cross the blood-brain barrier (► "Blood-Brain Barrier") and hamper histaminergic neurotransmission causing daytime somnolence and sedation.

A great advance occurred in the 1980s when second-generation antihistamines (e.g., cetirizine, desloratadine, and fexofenadine) were introduced. The second-generation agents share some structural similarity to the first-generation agents but have been modified to be more specific in action and limited in their distribution profiles. While possessing restricted ability to penetrate the central nervous system, minimal or no adverse effects were reported for these ligands. Despite their success, terfenadine and astemizole were withdrawn because they prolong QT interval and can be associated with the occurrence of potentially fatal cardiac arrhythmias.

The development of ligands acting as H_1 receptor agonists has been neglected due to their lack of clinical interest. A few molecules were developed, mostly as laboratory tools to determine H_1 receptor expression and function, and are generally obtained by modifications of histamine (Timmerman et al. 2017).

H_2 Receptor Ligands

H_2 antagonists were launched in the 1970s to treat patients presenting gastric or duodenal ulcers, dyspepsia, and gastroesophageal reflux disease (GERD). There are many ligands approved for their use (ranitidine, cimetidine, famotidine) although they were surpassed by proton pump inhibitors ("Proton Pump Inhibitors and Acid Pump Antagonists") and antibiotic therapies for *Helicobacter pylori*. The chemical structure of H_2 receptor blockers is based on the structure of histamine. Most of them contain an imidazole ring which may be replaced by 1) a furan ring or an aryl or heteroaryl ring bearing a basic substituent; 2) a so-called urea equivalent capable of undergoing H-bonding; and 3) a flexible chain connecting both π-electron systems (Dove et al. 2004). H_2 receptor antagonist treatment is considered safe, and lower doses of these ligands are available over the counter in pharmacies to be used for mild heartburn. Their safety profile is related to the inability of them to cross the blood-brain barrier and to act centrally. As with the H_1 receptor antagonists, H_2 receptor ligands were reclassified as inverse agonists or even more as possessing differential efficacies according to the intracellular pathway considered (Monczor and Fernandez 2016). Since H_2 receptor agonists have no clinical relevance, they were developed only to study the mechanisms of receptor activation or receptor expression. Histamine dihydrochloride has been approved for remission maintenance immunotherapy in acute leukemia (► "Cancer Immunotherapy") since, via H_2 receptor activation, it is able to potentiate IL2-promoted activation of T and NK cells conferring protection from tumor-induced immunosuppression (Martner et al. 2010).

H_3 Receptor Ligands

A considerable number of H_3 receptor selective ligands have been developed. Since the H_3 receptor inhibits the release of several neurotransmitters, those ligands that reach the central nervous system are potentially useful. The first H_3 receptor antagonists were imidazole based. However, non-imidazole molecules have become the main subject of the H_3 receptor antagonist design, because these structures deal with the issues noted with the imidazole-based ligands, especially their relatively poor central nervous system penetration (Timmerman et al. 2017). It has been observed that ligand pharmacology could be dependent on H_3 receptor isoform. H_3 receptor antagonists have the potential to increase the release of several neurotransmitters, and, remarkably, pitolisant, an orally active H_3 receptor inverse agonist, was recently approved for the treatment of narcolepsy. While agonists have been suggested for treating

insomnia, pain, and asthma, there are no currently available clinically useful agonists (Łażewska and Kieć-Kononowicz 2018).

H_4 Receptor Ligands

Since its discovery, the therapeutic benefits of targeting the H_4 receptor have been subjected to intensive research. Many ligands of the H_3 receptor, particularly imidazole-containing molecules, have high affinity for the H_4 receptor as well. With time, several selective non-imidazole H_4 receptor antagonists were developed (Timmerman et al. 2017). H_4 receptor ligands could have applications in the treatment of chronic inflammatory and immune diseases. The antagonist JNJ-39758979 significantly reduced histamine-induced itch in human subjects and reached phase 2 in a controlled clinical trial carried out in patients with moderate atopic dermatitis; however, the study was prematurely discontinued due to the appearance of serious adverse effects. Several clinical studies are being conducted to establish the putative therapeutic use of H_4 ligands in inflammatory and allergic disorders such as atopic dermatitis, pruritus, asthma, rheumatoid arthritis ("► Rheumatoid Arthritis"), and vestibular disease (Mehta et al. 2020).

Immune Checkpoint Blockade

Annamaria Brioli and Andreas Hochhaus
Universitätsklinikum Jena, Klinik für Innere Medizin II, Jena, Germany

Synonyms

Checkpoint inhibitors (CPI); Immune checkpoint inhibitors

Definition

Immune checkpoint blockade identifies a form of ► cancer immunotherapy that acts by unmasking the tumor cells from the host's immune system. The so-called checkpoint proteins present on cancer cells and/or on cells of the immune system have the function to keep the immune response

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

under control in physiological condition. In pathological conditions, such as in cancer, tumor cells can use this system to evade the immune response and proliferate undisturbed. Immune checkpoint blockade blocks this inhibitory signaling, thus restoring the immune system response against the tumor.

Basic Mechanism

Mechanism of Action

To prevent self-reactivity and autoimmunity, the immune system employs checkpoint pathways that regulate immune responses and maintain homeostasis. The activation of T cell response is a two-step process. First, the T cell recognizes its target cell toward the interaction between the T cell receptor (TCR) and the antigen presented by an antigen-presenting cell (APC); secondly the interaction between a co-stimulatory receptor on the T cell and its ligand on the target or on the APC is needed to fully activate the T cell. If this second step does not occur, the T cell is not activated and becomes anergic (Hawiger et al. 2001). Co-stimulatory receptors that can be upregulated during T cell activation are CD28, CD40, OX40, and CD137. Next to these co-stimulatory receptors, T cells also express inhibitory receptors that have the opposite function, inhibit T cell activation, and protect the host from uncontrolled immune response and autoreactivity. The inhibitory receptors cytotoxic T lymphocyte-associated protein 4 (CTLA-4), programmed cell death 1 (PD-1), lymphocyte activation gene 3 (LAG-3), T cell immunoglobulin and mucin 3 (TIM-3), and programmed death-1 homologue (PD-1H or VISTA) maintain the cells in a resting state. Cancer cells are able to use this system to escape immune surveillance and promote tumor growth. CTLA-4 and PD-1, both members of the immunoglobulin superfamily, are the better characterized among checkpoint proteins. The interaction between PD-1 (on T cells) and PD-L1 (on tumor cells) and the interaction between CTLA-4 (on T cells) and its ligand on an APC bring the T cell in an anergic state, effectively "hiding" the tumor from the host's immune system and preventing the immune mediate killing of tumor cells. That this pathway is one of the main mechanisms of tumor escape of the immune response is demonstrated by the fact that tumor-infiltrating lymphocytes (TIL) express higher levels of PD-1 as compared to lymphocytes present in normal tissue or in peripheral blood (Granier et al. 2017).

After binding to its ligand PDL-1 (expressed on immune cells and tumor cells), PD-1 clusters with the T cell receptor (TCR) and induces T cell inactivation via dephosphorylation of the proximal TCR signaling molecules (Yokosuka et al. 2012). Not only PD-1 but also its ligand PDL1 has an important role in tumor survival and progression. PD-L1 is not only responsible for PD-1-dependent activation of inhibitory signaling within the T cell but also has an intrinsic anti-apoptotic activity. It has been demonstrated that PD-L1 can send an anti-apoptotic signaling into the tumor cells upon binding with PD-1 (Clark et al. 2016). Monoclonal antibodies (MoAbs, ▶ "Cancer Immunotherapy") directed against PD-1 or PD-L1 are able to interrupt this pathway by impairing the binding of PD-1 and PD-L1, on one side restoring T cell activity and on the other side blocking the anti-apoptotic signal within the tumor cell. Increased levels of interferon gamma (IFN-γ), C-X-C motif ligand chemokine (CXCL)-9, and CXCL-10 (IFN-γ induced chemokines) are present in the serum of patients treated with MoAbs anti-PD-1 and PD-L1, confirming that checkpoint blockade can reactivate the adoptive immune system (Choueiri et al. 2016).

CTLA-4 shares the same ligands with the co-stimulatory receptor CD28, namely, CD80 and CD86. It therefore reduces T cell activation by competitive binding to the same ligands of a stimulatory receptor, preventing the link between CD28 and CD80/CD86. In addition to this competition, the binding of CTLA-4 to its ligands inhibits IL-2 production and T cell proliferation (Granier et al. 2017). Administration of MoAbs anti-CTLA-4 is able to restore the activation of the immune system, in analogy to what seen with PD-1/PD-L1 inhibition. Treatment with anti-CTLA-4 MoAb increases IFN-γ-producing T cells not only in the peripheral blood of the patients but also in the tumor itself (Ng Tang et al. 2013).

Additionally anti-CTLA-4 increases T cell diversity and reactivity, setting the basis for the clinical combination of anti-PD-1 and anti-CTLA-4 (van Rooij et al. 2013). Inhibition of CTLA-4 not only blocks the negative co-stimulatory pathways in T cells but also leaves CD80 and CD86 free for binding with CD28, enhancing positive co-stimulatory pathways.

If the main mechanism of action of immune checkpoint blockade is the unmasking of the neoplastic cells so that the immune system is able again to effectively recognize and kill the tumor, other mechanisms of the activity of checkpoint blockade have been identified as well. IgG1 antibodies anti-CTLA-4 can deplete regulatory T cells (Treg) via antibody-dependent cellular cytotoxicity. As Treg have been shown to inhibit anti-tumor effector T cell, their reduction due to CTLA-4 inhibition further increases the activity of immune checkpoint blockade (Simpson et al. 2013). Activated T cells depend on glucose and aerobic glycolysis to fully express their effector function. As tumor cells are also dependent on high quantity of glucose for their survival, the competitions for nutrients within the tumor microenvironment further reduce effector T cell activity. PDL-1 signaling can inhibit glycolysis through the mTOR/Akt pathway. Blockade of CTLA-4 and PD-1 increases the glycolytic capacity of tumor-infiltrating lymphocytes, thus reestablishing their effector function (Chang et al. 2015).

Biomarkers

The expression of PD-L1 (calculated as general expression, tumor proportion score, or combined positive score) is necessary for the treatment with immune checkpoint blockade in many indications, but it will not identify all the patients that will benefit from this treatment. Together with PD-L1 expression, microsatellite instability (MSI) and mismatch repair deficiency (dMMR) are other approved biomarkers to identify patients that will benefit from PD-1/PD-L1 therapy. MSI is thought to increase tumor mutational burden, and tumor mutational burden can identify patients that will respond to PD-1/PD-L1 blockade, irrespective of PD-1/PD-L1 expression. Unfortunately not all patients with MSI have a high tumor mutational burden, and a high tumor mutational burden can be found also in patients without MSI. Therefore, despite being useful, these markers of response to PD-1/PD-L1 blockade are not interchangeable. Inflammatory gene signatures, such as myeloid inflammatory gene expression, are also being investigated as possible biomarkers to predict which patients will respond to checkpoint blockade (Kruger et al. 2019).

Mechanisms of Resistance

Resistance to immune checkpoint blockade can be classified as intrinsic, i.e., tumor cells are able to escape again the host immune surveillance by altering processes connected to immune recognition, cell signaling, or DNA damage response, or extrinsic, i.e., the T cell activation process is impaired. Tumors with a low tumor mutational burden have a lower antigen expression and are therefore intrinsically more resistant to immune checkpoint blockade. Antigen loss from tumor cell surface or deficiency in antigen presentation can lead to acquired resistance to checkpoint inhibitors. Loss of major histocompatibility complex class I (MHC-I) or mutation in the TCR binding domain of MHC-I is also involved in acquired resistance. Alteration in the JAK/Stat pathway downregulates the expression of MHC-I and PD-L1, further contributing to treatment resistance. Another acquired mechanism of resistance is the upregulation of alternative suppressive checkpoint, such as TIM-3, LAG-3, and VISTA, which leads to T cell exhaustion. Epigenetic changes can also be linked to T cell exhaustion. Tumor microenvironment also plays a role in treatment resistance. Elevated levels of TGF-β have been linked in animal model to poor response to immune checkpoint inhibition. The number of TIL correlates with response to treatment. Regulatory T cells, myeloid-derived suppressor cells, and some cytokines like VEGF, CCL5, CCL17, CCL22, CXCL8, and CXCL12 can promote an immunosuppressive tumor microenvironment, conferring resistance to immune checkpoint inhibitors. VEGF expression can be unregulated also by MAPK signaling or *PTEN* deletion. Loss of *PTEN* results in constitutive activation of the PI3K pathway, and PI3K or

MAPK inhibition can enhance tumor cell cytotoxicity in mouse models. In addition to this, epigenetic silencing of CXCL9 and CXCL10 can also reduce the efficacy of checkpoint blockade (Fares et al. 2019).

Pharmacological Relevance

The importance of checkpoint inhibitors has been acknowledged by the Nobel Prize for Physiology or Medicine 2018 conferred to James P. Allison and Tasuku Honjo for the discovery of CTLA-4 and PD-1/PD-L1, respectively. Checkpoint inhibitors can induce durable remission and prolong progression-free survival in numerous cancer and are now standard therapy in the treatment of melanoma, lung cancer, urothelial cancer, head and neck squamous cell carcinoma (HNSCC), renal cell cancer, and Hodgkin's lymphoma (Gong et al. 2018). Further studies are investigating the role of checkpoint inhibitors also in other malignancies such as acute myeloid leukemia, triple negative breast cancer, hepatocellular carcinoma, or gastrointestinal cancers. Table 1 reports a summary of the main tumor entity treated with immune checkpoint blockade and their clinical indications.

Immune checkpoint inhibitors can be used alone, in combination with chemotherapy, or even combined between themselves. The anti-PD-1 MoAbs are approved as monotherapy in Europe and in the USA for the treatment of the advanced or metastatic solid tumors melanoma, non-small cell lung cancer (NSCLC), renal cancer, HNSCC, and urothelial cancer and for the treatment of relapsed or refractory Hodgkin's lymphoma. Monotherapy with the anti-PD-1 nivolumab is also indicated as adjuvant treatment for melanoma after complete resection of lymphonodal or solid metastasis. Other indications of immune checkpoint blockade vary according to the different lands (Table 1). Combination of immune checkpoint blockade and radiotherapy is also being explored, but results so far have been controversial. While good results have been observed in NSCLC with the combination of PD-L1 inhibition and chemoradiotherapy, results in head and neck cancer were dismal (Kruger et al. 2019). As chemotherapeutic drugs can also have immunological effects (▶ "Cancer Immunotherapy"), the combination of immune checkpoint blockade and conventional chemotherapy was a logical consequence. Polychemotherapeutic protocols including an immune blockade and one or more chemotherapeutic agents have been used with success in NSCLC, head and neck cancer, and triple-negative best cancer (Kruger et al. 2019). The combination of the anti-PD-1 pembrolizumab with a platinum-based chemotherapy is approved for the treatment of metastatic NSCLC. More than 150 clinical studies are investigating the combination of PD-1/PD-L1 blockade with chemotherapy (Tang et al. 2018). Checkpoint blockade can also be combined with other forms of cancer immunotherapy. The most studied is probably the combination of anti-PD-1 and anti-CTLA-4, with about 250 running clinical trials (Tang et al. 2018). The combination of ipilimumab (anti-CTLA-4) and nivolumab (anti-PD1) is approved in the USA and in Europe for the treatment of metastatic melanoma as well as for the treatment of advanced high-risk renal cancer. Despite this approach being extremely intriguing, pitfalls and potential problems should be highlighted. Combining two different agents active in the host's immune system could also have antagonist effects rather than provide a synergism. Toxicity could also be a concern. In this respect clinical trials on the combination of PD-1 inhibitors and immunomodulatory drugs in multiple myeloma were stopped after an excess of death in the PD-1 arm was seen in two phase III studies (KEYNOTE-183 and KEYNOTE-185) comparing the combination of pembrolizumab, immunomodulatory drugs (lenalidomide or pomalidomide), and dexamethasone versus the doublet immunomodulatory drugs and dexamethasone. Results of the trials failed to show an improvement with the addition of pembrolizumab to standard multiple myeloma treatment, raising questions about the future of treatment strategies targeting checkpoint blockade in this disease (Costello 2019).

Side Effects

The use of checkpoint inhibitors might be complicated by the development of autoimmune

reactions, such as pneumonitis, thyroiditis, colitis, or autoimmune hepatitis. Immune reactions due to the administration of immune checkpoint inhibitors have been reported in up to 85% of patients and are more frequent with CTLA-4 inhibition than with PD-1 inhibition. Severe immune adverse events have been reported in percentages as high as 27% with MoAb against CTLA-4 and

Immune Checkpoint Blockade, Table 1 Approved immune checkpoint inhibitors and combinations according to tumor entity

Tumor	Indication	Checkpoint containing treatment	Land of approval
Melanoma	Adjuvant indication	Nivolumab	EU, USA
		Pembrolizumab	USA
		Ipilimumab	USA
	Metastatic or advanced first line	Nivolumab	EU, USA
		Pembrolizumab	EU, USA
		Ipilimumab	EU, USA
		Nivolumab + ipilimumab	EU, USA
Cutaneous squamous cell carcinoma	Metastatic or advanced first line	Cemiplimab	EU, USA
Merkel cell carcinoma	Recurrent locally advanced or metastatic	Pembrolizumab	USA
	Metastatic first line	Avelumab	EU, USA
NSCLC	Metastatic or advanced second line	Nivolumab	EU, USA
		Atezolizumab	EU, USA
	Metastatic with PD-L1 TPS $\geq$50% (Europe) or $\geq$ 1% (USA) and no EGFR or ALK mutation first line	Pembrolizumab	EU, USA
	Metastatic with PD-L1 TPS $\geq$1% second line	Pembrolizumab	EU, USA
	Metastatic with PD-L1 expression $\geq$1% second line responsive to platinum	Durvalumab	EU, USA
	Metastatic without EGFR or ALK mutations first line	Pembrolizumab + pemetrexed + platinum chemotherapy	EU, USA
	Metastatic first line	Pembrolizumab + carboplatin +paclitaxel/ nab-paclitaxel	EU, USA
		Atezolizumab + bevacizumab + paclitaxel + carboplatin	EU, USA
		Atezolizumab + carboplatin + nab-paclitaxel	EU, USA
SCLC	Advanced first line	Atezolizumab + carboplatin+ etoposide	EU
cHL	Relapsed or refractory after ASCT and brentuximab vedotin	Nivolumab	EU, USA
	Relapsed or refractory after ASCT or ASCT ineligible and after brentuximab vedotin	Pembrolizumab	EU
	Refractory or fourth line	Pembrolizumab	USA
PMLBCL	Refractory or third line	Pembrolizumab	USA
RCC	Advanced second line	Nivolumab	EU, USA
	Advanced intermediate−/high-risk first line	Nivolumab + ipilimumab	EU, USA
	Advanced first line	Pembrolizumab + axitinib	EU, USA
		Avelumab + axitinib	EU, USA

Gastric cancer	Advanced or metastatic with PD-L1 CPS $\geq$1 third line after fluoropyrimidine and platinum	Pembrolizumab	USA
CRC	Metastatic MSI-H or dMMR second line after fluoropyrimidine, oxaliplatin, and irinotecan (from 12 years of age)	Nivolumab	USA
		Pembrolizumab	USA
Cervical cancer	Metastatic with PD-L1 CPS $\geq$1 second line	Pembrolizumab	USA
TNBC	Metastatic first line with PD-L1 expression >1% (USA)	Atezolizumab + nab-paclitaxel	EU, USA

NSCLC: non-small cell lung cancer; RCC: renal cell carcinoma; cHL: classical Hodgkin's lymphoma; PMLBCL: primary mediastinal large B cell lymphoma; TNBC: triple-negative breast cancer; TPS: tumor proportion score; CPS: combined positive score; MSI-H: microsatellite instability-high; dMMR: mismatch repair deficient; 5-FU: 5-fluorouracil; nivolumab, pembrolizumab, and cemiplimab: anti PD-1; avelumab, durvalumab, and atezolizumab: anti PD-L1; Ipilimumab: anti-CTLA-4; axitinib: tyrosine kinase inhibitor

19% with MoAb against PD-1. The frequency of adverse events varies not only based on the type of checkpoint inhibitor used (CTLA-4 or PD-1) but also according to the type of cancer in which treatment is used, with the lower incidence of adverse events being reported for NSCLC patients treated with the anti-PD-1 nivolumab as monotherapy. As expected the incidence of immune reaction is higher with the combination of anti-PD-1 and anti-CTLA (95% overall and 55% severe). Various organs can be involved in an autoimmune reaction. The skin is usually the first organ to be involved, with the onset of rash or pruritus in the first 4 weeks and a peak at about 6 weeks on treatment. Skin reactions are rare after the first 10 weeks of treatment. Autoimmune hepatitis and hypophysitis occur later on treatment, with an onset that starts usually after 7 weeks of treatment. Autoimmune hepatitis rarely occurs after the first 3 months of treatment, while the

risk of developing a hypophysitis remains unchanged during treatment. Colitis and diarrhea usually are evident between 5 and 10 weeks of treatment. Despite usually occurring during treatment, autoimmune reaction can become evident also once the treatment has been stopped. Anecdotal reports describe autoimmune reactions developing as far as 1 year after the end of checkpoint blockade therapy. When anti-PD-1 and anti-CTLA-4 are used together, immune-related side effects can occur earlier or can develop over a prolonged period of time. Treatment of immune-related adverse reaction requires the administration of glucocorticoids, although a generalized used of steroids should be avoided to prevent hindering the effectiveness of checkpoint inhibitor therapy. The management varies according to the organ involved. For example, in case of mild skin reaction the administration of topical emollients and corticosteroids might be sufficient, whereas in case of a pneumonitis treatment with checkpoint inhibitors should be discontinued event for low-grade events. The rare cases of myocarditis require immediate hospital admission for intravenous steroids. If steroid treatment is not sufficient to resolve the immune-related reaction, other types of immunosuppressive therapy should be considered. Mycophenolat mofetil (MMF) can be used in case of autoimmune hepatitis, pneumonitis, or severe myocarditis. Other immunosuppressive drugs to consider in case of insufficient response to steroids are tacrolimus or anti-thymoglobulin in case of autoimmune hepatitis, the MoAb anti-TNF-α infliximab in case of colitis or pneumonitis, and cyclophosphamide. Tacrolimus can have a role also in severe myocarditis. In case of neurological toxicity such as myasthenia or Guillain-Barré syndrome, plasmapheresis and administration of intravenous immunoglobulins should be considered. For any immune-related grade IV toxicity, treatment should be permanently discontinued (Haanen et al. 2017).

Inflammasome

Tao Gong and Rongbin Zhou
School of Basic Medical Sciences, University of Science and Technology of China, Hefei, China

Definition

Inflammasomes are cytoplasmic, multiprotein complexes that consist of a sensor molecule, the adaptor protein ASC, and the downstream protease pro-caspase-1. In response to microbial infection, environmental stimuli, or endogenous "danger signals," several innate immune receptors, known as pattern recognition receptors (PRRs), can act as sensor molecules to initiate inflammasome assembly. Inflammasome assembly and activation lead to the autocatalytic cleavage of pro-caspase-1 into activated caspase-1. The activation of caspase-1 not only initiates the maturation and release of interleukins 1β (IL-1β) and IL-18 but also induces inflammatory cell death, termed "pyroptosis."

Role of Inflammasomes in Infection and Diseases

The most well-described innate immune receptors initiating inflammasome assembly are NLRP1 (NLR family pyrin domain-containing 1), NLRP3, NLRP9b, NLRC4 (NLR family CARD domain-containing protein 4), IFI16 (interferon gamma-inducible protein 16), AIM2 (absent in melanoma 2), and pyrin (Gong et al. 2018a). Most inflammasomes are activated by specific pathogen-associated molecular patterns (PAMPs) derived from microorganisms. For example, bacterial flagellin and T3SS rod/needle proteins induce NLRC4 inflammasome activation through neuronal apoptosis inhibitory proteins (NAIPs). Microbial double-stranded DNA (dsDNA) can bind to AIM2 and activate the AIM2 inflammasome. Inflammasome activation not only initiates the maturation and release of interleukins 1β (IL-1β) and IL-18 but also induces

inflammatory cell death, termed "pyroptosis." IL-1β and IL-18 are important proinflammatory cytokines that play crucial roles in the activation and recruitment of inflammatory cells. Additionally, pyroptosis can also lead to the release of intracellular pathogenic microorganisms and endogenous pro-inflammatory mediators, amplifying inflammation. Thus, the activation of inflammasomes plays a crucial role in host defense against infection.

Although IL-1β and IL-18 release and pyroptosis play positive roles in host defense and promote the removal of pathogenic microorganisms, excessive inflammasome activation can elicit acute or chronic inflammation, which may lead to inflammatory diseases. In contrast to most inflammasomes, which are triggered by a limited number of PAMPs, the NLRP3 inflammasome can not only be activated by several PAMPs, such as viral RNA and bacterial toxins, but also by the widest array of damage-associated molecular patterns (DAMPs), including extracellular ATP, monosodium urate (MSU) crystals, cholesterol crystals amyloid-β, etc. Given that NLRP3 recognizes the broadest range DAMPs, the NLRP3 inflammasome is one of the most important inflammasomes and is broadly implicated in the pathogenesis of various acute and chronic inflammatory diseases, including ischemia-reperfusion injury-associated diseases (such as stroke and myocardial infarction), metabolic disorders (such as gout, type 2 diabetes and atherosclerosis), and neurodegenerative diseases (such as Alzheimer's disease and Parkinson's disease) (Table 1) (Mangan et al. 2018). In addition, gain-of-function NLRP3 mutations can lead to the autonomous activation of the inflammasome; these mutations are correlated with a group of autoimmune diseases termed cryopyrin-associated periodic syndromes (CAPS).

Inflammasome, Table 1 Sterile NLRP3 activators and associated inflammatory diseases

NLRP3 activator	Associated disease
Endogenous danger signal	
ATP	Ischemia-reperfusion injury (IRI), such as stroke and myocardial infarction
Monosodium urate (MSU) crystals	Gout
Calcium pyrophosphate dihydrate (CPPD)	Pseudogout
Free fatty acids (FFA), islet amyloid polypeptide (IAPP), glucose	Type 2 diabetes
Oxidized low-density lipoprotein (LDL), cholesterol crystals	Atherosclerosis
β-Amyloid (Aβ)	Alzheimer's disease
α-Synuclein	Parkinson's disease
Alu-RNA	Age-related macular degeneration (AMD)
Environmental insult	
Silica	Silicosis
Asbestos	Asbestosis
Skin irritants	Contact hypersensitivity reactions
Ultraviolet light	Sunburn

Mechanisms of NLRP3 Inflammasome Activation

Because the NLRP3 inflammasome can be activated by numerous endogenous and environmental stimuli, tremendous efforts have been made to investigate the molecular mechanisms of NLRP3 inflammasome activation. Generally, the activation of the NLRP3 inflammasome needs two signals, known as the "priming" signal and the "activation" signal. The priming signal (signal 1), provided by microbial or endogenous molecules, can activate the Toll-like receptor (TLR) signaling pathway, which not only increases the expression of the IL-1β precursor and NLRP3 but also facilitates the posttranscriptional modification of NLRP3. Once the process is primed, various DAMPs and PAMPs can act as activation signal (signal 2) to initiate the assembly of the NLRP3 inflammasome. Given the broad range of NLRP3 stimuli, it is impossible for NLRP3 to directly sense all of these activators. Previous studies have suggested that multiple cellular events, including ion flux, mitochondrial damage, lysosomal rupture, and Golgi dispersal, may act as the intracellular "second messenger" to induce

NLRP3 inflammasome assembly and activation (Fig. 1) (Gong et al. 2018b; Swanson et al. 2019).

Multiple NLRP3 agonists can induce the efflux of intracellular K^+ and Cl^-. Both K^+-free and Cl^--free media were sufficient to induce NLRP3 inflammasome activation in the absence of any NLRP3 agonist. In addition, intracellular Ca^{2+} can increase in response to various NLRP3 activators. Several inhibitors targeting either extracellular or intracellular Ca^{2+} storage have been reported to prevent intracellular Ca^{2+} mobilization and to inhibit the activation of the NLRP3 inflammasome.

Several studies have connected mitochondria to NLRP3 inflammasome activation. Although the exact role of mitochondria in NLRP3 activation needs to be further verified, NLRP3 activators have been shown to induce mitochondrial damage, thus promoting mitochondrial reactive oxygen species (mtROS) generation and oxidized mtDNA accumulation. Oxidized mtDNA has been shown to interact with NLRP3 and to promote NLRP3 inflammasome assembly.

Another well-known hypothesis to explain particulate-induced NLRP3 inflammasome is "lysosomal rupture." In this context, particle agonists, such as silica particles, cholesterol crystals, and amyloid-β, are taken up by macrophages or DCs into intracellular phagolysosomes, leading to lysosome rupture, lysosomal protease release, and NLRP3 inflammasome activation.

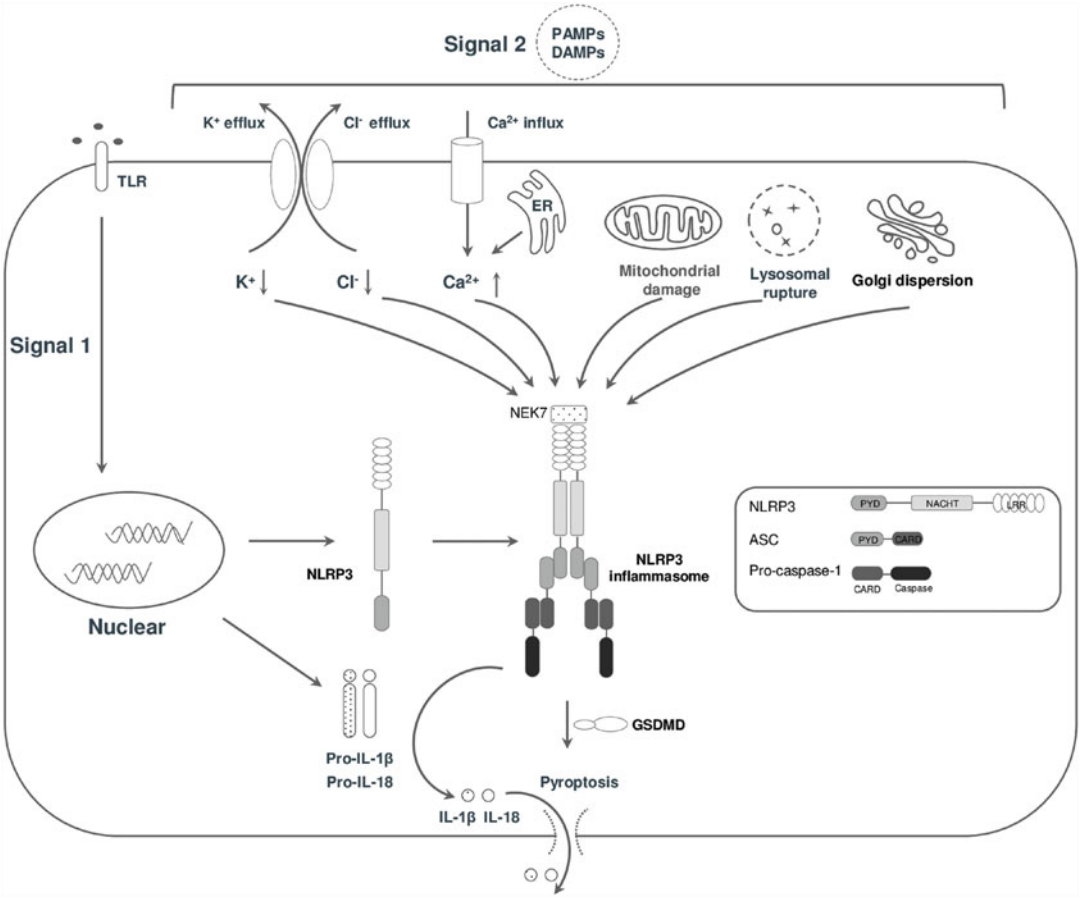
Recent research has also shown a crucial role of the Golgi apparatus in NLRP3 activation. Various NLRP3 activators can induce the disassembly of the trans-Golgi network (TGN), which then functions as a scaffold for the aggregation and polymerization of the NLRP3 inflammasome complex.

In response to various NLRP3 activators, these cellular events can induce the interaction between NEK7 and NLRP3, which facilitates the self-oligomerization of NLRP3. Oligomeric NLRP3 then recruits ASC and promotes its clustering via the homotypic pyrin domain (PYD). Clustered ASC interacts with pro-caspase-1 via the homotypic caspase recruitment domain (CARD), eventually leading to the autocleavage of pro-caspase-1. Activated caspase-1 cleaves the IL-1β precursor and IL-18 precursor, as well as gasdermin D (GSDMD). The cleaved N-terminal domain of GSDMD (GSDMD-N) can insert into the plasma membrane to form cytotoxic pores, which not only induce inflammatory cell death (pyroptosis) but also facilitate mature IL-1β and IL-18 release (Fig. 1).

In addition to canonical NLRP3 inflammasome activation, caspase-11-dependent noncanonical NLRP3 inflammasome activation can also be induced in response to intracellular LPS, a principal membrane component of gram-negative bacteria. Intracellular LPS has been shown to directly interact with and activate mouse caspase-11 (in human caspase-4/5). Activated caspase-4/5/11 directly cleaves GSDMD and pannexin-1, which induce cytotoxic pore formation and nonselective channel opening, respectively, promoting subsequent NLRP3 inflammasome activation and pyroptosis.

Therapies Targeting the NLRP3 Inflammasome

Excessive activation of the NLRP3 inflammasome in response to numerous endogenous or environmental stimuli has been implicated in the pathogenesis of various inflammatory diseases; therefore, inhibition of the NLRP3 inflammasome may be a promising strategy for the treatment of these inflammatory diseases (Mangan et al. 2018). Indeed, several reagents targeting the inflammasome products IL-1β and IL-18 have been developed to treat NLRP3-related diseases. For example, canakinumab, a neutralizing monoclonal anti-IL-1β antibody, significantly reduced the incidence of arthritis and gout clinically. In addition to targeting inflammasome products, several inhibitors can also inhibit NLRP3 inflammasome activation by targeting upstream activating events, the adaptor ASC or caspase-1. However, these inhibitors inevitably result in unexpected cascade reactions in vivo. Thus, numerous scientists have now turned their efforts to controlling NLRP3 inflammasome activation by directly targeting the NLRP3 protein. Several NLRP3-targeting



Inflammasome, Fig. 1 Priming and activation of the NLRP3 inflammasome. Generally, the activation of the NLRP3 inflammasome requires two signals, the "priming" signal (signal 1) and the "activation" signal (signal 2). The priming signal, provided by microbial or endogenous molecules, activates the Toll-like receptor (TLR) signaling pathway, which not only increases the expression of the IL-1β precursor and NLRP3 but also facilitates the post-transcriptional modification of NLRP3. Once the pathway is primed, various DAMPs and PAMPs function as activation signals to initiate the assembly of the NLRP3 inflammasome. Multiple cellular events, including K^+ efflux, Cl^- efflux, Ca^{2+} mobilization, mitochondrial damage, lysosome rupture, and Golgi dispersal, can act as the intracellular "second messenger" to induce NLRP3 inflammasome assembly and activation. Activated NLRP3 inflammasomes process cytokine precursors (pro-IL-1β/pro-IL-18) into their mature forms and induce pyroptosis in a caspase-1-dependent manner

compounds have been recently developed; these compounds not only exhibit anti-NLRP3 activity in vitro but also show excellent anti-inflammatory function in several NLRP3-dependent disease models (Table 2) (Bertinaria et al. 2019).

The ATPase activity of NLRP3 within its NACHT domain is necessary for self-oligomerization, and it has been recognized as a feasible target for the development of NLRP3 inhibitors. Previous studies have shown that multiple inhibitors can bind to NLRP3 and block its ATPase activity (Bertinaria et al. 2019). Several alkylating agents, including Bay11-7082, 3,4-methylenedioxy-β-nitrostyrene (MNS), and 2-cyclohexylimino-6-methyl-6,7-dihydro-5H-benzo [1,3]oxathiol-4-one (BOT-4-one), have been reported to inhibit NLRP3 ATPase activity via direct alkylation of NLRP3. All three NLRP3-

Inflammasome, Table 2 Pharmacological inhibitors of NLRP3

Inhibitor	Target domain or site	Inhibitory mechanism	Disease model
BAY 11–7082	–	Induces NLRP3 alkylation and inhibits the ATPase activity of NLRP3	Diabesity
MNS	LRR or NACHT domain		–
BOT-4-one	–		Peritonitis
MCC950	Within or close to the Walker B motif	Inhibits the ATPase activity of NLRP3	Cryopyrin-associated periodic syndromes (CAPS), Alzheimer's disease (AD), stroke, multiple sclerosis (MS), atherosclerosis, asthma, nonalcoholic fatty liver disease (NAFLD)
CY-09	ATP-binding site		Gouty arthritis, CAPS, type 2 diabetes (T2D)
OLT1177	–		LPS-induced peritoneal inflammation
INF39	–		Colitis
INF58	–		–
Oridonin	Cys279	Inhibits the NEK7-NLRP3 interaction	Peritonitis, gouty arthritis, T2D
NBC6/13	–	Inhibits NLRP3 assembly	LPS-induced peritoneal inflammation
Tranilast	NACHT domain	Inhibits NLRP3 oligomerization	Gouty arthritis, CAPS, T2D

alkylating agents inhibit NLRP3 inflammasome activation and IL-1β secretion in vitro. In addition, BAY 11-7082 was recently shown to inhibit NLRP3-dependent inflammation in a mouse model of high-fat, high-fructose diet-induced metabolic disorder. The anti-NLRP3 activity of BOT-4-one was confirmed in MSU-induced acute peritonitis in mice. One of the most difficult challenges limiting the clinical use of these alkylating agents is that they all have been reported to inhibit other kinases or proteins. For example, BOT-4-one completely inhibits IKKβ activity at 30 μM. Additionally, the exact alkylation site in NLRP3 remains to be determined.

In addition to NLRP3-alkylating agents, multiple small molecules, such as MCC950, CY-09, OLT1177, and INF39, have been developed to inhibit NLRP3 inflammasome activation by blocking the ATPase activity of NLRP3. MCC950, also known as CP456,773, is the best studied inhibitor of NLRP3 (Mangan et al. 2018). It specifically inhibits the activation of the NLRP3 inflammasome at an extremely low dose (IC50 = 8.1 nM based on ATP-induced IL-1β secretion in human monocytes). Mechanistic studies have indicated that MCC950 directly binds to the NLRP3 protein at a site within or close to its Walker B motif, which could inhibit ATP hydrolysis and NLRP3 oligomerization. Several studies have shown that MCC950 not only inhibits NLRP3 inflammasome activation in vitro but also displays anti-inflammatory activity in a wide range of NLRP3-related disease models, such as murine models of CAPS, stroke, atherosclerosis, multiple sclerosis (MS), AD, asthma, and nonalcoholic fatty liver disease (NAFLD). In addition, MCC950 has been tested in phase II clinical trials for the treatment of rheumatoid arthritis. However, these studies revealed that MCC950 may induce liver injury in some cases, and the clinical trials were not continued further. The reason for this liver toxicity needs to be further investigated. CY-09, a novel small molecule, was developed to specifically bind to the ATP-binding site on the NACHT domain of NLRP3, thereby inhibiting the ATPase activity of NLRP3. In vivo data suggest that CY-09 inhibits

NLRP3-dependent systemic inflammation and has remarkable preventive or therapeutic effects in mouse models of gouty arthritis, CAPS, and type 2 diabetes (T2D) (Mangan et al. 2018). More importantly, ex vivo data show that CY-09 also inhibits the preactivated NLRP3 inflammasome in synovial fluid cells (SFCs) from patients with gout, indicating the potential of CY-09 for the clinical treatment of rheumatic diseases. OLT1177, also known as dapansutrile, is another interesting NLRP3 inhibitor that blocks NLRP3 ATPase activity. OLT1177 is now under development by Olatec Therapeutics and is in phase II clinical trials for the treatment of osteoarthritis (Bertinaria et al. 2019). INF39 (ethyl 2-(2-chlorobenzyl)acrylate) and INF58 are two acrylic acid derivatives that inhibit NLRP3 inflammasome activation by inhibiting the ATPase activity of NLRP3. INF39 was shown to reduce inflammatory cytokine release and to exert a protective effect in a rat model of experimental colitis (Bertinaria et al. 2019).

Oridonin, a bioactive ent-kaurane diterpenoid, is the major active constituent of *Rabdosia rubescens*, which is often used in traditional Chinese medicine. Oridonin can covalently bind to cysteine 279 in the NACHT domain of NLRP3, thus inhibiting the interaction between NEK7 and NLRP3 (Bertinaria et al. 2019). In vitro data showed that oridonin can specifically inhibit the assembly and activation of the NLRP3 inflammasome at a very low dose (IC50 $\approx$ 0.5 μM). In addition, oridonin suppresses NLRP3 activation and alleviates disease progression in mouse models of multiple NLRP3-driven diseases, such as peritonitis, gouty arthritis, and T2D.

A series of boron-based inhibitors have been shown to inhibit NLRP3 inflammasome activation by directly targeting the NLRP3 protein (Bertinaria et al. 2019). It has been shown that the minimal pharmacophore for these inhibitors is a boron atom linked to an oxygen atom. Among these compounds, 5-acetyl-6-amino-2,2-diphenyl-4-(trichloromethyl)-2,3-dihydro-1,3,2-oxazaborinin-1-ium-2-uide (NBC6) is the most promising, with limited cytotoxicity and a low inhibitory dose (IC50 = 0.574 μM based on nigericin-induced NLRP3 activation in human THP-1 cell line). Indeed, NBC13, an analog of NBC6, has been evaluated for anti-inflammatory effects in vivo using an LPS-driven peritoneal inflammation model.

Tranilast, an analog of a tryptophan metabolite, is a relatively safe and well-tolerated drug in clinical use. It is used to treat various inflammatory diseases, such as bronchial asthma, atypical dermatitis, and hypertrophic scars. Most recently, tranilast has been shown to specifically bind to NLRP3 and inhibit the assembly and activation of the NLRP3 inflammasome in vitro. In vivo data revealed that tranilast has preventive or therapeutic effects in mouse models of NLRP3-dependent inflammatory diseases, including gouty arthritis, CAPS, and T2D (Bertinaria et al. 2019). Although the exact binding site of tranilast to NLRP3 has not been identified, the NACHT domain of NLRP3 is responsible for the interaction between NLRP3 and tranilast. More efforts are necessary to ascertain the clinical therapeutic effect of tranilast on NLRP3-related diseases.

Taken together, data indicate that targeting NLRP3 may be a feasible and effective strategy for the clinical treatment of NLRP3-related inflammatory diseases. It is time to accelerate the development of drugs targeting NLRP3 and to evaluate them in clinical trials.

Definition

Inflammation occurs when a living tissue is injured or infected by microorganisms. It is a beneficial, self-limited response that requires phagocytic cells and elements of circulating plasma to enter the affected area. In principle, it may achieve resolution and repair as the ideal outcome of inflammation. The persistent accumulation and activation of leukocytes is a hallmark of chronic inflammation.

Basic Mechanisms

Introduction

The clinical characteristics of acute inflammation are familiar to anyone who has suffered from a burned or infected finger. The account comprises the cardinal symptoms of inflammation with heat, redness, swelling, and pain that were reported by the Roman encyclopedist Aulus Cornelius Celsus (25 BC–50 AD) as calor, rubor, tumor, and dolor. Galen of Pergamon (129–199 AD) added a 5th cardinal symptom, the impaired function, or functio laesa. Though unpleasant, these signs are indicators of useful processes going on with the aim of limiting tissue damage and infection and initiating repair. Inflammation starts after an initial injury by mechanical trauma, infections, UV irradiation, burns, ischemia, and many others (Ley et al. 2007). It initially comprises the release of chemical mediators like histamine from a population of cells that are distributed throughout the connective tissue and are extremely sensitive to injury, the mast cells (Kubo 2018). The same is true for the blood basophil, which in many aspects resembles the mast cell (Kubo 2018). Histamine and secondary mediators like eicosanoids and nitric oxide cause vasodilation and increase the diameter of arterioles, capillaries, and venules, which results in increased blood flow to the injured area and consequently redness and heat. An increase in the vascular permeability causes the loss of solutes and proteins from the blood plasma, a process called exsudation, which leads to swelling and edema formation (tumor). The local increase in tissue turgor and the activation of the kinin cascade with the generation of particularly bradykinin are major factors causing pain, the fourth cardinal symptom of inflammation. Besides these changes of the microcirculation, the acute inflammatory response essentially requires the extravasation of leukocytes and phagocytosis of microorganism and cell or tissue debris.

Cells and Mediators of Acute Inflammation

The migration of phagocytic cells to the site of damage is one of the most fundamental components of the acute inflammatory response, and the key players in this process will be presented next.

The Endothelial Cell

The vascular endothelium plays an important role in regulation of vascular tone and permeability. Dilation of arterioles to increase blood flow and constriction of endothelial cells of postcapillary venules causing exsudation of plasma constituents illustrates the complex nature of this cell type. Moreover, by expression of adhesion molecules and secretion of chemokines, endothelial cells play an important role in the recruitment of leukocytes to the inflamed area. Endothelial cells express two basic types of adhesion molecules on their surface:

1. Selectins (E-selectin, P-selectin)
2. Members of the immunoglobulin gene superfamily (VCAM-1, ICAM-1, ICAM-2)

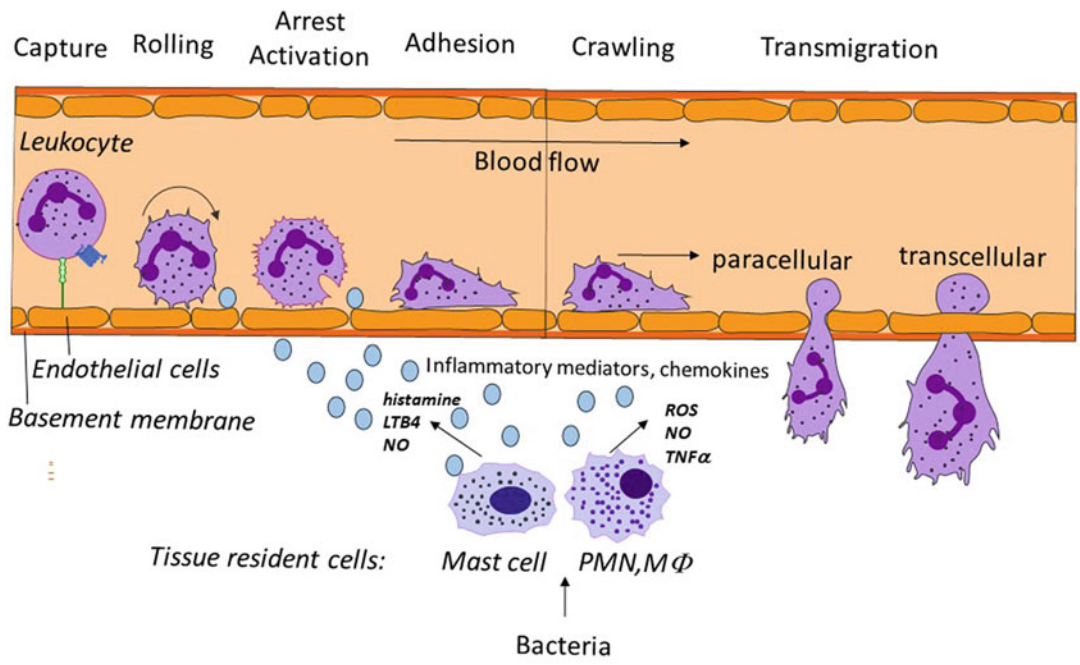
Selectins are a family of glycoproteins that allow the initial attachment and rolling of leukocytes on endothelial cells. Selectins are not expressed on the surface of resting endothelial cells but are exposed upon activation with a number of mediators like interleukin-1 (IL-1), tumor necrosis factor α (TNFα), lipopolysaccharide, or thrombin. Two endothelial selectins have been reported. E-selectin is synthesized de novo and expressed on endothelial cell surface following stimulation. The specific ligand for E-selectin is stored in Weibel–Palade bodies of endothelial cells and in α-granules of platelets and is translocated within minutes to the plasma membrane following exposure to inflammatory mediators. The ligand for P-selectin is the so-called P-selectin glycoprotein ligand-1 (PSGL-1), which has the sugar lacto-n-fucopentaose III in its core domain and is present on hematopoietic cells.

The second class of adhesion molecules expressed on endothelial cells belong to the immunoglobulin gene superfamily. These transmembrane glycoproteins structurally resemble in certain parts the structure of immunoglobulins. Whereas intercellular cell adhesion molecule-1 (ICAM-1) and ICAM-2 are constitutively expressed on endothelial cells, the third member vascular cell adhesion molecule-1 (VCAM-1) is not present on resting endothelial cells but is upregulated together with ICAM-1 in the course of acute inflammation by cytokines like IL-1 or TNFα within a few hours. The counterreceptor on the cell membrane of leukocytes that binds to ICAMs and VCAM-1 belongs to the integrin family of adhesion molecules.

The Neutrophil

In the very early phases of the acute inflammatory response, most of the cells invading the damaged area are polymorphonuclear neutrophils, also denoted as PMNs, which serve as initial line of defense and source of proinflammatory cytokines (Liew and Kubes 2019). These cells, which usually live for 4–5 days, circulate in the blood until they are attracted by chemokines into injured tissues. Whereas physical injury does not recruit many neutrophils, infections with bacteria or fungi elicit a striking neutrophil response. Under inflammation, the life span of neutrophils increases by several fold, which is important to ensure their continuous presence at the site of inflammation. The characteristic pus of a bacterial abscess is composed mainly of apoptotic (*apoptosis*) and necrotic PMNs. Emigration of neutrophils from the blood starts with a process denoted as margination where neutrophils come to lie at the periphery of the cross-sectional lumen of the blood vessel and adhere to endothelial cells (Fig. 1). L-Selectin is expressed constitutively on most leukocytes and interacts with ligands that are induced in endothelial cells exposed to inflammatory cytokines. The second class of surface molecules that mediate adhesion of neutrophils and monocytes to endothelial cells are the integrins. Leukocyte integrins are heterodimeric transmembrane proteins consisting of α and β chains with short cytoplasmic domains that are engaged in signal transduction. Many cells express integrins, and some of the known integrins are cell-type specific. Integrins mediate firm adhesion that follows the initial rolling of leukocytes along the endothelial cell lining. All the leukocyte integrins share a common small subunit, the β_2 subunit. There are at least four larger α subunits known that can associate with the β_2 subunit to form unique receptors. These β_2-integrins will adhere to the endothelial ICAMs in the course of acute inflammation. Once the neutrophils have made firm contact to the endothelial cells, they protrude pseudopodia and leave the blood vessel by transmigration either by a paracellular route (between endothelial cells), or a transcellular route (through an endothelial cell), and subsequently pass the basement membrane (Fig. 1) (Liew and Kubes 2019). The whole process takes a few minutes.

The most important function of neutrophils is the killing of bacteria, which is executed by various mechanisms including phagocytosis, generation of reactive oxygen species, degranulation of cytotoxic and antimicrobial proteases, and by release of neutrophil extracellular traps (NET). The latter consist of DNA, associated citrullinated histones, and a series of proteases (Sorensen and Borregaard 2016; Liew and Kubes 2019).



Inflammation, Fig. 1 Sequence of events in the recruitment of leukocytes in postcapillary venules adjacent to injured tissue. At the site of lesion, diverse reactive substances stimulate the endothelium to produce inflammatory cytokines, chemoattractants, and other inflammatory mediators. The cytokine-activated endothelium expresses adhesion molecules that lead to the low affinity interactions between leukocytes and endothelium, which is mediated by selectins and described as rolling. Subsequently integrins mediate the firm adhesion of leukocytes, which allows emigration of the cells from venules into the interstitial compartment. Activated mast cells, PMNs, and macrophages secrete cytokines (TNFα), lipid mediators (LTB_4), and other inflammatory players (histamine, NO)

The Monocyte/Macrophage

The very early peak of neutrophil invasion into an inflamed area is followed several hours later by a wave of a second class of phagocytic cells, the macrophages. This biphasic pattern of inflammatory cell movement and accumulation is observed in most acute inflammatory responses. The mononuclear phagocyte in the blood is known as the monocyte and differentiates into the macrophage upon entering into tissues. Depending on the local cytokine and growth factor milieu, monocytes and tissue-resident macrophages differentiate into macrophages of different phenotypes, an event that is also known as macrophage polarization (Shapouri-Moghaddam et al. 2018). Two main phenotypes exist, which include the classically activated or inflammatory (M1) macrophage and the alternatively activated or anti-inflammatory (M2) macrophage. M1 macrophages are typically induced by interferon-γ, TNFα, or the bacterial product LPS, and, in turn, produce and secrete pro-inflammatory cytokines. M1 macrophages have an important function in removing pathogens during infection, thus are antimicrobial, but also induce tissue damage, impair tissue regeneration and wound healing, and have antitumoral activity. M2 macrophages are induced by IL-4, IL-13, and IL-33, and trigger rather anti-inflammatory cytokine and chemokine production, like IL-10 and transforming growth factor β (TGFβ). M2 macrophages have an anti-inflammatory function and show a potent phagocytic and tissue remodeling capacity.

Chemotactic factors that act on macrophages include complement cleavage products, membrane components of microorganisms, and fibrin degradation products that also attract neutrophils. In addition, there are specific chemokines that act

exclusively on macrophages. Macrophages in turn release large amounts of growth factors and cytokines.

Over the last decade, evidence has accumulated that not all the tissue macrophages derive from invaded blood monocytes, but that a subpool of macrophages are established during embryonic development to reside in the different organs and persist to adulthood independent of blood monocytes (Davies et al. 2013). These include Kupffer cells in the liver, osteoclasts in the bone, microglia in the central nervous system, alveolar macrophages in the lung, and dermal macrophages in the skin. These tissue-resident macrophages are classified as M2-like and exert specialized organ-specific functions such as immune surveillance of the organ, clearance of cell debris, and maintenance of homeostasis.

Mediators of Inflammation

Many low-weight compounds produced by microorganisms, like formylated peptides as well as endogenous mediators, are chemotactic for leukocytes and promote the inflammatory process. The main endogenous compounds are listed in Table 1 and are derived from activated plasma protein cascades that function as amplification mechanisms, are performed and released from activated cells, or are de novo synthesized on demand by cells participating in or being affected by inflammatory events. The major modulators of leukocyte adhesion to endothelial cells are listed in Table 2.

Inflammation, Table 1 Endogenously produced mediators of inflammation

Category	Mediators
Preformed mediators released from activated cells	Histamine
	Serotonin
	Lysosomal enzymes
Mediators derived from activated plasma protein cascades	Complement system
	Kinin cascade
	Clotting pathway
	Fibrinolytic system
De novo synthesized mediators	Prostaglandins
	Leukotrienes
	Cytokines
	Reactive oxygen species
	Gasotransmitters (NO, CO, H_2S)

Healing

The objectives of the inflammatory response can be viewed as a hierarchical ordered panel of events. The most successful consequence of an inflammatory response is the complete restoration of function and structure of the affected tissue, also denoted as resolution. If this is not possible, inflammation aims for healing by repair and replacement of lost tissue by scar tissue.

For many years, the mechanism of resolution was thought to solely include proinflammatory mediator catabolism that fades out the inflammatory response. This is, however, only the one side of the story as recent discoveries highlight the involvement of an active program of resolution that is activated during inflammation (Serhan and Levy 2018; Serhan et al. 2007). Certainly, the cessation of initiating stimuli, e.g., the killing of invading bacteria and microorganisms and the complete removal of inflammatory exudate, is an important event to slow down inflammation. Neutrophils carry out the killing of invading microorganisms that subsequently die by apoptosis, whereas macrophages are mainly responsible for clearing dead neutrophils and fluid phase debris by phagocytosis and extremely active pinocytosis. It should be emphasized that the clearing of apoptotic cells by phagocytes is extremely fast and efficient, and dying cells release chemokines to speed up their removal by attracting macrophages. However, cytokines, like interleukin-6 and anti-inflammatory lipid mediators, such as the specialized pro-resolving mediators (SPM), including resolvins, protectins, maresins, and lipoxins (Serhan and Levy 2018; Serhan et al. 2007), or prostaglandins D_2 and E_2, play important roles in providing stop signals for acute inflammatory processes. Most macrophages emigrate from the inflamed site to reach draining lymph nodes. Subsequently tissue that has been

lost must be replaced in an orderly fashion. The replacement of lost cells by compensatory proliferation and phenotypic change of surviving resident cells is part of the healing process. The exsudate is invaded by macrophages and fibroblasts and the formation of new blood vessels (angiogenesis) is initiated. This series of events finally results in fibrosis and the formation of tissue scar, which may be considered as an essential component of wound healing and repair (Wynn and Ramalingam 2012).

Chronic Inflammation

If the endogenous control mechanisms of inflammation fail and resolution or healing by repair cannot be achieved, the inflammatory process may persist for weeks, months, or even years and is termed chronic. The inflammatory macrophage is not only a ringmaster for safe resolution and repair of inflammation but also for chronicity of the disease. Some of the products secreted by macrophages are relevant to chronic inflammation such as IL-1, TNFα, IL-6, or IL-10, just to name a few. A further characteristic feature is the presence of activated B and T lymphocytes, which represent a local immune response to antigens presented to them by macrophages or dendritic cells. B cells differentiate upon activation to plasma cells that release immunoglobulins which in most cases is a good indicator of chronicity of inflammation.

There are now several diseases described as chronic inflammatory, where no clearly defined initiating trigger is known. These are of particular interest as they affect a great proportion of people of Western countries and include type 2 diabetes mellitus, obesity, atherosclerosis, and cancer (Medzhitov 2010).

Synonyms

INSR (gene name)

Definition

The insulin receptor (INSR) is a transmembrane receptor tyrosine kinase located in the plasma membrane of insulin-sensitive cells (e.g., adipocytes, myocytes, hepatocytes, neurons). It mediates the effect of insulin on specific cellular responses (e.g., glucose transport, glycogen synthesis, lipid synthesis, protein synthesis).

Basic Characteristics

Structure and Function

The INSR is a heterotetrameric protein which consists of two extracellular α-subunits (molecular weight 135 kDa) and two membrane spanning

β-subunits (molecular weight 95 kDa). These subunits are covalently linked by disulfide bonds ($\alpha_2\beta_2$-structure) (Fig. 1). The receptor is encoded by a single gene which is located on human chromosome 19 and consists of 22 exons (exon 1–11 = α-subunit, exon 12–22 = β-subunit). The single chain polypeptide precursor is posttranslationally cleaved in the endoplasmic reticulum into the α- and β-subunits which subsequently dimerize. Both subunits are glycosylated in the Golgi apparatus.

In addition to insulin, the INSR can also bind insulin-like growth factors (IGF1 and IGF2, the latter activates INSR predominantly during the prenatal period) albeit with considerably lower affinity (2 and 3 orders of magnitude, respectively).

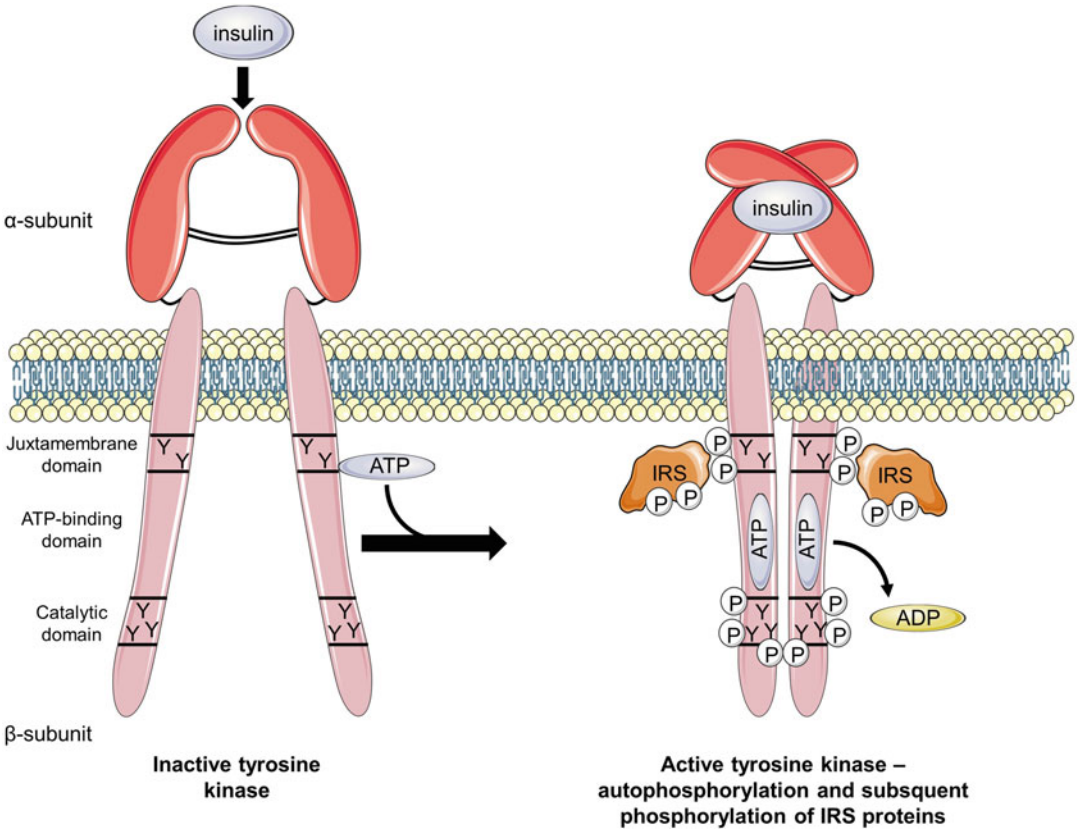
The insulin-binding domain of the INSR is located within a cysteine-rich region of the α-subunits. Alternative splicing of exon 11 generates two isoforms of the α-subunit which differ in their C-terminus and in their tissue distribution (type A: brain; type B: liver; type A and B: skeletal muscle and fat). The isoforms differ in their affinity to insulin (A > B), but their relevance for normal and impaired insulin action is not entirely clear. It has been suggested that INSR A isoform evokes more mitogenic and INSR B isoform more metabolic effects (Belfiore et al. 2009).

Activation of the tyrosine kinase activity of the INSR is essential for the receptor function. The tyrosine kinase domain of the INSR is localized in the cytoplasmic region of the β-subunit. In the absence of insulin, the α-subunits strongly repress the tyrosine kinase activity of the β-subunits. Binding of insulin releases this block through a conformational change and induces dimerization and/or oligomerization of β-subunits which results in receptor transautophosphorylation. While several phosphorylated tyrosine residues in the catalytic domain (Y1158, Y1162, Y1163 of human INSR B isoform) are essential for the kinase activity of the receptor, phosphorylation of two tyrosine residues in the juxtamembrane domain (Y965 and Y975 of human INSR) is critical for the interaction of the receptor with other signaling components of the insulin receptor signaling cascade (Fig. 1) (Kido et al. 2001; Frojdo et al. 2009).

Signaling through the INSR systems has evolved early and has been highly conserved during evolution. Proteins related to the human INSR gene product have been found in *Caenorhabditis elegans* (DAF-2) as well as in *Drosophila melanogaster* (DIR). Insulin-like signaling peptides (e.g., bombyxin) have been found in such distantly related organisms as the silkworm (Kido et al. 2001).

Structurally and functionally related receptors to the INSR in mammalian organisms are the insulin-like growth factor 1 receptor (IGF1R) and the insulin receptor-related receptor (INSRR). Although the function and signal transduction of the IGF1R and the INSRR resembles that of the INSR, major differences appear in the tissue distribution of the receptors. In contrast to the INSR, the IGF1R is expressed in adipocytes only at low levels and is almost absent in hepatocytes, yet more abundant expressed in brain compared to the INSR. The INSRR is an orphan receptor whose endogenous ligand is yet unknown and acts as an extracellular alkali sensor. It has been found in adrenal glands, kidney, and testis and a few neuronal cell types (e.g., dorsal root ganglion and trigeminal neurons).

Deletion of the INSR gene results in normal development but early postnatal lethality because of ketoacidosis. Organ-specific INSR-knockout models (>95% reduction of the receptor protein content in the organ) exhibit less severe phenotypes. Mice with a **l**iver-specific **i**nsulin **r**eceptor **k**nock **o**ut (LIRKO) showed severe insulin resistance and hyperglycemia due to an increased hepatic gluconeogenesis, whereas the tissue-specific knockout of the insulin receptor in pancreatic β-cells (β-IRKO) results in an altered insulin secretion comparable to that seen in type-2-diabetes. Specific knockout of the IGF1R in β-cells results in a similar phenotype. In contrast, mice with a skeletal **m**uscle-specific **i**nsulin **r**eceptor **k**nock **o**ut (MIRKO) had normal blood glucose and normal glucose tolerance but elevated serum-free fatty acids and triglycerides. Mice deficient for insulin receptor in adipose tissue exhibited a lipodystrophic-like phenotype with a strong reduction of white adipose tissue mass, lipid accumulation in peripheral tissues, hyperglycemia,



Insulin Receptor, Fig. 1 Structure and function of the INSR. Binding of insulin to the α-subunits (red) leads to activation of the intracellular tyrosine kinase (β-subunit) by autophosphorylation. The insulin receptor substrates (IRS) bind via a phosphor-tyrosine binding domain to phosphorylated tyrosine residues in the juxtamembrane domain of the β-subunit. The receptor tyrosine kinase then phosphorylates specific tyrosine motifs (YMxM) within the IRS. These tyrosine phosphorylated motifs serve as docking sites for various adaptor proteins with SRC homology 2 (SH2) domains like the regulatory subunit of PI 3-kinase

hyperlipidemia, and hyperinsulinemia, a phenotype worsened by the loss of INSR and IGF1R in adipose tissue. Immense progress has been made in understanding the role of INSR in the brain. Mice with a neuron-specific INSR knockout (NIRKO) developed an obese phenotype with mild insulin resistance and impaired fertility. These central effects of insulin fine tune peripheral metabolism via, for example, regulation of orexigenic and anorexigenic neuronal populations (NPY, Agrp, and POMC) in the brain. In addition, brain INSR signaling regulates peripheral metabolism, by, for example, suppressing hepatic glucose production, regulating brain glucose sensing mechanisms, and altering the reward system. Combined deletion of the INSR, IGF1R, and the INSRR in male (XY) mice results in a female phenotype with ovaries, thereby providing evidence that the insulin receptor tyrosine kinase family is essential for male sex differentiation.

Taken together, these data emphasize the importance of insulin action in the liver and adipose tissue for glucose homeostasis, in the regulation of insulin secretion from β-cells, and indicate that the INSR plays an important role in the central regulation of body weight and reproduction (Kleinridders et al. 2014; Kubota et al. 2017).

There are a few clinical syndromes with an impaired function of the INSR: Leprechaunism

and Rabson-Mendenhall syndrome are rare genetic diseases characterized by growth retardation, hyperinsulinemia, and insulin resistance due to mutations in the INSR gene. Acanthosis nigricans is a syndrome of hyperpigmentation and hyperandrogenism associated with hyperinsulinemia and diabetes mellitus. Insulin resistance in this syndrome is either due to mutations in the insulin receptor gene (type A) or to autoantibodies to the INSR (type B). Some patients with insulin resistance due to decreased expression, increased degradation, or impaired insulin binding of the INSR, as well as mutations in insulin signaling molecules have been described (Boucher et al. 2014).

Signal Transduction and Insulin Action

Stimulation of the insulin receptor results in the activation of two major pathways (Taniguchi et al. 2006): (i) the **m**itogen- **a**ctivated **p**rotein (MAP) kinase cascade (discussed in chapter MAP kinase cascade) and (ii) the phosphatidylinositol 3-kinase (PI 3-kinase) pathway which has been extensively studied in the context of the metabolic responses to insulin (summarized in Table 1 and Fig. 2).

Other, more general effects of insulin on cellular function include stimulation of cell growth (increase in DNA and protein synthesis), inhibition of apoptosis, and modulation of ion-channel activity.

The major intracellular target molecules of the tyrosine kinase activity of the INSR β-subunit are the **i**nsulin **r**eceptor **s**ubstrates (IRS). Interaction of phosphotyrosine-binding domains (PTB) within the N-terminal region of an IRS with the juxtamembrane phosphotyrosines of the INSR β-subunit results in tyrosine phosphorylation of consensus motifs (YMXM) in the C-terminus of IRS (Fig. 1). Six different mammalian IRS isotypes have been identified (IRS1-6), with IRS3 being a pseudogene in humans. IRS1 knockout mice develop a mild state of insulin resistance (impaired glucose intolerance) without diabetes, whereas knockout of the IRS2 gene causes a phenotype with severe insulin resistance (liver > muscle), diabetes, and impaired pancreatic β-cell function. IRS1 and IRS2 knockout mice exhibit growth retardation (IRS1 > IRS2). Disruption of the IRS4 gene produces mild glucose intolerance and growth retardation in male animals. While IRS1 and IRS2 are ubiquitously expressed, IRS4 mRNA is detected in thymus, brain, and kidney, while IRS3 is expressed only in adipocytes, β-cells, and hepatocytes in rodents but is not expressed in humans. Taken together, the data suggest that the major effects of insulin on metabolism are mediated via IRS1 and IRS2 (Boucher et al. 2014).

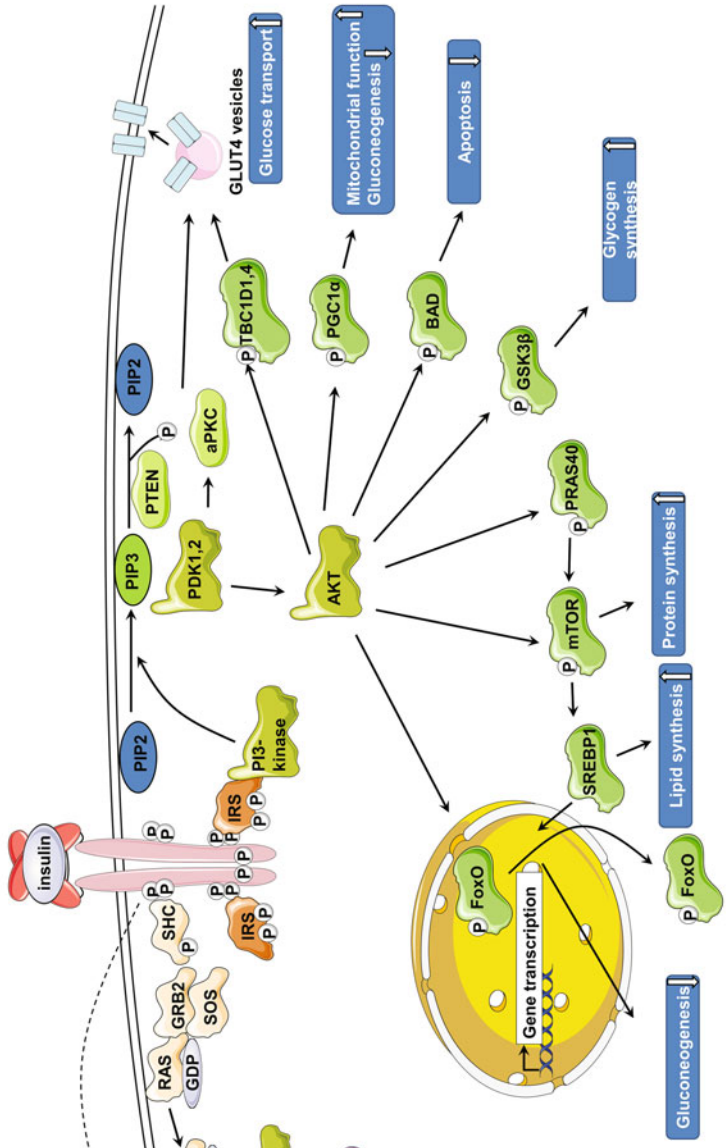
Tyrosine phosphorylated IRS interacts with and activates PI 3-kinase (Taniguchi et al. 2006). Binding takes place via the **S**RC **h**omology **2** (SH2) domain of the PI 3-kinase regulatory subunit. The resulting complex consisting of INSR, IRS, and PI 3-kinase facilitates interaction of the activated PI 3-kinase catalytic subunit with the phospholipid substrates in the plasma membrane. Generation of PI 3-phosphates in the plasma membrane recruits **p**hospholipid-**d**ependent **k**inases (PDK1 and PDK2) which subsequently phosphorylate and activate the serine/threonine kinase Akt (synonym: **p**rotein **k**inase **B**, PKB). Three isotypes of Akt have been identified (Akt1, 2, 3). AKT1-knockout mice exhibit growth retardation and increased apoptosis, but no increased prevalence in diabetes. Disruption of the Akt2 gene produces diabetes due to insulin resistance of skeletal muscle and liver. Double knockout of AKT1 and 2 showed severe growth deficiency and died shortly after birth. There is solid evidence that activation of Akt is essential for the effect of insulin on glucose transport (GLUT4), glycogen synthesis, gluconeogenesis, protein synthesis, and gene expression (Boucher et al. 2014; Taniguchi et al. 2006) (summarized in Table 1 and Fig. 2). Substrates of Akt are glycogen synthase kinase 3 (GSK3) and FoxO1a (previously known as FKHR), a transcription factor regulating the expression of gluconeogenic enzymes. Also, phosphorylation of Akt results in activation of sterol regulatory-element binding protein 1 (SREBP1), a key transcription factor involved in regulation of lipogenic enzymes. In

Insulin Receptor, Table 1 The effect of insulin on energy and glucose homeostasis

Organ	Effect	Mechanism	Comments
Liver	Activation of glycogen synthesis	Activation of glycogen synthase (GS)	Inactivation of glycogen synthase kinase 3 (GSK3) through phosphorylation by Akt
	Inhibition of gluconeogenesis/ increased glycolysis	Inhibition of gluconeogenic gene expression/activation of some glycolytic enzymes	Akt-dependent inhibition of phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase) gene expression; Akt-dependent inhibition of PGC1α
			Decrease of cAMP, the second messenger of glucagon. Induction of pyruvate kinase and glyceraldehyde-3-phosphate dehydrogenase
Fat	Increased glucose transport	GLUT4-translocation	PI 3-kinase/Akt mediated translocation of GLUT4 into the plasma membrane. Potential involvement of atypical forms of protein kinase C (PKC ζ and λ)
	Increased lipid synthesis/ inhibition of lipolysis	Activation of lipoprotein lipase (LPL)/ induction of fatty acid synthase (FAS)/ inactivation of hormone sensitive lipase (HSL)	Facilitated uptake of fatty acids by LPL-dependent hydrolysis of triacylglycerol from circulating lipoproteins. Increased lipid synthesis through Akt-mediated FAS-expression. Inhibition of lipolysis by preventing cAMP-dependent activation of HSL
Skeletal muscle	Increased glucose transport	GLUT4-translocation	See above (fat)
	Activation of glycogen synthesis	Activation of glycogen synthase	See above (liver)
	Increased protein synthesis/ decreased protein degradation	Increased amino acid uptake/increased translation of mRNA/ reduced proteasomal and autophagy-lysosomal degradation	Akt-mediated stimulation of system A amino acid transporter and stimulation of mRNA-translation through activation of p70S6kinase and elongation initiation factor 4 (eIF4). Possible involvement of atypical PKCs
Central nervous system	Reduction of body weight	Reduced appetite and reward behavior	Changed expression of anorexigenic (e.g., POMC) and orexigenic (e.g., NPY) hypothalamic neuropeptides and alterations in the dopaminergic system, potential involvement of mitochondrial function

addition, some of the effects of insulin on cell proliferation and survival may be explained by an Akt-dependent inhibition of apoptosis through phosphorylation and inactivation of proapoptotic proteins (e.g., BAD, Caspase 9).

INSR signaling is terminated by specific phosphotyrosine phosphatases (e.g., PTP1B) (tyrosine phosphatases), and mice lacking the PTP1B gene exhibit increased insulin sensitivity. Furthermore, it has been suggested that the lipid phosphatases PTEN and SHIP2 act as negative modulators of insulin signaling. The ligand-induced endocytosis and degradation of the activated INSR and the degradation of insulin by insulin-degrading enzyme are involved in the termination of insulin signaling.



Insulin Receptor, Fig. 2 Signal transduction of the insulin receptor. Activation of the insulin receptor leads to stimulation of the PI 3-kinase and MAP kinase pathway. Generation of 3′-phosphorylated PI-phospholipids mediates the effect of insulin on glucose transport, cell survival, protein synthesis, glycogen- and lipid synthesis, gene expression, and gluconeogenesis. The protein kinase Akt plays a central role in the regulation of these PI 3-kinase-dependent processes. The activation of MAP kinase cascade regulates mainly proliferation and mitochondrial function

Drugs

Agents Stimulating the Receptor or the Signaling Pathway

Insulin Analogs. At present, the only known ligands of the insulin receptors are insulin isotypes from different species and a number of synthetic analogs with insulin-like activity. Five analogs generated by site-directed DNA mutagenesis are used in clinical practice because of their pharmacokinetic characteristics: insulin lispro (swap of proline B28 and lysine B29), insulin aspart (generated by exchange of proline B28 for aspartate), and insulin glulisin (generated by exchange of lysine B29 for glutamate) are rapid and short-acting insulins (diabetes mellitus). Insulin glargine and insulin detemir are long-acting analogs. Because of two additional arginines at B31 and B32, insulin glargine is soluble at low pH and precipitates after injection, forming a stable, long-acting depot. Insulin detemir is a truncated insulin derivative (threonine B30) that has been coupled to a long-chain fatty acid at lysine B29. This results in the formation of a slowly dissociating complex and an increased binding to albumin, which further delays its inactivation. An ultra-long lasting insulin analog is degludec with a duration of action of up to 40 hours. Its protein sequence is based on human insulin, but modified by acylating DesB30 at the ε-amino group of LysB29.

Thiazolidinediones (synonyms glitazones, insulin sensitizers; rosiglitazone, pioglitazone) are a class of oral antidiabetic drugs that activate the transcription factor peroxisome proliferator-activated receptor (PPARγ). Thiazolidinediones ameliorate insulin resistance in obese animal models and in individuals with type-2 diabetes. They enhance the insulin-dependent activation of the PI 3-kinase/Akt pathway, stimulate differentiation of preadipocytes, and redistribute intra-abdominal and hepatic triglycerides to subcutaneous adipose tissue stores. The marked reduction of hepatosteatosis is believed to be the primary reason for its antidiabetic effect. Furthermore, anti-inflammatory properties of thiazolidinediones have been suggested to contribute to their effect on insulin resistance in type-2 diabetes.

Concanavalin A is a plant lectin from the jack bean (*Canavalia ensiformis*) which binds with high affinity to mannose residues of glycoproteins. Concanavalin A is known to stimulate the tyrosine kinase activity of the INSR β-subunit with consecutive activation of kinases downstream the insulin receptor (IRS, PI 3-kinase). It is believed that Concanavalin A stimulates the activation and autophosphorylation of the INSR kinase through aggregation of the receptor, although the precise mechanism of action is unclear.

Vanadate (sodium orthovanadate or peroxovanadate) exhibits insulin-like effects in vitro (activation of insulin receptor tyrosine kinase, PI 3-kinase, Akt) and in vivo (diabetic rats, humans). These effects can be explained at least in part by the inhibition of phosphotyrosine phosphatases which deactivate the INSR tyrosine kinase.

Hydrogen peroxide (H_2O_2) exhibits insulin-like activity in isolated cells. Like that of vanadate, this effect is thought to be mediated by inhibition of protein-tyrosine phosphatases.

XMetA is a monoclonal antibody, enhances insulin binding to the receptor, and acts as a partial agonist and improves metabolism in a diabetes mouse model.

Agents Inhibiting Insulin Receptor Signaling

Insulin Analogs. Interestingly, several covalently dimerized insulin analogs are partial agonists of the insulin receptor. The intrinsic activity of the dimers decreases with the length of the spacer, with B29-B29'-suberoyl-insulin exhibiting the highest antagonist efficacy at the receptor (Weiland et al. 1990).

Wortmannin is a fungus-derived inhibitor of PI 3-kinase. The agent binds and inhibits the enzyme covalently and irreversibly. It is very potent and considered to be highly specific (IC_{50} in most cells in the low nanomolar range).

LY294002 is a synthetic drug which reversibly inhibits PI 3-kinases. It is less toxic and also less potent than wortmannin. The IC_{50} in most cells is in the micromolar range.

Rapamycin is an immunosuppressive drug and an inhibitor of S6K1 (also known as p70S6-kinase) which phosphorylates ribosomal S6 protein. S6K1 is activated in response to insulin via activation of Akt. Rapamycin binds to a specific target protein (mTOR, mammalian target of rapamycin) which is functionally located downstream of Akt, but upstream of S6K1. The IC_{50} in most cells is in the high nanomolar range.

S961 is an insulin receptor antagonist peptide of 43 amino acids and causes an overt diabetes-like phenotype in rodents. But when used in low nanomolar concentrations, S961 can also act as a partial agonist.

Integrins as Drug Targets: Is There a Future?

Dermot Cox
School of Pharmacy and Biomolecular Sciences, Royal College of Surgeons in Ireland, Dublin, Republic of Ireland

Background

In 1981 fibroblasts were found to adhere to a surface coated in fibronectin and by 1984 the amino acid sequence Arg-Gly-Asp-Ser (RGDS) was identified in a 30-mer fragment of fibronectin as the site essential for supporting adhesion. The RGD sequence was subsequently found to be a common motif with many proteins containing this sequence such as fibronectin, vitronectin, and fibrinogen suggesting a family of RGD-containing proteins that were involved in cell adhesion (Humphries et al. 2006).

The initial characterization of the RGD-dependent fibronectin receptor identified a 140 kDa protein. At the same time work on immune cell antigens showed that two antigens, LFA-1 (T cells) and Mac-1 (macrophages), while expressed on different cells had similar structures. Both were composed of an α- and β-subunits. While both α-subunits were different both β-subunits were probably identical. The platelet fibronectin receptor was identified as a complex of glycoproteins (GP) IIb and IIIa. The vitronectin receptor was also found to have two subunits and while it bound RGD peptides it did not bind to fibronectin. Thus, there was a picture developing of a family of heterodimeric adhesion proteins that interact with RGD-containing proteins. While all bound RGD there was evidence that some of the receptors were specific for certain RGD-

containing proteins. It was also evident that leucocytes have a family of three α/β heterodimeric proteins that share a common β-subunit. Evidence that an anti-GPIIb/IIIa antibody also bound to leucocytes suggested that GPIIb/IIIa may be related to the leucocyte surface markers. This was confirmed in a study which showed that all of the α-subunits came from the same gene family. The cDNA for an 89 kDa subunit of a glycoprotein that mediates cell adhesion was isolated and characterized and this protein was called integrin. By 1987 it had become clear that these three different receptor families – leucocyte surface receptors, platelet GPIIb/IIIa (αIIbβ3), and matrix adhesion receptors – were all related. They were grouped together into a super family of distinct but related receptors called Integrins (Hynes 1987). Some but not all of these receptors bound to a family RGD-containing proteins in an RGD-dependent manner.

Initial evidence suggested that α-subunits only interacted with a single β-subunit (only 3 β-subunits were known) and that ligand specificity was conferred by the α-subunit. Thus, integrins were thought to consist of three families based around the unique β-subunits. However, there are currently 18 identified α-subunits and 8 β-subunits and it is clear that some α-subunits, especially αV, are capable of interacting with multiple β-subunits. Thus, integrins can be grouped into sub-families, although the precise arrangement is complex (Cox et al. 2010) (Fig. 1). One approach to categorizing integrins is to use a phylogenetic tree where integrin subunits can be grouped according to similarity in their gene sequences (Hight-Warburton and Parsons 2019).

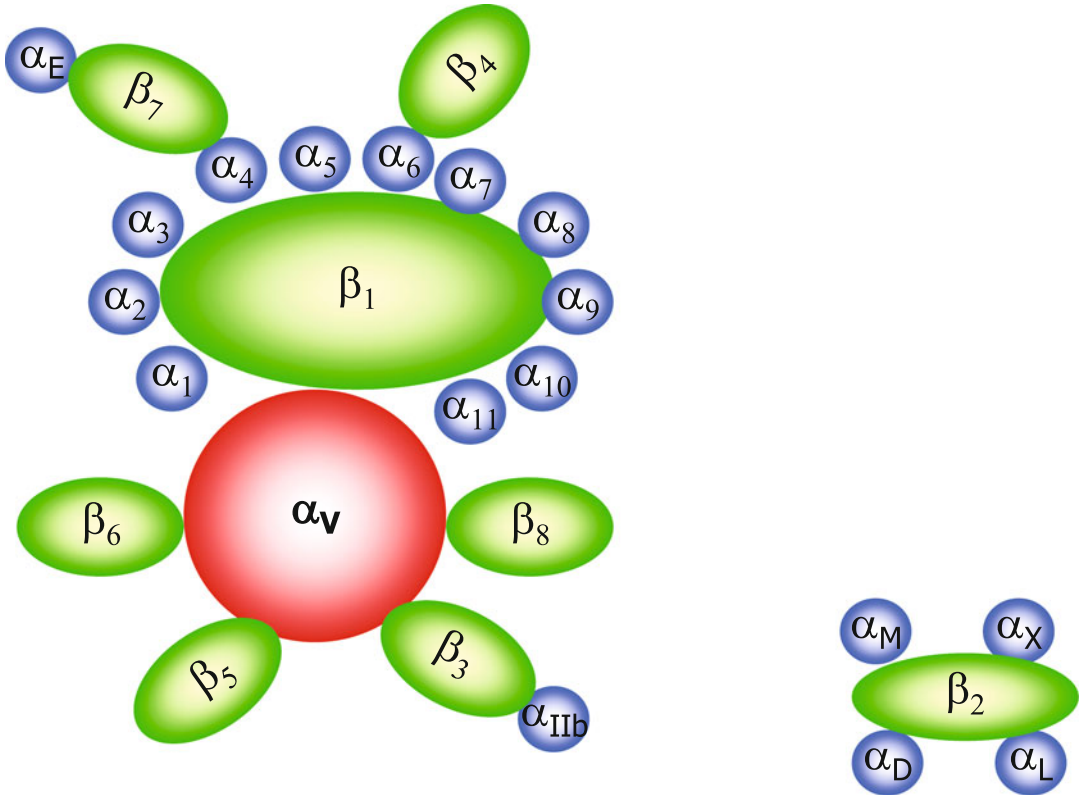
This discovery of integrins created great opportunity for drug discovery. Integrins were associated with many major diseases with unmet needs. Their presence on leucocytes suggested a role in autoimmune diseases. Their role as cell adhesion molecules suggested a potential role in cancer and their presence on platelets suggested a role in thrombosis and cardiovascular disease. Furthermore the RGD-dependent nature of the interactions provided a hit compound for a small molecule discovery program and the discovery of inhibitory monoclonal antibodies provided the potential for a biotechnology solution. While monoclonal antibody technology had been around for over 10 years they had yet to be deployed clinically.

Thrombosis

Not surprisingly thrombosis was the first target for anti-integrin therapy. Around the time of the discovery of integrins platelets were shown to be the critical factor in ischemic heart disease. Considering that cardiovascular disease was the major cause of death, that platelets played a critical role in the pathogenesis of heart disease, and that targeting platelets was shown to improve outcome (25% reduction in events with aspirin), there was a lot of commercial interest in developing new and improved antiplatelet agents (Cox 2019).

The discovery that GPIIb/IIIa was the fibrinogen receptor on platelets and an RGD-dependent integrin (Hawiger et al. 1989) clearly identified GPIIb/IIIa as a drug target. Platelet agonists are divided into strong and weak agonists. Weak agonists such as ADP activate platelets via phospholipase (PL) A2 and cyclooxygenase (COX) while strong agonists such as thrombin activate platelets via PLC. Thus, antiplatelet agents such as aspirin (COX inhibitor) were always going to be hampered in their antithrombotic activity because they only inhibited one platelet activation pathway. It was believed that this could account for their limited clinical benefit and that a stronger agent would be more effective. GPIIb/IIIa antagonists were seen as the ideal agent because no matter what agonist was involved platelet activation resulted in activation of GPIIb/IIIa with subsequent fibrinogen binding that cross-linked platelets into a thrombus. This was often described as the "final common pathway" in aggregation. Everybody was so enthusiastic about this new class of antiplatelet agent that they were known as "super-aspirin" in the media.

The first approach to discovering a GPIIb/IIIa antagonist was to take advantage of the



Integrins as Drug Targets: Is There a Future?, Fig. 1 Integrin receptors

monoclonal antibodies that had been generated to characterize GPIIb/IIIa. One of these that attracted a lot of attention was 7E3 (Coller and Scudder 1985). Abciximab is a chimeric antibody generated from 7E3 and commercialized as ReoPro®. It was only the second monoclonal antibody to come to the market (Investigators 1994). However, as of 2019 it appears to be withdrawn from the market by the manufacturer for commercial reasons.

As an alternative approach to antibodies there were efforts to discover small molecule inhibitors and the obvious approach was to use RGDS as a hit compound with modest potency (IC_{50} 60 μM (Cox et al. 1992)). However, the discovery of disintegrins – RGD-containing snake venom peptides – was critical in developing potent small molecules (Huang et al. 2016). Unlike the simple RGDS peptide these disintegrins are very potent and thus a good starting point for a drug discovery program. Barbourin, a disintegrin from *Sistrurus m. barbouri*, was used as the starting point for a cyclic-peptide inhibitor. Unusually, barbourin had a KGD sequence rather than an RGD sequence. Modification of barbourin led to the cyclic peptide eptifibatide (Scarborough 1999), which was commercialized as Integrilin®. A second approach was based on the idea that disintegrins were cyclic peptides in a highly constrained conformation which was optimum for activity. Echisatin, a disintegrin from *Echis carinatus*, was purified, crystallized and subjected to NMR analysis to determine the conformation of the RGD sequence. This was then mapped onto chemical scaffolds and used to discover small molecule peptidemimetics (Garsky et al. 1989). This led to the discovery of tirofiban, which was commercialized as Aggrestat®.

While all of these agents were very potent (low nanomolar Kd) none were orally active and thus were only useful for acute conditions such as acute myocardial infarction, stenting, etc. As the market for acute use is relatively small, companies searched for bioavailable small molecules. One approach was to make incremental changes to RGDS to both stabilize the molecule and increase its potency. This led to the discovery of xemilofiban and orbofiban (Anders et al. 2001) and sibrafiban (Refino et al. 1998). Another approach was the identification of compounds with a profile suggestive of anti-GPIIb/IIIa activity such as the anti-parasite agent pentamidine (Cox et al. 1992) (an early example of repurposing existing drugs), which led to the discovery of FK633 (Cox and Seki 1998). The result was a family of very potent compounds with varying levels of oral activity.

So within a few years of the discovery of GPIIb/IIIa there was a plethora of agents – antibodies, peptides, and non-peptides – entering clinical trials. Ultimately the IV agents were shown to be beneficial in preventing thrombosis during percutaneous coronary intervention (PCI) (Boersma et al. 2002). So while there was evidence of efficacy it was clear that these agents were hampered by the short duration of administration due to the need for intravenous infusion. All eyes were then on the oral agents as they could be administered for longer duration and thus more likely to be of use.

A number of orally active agents made it to PIII trials – xemilofiban, orbofiban, and sibrafiban. Despite large clinical trials with all of these agents the results were disappointing. They all showed an increase in mortality and surprisingly this was due to an increase in cardiovascular events rather than some off-target toxicity (Chew et al. 2001). Ultimately none of the oral agents made it to market and the key question was how everybody got it so wrong. This failure was multifactorial and involved both pharmacokinetic and pharmacodynamic properties of the drugs (Cox et al. 2010; Cox 2004).

In hind-sight the problem was obvious. While all drugs were described as GPIIb/IIIa antagonists because they inhibited fibrinogen binding and platelet aggregation they were in fact agonists on the receptor. This was seen with increased platelet activation with these agents (Cox et al. 2000) and increased fibrinogen binding when these agents dissociate from GPIIb/IIIa (Cox et al. 1996). This is hardly surprisingly as they were all modeled on RGDS which is the natural agonist for the receptor. One reason for this was that integrins were not considered to be true receptors as there were no obvious signaling domains in the receptor and thus thought not to generate a signal. Thus, GPIIb/IIIa was considered to be a fibrinogen-binding protein rather than a fibrinogen receptor. Furthermore, the two outputs that were used to assess the actions of these agents were fibrinogen binding and platelet aggregation both of which were entirely dependent on fibrinogen binding and did not involve signaling. In reality even if there was a wish to investigate signaling potential it was not possible as no signaling pathway had been identified.

Signaling

GPIIb/IIIa is the best studied integrin due to the interest in it as a drug target. However, the principles of signaling associated with GPIIb/IIIa apply to other integrins (Li et al. 2010). Like most integrins GPIIb/IIIa exists in a resting conformation that does not allow it to bind to its ligand – fibrinogen – and must be activated to support aggregation and to generate signals. In the case of GPIIb/IIIa this can occur in two ways. Firstly, the receptor can be directly activated by certain ligands. For instance RGD peptide binding to GPIIb/IIIa induces a conformational change (Quinn et al. 2002) leading to receptor activation (Cox et al. 1996; Peter et al. 2001). While resting GPIIb/IIIa cannot bind soluble fibrinogen it can bind to immobilized fibrinogen. In this case interaction with the Asn-Gly-Arg (NGR) sequence in fibrinogen leads to receptor activation (Moriarty et al. 2015). Inside-out signaling is the process by which integrins are converted to an active form and become capable of binding their ligand in response to activation of other receptors on the cell surface which in the case of platelets are

usually G-protein-coupled receptors. Activation is mediated by binding of proteins such as talin, paxillin, and kindilin leading to an increased affinity for the ligands and also the formation of adhesion complexes which are essential for the signal transduction process (Humphries et al. 2019). The intracellular cytoplasmic tails of both the α- and β-subunits are critical for his activation process as they support the binding of the signaling molecules (Coller and Shattil 2008).

Outside-in signaling is the signaling that occurs upon ligand binding and the transmission of the signal into the cell and altering cellular processes as a result. This outside-in signaling is critical to the concept of integrins as receptors rather than adhesion molecules. Activated GPIIb/IIIa binds Src family kinases such as Src, Lyn, and Fyn which in turn phosphorylate focal adhesion kinase (FAK), Syk (tyrosine kinase), etc. (Shattil et al. 2010). Integrin clustering both with other integrins and other receptors is important to generate a signal. For instance, Syk can bind to both β3 cytoplasmic tail and to the immunoreceptor tyrosine-based activation motif (ITAM) domain of FcγRIIa. Interestingly, *Staphylococcus aureus* can utilize this by crosslinking both GPIIb/IIIa and FcγRIIa to trigger platelet activation (Fitzgerald et al. 2006). Resting GPIIb/IIIa cannot bind soluble fibrinogen – it must be converted into an active conformation usually by an inside-out signaling mechanism. As agonists, when the GPIIb/IIIa inhibitors bind they induce a conformational change in GPIIb/IIIa converting it into the active conformation of the receptor. Since these agents bind reversibly they leave the receptor but there is a delay for the receptor to return back to the resting conformation. Prior to this return to a resting conformation fibrinogen can bind (there are high levels of fibrinogen in plasma) and once fibrinogen binds it can support aggregate formation (Peter et al. 2001).

So while there were clear pharmacodynamic problems with GPIIb/IIIa antagonists there were also pharmacokinetic problems as well. While all of these agents were used on a once-per-day schedule many would have been better used with a twice daily dosing regimen (Quinn et al. 2000). Thus, there were very significant trough periods with these agents. Furthermore there were significant numbers of spare receptors on platelets. There are around 50–80,000 GPIIb/IIIa molecules on a platelet (Quinn et al. 2000) and clinical studies measuring receptor occupancy and inhibition of platelet aggregation showed that 90% inhibition was the target for benefit. While IV agents are dosed as infusions to maintain this level of inhibition the oral agents with their PK profile were incapable of delivering that level of inhibition over 24 h. With a large number of spare receptors GPIIb/IIIa antagonists must occupy a large percentage of receptors but as agonists they can exert their full activity with the occupation of a small percentage of receptors. This was confirmed when it was shown that orbofiban at doses too low to inhibit platelet aggregation could enhance aggregation to low dose platelet agonists (Cox et al. 2000).

Thus, oral GPIIb/IIIa antagonists failed because there was a lack of understanding of both the PK and PD properties of these agents. While there were clear signals of potential problems speed was (and still is) essential in the drug development timeline. Every effort is made to get the drug through clinical trials and onto the market as soon as possible – this includes overlapping timelines for the different phases of the clinical trials. Considering that RGD was only shown to be the GPIIb/IIIa recognition domain on fibrinogen in 1989 and 5 years later we have the first clinical trials of GPIIb/IIIa antagonists, there was no time to understand the structure and function of this new family of receptors. Since then agents have been discovered with high bioavailability, no agonist-like properties and are truly once-a-day agents. However, the pharmaceutical industry has lost all interest in oral GPIIb/IIIa antagonists so these will never make it to market. Despite the fact that the arguments for an oral GPIIb/IIIa antagonist are as valid today as 20 years ago and that agents with the ideal profile are available, the pharmaceutical industry will not go there.

Cancer

Cell adhesion and its regulation is critical in the pathogenesis of cancer especially in the metastatic process where primary tumor cells must downregulate their ability to adhere to allow cells to breakaway but must regain this ability to attach to a new site. As integrins are important cell adhesion molecules it is reasonable to assume that they are potential drug targets in cancer. They play important roles in tumor metastasis where regulating the ability to adhere is critical. They also play a significant role in angiogenesis which is an essential step in tumor growth (Hamidi and Ivaska 2018). The importance of integrins in cancer became more obvious as it became clear that as true receptors integrins were far more significant than simple cell adhesion molecules. For instance, integrins play an important role in the metabolic reprogramming in cancer cells (Ahmad et al. 2019). This of course creates problems similar to that seen with GPIIb/IIIa antagonists – drugs based on RGD may be agonists rather than antagonists (Alghisi et al. 2009). Thus, while they would prevent metastatic cell adhesion they could also stimulate tumor growth (Paladino et al. 2019). While numerous integrins have been associated with cancer, the αV integrins attracted the most attention as the most important family of cancer-associated integrins. However, unlike platelets which have a single integrin associated with thrombosis, many cancers are associated with multiple integrins, for example, breast cancer is associated with at least 10 different integrins and all cannot play critical roles. Inhibiting a single receptor may have little effect as other integrins can compensate. Thus, there may be a need to screen a patient's tumor to determine if it is sensitive to a specific anti-integrin. Another approach is to develop nonspecific inhibitors that would target multiple integrins. However, this also greatly increases the chance of adverse effects.

As tumor growth is complex it may be unreasonable that inhibiting a single integrin prevents tumor growth. An alternative possibility is that anti-integrin therapy may be effective in combination with other treatment options. This can even by synergistic and act to sensitize the tumor to other agents. However, there are many anti-cancer agents and a lack of clarity on which ones would best respond to anti-integrin therapy. With the failure of anti-integrin monotherapy there were studies to investigate the role of anti-integrin therapy as part of combination therapy. Anti-integrin therapy does alter the sensitivity to other chemotherapeutic agents. However, even then the results were unclear as in breast cancer inhibition of αV enhanced sensitivity to chemotherapy while in melanoma it decreased sensitivity to chemotherapy.

Table 1 shows the anti-integrin agents that were investigated in cancer. Despite initial promising PII success none progressed to the market due to lack of efficacy. All of these failed studies in cancer must raise the question of whether there is a role for anti-integrin therapy in cancer. Certainly, numerous questions still remain unanswered: as multiple integrins are involved in carcinogenesis are other integrins more appropriate targets? Furthermore, it is not clear how they should be used: monotherapy or part of combination therapy. Is the aim of treatment to inhibit

Integrins as Drug Targets: Is There a Future?, Table 1 Integrin targeted agents in cancer

Drug	Integrin	Target	Reference
Cilengitide	αVβ3 αVβ5	Glioblastoma	Stupp et al. (2014)

Abituzumab	αV	Prostate cancer	Hussain et al. (2016)

tumor growth, metastasis, or angiogenesis? In reality until these questions are answered, it is unlikely that there will be a successful anti-integrin in cancer.

Infection and Immunity

One of the most promising areas in integrin pharmacology is immunology especially since the original integrins that were identified were the leucocyte adhesion molecules and are now known as the β2 integrins. While the β2 integrins are restricted to leucocytes there are other integrins that are involved in immune cell function as well. A key function of integrins in immune cells is to localize the inflammatory response to a site of infection. Integrins mediate the adhesion of immune cells to a site of injury and trigger a co-stimulatory signal necessary for full immune cell activation (Smith-Garvin et al. 2009).

Pharmacologically there are a few integrins that are important in the immune system. When complexed with β1 the α1 subunit plays an important role in T-cell adhesion and migration (Hight-Warburton and Parsons 2019). However, integrins are not just adhesion receptors, especially in the immune system. For instance complement receptors 3 and 4 are integrins – αMβ2 and αXβ2, and αIIbβ3 is a receptor for C-reactive protein (Brennan et al. 2008).

The role of α4 integrins in T-cell migration (Hight-Warburton and Parsons 2019) suggested that it might be a suitable target in autoimmune disease. T-cell migration across the blood-brain barrier is important in multiple sclerosis and across the gut in Crohn's disease. Monoclonal antibodies to α4 (natalizumab and vedozilumab) were generated and tested and shown to be effective in these two diseases. Furthermore, the β7 integrin subunit, a common binding partner for the α4 subunit, was also targeted (etrolizumab). The other integrin that was targeted by efalizumab was αLβ2 which proved to be effective in treating psoriasis (Gordon et al. 2003). Table 2 shows the anti-integrins that were developed as immunomodulators.

A limitation with the anti-integrins used as immunomodulators are their safety profiles. It appears that integrins are very important co-stimulatory receptors in the immune system and when inhibited this leads to a significant immune suppression that puts patients at risk of infection. One very serious adverse effect is progressive multifocal leukoencephalopathy (PML) which is of particular concern with the use of natalizumab in multiple sclerosis and efalizumab in psoriasis. This is due to reactivation of JC virus infection leading to lysis of neurons and permanent destruction of the myelin sheath (Khalili et al. 2019). In patients that are JC virus positive the incidence of PML is 1% with a 25% mortality rate and 30% of survivors will have severe neurological complications. As a result, efalizumab was withdrawn from the market although natalizumab remained on the market subject to a risk evaluation and mitigation strategy (REMS) and became a blockbuster. The one exception appears to be vedozilumab, which targets α4β7. It may be the case that the localization of this receptor to the gut ensures that there

Integrins as Drug Targets: Is There a Future?, Table 2 Integrin-targeted agents as immunomodulators

Drug	Integrin	Target	Reference
Natalizumab	α4β1 α4β7	Multiple sclerosis Crohn's disease	Pucci et al. (2011) and Nelson et al. (2018)
Vedozilumab	α4β7	Ulcerative colitis Crohn's disease	Feagan et al. (2013) and Sandborn et al. (2013)
Etrolizumab	β7	Ulcerative colitis Crohn's disease	Vermeire et al. (2014)
Efalizumab	αLβ2	Psoriasis	Gordon et al. (2003)
Firategrast	α4	Multiple sclerosis	Miller et al. (2012)

are no systemic effects from the immune suppression.

Conclusion

There is no doubt that the discovery of integrins and their important roles in the most significant human diseases created great opportunities for the pharmaceutical industry. Thirty years later there must be great disappointment in this class of agents as, despite many clinical trials, few agents made it to the market and those that did all have limited sales. There were multiple reasons for these failures including poor PK profile, lack of efficacy, adverse effects, and poorly defined targets. In the case of cardiovascular disease the lack of orally active agents meant that they were restricted to short-term use in acute patients. The discovery of P2Y12 antagonists such as clopidogrel, prasugrel, and ticagrelor soon displaced GPIIb/IIIa antagonists as they were every bit as effective and orally active. As a result the peak annual global sales for all GPIIb/IIIa antagonists are equivalent to the peak global sales for 1 month for clopidogrel. Efficacy was a problem with the cancer target and none of the agents proved to be effective. In this case the lack of a validated target played a key role. It is not clear what integrin should be targeted and even what part of the cancer process should be targeted. Adverse effects are a major problem with many anti-integrins. Those used as immune suppressants are associated with very serious adverse effects such as PML and the oral antiplatelet agents were associated with increased cardiovascular mortality. While natalizumab sales were initially very promising the advent of orally active disease modifying agents such as fingolimod and dimethyl fumarate which did not have a significant toxicity problem soon relegated natalizumab to a second tier agent.

So is there a future for anti-integrins? Existing antiplatelet agents are so successful and cheap (many are now generic) and it is hard to see any role for anti-integrin agents in thrombosis. The lack of success in cancer suggests that industry will lose interest in this area soon unless there is a validated integrin target with a clear role in cancer. The most promising area for anti-integrin agents is immunomodulation. The agents such as natalizumab were game changers in the treatment of multiple sclerosis, although with significant adverse effects. However, like with GPIIb/IIIa antagonists newer agents became available without the adverse effects relegating the anti-integrins to second-line agents. The best opportunity is specifically targeting integrins that are highly localized such as α4β7 in the gut. As they are not widely distributed it minimizes systemic effects.

Anti-integrins, once thought of as the next big blockbuster drugs, have been relegated to minor, second level therapeutic agents. The pharmaceutical industry has stuck with this family of agents for over 30 years with little to show for it. With a lack of clarity on a future direction it is not clear for how long the pharmaceutical industry will retain an interest in anti-integrin agents.

Synonyms

Anakinra; Autoinflammation; Canakinumab; IL-1; IL-1R

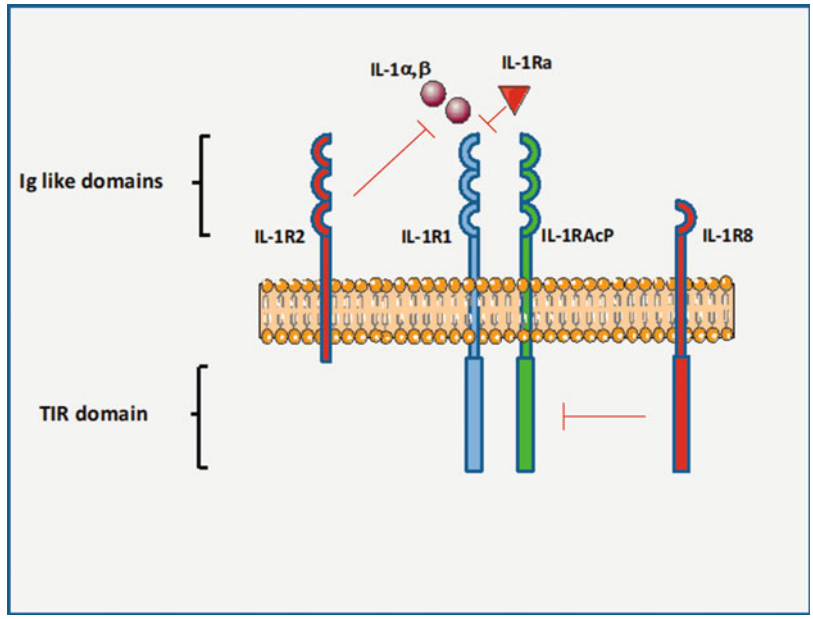
Definition

Interleukin-1 (IL-1) refers to two of the earliest identified cytokines, which act primarily as intercellular protein messengers with important roles in mediating the inflammatory response. Originally described as an endogenous pyrogenic factor, Interleukin-1 in fact refers to two distinct cytokines, encoded by separate genes, designated as Interleukin-1α and Interleukin-1β (Dinarello et al. 1977; Dinarello 2010). Although both cytokines engage the same Interlukin-1 receptor to elicit pro-inflammatory responses on a diverse array of target cells, their modes of expression and activation are distinct, underlying several notable differences in terms of their roles in human physiology and disease. Since the original description of IL-1 over 40 years ago, subsequent discoveries have identified an expanded family of IL-1 related cytokines with a broad range of functions as mediators of tissue homeostasis and inflammation (Hernandez-Santana et al. 2019). As the prototypical members of this cytokine family, efforts aimed at modulating the activity of IL-1α and Il-1β in human disease have, to date, yielded the most progress.

Basic Characteristics

The IL-1 Receptor

Both IL-1α and Il-1β bind to the same specific receptor on target cells known as the Interleukin-1 receptor (IL-1R). Upon ligand binding, the Interleukin-1 receptor 1 chain hetero-dimerizes with the Interleukin-1 receptor accessory protein (IL-1RAcP) to form the IL-1R (Fig. 1). Both chains of the IL-1R comprise of extracellular Immunoglobulin (Ig)-like domains and



Interleukin-1 (IL-1), Fig. 1 The heterodimeric IL-1 receptor consisting of IL-1R1 and IL-1AcP chains, each with extracellular Immunoglobulin (Ig) like domains responsible for binding of ligands, IL-1α and IL-1β, and intracellular Toll-IL-1R Resistance (TIR) domains required for activation of downstream signaling. Activation of the receptor can be negatively regulated by endogenous mechanisms including the Interleukin-1 receptor antagonist, the decoy IL-1R2 receptor, and negative regulatory receptors such as IL-1R8

intracellular Toll-IL-1R Resistance (TIR) domains, which upon dimerization facilitate the activation of downstream intracellular signaling pathways. Activation of these pathways is initiated through the recruitment of the TIR domain containing signaling adaptor protein MyD88 which results in the subsequent downstream activation of IL-1R associated kinases (IRAKs) and Tnf receptor associated-factor 6 (Traf6). These events ultimately lead to the induction of pro-inflammatory gene expression through the activation of NF-κB transcription factor and other MAPK dependent transcription pathways (Mantovani et al. 2019). Despite sharing the same receptor and signaling events, significant differences exist with regards to the modes of expression and activation of both IL-1α and IL-1β.

Overlapping and Distinct Features of IL-1α and IL-1β

While IL-1α expression is widespread across many different cell and tissue types, IL-1β expression is largely confined to cells of myeloid origin. Additionally, IL-1α is expressed for the most part on the cell surface, whereas IL-1β is expressed in secreted form. This has led to the hypothesis that while IL-1α acts predominantly in a localized fashion, IL-1β exerts its pro-inflammatory effects more systemically.

Both cytokines are expressed as pro-proteins whose function is regulated through cleavage by specific proteases. While full-length IL-1α has been reported to exhibit functional activity, it can be further processed by proteases, such as calpain leading to enhanced pro-inflammatory capacity. In contrast, full length IL-1β (ProIL-1β) is not biologically active and is required to undergo a highly coordinated process in order to acquire full activity. Firstly, expression of ProIL-1β is induced, either by microbe, or "damage" associated molecular patterns, or by other pro-inflammatory cytokines such as TNF or the IL-1 cytokines themselves. Once expressed, ProIL-1β is activated through proteolytic cleavage by caspase-1 in a process mediated by inflammasomes, such as containing the NOD-like receptor protein 3 (NLRP3) (Garlanda et al. 2013a, b).

As well as acting at the cell surface where it can stimulate the IL-1R, IL-1α is also expressed intracellularly, in both the cytoplasm and the nucleus, in many cell types. Indeed, IL-1α localized to the nucleus has been proposed as a regulator of pro-inflammatory gene transcription. Intracellular IL-1α is also recognized as an "alarmin" molecule and can act as a potent mediator of sterile inflammation, upon its release from injured or necrotic cells. With distinct patterns of expression and activity, both IL-1 cytokines act in a highly regulated fashion to control local and systemic inflammatory responses.

Endogenous Regulators of IL-1 Activity

Underlining the importance of IL-1 cytokines as mediators of inflammation, a number of distinct mechanisms have evolved to ensure that their activity is highly regulated under homeostatic and inflammatory conditions (Garlanda et al. 2013a, b). As well as IL-1α and IL-1β, a separate IL-1 family gene encodes a specific Interluekin-1 receptor antagonist (IL-1Ra). IL-1Ra, when present, binds to the IL-1R1 chain thereby preventing the interaction with IL-1α and IL-1β and inhibiting their activity. Unlike IL-1α and IL-1β, IL-1Ra binding does not result in the recruitment of IL-1RAcP to the receptor complex and does not initiate intracellular signaling. The discovery of this natural antagonist of IL-1 signaling has been exploited with some success for the treatment of several inflammatory diseases in humans discussed in more detail below.

As well as IL-1Ra, there is also a decoy IL-1 receptor chain encoded by the *IL1R2* gene. The extracellular domain of the IL-1R2 receptor shares significant homology with IL-1R1 and can bind IL-1β with high affinity. IL-1R2 can be found expressed both on the cell surface and in soluble form and acts as a molecular "sink" to neutralize the bioavailability of IL-1 cytokines. Although cell surface bound IL-1R2 can heterodimerize with IL-1RAcP upon ligand binding, it lacks an intracellular TIR domain required to initiate downstream signaling pathways and as a result inhibits the activation of pro-inflammatory gene transcription (Fig. 1). Similar to IL-1R2, IL-1R1 can also be expressed in soluble form,

where it may also exert neutralizing effects in a cell extrinsic fashion. A further layer of regulation of IL-1 activity is provided by negative regulatory receptors of the IL-1 family such as IL-1R8 (Garlanda et al. 2013b; Russell et al. 2013). IL-1R8 can act to restrict IL-1 activity through interfering with appropriate assembly of the IL-1R heterodimer complex as well as through preferential sequestering of intracellular signaling intermediates such as MyD88 (Qin et al. 2005).

These multiple regulatory mechanisms point to the undesirable effects associated with uncontrolled IL-1 activity, which are recognized as a characteristic of several human inflammatory disease conditions.

IL-1 in Human Disease

IL-1 cytokines have been implicated as important mediators of a range of inflammatory diseases. Several of these diseases are associated with disruption of the endogenous regulatory mechanisms of IL-1 activity described above. These include autoinflammatory conditions resulting from monogenic mutations in key genes, which regulate IL-1β secretion and activation such as the genes, which encode IL-1RA and NLRP3. Perhaps, unsurprisingly these disorders which include deficiency of the IL-1R antagonist (DIRA), familial Mediterranean fever (FMF), and cryopyrin-associated periodic syndrome (CAPS) have been found to respond relatively well to therapeutic strategies aimed at targeting IL-1 described in detail below. As well as these rare autoinflammatory disorders, IL-1 activity has been described as an important pathogenic factor in more prevalent inflammatory disorders such as rheumatoid arthritis, gout, metabolic syndrome, cardiovascular disease, and certain types of cancer (Dinarello et al. 2012).

Drugs

Specific therapeutic strategies targeting IL-1 cytokines in rare autoinflammatory disorders have proven relatively successful. Currently, three different therapeutic strategies targeting IL-1 cytokines have been licensed to date (Table 1), with more in clinical development with potential for treating an expanding number of systemic inflammatory diseases.

Anakinra, a recombinant human IL-1Ra, which inhibits inflammation mediated by both IL-1α and IL-1β, first received regulatory approval in 2001 for the treatment of patients with adult rheumatoid arthritis (RA) and the autoinflammatory disorder neonatal-onset multisystem inflammatory disease (NOMID). Another approved agent, Rilonacept, is in clinical use for the treatment of CAPS. Rilonacept, also referred to as "IL-1Trap," is a dimeric fusion protein consisting of portions of IL-1R1 and the IL-1RAcP. As such, it not only binds and neutralizes IL-1α and IL-1β, but also IL-1Ra. A third approach is an anti-IL-1β monoclonal antibody, Canakinumab, which binds to and neutralizes human IL-1β by blocking its interaction with IL-1 receptors without effecting IL-1α or IL-1Ra. Canakinumab is indicated to treat CAPS, including familial cold autoinflammatory syndrome (FCAS) and Muckle Wells syndrome (MWS), as well as systemic juvenile idiopathic arthritis (sJIA) (Dinarello et al. 2012; Hernandez-Santana et al. 2019).

Other IL-1 targeting therapeutic strategies which have not yet been approved but are currently in clinical development include MABp1, a monoclonal antibody specifically targeting IL-1α, CAN-04 a first-in-class fully humanized monoclonal antibody targeting IL-1RaAcP, thereby blocking IL-1α and β signaling, and OSP-101, the first and only inhaled IL-1Ra. In addition,

Interleukin-1 (IL-1), Table 1 Currently approved therapies targeting Interleukin-1

Drug name	Therapeutic strategy	Mechanism of action
Anakinra	Recombinant Interleukin-1R antagonist	Binding to IL-1R
Rilanocept (IL-1Trap)	Recombinant IL-1R fusion protein	Binding to IL-1α, IL-1β and IL-1Ra
Canakinumab	Monoclonal Ab specific to human IL-1β	Neutralizing IL-1β

small molecule inhibitors of inflammasome components such as NLRP3 are showing considerable promise in preclinical development (Dinarello et al. 2012; Coll et al. 2015). Notwithstanding the clear efficacy of these drugs in the treatment of monogenic autoinflammatory disorders associated with unregulated and enhanced IL-1 activity, the evidence that they may also provide benefit in other more prevalent disease settings is also accumulating. For example, IL-1 has long been at the center of hypotheses linking inflammation with the pathogenesis of atherosclerosis. This is now more clearly evident from the recently reported CANTOS study, one of the largest phase III clinical trials ever established, investigating the efficacy of the monoclonal anti IL-1β antibody Canakinumab, to prevent secondary cardiac events among cardiovascular disease patients (Ridker et al. 2017a). The results of this trial not only confirmed the contributory role for inflammation, through an IL-1β mediated process, as an important driving factor in the pathogenesis of atherosclerosis, but opens up the possibility of adding more specific modes of anti-inflammatory therapeutic intervention to cardiovascular disease patients. IL-1 has also been implicated as mediating pathological events that can occur in the heart following a myocardial infarction, including inflammation and remodeling processes which further weaken viable heart muscle tissue contributing to subsequent heart failure. Pilot studies, examining anakinra administration following myocardial infarction, led to lowering of CRP levels, as well as a reduced progression to heart failure. In other cardio-metabolic disease states, such as Type 2 diabetes, administration of the anti-IL-Iα monoclonal antibody, MABp1, reduced levels of glycosylated hemoglobin (HbA1c), an indicator of the average blood glucose levels. The beneficial effects of targeting IL-1 in patients with an array of cardiovascular diseases will likely prompt further investigations, as more information concerning the role of IL-1 in cardiovascular pathology is uncovered.

The significance of IL-1 in tumourigenesis is also currently under investigation. IL-1α and IL-1β have been found to be abundantly expressed in advanced tumors and associated with higher tumor grade and invasiveness. Anakinra, which neutralizes both IL-1 ligands, has been reported to inhibit colon tumor growth in preclinical studies and has been investigated as a therapy across various malignancies. Due to its relatively shot half-life, anakinra requires continuous administration, which may lead to reduced patient adherence. Therefore, the anti-IL-1 neutralizing antibodies may represent a more suitable approach and are currently being investigated. Interestingly, during the CANTOS trial, incident cancers were tracked and a reduced incidence of lung cancer and deaths from all cancers was reported among patients administered Canakinumab (Ridker et al. 2017b). This has subsequently led to the design of a combination trial investigating its use alongside a programmed cell death protein 1 (PD-1) immune checkpoint inhibitor in patients with non small cell lung cancer. Other unlicensed therapeutics, such as CAN-04 and MABp1, are also under clinical investigation to determine whether they may improve outcomes for patients with different types of tumor (Mantovani et al. 2018). As more trial results are reported, greater evidence supporting a role for targeting IL-1 in cancer therapy programs will likely be revealed.

Beyond cardiovascular disease and cancer, the therapeutic benefit of targeting IL-1 is also under investigation across a wide range of human inflammatory conditions (Dinarello 2014). These include chronic inflammatory skin conditions such as hidradenitis suppurativa and severe atopic dermatitis, inflammatory lung conditions such as chronic obstructive pulmonary disease, and chronic rheumatologic disorders such as osteoarthritis. As the results of such investigations are revealed, the benefits of targeting IL-1 activity in the clinic are likely to further expand. To date targeting IL-1 has not been associated with an increased risk of opportunistic infections; however, continued vigilance is required for the risk of potential serious infections with chronic therapy, particularly as IL-1 plays an important role in host defense against invading pathogens.

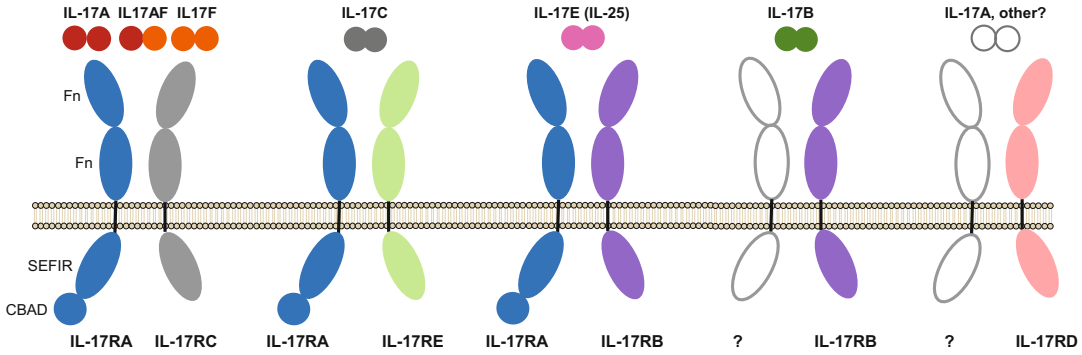
Definition

Interleukin-17 (IL-17) is a cytokine, that is, a low molecular weight cellular messenger contributing to the regulation of immune responses. IL-17, also referred to as IL-17A, is the founding member of a whole family of six cytokines (IL-17A to IL-17F). These proteins form mostly homodimers, with the exception of IL-17A and IL-17F that can also form the heterodimer IL-17A/F. IL-17 family members signal through specific IL-17 receptor complexes consisting of two different subunits (IL-17RA to IL-17RE) that also constitute their own receptor family. IL-17A, the most widely characterized member, has mainly pro-inflammatory effects. It is produced by Th17 and other immune cells upon their activation, and stimulates a range of cells including epithelial cells, keratinocytes, fibroblasts, and endothelial cells to produce inflammatory mediators, which in turn attract and activate immune cells to combat pathogens and to ensure barrier integrity. The chronically dysregulated pathway plays a pivotal role in several inflammatory/autoimmune diseases including psoriasis, psoriatic arthritis, and ankylosing spondylitis, as underscored by the beneficial effect of IL-17 blockade in the clinic.



Interleukin-17, Fig. 1 IL-17 cytokine and receptor family. Schematic overview of the known IL-17 receptor complexes with their respective IL-17 cytokines. Unknown co-receptors and ligands are indicated with non-colored symbols. CBAD, C/EBPβ activation domain; Fn, Fibronectin-like domain; SEFIR, SEF/IL-17R domain

Basic Characteristics

IL-17 Cytokine and Receptor Family

The rodent *IL17* gene and IL-17 protein were discovered 25 years ago in T cells, and were originally named as cytotoxic T lymphocyte-associated antigen 8 (CTLA8). Human IL-17 was identified 2 years later, and renamed IL-17A when additional family members, that is, IL-17B, IL-17C, IL-17D, IL-17E (also known as IL-25), and IL-17F, were identified based on sequence homology (for review see McGeachy et al. 2019). IL-17A shares the highest homology (55%) with IL-17F. The cytokines exert their functions mostly as homodimers, with the exception of IL-17A and IL-17F that can form also the heterodimer IL-17A/F (Fig. 1). IL-17A also commonly known as IL-17 is the founding member of this family, and also the best characterized. The biology of IL-17A and its closest relative IL-17F is linked, and IL-17F is often but not exclusively co-expressed with IL-17A. In cellular systems, the effects of IL-17A, IL-17F and the heterodimer largely overlap, while their potency is IL-17A > IL-17A/F > IL-17F.

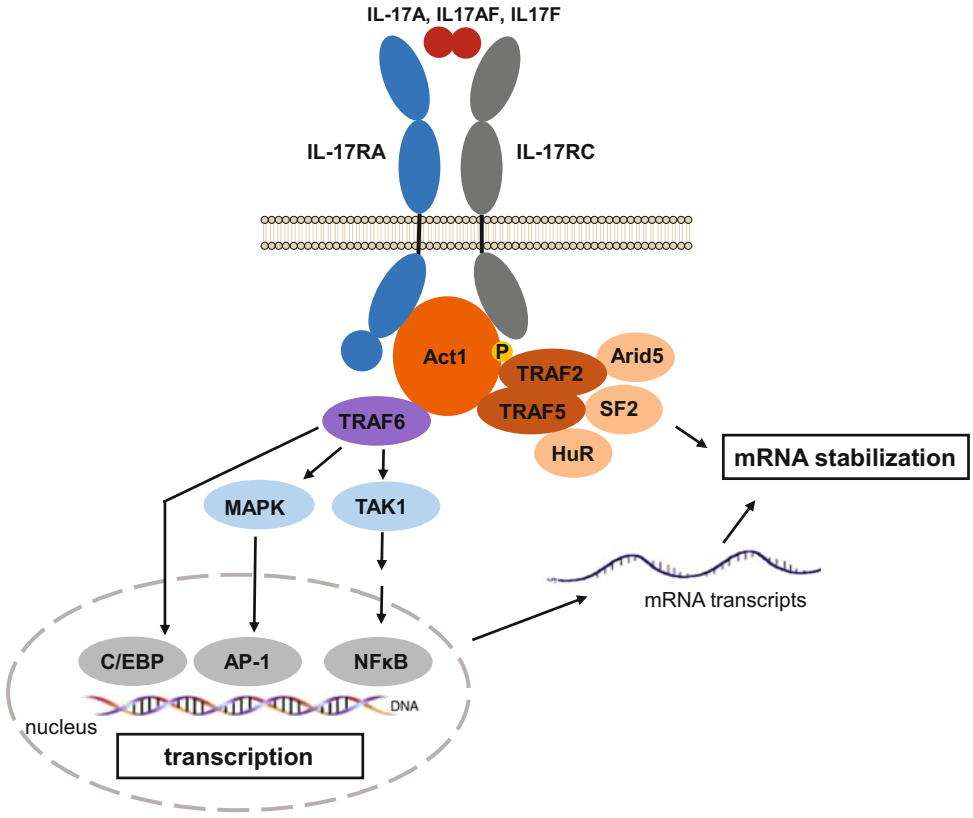
In analogy to the IL-17 family, the receptors for IL-17 (IL-17R) also form their own family, with five homologous subunits, IL-17RA to IL-17RE, identified (Fig. 1). IL-17RA, the founding member, was discovered in 1995. The receptors share an intracellular conserved signaling motif termed SEFIR (similar expression of fibroblast growth factor genes and IL-17 receptor) which is distantly related to the Toll/Interleukin-1 receptor (TIR) domain from Toll-like receptors (TLRs) and IL-1 receptors (IL-1Rs). IL-17RA and IL-17RC contain also an extension of the SEFIR domain (SEFEX, SEFIR extension), and IL-17RA harbors in addition a CBAD (C/EBPβ activation domain) at the C terminus. All IL-17 receptors express two extracellular fibronectin-like (FN) domains to mediate protein-protein interaction and ligand binding, and a single transmembrane domain. The IL-17 cytokines signal via a receptor complex consisting of two different subunits. IL-17A and IL-17F homodimers as well as the IL-17A/F heterodimer bind to the same receptor complex consisting of the IL-17RA and IL-RC subunit (Fig. 1). A recent publication suggests that IL-17A may also bind and signal through IL-17RD (Su et al. 2019). IL-17RA is also the co-receptor used by two other IL-17 family members: IL-17C binds to the IL-17RA/IL-17RE complex, and IL-17E to the IL-17RA/IL-17RB complex. In addition, there is evidence for interaction of the IL-17RA/IL-17RC complex with the epidermal growth factor receptor family. Little is known, however, about the other IL-17 homodimers and the IL-17RD complex.

IL-17 Signaling

While members of the IL-17R family are defined by the conserved SEFIR domain, the only other known protein with a SEFIR domain is the

adaptor protein Act1, the usage of which is a unique feature of IL-17R signaling. IL-17RA/IL-17RC signaling has been studied most comprehensively (McGeachy et al. 2019). Binding of the ligand (IL-17A, IL-17AF, IL-17F) to the receptor complex induces conformational changes that enable the recruitment of the cytosolic adapter protein Act1 via homotypic SEFIR-SEFIR domain interaction (Fig. 2). The central role of Act1 in IL-17A signaling has been shown by the deletion of the *act1* gene, which abrogates all responses to IL-17A. Act1 directs the two main signaling cascades and functions of IL-17, a transcriptional arm and an mRNA stabilization arm. To direct these two downstream signaling cascades, Act1 interacts via its TNF receptor-associated factor (TRAF) binding motif with TRAF proteins. The cascade leading to (overall weakly increased) gene transcription is TRAF6 dependent. Act1 activates TRAF6 via K63 polyubiquitinylation, which leads to initiation of the canonical NF-κB pathway via TAK1, MAPK signaling cascades (p38, JNK and ERK) and activation of C/EBP transcription factor. C/EBPβ was recently also shown to be directly activated by IL-17RA. Of note, the atypical IκB family member IκBζ emerged as an important signaling node of the IL-17 pathway. Its expression is dependent on IL-17 and it acts in the nucleus as a transcription factor modulator to increase a set of NF-κB-driven genes that constitute a major portion of IL-17 target genes.

The signaling cascade resulting in mRNA stabilization involves TRAF2 and TRAF5 and is initiated by the phosphorylation of Act1 by activated inducible IκB kinase IKKi (also known as IKKε) or TANK binding kinase 1 (TBK1). The phosphorylated Act1 recruits TRAF2 and TRAF5



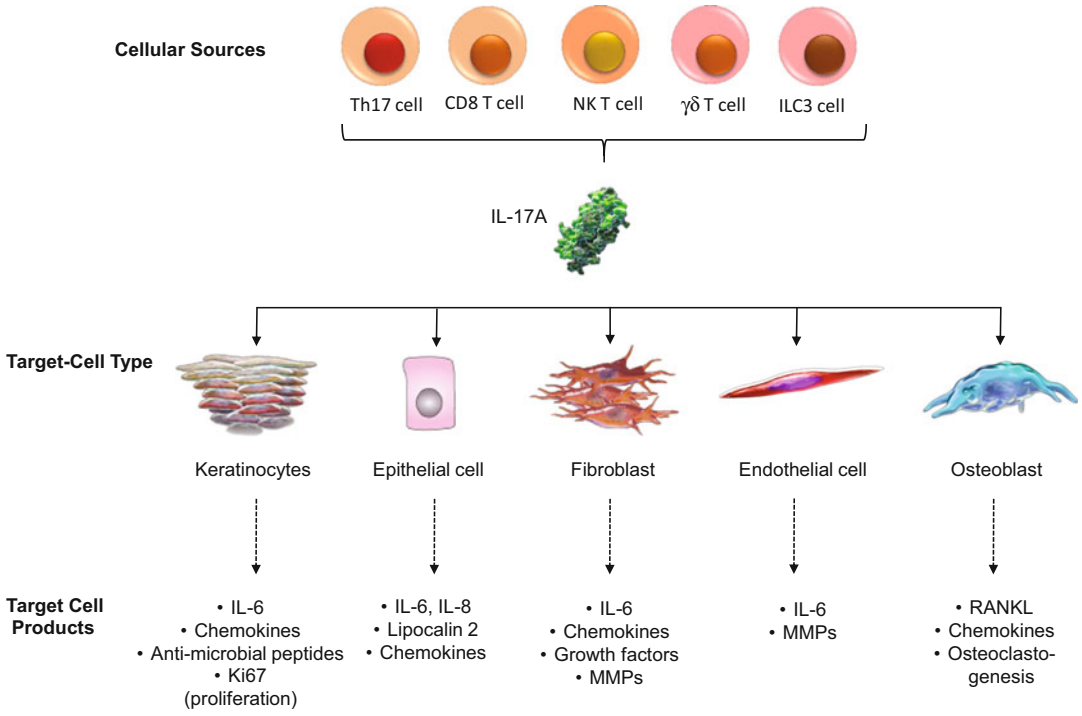
Interleukin-17, Fig. 2 Simplified scheme of IL-17 signaling. The adaptor protein Act1 plays a central role to direct the two main signaling cascades: initiation of transcription involving TRAF6, and mRNA stabilization mediated via TRAF2, TRAF5, and mRNA binding proteins. See text for details

to form a complex with several proteins involved in mRNA stabilization, for example, preventing the mRNA destabilizing SF2 from mRNA binding, and promoting binding of the mRNA stabilizing proteins HuR or Arid5 to act on a subset of IL-17 target gene transcripts. Arid5 stabilizes mRNA by counteracting mRNA degradation mediated by the endoribonuclease Regnase-1. The net effect is increased stability of transcripts from a set of inflammatory genes dependent on IL-17. IL-17 signaling is tightly controlled at several levels, that is, TRAFs such as TRAF3 and TRAF4 disrupt signaling complex formation, enzymes including A20 or USP25 modulate the ubiquitination status of TRAF5 or TRAF6, and binding of the heat shock protein 90 (hsp90) modulates IL-17 signaling by enhancing proteasomal degradation of Act1. Importantly, IL-17A alone is only a moderate transcription and NF-κB activator, and a major role of IL-17A is to act cooperatively with other cytokines such as tumor necrosis factor (TNF) or IFN-γ which are upregulated during inflammation and autoimmune disease.

While IL-17RA is ubiquitously expressed, the expression of IL-17RC appears less prominently on hematopoietic cells and is more evident on epithelial cells including keratinocytes, fibroblasts, and endothelial cells, which thus constitute the main target cells of IL-17 action (Fig. 3).

Cellular Sources of IL-17

IL-17A is produced by several immune cells upon stimulation (Fig. 3). IL-17 is the hallmark cytokine of Th17 cells, a subset of $CD4^+$ T helper (Th) cells, and led to the identification of this new Th cell subset in addition to the already established Th1 and Th2 cells. The differentiation of naive T cells to inflammatory Th17 cells is driven by pro-inflammatory cytokines (IL-1β, IL-6, IL-21) to promote the transcription of the Th17 master regulator retinoid-related orphan receptor-γt (RORγt), which subsequently instructs the cell to increase IL-23R expression. In a feed forward loop, IL-23 signaling then results in the stabilization of Th17 cells with expression of the associated receptor CCR6 and ligand CCL20, and



Interleukin-17, Fig. 3 Cellular sources of IL-17 and main targets of IL-17 with respective responses. MMP, matrix metalloproteinase; RANKL, receptor activator of NF-κB ligand

production of their associated pro-inflammatory type 17 signature cytokines such as IL-17A, IL-17F, granulocyte macrophage colony stimulating factor (GM-CSF), TNF, IL-6, and IL-22. Other immune cells beyond Th17 cells have also emerged as producers of IL-17 depending on the pathological conditions. Those include $CD8^+$ cytotoxic T cells, γδ T cells, natural killer T (NKT) cells, and innate lymphoid cells of the subtype 3 (ILC3). These cells release IL-17A and the aforementioned pro-inflammatory cytokines upon activation by IL-23 or other stimuli. The evidence of IL-23- induced activation of Th17 cells and other leukocytes to release IL-17 has led to an association between these two cytokines and establishment of the IL-23/IL-17 axis. However, IL-17 production and activity without the involvement of IL-23 has also been described, and depends on the cellular, organ, and disease context.

IL-17 Roles in Health and Disease

In healthy individuals, IL-17A and other family members including IL-17F play a role in skin and mucosal barrier homeostasis and in host defense against specific fungal and bacterial infections. Innate immune cells, especially dendritic cells located throughout the body in non-lymphoid compartments, act as sentinels and respond to foreign insults due to tissue injury, pathogen particles, or other infections by mounting an immune response. They release IL-23 and other mediators to activate immune cells including γδ T cells to elicit locally IL-17A, IL-17F, and other cytokines encompassing the IL-17 signature. IL-17 in turn activates, for example, epithelial cells and keratinocytes (Fig. 3) to release chemokines CXCL-1, CXCL-2, CXCL-5 that attract neutrophils to the infected or injured site. Further, to mount the defense, IL-17 stimulates the cells to release antimicrobial peptides (AMPs) such as β-defensin 2 (BD-2), lipocalin 2, S100A7 (psoriasin), and S100A8. The IL-17 pathway was shown to be especially important to defend against *Candida albicans* infection. This is corroborated by genetic studies indicating that individuals with genetic defects affecting IL-17 immunity (e.g., *IL17F, IL17RA, IL17RC*) have chronic mucocutaneous candidiasis. *Candida albicans* infection is also noted as an adverse side effect in clinical trials with antibodies against IL-17 or the receptor. In the gastrointestinal tract, IL-17 is required to maintain barrier integrity, substantiated by the observation that neutralizing IL-17 in patients with Crohn's disease was not beneficial and in some cases disease worsening was observed.

IL-17 in Autoimmune Disease

When chronically activated during autoimmune disease, the IL-17 pathway can constitute an important driver of the pathophysiology. A pivotal role of the dysregulated pathway has been shown in psoriasis, in psoriatic arthritis (PsA) and ankylosing spondylitis (AS), underscored by the treatment efficacy of therapeutic agents inhibiting IL-17.

Psoriasis

Psoriasis is a chronic autoinflammatory disease with prominent skin involvement that affects approximately 2–4% of the world's population and occurs more commonly in patients with a family history of the disease. The disease is characterized by increased epidermal thickness (acanthosis), thickening of the stratum corneum (hyperkeratosis), retention of nuclei in the cornified layer (parakeratosis), dilated blood vessels, and dense clusters of inflammatory cells composed of T cells and dendritic cells in the dermis, and $CD8^+$ T cells and neutrophils in the epidermis (Hawkes et al. 2018). Psoriasis patients thus develop thick red skin with flaky, silver-white scales. The severity of psoriasis ranges from mild disease with limited number of local inflammatory skin lesions to more severe disease involving widespread plaques that cover more than 10% of the body surface. Especially the moderate and severe forms of psoriasis have been difficult to treat. While the advance of antibodies targeting TNF about 20 years ago was a milestone, neutralizing IL-17 or IL-23 with monoclonal antibodies showed even better results, and these agents have transformed the treatment of moderate-to-severe-psoriasis. Antibodies directed against IL-17A or against IL-17RA showed strong efficacy with 60–

90% of patients achieving a 75% reduction in the psoriasis activity and severity index (PASI75). Depending on trial design, 40% of patients achieved PASI100 indicative of cleared skin. The strong efficacy of both IL-23 and IL-17 blockade suggests a pivotal role of IL-23-dependent IL-17 production in this disease (Fig. 4). Keratinocytes seem to be central to mediate the effects of IL-17, eliciting cytokines including IL-19 and IL-36 that activate keratinocyte proliferation to drive epidermal hyperplasia, and releasing chemokines (CXCL-1, CXCL-2, etc.) to recruit neutrophils, and CCL20 to recruit $CCR6^{+}$ cells, that is, dendritic cells and more Th17 cells. This will in turn lead to more IL-17 production. Furthermore, IL-17-stimulated keratinocytes increase the production of AMPs (β-defensin 2, lipocalin 2, S100A7, S100A8, and LL-37). LL-37 in complex with DNA can activate more dendritic cells, thus perpetuating a vicious circle of events (Fig. 4).

Spondyloarthritides and Other Diseases

The spondyloarthritides comprise related but phenotypically distinct inflammatory diseases including psoriatic arthritis (PsA) and axial spondyloarthritis (axSpA). The clinical manifestations of PsA are diverse, and can manifest as peripheral arthritis, inflammation of the enthesis (i.e., the tendon or ligament insertion sites into the bone), inflammation of an entire digit, skin and nail disease, as well as other manifestations. PsA occurs in a substantial portion of patients with psoriasis. Genetic studies had pointed to a role of the IL-23 pathway in this disease, and components of both IL-23 and IL-17 pathways were shown to be elevated in PsA patients. Subsequently initiated clinical trials with IL-17 blockade demonstrated beneficial treatment responses, and both anti-IL17A antibodies secukinumab and ixekizumab were approved for this indication (Table 1; McGonagle et al. 2019). Blocking IL-23 with guselkumab also showed positive outcomes in PsA phase 3 clinical trials, suggesting that the IL-23/IL-17 axis contributes to a substantial portion to the pathobiology.

AxSpA affects mainly the sacroiliac (SI) joint, and possibly the spine. The subtype ankylosing spondylitis (AS) is also referred to as radiographic axSpA and characterized by the presence of radiographic sacroiliitis. Of note, systemic bone loss and at the same time local bone formation at the entheses can occur. Genetic studies and evidence

Interleukin-17, Table 1 Therapeutic agents targeting IL-17 in clinical use or late clinical development. mAb monoclonal antibody, PsA psoriatic arthritis, AS Ankylosing spondylitis/axSpA axial Spondyloarthritis

Target	Agent (trade name)	Type	Approved indication (or as specified)
IL-17A	Secukinumab (Cosentyx®)	Fully human mAb	Psoriasis, PsA, AS/ax SpA
IL-17A	Ixekizumab (Taltz®)	Humanized mAb	Psoriasis, PsA (in development, including AS)
IL-17A	Netakimab (Efleira®, Russia)	Humanized mAb	Psoriasis (in development, including PsA, AS)
IL-17A + IL-17F	Bimekizumab	Humanized mAb	(in development, including psoriasis, PsA, AS)
IL-17RA	Brodalumab (Siliq® (US), Kyntheum® (EU))	Fully human mAb	Psoriasis

of elevated IL-23 and IL-17 in human axSpA as well as data from preclinical models were the basis to initiate clinical trials with IL-23 or IL-17 blockade in AS. While IL-17 blockade showed beneficial treatment effects, the results obtained with IL-23 blockade were surprisingly negative, indicating a divergence of the roles of the two cytokines in this disease. This is an area of further research (Bravo and Kavanaugh 2019; McGonagle et al. 2019).

Initial studies of IL-17 function were performed in synovial fibroblasts from patients with rheumatoid arthritis (RA). They provided evidence of a strong effect of IL-17, especially in combination with TNF, to activate the release of chemokines (CXCL-1, CXCL-2, etc.), cytokines including IL-6, growth factors, and prostaglandin (PGE_2). Furthermore, a key function of IL-17 is to activate matrix metalloproteases resulting in structural damage of tissue, supported by preclinical murine model evidence that a combination of IL-17 and TNF led to cartilage damage. Although there is preclinical evidence of IL-17 pathway upregulation in the synovium from RA patients, IL-17 blockade did not show strong effects in RA clinical trials, although a more detailed analysis of the trial data may identify subsets of responders. Of note, RA is similar to PsA an inflammatory arthritis, yet does not belong to the spondyloarthritides (Bravo and Kavanaugh 2019).

Th17 cells were originally identified in a rodent model for multiple sclerosis (MS), where their ablation caused a strong reduction of the inflammation. This led to a broad investigation of IL-17 roles in this area (Kolbinger et al. 2016), with most evidence pointing to a pathogenic role of IL-17 when produced in the brain. In a phase 2 trial, the anti-IL17 antibody secukinumab significantly reduced the number of cumulative new gadolinium-enhancing T1 lesions, and showed a tendency to reduce the number of active brain lesions on magnetic resonance imaging scans in patients with relapsing-remitting MS. This is an area of further investigation.

Drugs

An overview of the IL-17-directed agents in clinical use or clinical development is given in Table 1. Antibodies targeting IL-17A are the most advanced. Secukinumab is the first-in-class anti-IL17A antibody. It is a fully human monoclonal antibody and was approved for moderate-to-severe psoriasis in 2015 and a year later for PsA and AS/axSpA. Subsequently, Ixekizumab, a humanized monoclonal antibody, was licensed for psoriasis in 2016 and lateron in PsA. This year, Netakimab, a humanized monoclonal antibody, was approved for the treatment of moderate-to-severe psoriasis in Russia. Bimekizumab is a monoclonal antibody directed against IL-17A and IL-17F, and is in late clinical development

for psoriasis, PsA, and AS. Further to the array of IL-17 inhibitors, there is a monoclonal antibody, brodalumab, directed against IL-17RA. As this receptor subunit is shared with other receptor complexes, it inhibits IL-17A, IL-17F, IL-17C, and IL-17E. Brodalumab was approved for moderate-to-severe psoriasis treatment in 2017. Furthermore, efforts to identify low molecular weight compounds that prevent IL-17 pathway activation are ongoing.

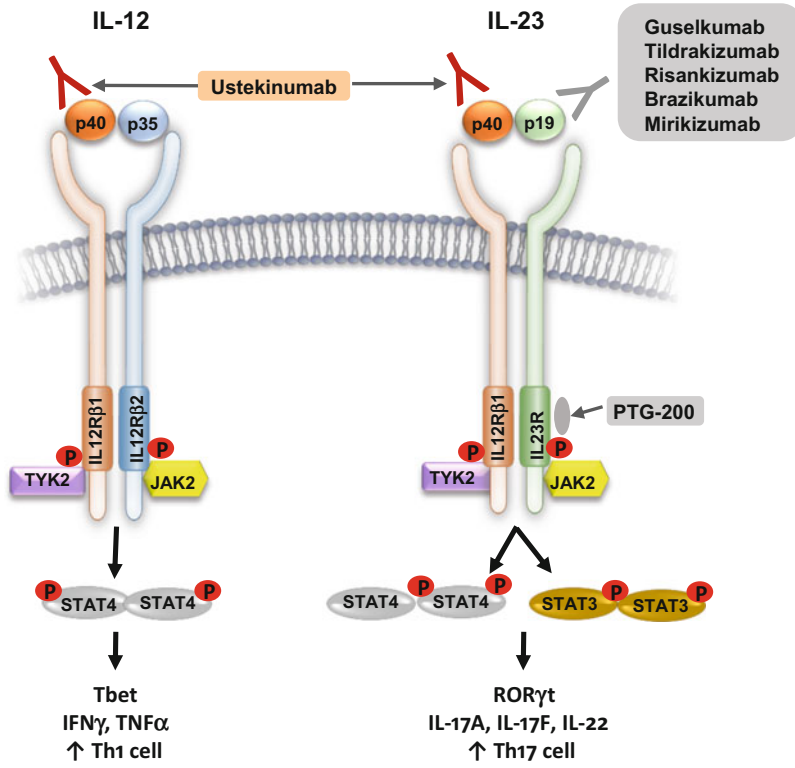
Definition

Interleukins (Latin derivation – communication between leukocytes) are a subset of low molecular weight cellular messengers known as cytokines, which contribute to the regulation of immune responses. Interleukin (IL)-23 is a heterodimer (i.e., consisting of two different subunits). As a member of the IL-12 family, it harbors the common p40 subunit that is characteristic of that family. What distinguishes IL-23 is a p19 component (whereas IL-12 comprises a p35 subunit) covalently bound to p40. In turn, IL-23 binds to a receptor (R) comprised of IL-12Rβ1 and IL23Rα to trigger an array of inflammatory processes. The role of IL-23 in inflammation and autoimmunity has been validated in the clinic by the success of anti-IL-23 antibodies.

Basic Characteristics

IL-23 Discovery and Signaling

IL-23 is a heterodimer consisting of p19 and p40 (Fig. 1). In 2000, Oppmann et al. discovered the p19 subunit, with a 4-helix bundle assembly typical of both IL-6 and IL-12 categories of cytokines via a computational screen (Oppmann et al. 2000). Although p19 alone was inactive, when associated via a disulfide bond with p40, it became a biologically active moiety and was subsequently named IL-23. Given the fact that it shares the p40 subunit with IL-12, IL-23 is recognized as one of the IL-12 family members with the p19 moiety



Interleukin-23, Fig. 1 Organization of the IL-23 receptor complex and signaling cascade in comparison to IL-12. Monoclonal antibodies blocking IL-12 and IL-23 and a peptide IL-23R antagonist which are in clinical use or development are indicated as well. See text for details

showing a distant homology to IL-12's p35 constituent.

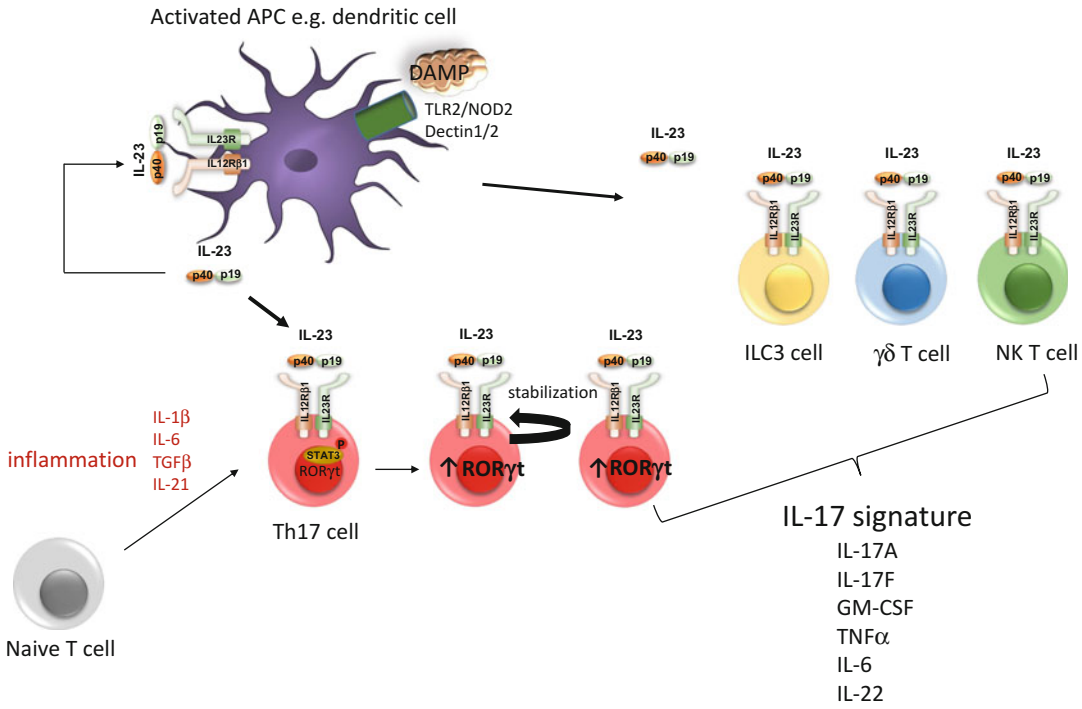
The corresponding receptors are also heterodimeric with both IL-23 and IL-12's p40 subunits binding IL-12Rβ1, but unlike IL-12p35's engagement with IL-12Rβ2, IL-23p19 associates with a subunit termed IL-23R (Fig. 1). By examining the crystal structure of the IL-23 ligand and receptor complex, it was established that for signaling to occur, the N terminal portion of the IL-23p19 subunit first associates with the IL-23R subunit to cause a restructuring of the helical domain that in turn facilitates a high affinity interaction of the p40 subunit to IL-12Rβ1 (Bloch et al. 2018). Binding of IL-23 to its receptor triggers the phosphorylation of several tyrosine residues within the intracellular domains of the receptor by the Janus kinase (JAK) family members JAK2 and TYK2, followed by the recruitment and phosphorylation of the signal transducer and activator of transcription (STAT) family members, especially STAT3. STAT3 subsequently dissociates from the IL23R intracellular portion and translocates to the nucleus to initiate various transcriptional events. IL-23 activates predominantly STAT3 but also more weakly, STAT4, whereas IL-12 signaling mainly triggers the latter. This may account for some of the differential biological effects observed for these two cytokines. Other pathways suggested to be activated by IL-23 engagement with its receptor are mitogen-activated protein kinases (MAPK), and phosphatidylinositol-3-kinase (PI3K) signaling cascades.

Expression of IL-23 and IL-23R

Whether IL-23 is expressed is due to the tight regulation of the p19 subunit from activated cells. p19 is thus understood to be the limiting subunit since p40 can be produced in great quantities. Further, although the p19 subunit is expressed in several cell types such as endothelial cells and polarized T cells, without the p40 moiety, which is absent from these cells, p19 is inactive. Biological activity is only achieved if both p19 and p40 subunits are synthesized within the same cell and these are mainly hematopoietic

derived cells of the myeloid lineage. Antigen-presenting cells (APC), dendritic cells especially, and macrophages release IL-23 upon encounter with triggers associated with host defense against pathogens, inflammatory and wound healing signals. In particular, IL-23 production is elicited via either microbial or damage-associated molecular pattern (DAMP) signals engaging toll-like receptor 2 (TLR2) or nucleotide-binding oligomerization domain-containing protein 2 (NOD2) or dectins 1 and 2 (Fig. 2). ATP and prostaglandin E_2 also act as DAMPs to elicit IL-23 production.

The expression of the IL-23R is limited to certain $CD4^+$ T cell subsets including the inflammatory effector T helper cell 17 (Th17) subset, some γδT cells, memory cells, and innate lymphoid cells (ILC), a small number of B cells and dendritic cells (Moschen et al. 2019). IL-23 is proposed to indirectly generate the Th17 subset from naive T cells as the latter do not express (in mouse) or have absent to negligible levels (in human) of the IL-23R. Under conditions where Th17 cells are generated (i.e., cytokine cocktail of IL-1β, IL-6, IL-21, TGFβ, Fig. 2), the IL-23-IL-23R axis via STAT3 activation promotes the transcription of the Th17 master regulator retinoid-related orphan receptor-γt (RORγt encoded by the RORC gene), which subsequently instructs the cell to increase IL-23R expression (in mouse and human). In a feed forward loop, IL-23 signaling then results in the stabilization of Th17 cells with expression of the associated receptor CCR6 and ligand CCL20, and production of their associated pro-inflammatory type 17 signature cytokines such as IL-17A, IL-17F, granulocyte macrophage colony stimulating factor (GM-CSF), tumor necrosis factor (TNF), IL-6, and IL-22. Th17 cells are thus a major source of the IL-17 signature cytokines (Fig. 2). In addition, as well as stimulating memory T cell proliferation, IL-23 signaling also activates innate and acquired immune cell subtypes including γδT cells, natural killer T (NKT) cells, and ILC, especially ILC3 to release these aforementioned pro-inflammatory



Interleukin-23, Fig. 2 Activated antigen-presenting cells (APC) release IL-23 that results in stabilization of Th17 cells, and together with innate lymphoid cells (ILC3), γδT and natural killer T (NKT) cells, elicits release of an IL-17 pro-inflammatory signature. See text for details

cytokines, particularly IL-17. These observations indicate that IL-23 mediates some of its influence through activating IL-23R positive innate immune cells to elicit pro-inflammatory cytokines including IL-17 (Fig. 2). Of note, however, IL-23 activity without the involvement of IL-17 has also been described as will be discussed below.

Biological Consequences of IL-23 Signaling in Health

IL-23 and its resultant Th17 related cytokine signature are required to both maintain the integrity of mucosal and skin barriers as well as protect against specific bacterial and fungal infections. IL-23R bearing innate cells are distributed throughout the body in nonlymphoid compartments, act as sentinels, and are quick to respond to foreign insults by releasing IL-17 signature cytokines. Consequently IL-17, in turn, triggers especially epithelial, endothelial, and other stromal cells to release chemokines such as CXCL-1, CXCL-2 that attract neutrophils to sites to combat inflammation.

Biological Consequences of IL-23 Signaling in Autoimmune Diseases

However, it has also become evident that the IL-23–IL-23R axis has a strong connection to autoimmune disease pathogenesis. Both genetic evidence from genome-wide association studies (GWAS) and preclinical work in mice have highlighted this. Several polymorphisms in IL-23 and genes along the IL-23 signaling axis such as *IL23R*, *IL12B*, *TYK2,* and *RUNX3* are associated with human autoimmune diseases, including psoriasis, psoriatic arthritis, Crohn's disease (CD), and autoimmune thyroiditis. There has also been a genetic link described for ankylosing spondylitis; however, unexpectedly, blocking IL-23 did not ameliorate this disease.

Many protective functions in autoimmune disease preclinical models originally attributed to inhibition of IL-12 from observations with p40 knockout mice or animals treated with anti-p40 antibody have now been reevaluated in light of the fact that p40 is shared between both IL-12 and IL-23. Indeed, mice lacking the IL-12 subunit p35 showed exacerbated encephalomyelitis, for example, in a mouse model for multiple sclerosis whereas p19 knockout mice were protected in the same model. The fact that IL-23 p19 knockout animals are resistant to several autoimmune disease models including inflammatory bowel disease (IBD) and collagen-induced arthritis, a model for rheumatoid arthritis, further underlines the critical role that dysregulated IL-23 appears to play in autoimmune diseases. Animal models of IBD have provided evidence of IL-23 mediating some of its effects through IL-17 producing cells. ILC and γδT cells via the IL-17/IL-23 axis drive mouse IBD pathology, for example, and in humans, increased numbers of IL-17 producing IL-23R positive ILC and γδT cells are present in tissues of IBD patients. Preclinical data has to be taken with caution, however, as anti-IL-17 therapy in humans with CD was ineffective thus highlighting IL-23 mediated effects independent of IL-17. Nonetheless, there is an abundance of evidence to relate IL-23 to psoriasis preclinically. Mice injected intradermally with IL-23 exhibit psoriasiform changes in the skin accompanied by Th17 infiltration, IL-22 production, and evidence of dendritic cell and γδT cell involvement similar to the human situation. In mice overexpressing STAT3 in keratinocytes, psoriatic-like lesions are formed, and anti-IL-23p19 treatment abrogated disease pathogenesis and reduced Th17 cell signatures. Imiquimod if continuously applied topically causes a psoriasis-like disease in mice with increased epidermal expression of IL-23 and IL-17 in the skin. Anti-IL-23p19 knockout mice are resistant to imiquimod induced psoriasis again strongly implicating this cytokines connection to psoriasis.

Thus, there is an abundance of evidence that the dynamic interplay between IL-23 and IL-17, if dysregulated, can lead to pathological consequences. This association is recognized by various groups and thus the IL-23-IL-23R axis has become an attractive pathway to target therapeutically.

Other Biological Consequences of IL-23 Signaling

IL-23 action is not limited to IL-17 producing immune cells. Other target cells such as the

IL-23R positive bone forming osteoblasts release receptor activator of NF-κB ligand (RANKL) in response to IL-23. Subsequently, RANKL together with M-CSF stimulates osteoclastogenesis and subsequent bone destruction.

More recently, IL-23 driven inflammation is being investigated in terms of cancer biology. Elevated levels of IL-23 are found in serum of patients bearing breast, colorectal, and pancreatic tumors, and it is overexpressed especially in tumors with profound myeloid infiltrates. In preclinical models, IL-23 promoted tumor growth and metastasis but conversely, was reported to have tumor suppressive effects when overexpressed in some tumor lines implanted into mice. Thus, the biology surrounding this is complex and made more so by virtue of the fact that IL-23 can exhibit both direct effects in some IL-23R positive tumor models, and indirect effects, suppressing the activity of $CD8^+$ and NK cells via induction of immunomodulatory agents from IL-23R positive cells. The balance between IL-12 and IL-23 in the tumor microenvironment also seems to be a pivotal factor that needs to be taken into account. Especially tumors with an inflammatory component, at least in humans, appear to have an IL-23 driven component that may be worth considering for therapeutic intervention.

Therapeutic Agents Targeting IL-23

The most advanced therapeutic agents targeting IL-23 are monoclonal antibodies directed against the subunits of this cytokine (Fig. 1). An overview of the IL-23-directed agents in clinical use or clinical development for autoimmune diseases is given in Table 1 and discussed together with the indications that they are registered for below.

Psoriasis is a chronic autoinflammatory disease with prominent skin involvement that affects approximately 2–4% of the world's population. The disease is characterized by increased epidermal thickness (acanthosis), thickening of the stratum corneum (hyperkeratosis), retention of nuclei in the cornified layer (parakeratosis), dilated blood vessels, and dense clusters of inflammatory cells composed of T cells and dendritic cells in the dermis, and $CD8^+$ T cells and neutrophils in the epidermis (Hawkes et al. 2017). Ustekinumab is

Interleukin-23, Table 1 Therapeutic agents targeting IL-23 in clinical use or in clinical development in immune-mediated diseases

Target	Action	Generic name (trade name)	Agent	Approved indications (or as specified)
p40 subunit of IL-12 and IL-23	Inhibits IL-12 and IL-23	Ustekinumab (Stelara®)	Monoclonal antibody, fully human, IgG1κ	Psoriasis, psoriatic arthritis, Crohn's disease, ulcerative colitis
p19 subunit of IL-23	Inhibits IL-23	Guselkumab (Tremfya®)	Monoclonal antibody, fully human, IgG1	Psoriasis
p19 subunit of IL-23	Inhibits IL-23	Tildrakizumab (Ilumya® (USA), Ilumetri® (EU))	Monoclonal antibody, humanized, IgG1	Psoriasis
p19 subunit of IL-23	Inhibits IL-23	Risankizumab (Skyrizi®)	Monoclonal antibody, fully human, IgG1	Psoriasis
p19 subunit of IL-23	Inhibits IL-23	Brazikumab	Monoclonal antibody, fully human, IgG2	In clinical development (incl. Crohn's disease)
p19 subunit of IL-23	Inhibits IL-23	Mirikizumab	Monoclonal antibody, humanized, IgG4	In clinical development (incl. Crohn's disease and ulcerative colitis)
IL-23R	IL-23R antagonist, inhibits IL-23	PTG-200	Oral peptide designed to act locally in the gastrointestinal tract	In early clinical development (incl. Crohn's disease)

one of the first agents that underwent clinical trials for psoriasis. It is a monoclonal antibody directed against the IL-12/IL-23p40 subunit, and thus inhibits both IL-12 and IL-23 action, and reduces responses of both Th1 and Th17 cells as well as other cell types expressing the receptors for these two cytokines (Fig. 1, Table 1). The antibody showed strong efficacy in psoriasis clinical trials with approximately 75% of patients achieving a 75% reduction in the psoriasis activity and severity index (PASI75), leading to its approval for moderate or severe psoriasis in 2009. While the treatment effects of ustekinumab were already substantial, even stronger effects were obtained with selective inhibition of the IL-23/T17cell/IL-17 axis using anti-IL-23p19 or anti-IL-17 antibodies. The first-in-class antibody directed against IL-23p19 and thus targeting IL-23 selectively is guselkumab, a fully human monoclonal antibody (Table 1, Fig. 1). Two clinical phase 3 trials for the treatment of moderate-to-severe plaque psoriasis with guselkumab have been conducted. Results from the two studies were very similar and indicated that 73% and 70% of patients treated with guselkumab achieved a 90% reduction in the psoriasis activity and severity index (PASI90) at week 16. More than 30% of patients achieved a PASI100 response, leading to its approval for moderate-to-severe psoriasis in 2017 (Hawkes et al. 2017). Additional IL-23p19 antibodies have demonstrated excellent efficacy in clinical trials and were recently approved for moderate-to-severe psoriasis, i.e., tildrakizumab which is a humanized, IgG1 monoclonal antibody approved in 2018, and risankizumab, a fully human IgG1 monoclonal antibody which was approved in 2019 (Table 1, Fig. 1). The strong efficacy of both IL-23 and IL-17 blockade suggests that there is a crucial role of IL-23-dependent IL-17 in this disease. IL-17 (in synergy with TNF) is assumed to stimulate keratinocytes, dermal fibroblasts to release pro-inflammatory mediators and chemokines (CXCL-1, CCL20, others), which attract more inflammatory cells and thus perpetuate a vicious circle of events. IL-23 antibodies and IL-17 antibodies have transformed the treatment of psoriasis, especially the moderate and severe forms of the disease.

Psoriatic arthritis (PsA) is an inflammatory arthritis which belongs to the spondyloarthritides (SpA). The clinical manifestations of PsA are diverse and can manifest as peripheral arthritis, enthesitis (inflammation of the tendon or ligament insertion sites into the bone), dactylitis (inflammation of an entire digit), skin and nail disease, and others. PsA occurs in a substantial portion of patients with psoriasis. Ustekinumab was already approved for PsA in 2013. Selectively blocking IL-23 with guselkumab also showed positive outcomes in PsA phase 3 clinical trials. Genetic studies and evidence of elevated IL-23 in human axial spondyloarthritis (axSpA) as well as data from preclinical models were the basis to initiate clinical trials with IL-23 or IL-12/23 blockade in ankylosing spondylitis, a subtype of axSpA. However, the results were negative (Bravo and Kavanaugh 2019). Since IL-17 blockade is an effective treatment, there is obviously a divergence of the roles of the two cytokines which is an area of further research. Interestingly, IL-23 or IL-17 blockade did not show strong effects in rheumatoid arthritis, which is similar to PsA an inflammatory arthritis, yet does not belong to the spondyloarthritides (Bravo and Kavanaugh 2019). While a more detailed analysis of the trial data may identify subsets of responders, the data suggest a crucial role of other drivers.

Inflammatory bowel disease (IBD) encompasses Crohn's disease (CD) and ulcerative colitis (UC) (for review, see Moschen et al. 2019). While the advance of antibodies targeting TNF about 20 years ago was a milestone for IBD treatment, there is still an unmet medical need, as not all patients respond to this agent or lose response over time. CD has been targeted first with anti-IL-12/IL-23 antibodies as it displays characteristics of a Th1-cytokine driven disease with increased production of the hallmark cytokine IFN-γ. Furthermore, there was evidence of cells secreting IL-12 in the lamina propria from CD patients. Ustekinumab showed positive outcome in the treatment of CD patients, including patients who did not respond to TNF blockade or to

conventional drugs, leading to its approval for treatment of moderate-to-severe CD in 2016. While UC and CD are often discussed as divergent (with a Th1 and Th2 feature, respectively), there are shared genetic polymorphisms between both indications suggesting pathogenic similarity. Ustekinumab also showed efficacy in the UC development program and was recently approved in 2019. While the treatment effect seen with ustekinumab could be due to IL-12 and/or IL-23 action, several anti-IL-23 antibodies including brazikumab, risankizumab, mirikizumab, and guselkumab are in clinical development for CD, and in some instances, for UC. Furthermore, an oral peptide selectively antagonizing the IL-23R and thus inhibiting IL-23 action, PTG-200 (Fig. 1, Table 1) designed to act locally in the gastrointestinal tract, has been reported to be in early development for CD (Moschen et al. 2019). Taken together, the treatment of IBD underwent a major improvement with the advance of IL-12/IL-23 and IL-23 blockers.

The advent of antibodies blocking IL-23 or IL-17 in the clinic thus help to delineate the respective roles of the cytokines.

Introduction

Interleukin (IL)-5 is a cytokine dimer derived from both hematopoietic and non-hematopoietic cell lines that primarily contribute to the proliferation, differentiation, and survival of eosinophils. While other cytokines have been implicated in the maturation, survival, and function of eosinophils (Matucci et al. 2019), IL-5 remains the only known human "eosinophilopoietin," as one of its primary roles includes stimulating production of these cells from the bone marrow (Patterson et al. 2015). Given eosinophilic prominence in a variety of disease states, considerable research has focused on the development of therapeutic drugs targeting IL-5-dependent signaling.

Background

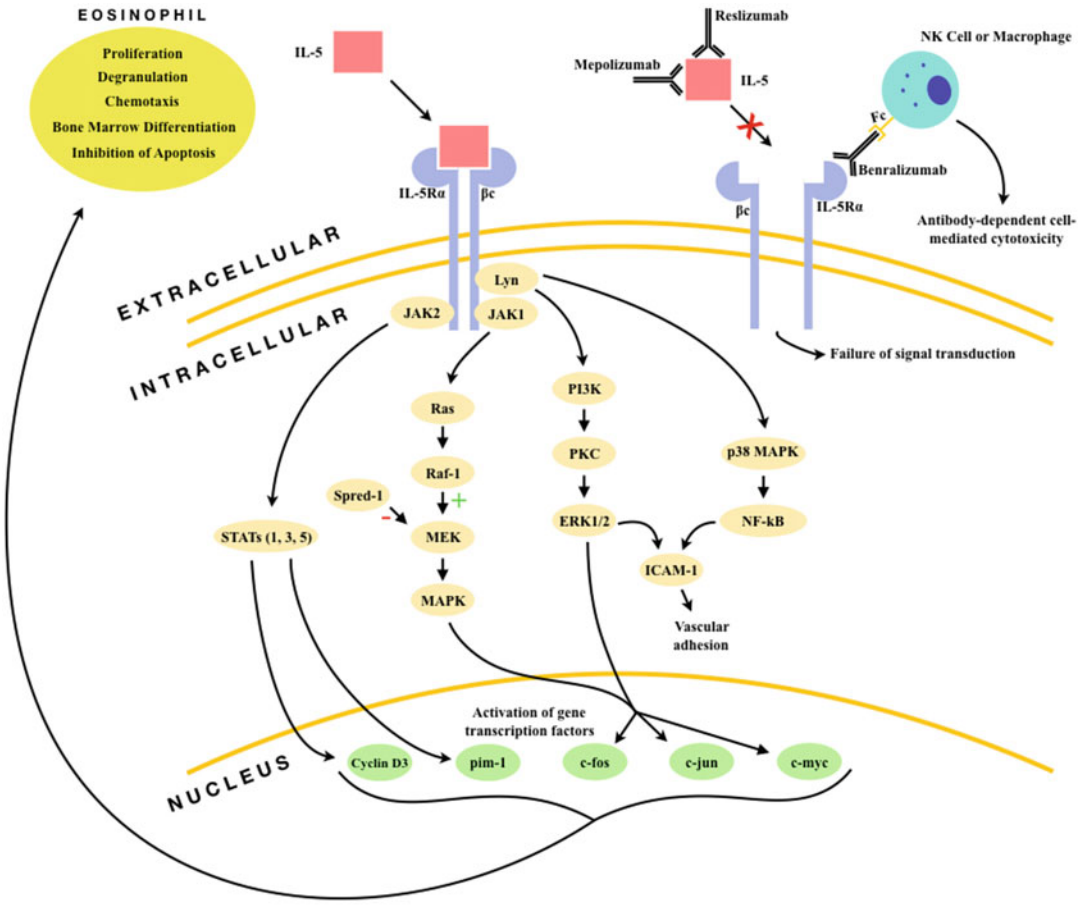
In the late 1870s, German scientist Paul Ehrlich discovered bilobed nucleated cells known as "eosinophils" utilizing a new staining method requiring alkaline dyes. Eosinophils, or "acid-loving," derive their name from their ability to uptake eosin, a dye that binds to cationic proteins within granules located inside the eosinophil (Varricchi et al. 2016). These cells comprise ~1–6% of the white blood cells and are important defenders against parasitic infection (Patterson et al. 2015). They have also been identified as a key cell type involved in the inflammatory process of eosinophilia-associated clinical conditions. However, despite Ehrlich's discovery of eosinophils, over 100 years would pass before understanding of eosinophil regulation would advance. Historically, Campbell et al. cloned eosinophil differentiation factor (EDF) in 1987 using a murine EDF cDNA clone as a probe (Campbell et al. 1987). During the same year, Tanabe et al. cloned the IL-5 gene (Tanabe et al. 1987). Subsequently, IL-5 was identified and determined to be important in every step of the eosinophil life cycle, including the maturation of CD34+ progenitor cells into mature eosinophils within the bone marrow. As IL-5 stimulates eosinophils to transition out of bone marrow into the blood, they are recruited to sites of tissue inflammation or stored until activated (Matucci et al. 2019). In varying disease states, eosinophils may migrate to affected organs such as the nose, esophagus, lung, and skin (Molfino et al. 2012). The generation of IL-5 and other cytokines and chemokines is important in the chemotaxis of eosinophils.

While eosinophils and mast cells are involved in the production of IL-5, the main source is largely from T lymphocytes and type 2 innate lymphoid cells (ILC2). IL-5 production within T lymphocytes and ILC2s is triggered primarily by IL-25 and IL-33, which are potent inducers of the inflammatory and pro-allergic cytokines IL-4, IL-5, and IL-13 (Matucci et al. 2019; Varricchi et al. 2016; Yanagibashi et al. 2017). In vivo analysis demonstrates that IL-33 (compared to IL-25) has a greater effect on proliferation of IL-5-producing ILC2 (Yanagibashi et al. 2017). In addition to IL-5, cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3 are also expressed by activated peripheral blood T cells and may be involved in eosinophil survival, growth, activation, and function (Matucci et al. 2019).

The Axis of IL-5 and IL-5R

IL-5 is comprised of four distinct α-helices on two separate polypeptide chains, a structure similar to cytokines IL-3 and GM-CSF (Matucci et al. 2019; Pelaia et al. 2017; Varricchi et al. 2016). Of the four α-helices, three originate from one of the polypeptide chains, while the fourth helix extends from the second chain (Molfino et al. 2012).These native IL-5 α-helices confer its higher affinity to IL-5R (Molfino et al. 2012). As eosinophils and B cells express IL-5 receptor (IL-5R), selective binding with IL-5 is mediated by IL-5Rα and IL-5Rβc, which form the subcomponents of the receptor. IL-5Rα and IL-5Rβc confer high and low affinity for IL-5, respectively (Pelaia et al. 2017). IL-5Rβc provides the non-specific protein structure, which also allows binding with other cytokines such as IL-3 and GM-CSF (Molfino et al. 2012).

Binding of IL-5 to IL-5Rα leads to complex-associated activation of IL-5Rβc, initiating specific signal transduction pathways that confer IL-5-mediated effects on eosinophils (Pelaia et al. 2017). These signal transduction pathways are characterized in Fig. 1. After complex formation, there is a series of downstream signaling events that originates from the tyrosine kinase-mediated phosphorylation of Janus kinase proteins (JAK1/JAK2). JAK1 and JAK2 are inherently associated with IL-5Rα and IL-5Rβc, respectively, independent of IL-5 activation (Molfino et al. 2012; Pelaia et al. 2017). JAK1 and JAK2 phosphorylate signal transducer and activator of transcription (STAT) proteins, including STAT1, STAT3, and STAT5, interactions that are indispensable to IL-5 signaling within eosinophils. Phosphorylations of STAT1, STAT3, and STAT5 cause gene transcription of pim-1 and cyclin D3, which contribute to eosinophil survival



Interleukin-5, Fig. 1 Current understanding of IL-5 monoclonal antibody blockade and IL-5 signaling pathways, receptor interactions, and effects on eosinophils

via production of leukotrienes, eosinophil cationic protein, major basic protein, and other eosinophil mediators (Molfino et al. 2012; Pelaia et al. 2017; Yanagibashi et al. 2017). In conjunction with JAK2, Lyn and Raf-1 kinases are also involved in survival of eosinophils via inhibition of apoptotic pathways (Molfino et al. 2012; Pelaia et al. 2017; Yanagibashi et al. 2017).

Although the JAK/STAT pathway is invariable to eosinophilic survival and function, mitogen-activated protein kinases (MAPK) (primarily extracellular signal-regulated kinases [ERK]1, ERK2, and p38) play an equally important role. ERK expression is mediated by activation or inhibition from Raf-1 and Spred-1, respectively (Molfino et al. 2012). Raf-1, in particular, contributes to activation of ERK, which leads to induction of c-fos gene transcription and promotion of leukotriene C_4 release (Pelaia et al. 2017). While, both ERK1/2 MAPK and p38 are involved with promoting cytokine production and cell degranulation, p38 (in conjunction with NF-κB) contributes more to eosinophil chemotaxis and cytokine release at sites of allergic inflammation (Pelaia et al. 2017). Prior to p38-mediated chemotaxis, the interaction between eosinophils and intercellular adhesion molecule-1 (ICAM-1) is imperative for eosinophil vascular wall adhesion. This adhesion is primarily mediated by phosphoinositide 3-kinase (PI3K) via protein kinase C (PKC) activation and subsequent phosphorylation of ERK (Molfino et al. 2012; Pelaia et al. 2017).

Ultimately, IL-5-dependent pathways collectively activate multiple gene transcription factors, including c-myc, c-fos, c-jun, cyclin D, and pim-1, which serve to enhance eosinophil proliferation, differentiation, chemotaxis, and degranulation (Molfino et al. 2012).

Eosinophils and Disease

Eosinophils are uniquely associated with a spectrum of diseases, including hypereosinophilic syndromes, nasal polyposis, eosinophilic granulomatosis with polyangiitis, eosinophilic esophagitis, atopic dermatitis, and bronchial asthma (Hassani and Koenderman 2018; Varricchi et al. 2016). Given the ability of IL-5 to dramatically influence eosinophil function, it has been long hypothesized as a susceptible therapeutic target. While eosinophilia and IL-5 are important aspects of the aforementioned conditions, asthma affects many more people, and this disease has historically been identified for its potential benefit concerning therapies directed toward IL-5. Research of asthma serves as a unique template to illustrate the clinical impact of IL-5 antagonism.

Therapeutic Interventions with IL-5 Antagonism

Asthma is a chronic disease characterized by airway inflammation, leading to bronchial hypersensitivity and reversible airway obstruction. Notable clinical symptoms suggestive of asthma include wheezing, cough, and shortness of breath. A wide variety of therapeutic medications have been developed to alleviate these symptoms and/or prevent their recurrence. Asthma, similar to many chronic diseases, demonstrates a spectrum of phenotypic endotypes compounded by variable symptoms, pathophysiology, and pharmacological treatment options (Pelaia et al. 2017). While traditional therapy of inhaled corticosteroids and bronchodilators targeting β2-adrenergic receptors addresses the vast majority of patients, there are subsets of uncontrolled asthmatic individuals that require prolonged oral glucocorticoid treatments.

Eosinophils have been identified as a culprit in severe asthmatics not controlled with standard therapy (Matucci et al. 2019; Molfino et al. 2012; Pelaia et al. 2017). Eosinophilic asthma is characterized by eosinophilia localized throughout the bronchial tract, which causes chronic degranulation and remodeling of airways (Patterson et al. 2015). Remodeling in the context of chronic bronchial inflammation includes basement membrane thickening and mucosal infiltration by eosinophils, Th2 lymphocytes, and mast cells (Matucci et al. 2019; Pelaia et al. 2017). Specifically, Th2 lymphocytic infiltration contributes to two distinct endotypes termed T2 "high" or T2 "low," based on the degree of Th2 infiltration. Due to their proinflammatory nature, blood and sputum eosinophilia contributes largely to the Th2 "high" endotype (Matucci et al. 2019).

Initially, supporting a relationship between IL-5 and asthma severity proved difficult. While elevated concentrations of IL-5 were shown in bronchial biopsies of patients with asthma (Tang et al. 1997), early studies evaluating improvement of lung function in humans provided anti-IL-5 monoclonal antibodies were disappointing (Patterson et al. 2015). In fact, two studies recruited asthmatics to receive anti-IL-5 or placebo with the primary end points of improved lung function and quality of life. While both studies showed significant depression of peripheral eosinophilia, neither showed improvements in the primary outcomes, leaving significant questions regarding the utility of these antibodies (Flood-Page et al. 2007; Leckie et al. 2000; Menzella et al. 2016; Molfino et al. 2012; Patterson et al. 2015; Varricchi et al. 2016). Despite the negative data, the scientific community learned from these studies, especially regarding the importance of defining study populations and primary end points. As more information became available regarding eosinophilic asthma, many recognized this as a phenotype that might better respond to anti-IL-5 medications. Subsequently, various clinical trials emerged involving

the use of monoclonal antibodies targeting IL-5 and IL-5Rα. Currently, there are two biologics that target IL-5, mepolizumab and reslizumab, and one that targets IL-5Rα, benralizumab (Table 1).

Mepolizumab

Mepolizumab (US trade name Nucala), produced by GlaxoSmithKline in Brentford, UK, was approved by the US Food and Drug Administration (FDA) in November 2015 for use in severe asthma with eosinophilic phenotype for ages 12 years and older. Subsequent studies (discussed below) have lowered the age range for administration down to 6 years. Derived from ovaries of Chinese hamsters, it is a selective humanized monoclonal antibody targeting the α-chain of IL-5, which disrupts binding with the α-subunit of IL-5R (Abonia and Putnam 2011).

Mepolizumab debuted in December of 2000. A randomized, double-blind, placebo-controlled study demonstrated decreased eosinophils in both peripheral blood and sputum samples among three distinct groups of eight patients. Unfortunately, clinically significant outcomes pertaining to improvements in forced expiratory volume in one second (FEV1), peak expiratory flow rate, and histamine-responsive airway hyperactivity were not readily apparent when considering all-comers with asthma (Abonia and Putnam 2011; Flood-Page et al. 2007; Leckie et al. 2000). In fact, until 2012, only two studies had shown evidence of clinically significant improvement in asthma exacerbations with marginal increases in FEV1 from baseline for prednisone-dependent severe asthmatics with significant sputum eosinophilia (≥3%) (Haldar et al. 2009; Nair et al. 2009). However, in 2012, Pavord et al. published the Dose Ranging Efficacy and Safety with Mepolizumab (DREAM) clinical trial, which was the single-largest clinical study (621 patients) for severe *eosinophilic* asthma to date (Menzella et al. 2016; Pavord et al. 2012). The DREAM findings showed significant decreases in blood and sputum eosinophil levels and, finally, a reduction in acute exacerbations of asthma. Following the work of Pavord et al., Bel et al. and Ortega et al. published supportive conclusions highlighting improvements in the Asthma Control Questionnaire (ACQ)-5 scores, reduction in exacerbations, and decreased dependence upon glucocorticoids (Bel et al. 2014; Ortega et al.

Interleukin-5, Table 1 Characteristics of biologics involved in the inhibition of IL-5 pathway signaling. IL-5 associated biologics

	Mechanism of action	Biomarkers	FDA approved	Dosing frequency	Route
Mepolizumab	Directly binds to IL-5	Peripheral eosinophilia (>150 cells/mcL) within 6 weeks of treatment initiation	Eosinophilic asthma (6 years or older) and eosinophilic granulomatosis with polyangiitis (18 years and older)	*Eosinophilic asthma*: 6–11 years old, 40 mg for 4 weeks; 12+ years, 100 mg for 4 weeks *EGPA*: 300 mg every 4 weeks	Subcutaneous
Reslizumab	Directly binds to IL-5	Sputum eosinophilia (>3%)	Eosinophilic asthma (18 years or older)	3 mg/kg every 4 weeks via IV infusion for 20–50 min	Intravenous
Benralizumab	Directly binds to IL-Rα leading to antibody-mediated cytotoxicity	Peripheral eosinophilia (>300 cells/mcL)	Eosinophilic asthma (12 years or older) and eosinophilic esophagitis (approved under Orphan Drug Designation)	30 mg (single dosed pre-filled syringe) every 4 weeks (for three doses) then every 8 weeks	Subcutaneous

2014). Cumulative findings demonstrated that treatment with mepolizumab was most beneficial for patients with a baseline eosinophilia of ≥150 cells/mcL obtained within 6 weeks of treatment initiation.

Current dosing guidelines suggest 100 mg mepolizumab given subcutaneously every 4 weeks. In 2017, the FDA approved mepolizumab for the treatment of adult patients with eosinophilic granulomatosis with polyangiitis at a slightly higher dose than that considered in eosinophilic asthma (300 mg every 4 weeks) (Pelaia et al. 2017). Within the same year, mepolizumab was also approved for the treatment of severe eosinophilic asthma in patients as young as 6 years old. Dosing for eosinophilic asthmatics receiving mepolizumab is 40 mg for 4 weeks and 100 mg for 4 weeks for patients 6–11 years old and 12 years and older, respectively (Lexicomp; Pelaia et al. 2017).

Reslizumab

Developed by Teva Pharmaceuticals, reslizumab was approved for use in March 2016 under its trade name, Cinqair (Varricchi et al. 2016). Reslizumab is indicated for eosinophilic asthma in patients above 18 years of age that have failed empiric treatments. At its core, reslizumab is an IgG4-kappa immunoglobulin that selectively binds IL-5 in order to decrease eosinophilic proliferation by blocking interactions with IL-5Rα (Bagnasco et al. 2017).

The first clinical trial for reslizumab was performed in 2003 when Kips et al. showed significantly decreased blood eosinophil levels in patients with severe persistent asthma (Kips et al. 2003). Then, in 2011, Castro et al. published a 271-patient phase III clinical trial demonstrating improved FEV1, asthma symptom profile, and frequency of exacerbations when compared to placebo among patients with evidence of sputum eosinophilia (≥3%) (Castro et al. 2011). Building on the work of Castro et al., Bjermer et al. demonstrated similar findings with patients having blood (vs sputum) eosinophilia (≥ 400 cells/μL) (Bjermer et al. 2016). Numerous trials have repeated the work of Castro and Bjermer et al., highlighting the clinically significant impact reslizumab has in patients with active eosinophilic airway inflammation. Currently, reslizumab is available in 100 mg/10 mL (10 mg/mL) single-use vials for IV infusion only. Dosing is determined based on patient weight at 3 mg/kg every 4 weeks and require 20–50-minute infusion times (Lexicomp).

Benralizumab

Benralizumab (US trade name Fasenra) was developed by AstraZeneca (formerly MedImmune) and approved by the FDA in November 2017 and August 2019 for eosinophilic asthma and eosinophilic esophagitis, respectively. This humanized monoclonal antibody of the IgG1-kappa subclass differs from mepolizumab and reslizumab in that it selectively binds IL-5Rα on eosinophils and basophils (Yanagibashi et al. 2017). Besides its ability to block IL-5 signaling through the receptor, benralizumab is also uniquely afucosylated during production, which confers a high affinity for the FcγRIIIα in natural killer cells, macrophages, and neutrophils (Dhanji et al. 2005; Yanagibashi et al. 2017). This unique approach results in depletion of eosinophils via antibody-dependent cell-mediated cytotoxicity. Benralizumab has been shown to substantially reduce or eliminate *tissue* eosinophilia associated with specific eosinophilic diseases (Matucci et al. 2019).

Three placebo-controlled clinical trials provide evidence for clinical effectiveness (in order of date performed): SIROCCO, CALIMA, and ZONDA. SIROCCO examined the safety and efficacy of benralizumab, specifically, its effect on the frequency of asthma exacerbations over 48 weeks (Bleecker et al. 2016). CALIMA focused on the efficacy and safety of benralizumab as add-on therapy for those with severe, uncontrolled asthma and elevated blood eosinophils (FitzGerald et al. 2016). Both SIROCCO and CALIMA demonstrated a

significant decrease in exacerbation frequency while improving FEV1 when compared to placebo in those with blood eosinophils ≥300 cells/μL. In ZONDA, researchers questioned whether administration would decrease the need for oral corticosteroids over 28 weeks. Outcomes from this trial confirmed a 75% reduction in oral corticosteroid dosage for those on benralizumab as compared to 25% reduction for the placebo group (Nair et al. 2017). In regard to dosing and administration, benralizumab is given subcutaneously via a single-dose pre-filled syringe with a recommended dose of 30 mg. Initial injections are given every 4 weeks for three doses and then every 8 weeks (Lexicomp).

Conclusions

Further investigation is underway for use of mepolizumab, reslizumab, and benralizumab in the treatment of other diseases attributed to eosinophilic inflammation. As collective understanding of IL-5 expands, new disease phenotypes and endotypes will emerge that may benefit from IL-5 antagonism. However, ongoing research is needed to establish clear biomarkers that will identify the particular patients that will most benefit from these interventions. In reflection, IL-5 uniquely represents an exciting step for the scientific community as it illustrates the cumulative effort from the research bench to clinical practice.

Interleukin-6

Stefan Rose-John
Biochemical Institute, University of Kiel Medical School, Kiel, Germany

Synonyms

B-cell stimulating factor 2; Hepatocyte stimulating factor; Hybridoma-plasmacytoma growth factor, 26 kDa protein

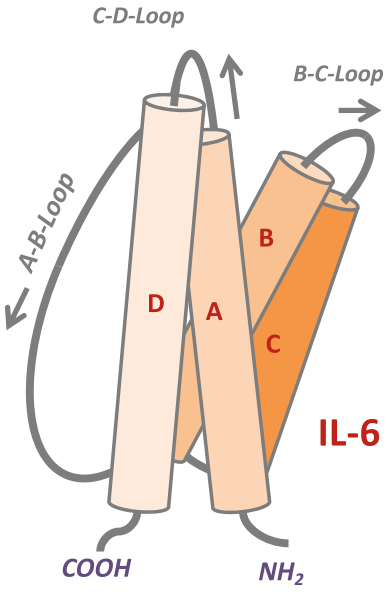
Definition

Interleukin-6 (IL-6) together with IL-1 and tumor necrosis factor alpha (TNFα) are regarded as the most important inflammatory cytokines, which are involved in many if not all inflammatory states of the human body including many autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease (Scheller et al. 2011b).

The cytokine IL-6 is a four-helical protein (Fig. 1), which is synthesized by many cells during immunological stress situations (Hunter and Jones 2015; Jones and Jenkins 2018). Such immunological stress situations include the detection of so-called pathogen-associated molecular patterns or PAMPs by Toll-like receptors on neutrophils, monocytes, macrophages, and other cells of the innate immune system (Akira et al. 2006). Structurally, IL-6 belongs to a large family of mediators, which show the same four-helical topology and bind to a family of receptor molecules, which are called type I cytokine receptors (Rose-John 2012; Rose-John et al. 2015).

Basic Characteristics

On target cells, IL-6 first binds to a type I membrane protein called IL-6 receptor (IL-6R). The complex of IL-6 and IL-6R associates with a second type I membrane protein called gp130, which consequently dimerizes and initiates intracellular signal transduction (Rose-John 2012). As



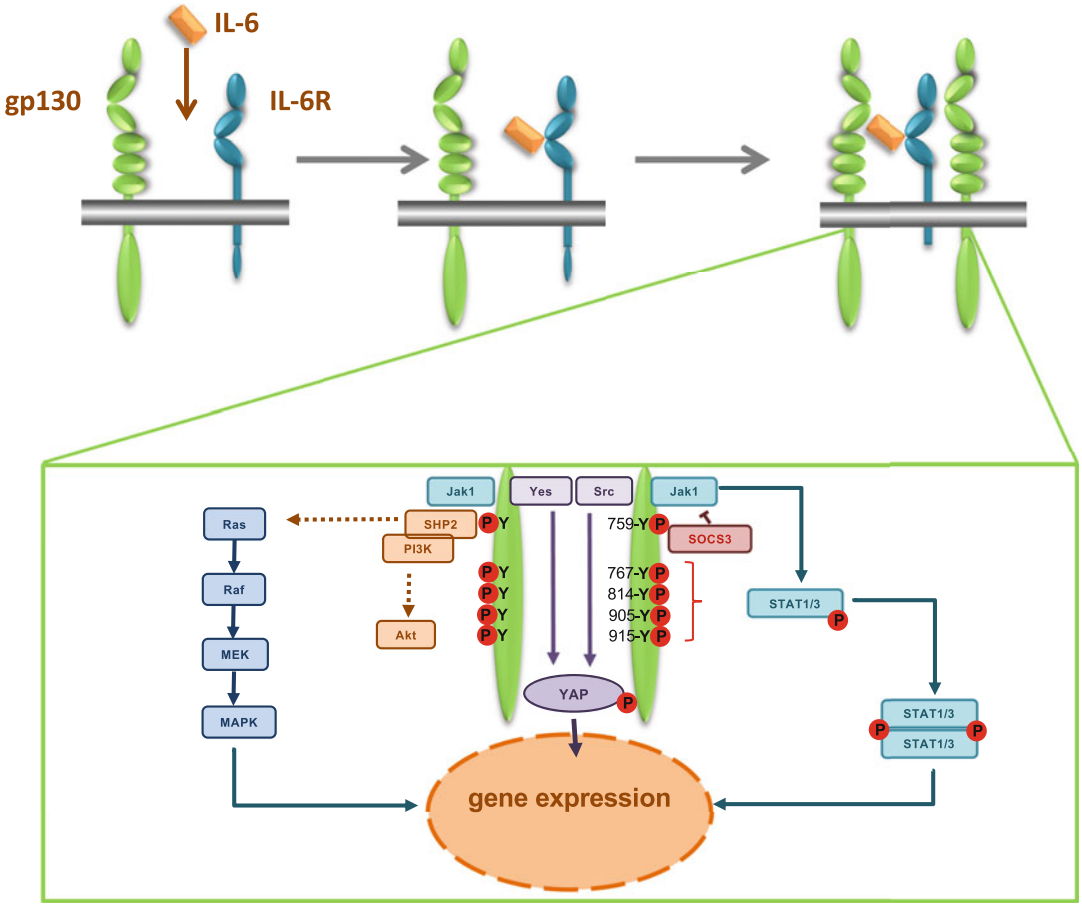
Interleukin-6, Fig. 1 Schematic view of the four-helical protein Interleukin-6 (IL-6). Note that as a consequence of the long loop between helix A and helix B, followed by the short loop between helix B and helix C and followed by the long loop between helix C and helix D, helix A and helix B are oriented upwards whereas helix C and helix D are oriented downwards. This topology is common to all four helical cytokines

shown in Fig. 2, the dimerization of gp130 leads to activation of the cytoplasmic tyrosine kinase called Janus kinase 1 or JAK1, which is constitutively associated with the cytoplasmic portion of gp130 (Schaper and Rose-John 2015). Upon tyrosine phosphorylation of the gp130 cytoplasmic domain, STAT factors (STAT3 and to some extent STAT1) become recruited via their SH2 domains and are phosphorylated by the JAK1 whereupon they dimerize, translocate into the nucleus, and activate STAT1/3 target genes. The membrane-proximal tyrosine of the gp130 cytoplasmic domain recruits the phosphatase SHP2, which leads to the activation of the MAP kinase cascade (Fig. 2). STAT3 activation additionally leads to the transcriptional activation of the negative feedback inhibitor SOCS3, which targets the membrane-proximal membrane-proximal tyrosine residue of the gp130 cytoplasmic domain thereby blocking the activity of JAK1 and leading to feedback inhibition of gp130 signaling. Furthermore, activation of src family kinases leads to activation of the YAP pathway and to the transcription of YAP target genes (Fig. 2).

Whereas the gp130 receptor is expressed on all cells of the human body, the IL-6R is only expressed on some cells including hepatocytes and some leukocytes (Rose-John 2012). Since IL-6 only exhibits a measurable affinity to the IL-6R but not to gp130, it follows that only cells, which express the IL-6R can respond to the cytokine IL-6. It was, however, discovered that the IL-6R from the cell membrane can be proteolytically cleaved by the membrane-bound metalloprotease ADAM17 leading to the generation of a soluble IL-6R (sIL-6R) (Mullberg et al. 1993). In human cells the sIL-6R can also be generated by translation from an differentially spliced mRNA (Lust et al. 1992), although this mechanism leads only to a small fraction of the total sIL-6R moiety in the circulation (Riethmueller et al. 2017). Interestingly, IL-6 can bind not only to the membrane-bound IL-6R but also to the sIL-6R. The complex of IL-6 and sIL-6R can bind to gp130 on cells, which do not express IL-6R. In such a way, these cells, which in the absence of sIL-6R would be completely refractory to IL-6, can now respond to the cytokine. Consequently the range of target cells of IL-6 is dramatically enlarged by the IL-6 trans-signaling mechanism. This paradigm of IL-6 signaling has been named IL-6 trans-signaling (Rose-John and Heinrich 1994) whereas IL-6 signaling via the membrane-bound IL-6R is referred to as classic signaling (Fig. 3a).

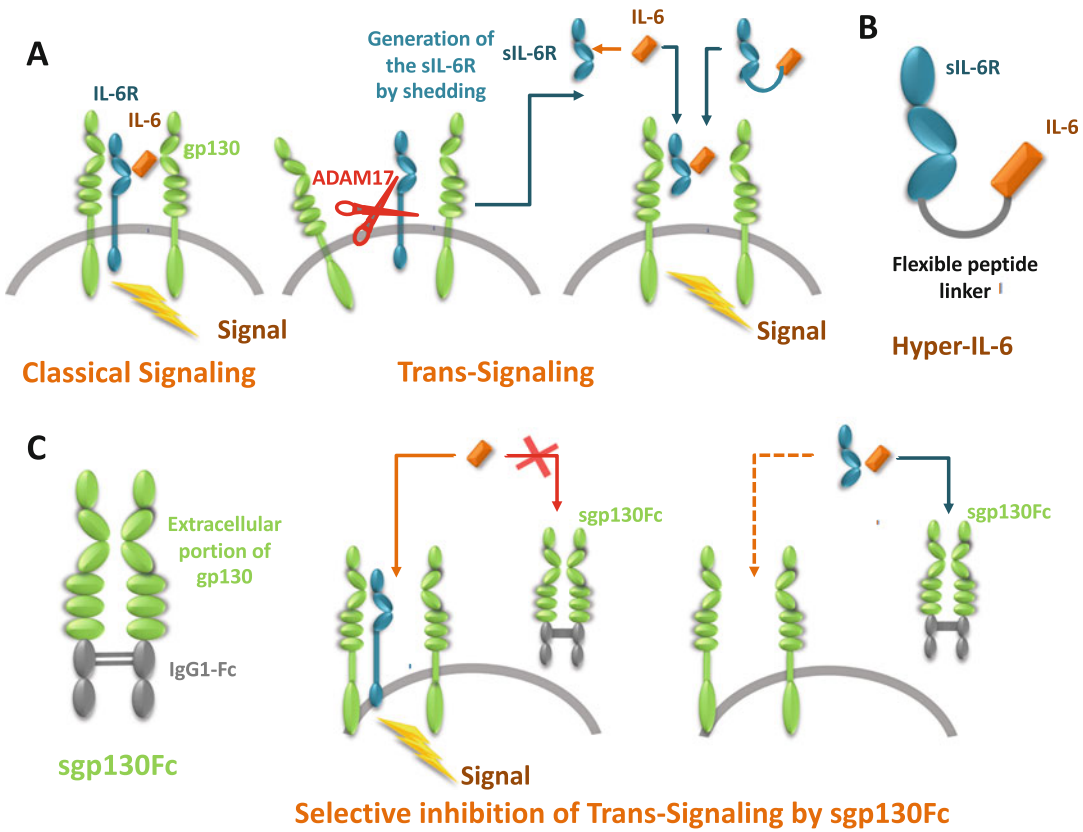
Molecular Tools to Study Interleukin-6

To analyze the physiologic role of IL-6 trans-signaling in vitro and in vivo, we generated two designer proteins, which could be used as molecular tools. Hyper-IL-6 is a fusion protein of IL-6 and sIL-6R in which the two proteins are covalently linked by a flexible peptide linker (Fischer et al. 1997) (Fig. 3b). With Hyper-IL-6, cells can be stimulated regardless of their IL-6R expression. A comparative stimulation with IL-6 and Hyper-IL-6 can be used in vitro and in vivo to



Interleukin-6, Fig. 2 Binding of IL-6 to the IL-6R leads to the assembly of the signaling IL-6 receptor complex. Top, IL-6 binds to IL-6R and subsequently assembles two molecules of the signaling receptor gp130. Bottom, dimerization of gp130 leads to the activation of the JAK1 kinase, which phosphorylates the cytoplasmic portion of gp130. The phosphorylated tyrosine residues recruit signaling molecules such as SHP2, which leads to an activation of the PI3K, Akt, Ras, and MAPK pathways. Furthermore, STAT1 and STAT3 molecules are recruited, become phosphorylated, homo- or heterodimerize and translocate into the nucleus, where they act as transcription factors. Additionally, non-receptor tyrosine kinases such as Src or Yes activate the YAP pathways, which also leads to changes in gene expression. SOCS3 is a feedback inhibitor, which is induced transcriptionally by STAT3 and which binds to the membrane-proximal phosphorylated tyrosine residue leading to inhibition of JAK1 activity. Akt, serine/threonine kinase involved in many cellular processes; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; MEK, mitogen-activated protein kinase kinase; PI3K, phosphoinositide 3-kinase; Raf, serine/threonine kinase involved in many cellular processes; RAS, small G-protein; SOCS, suppressor of cytokine signaling; Src, proto-oncogene tyrosine-protein kinase; STAT, signal transducer and activator of transcription; YAP, proto-oncogene yes associated protein; Yes, cellular homolog of the Yamaguchi sarcoma virus oncogene

define cellular reactions, which depend on the presence of the sIL-6R. Using Hyper-IL-6, we could demonstrate that regeneration of the liver and survival of neurons is largely accelerated via the IL-6 trans-signaling mechanism (Scheller et al. 2011b). The soluble gp130Fc protein (sgp130Fc) is a fusion of the entire extracellular portion of gp130 with the Fc portion of human IgG1 antibody (Fig. 3c). This protein has the interesting property that it exclusively blocks IL-6 trans-signaling without affecting classic signaling via the membrane-bound IL-6R (Jostock et al. 2001). Thus, the sgp130Fc protein can be used as a molecular tool to dissect between IL-6



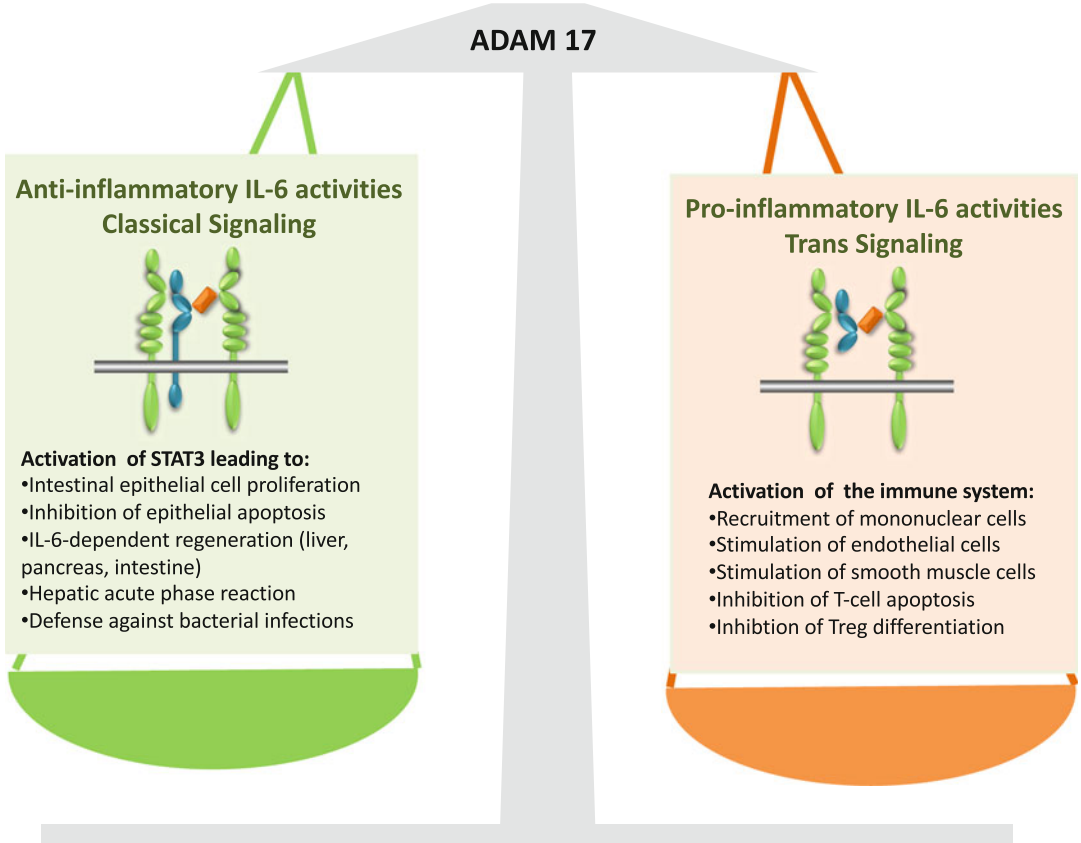
Interleukin-6, Fig. 3 Classic signaling and trans-signaling of IL-6. (**a**) Left, in classic signaling, IL-6 binds to the IL-6R which subsequently associates with gp130 that initiates signaling. Right, the protease ADAM17 cleaves the IL-6R close to the cell membrane, thereby releasing sIL-6R. The sIL-6R can still bind IL-6 and the complex of IL-6/sIL-6R complex can bind to and activate gp130 on cells, which do not express IL-6R leading to gp130 signaling. (**b**) The designer cytokine Hyper-IL-6 is a fusion protein of IL-6 and sIL-6R, which can mimic IL-6 trans-signaling in vitro and in vivo. (**c**) The sgp130Fc protein consists of the extracellular portion of gp130 fused to the constant region of human IgG1. The sgp130Fc protein specifically blocks IL-6 trans-signaling without affecting IL-6 classic signaling. ADAM, a disintegrin and metalloprotease; sIL-6R, soluble IL-6R

classic- and trans-signaling (Scheller et al. 2011b).

When the IL-6 cDNA was cloned in the group of Kishimoto it became clear that several biologic activities, which were analyzed by groups around the world, including B-cell stimulatory factor, hepatocyte stimulatory factor, hybridoma-plasmacytoma growth factor, and Interferon β2 were identical with IL-6, underlining the pleiotrophic activity of this cytokine (Rose-John 2018). In the meantime it was found that many physiologic functions in the body and within the immune system are regulated by IL-6 and that the coordination of the innate and acquired immune system is mediated by this cytokine (see reviews (Hunter and Jones 2015; Garbers et al. 2018; Jones and Jenkins 2018; Kang et al. 2019)).

Pharmacological Relevance

Neutralizing antibodies directed against IL-6 or IL-6R block both classic- and trans-signaling whereas the sgp130Fc protein only blocks trans-signaling. A systematic comparison of IL-6 or IL-6R neutralizing antibodies and sgp130Fc protein was performed in mouse models of human diseases to define the nature of classic- and trans-



Interleukin-6, Fig. 4 Pro- and anti-inflammatory activities of IL-6. Anti-inflammatory activities of IL-6 are mediated by classic signaling via the membrane-bound IL-6R (left) whereas pro-inflammatory activities of IL-6 are mediated by IL-6 trans-signaling via the soluble IL-6R (right). The balance between classic- and trans-signaling is orchestrated by the membrane-bound metalloprotease ADAM17

signaling in vivo. As depicted in Fig. 4, it turned out that IL-6 classic signaling mainly consists of protective, regenerative, and anti-inflammatory responses whereas IL-6 trans-signaling is rather pro-inflammatory (Garbers et al. 2018; Kang et al. 2019).

IL-6 plasma levels in normal, healthy individuals are in the 1–5 pg/ml range. In contrast, levels of sIL-6R are about 40–80 ng/ml. Moreover, levels of sgp130 in normal individuals are in the range of 400 ng/ml. Since the affinity of IL-6 to the IL-6R is in the range of 1 nM whereas the affinity of the IL-6/IL-6R to gp130 is about 100 times higher, that is, in the range of 10 pM, IL-6 secreted into the plasma will bind to sIL-6R and the complex will immediately bind to sgp130 and be neutralized. Therefore, we have hypothesized that sIL-6R and sgp130 in the plasma form a biologic buffer for IL-6 and that the capacity of the buffer is determined by the concentration of the sIL-6R (Garbers et al. 2015). Interestingly, a single nucleotide polymorphism (rs7529229) has been identified, which leads to the change of aspartate at position 358 to alanine. It was demonstrated that the IL-6R protein with alanine at position 358 is cleaved more efficiently by the protease ADAM17, and therefore, individuals with this mutation show about twofold higher sIL-6R levels in the blood as compared to individuals with IL-6R with aspartate at position 358 (Garbers et al. 2014).

Interestingly, it has been shown that that individuals carrying the SNP rs7529229 in the IL-6R gene are protected from coronary heart disease, rheumatoid arthritis, atrial fibrillation, and abdominal aortic aneurysm (Interleukin-6 receptor pathways in coronary heart disease: a collaborative meta-analysis of 82 studies, 2012; The interleukin-6 receptor as a target for prevention of coronary heart disease: a Mendelian randomization analysis, 2012; Ferreira et al. 2013). These data demonstrated that the steady-state concentration of sIL-6R and hence the capacity of the biologic buffer for IL-6 is important for the susceptibility of inflammatory diseases (Garbers et al. 2018).

Pathophysiological and Therapeutic Relevance

We systematically compared the neutralizing activity of antibodies directed to IL-6 or IL-6R with the more specific activity of sgp130Fc, which only blocks IL-6 trans-signaling but not IL-6 classic signaling via the membrane-bound IL-6R (Garbers et al. 2018). These analyses revealed that IL-6 activities via the membrane-bound and via the soluble IL-6R were fundamentally different. IL-6 responses via the membrane-bound were protective or regenerative. We could demonstrate that the regeneration of intestinal epithelial cells was dependent on classic IL-6 signaling (Grivennikov et al. 2009). Furthermore, global blockade of IL-6 activities with the help of neutralizing IL-6 antibodies or the use of IL-$6^{-/-}$ mice led to a decline in the defense against bacteria such as *Listeria monocytogenes* or *Mycobacteria tuberculosis* (Sodenkamp et al. 2012; Hoge et al. 2013). In contrast, specific blockade of IL-6 trans-signaling by the sgp130Fc protein or in sgp130Fc expressing transgenic mice did compromise the control of bacterial infection. Likewise, in a mouse model of abdominal aortic aneurysm, global IL-6 blockade aggravated whereas specific blockade of IL-6 trans-signaling improved the condition of the animals (Paige et al. 2019). On the other hand, selective blockade of IL-6 trans-signaling by the sgp130Fc protein led to significant improvement in many mouse models of human inflammatory diseases and cancer (Table 1). The different activities of IL-6 are depicted in Fig. 4, where it is shown that IL-6 responses via the membrane-bound IL-6R are anti-inflammatory whereas IL-6 activities executed by trans-signaling via the sIL-6R are rather pro-inflammatory and might also reflect stress situations of the immune system (Garbers et al. 2018; Kang et al. 2019). As depicted in Fig. 4, the result of our systematic analysis was that IL-6 classic signaling is predominantly anti-inflammatory and protective whereas IL-6 trans-signaling is rather pro-inflammatory and plays a prominent role in the induction of many neoplastic diseases (Garbers et al. 2018). Interestingly, the balance between these two IL-6 activities is

Interleukin-6, Table 1 Efficacy of specific blockade of IL-6 trans-signaling by the sgp130Fc protein in animal models of inflammation

Disease model	Study outcome	Reference
Intestinal inflammation	Suppression of inflammatory bowel disease	(Atreya et al. 2000)
Atherosclerosis	Regression of atherosclerosis plaques	(Schuett et al. 2012)
Rheumatoid arthritis	Improvement of established arthritis	(Nowell et al. 2009)
Sepsis	Up to 100% survival in sepsis models	(Barkhausen et al. 2011)
Pancreatitis-lung failure	100% survival of severe, acute, experimental pancreatitis	(Zhang et al. 2013)
Lung emphysema	Improvement of disease by blockade of alveolar cellular apoptosis	(Ruwanpura et al. 2016)
Abdominal aortic aneurism	Improved survival in two animal models	(Paige et al. 2019)

apparently governed by the activity of the membrane-bound metalloprotease ADAM17, which is responsible for the generation of the sIL-6R (Scheller et al. 2011a). Importantly, it turned out that ADAM17 not only orchestrates the IL-6 pathway but also signaling via TNFα and ligands of the EGF-R (Zunke and Rose-John 2017). TNFα and all ligands of the EGF-R are transmembrane proteins, which need to be cleaved in order to be systemically active (Scheller et al. 2011a). It has for instance been shown that in the absence of ADAM17, activation of the EGF-R and subsequent milk duct formation in female mice is severely compromised (Chalaris et al. 2010).

In diagnostic terms, the acute phase response of the liver in response to microbial stimuli such as bacteria or viruses leading to the strong induction of C-reactive-protein (CRP) was a hallmark of the biologic activity of IL-6 in inflammatory situations (Baumann and Gauldie 1994). In the last decade, the scientific interest in IL-6 biology was strongly rekindled by two novel insights.

First, about 10 years ago it was demonstrated by three groups that IL-6-induced STAT3 activation in combination with TGFβ was essential for the differentiation of so-called TH_{17} cells whereas TGFβ alone induced the differentiation of regulatory T cells or T_{regs}. These results clearly demonstrated that besides its important role in the innate immune response, IL-6 plays a crucial role in the orchestration of the innate and acquired immune system (reviewed in (Garbers et al. 2018)).

Secondly, TNFα neutralization of autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease in the 1990s was a historical breakthrough in the treatment of these debilitating disorders (Aggarwal et al. 2012). In the 2010s, a neutralizing monoclonal antibody (Tocilizumab) directed against the human IL-6R for treatment of rheumatoid arthritis and other autoimmune diseases such as systemic juvenile idiopathic arthritis was approved by the regulatory agencies in Japan, the USA, and Europe. This was followed by the approval of an additional neutralizing antibody (Sarilumab) against the human IL-6R in 2017 (Garbers et al. 2018; Kang et al. 2019). Remarkably, these IL-6R neutralizing antibodies outperformed the TNFα neutralizing antibody adalimumab when given as monotherapy (Gabay et al. 2013; Burmester et al. 2017), indicating that blockade of IL-6 biologic activity is an extremely promising strategy in the treatment of autoimmune diseases (Jones et al. 2011; Garbers et al. 2018; Kang et al. 2019).

Outlook

The sgp130Fc protein under the name Olamkicept is currently in phase II clinical trials in Germany and Asia in patients with inflammatory bowel disease. This can be seen as a proof of the concept that the specific blockade of IL-6 trans-signaling without affecting classic signaling via the membrane-bound IL-6R not only efficiently inhibits the progression of the inflammatory state in an autoimmune disease but that the IL-6 activities mediated by classic IL-6 signaling indeed govern regenerative and protective functions, which are important for the functioning of the human immune system and which are not blocked when IL-6 trans-signaling is specifically blocked (Hunter and Jones 2015; Garbers et al. 2018; Jones and Jenkins 2018).

Synonyms

Anomalous rectifiers; Inward rectifiers; Inwardly rectifying potassium channels; Kir channels

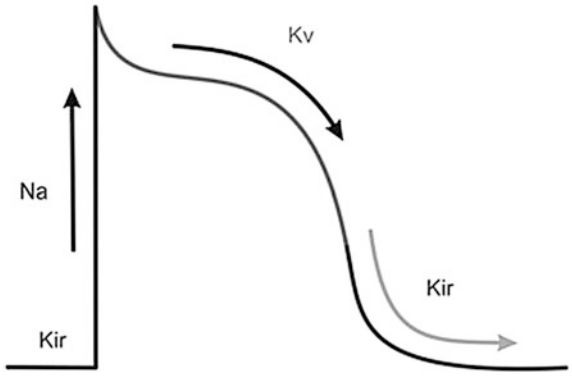
Definitions

Inward Rectifier Potassium Channels or Kir Channels: a class of potassium channels generated by tetrameric arrangement of one-pore/two-transmembrane helix (1P/2TM) protein subunits, often associated with additional beta subunits. Kir channels modulate cell excitability, being involved in repolarization of action potentials (Fig. 1), setting the resting potential (Fig. 1) of the cell, and contributing to potassium homeostasis.

Inward Rectification: decreased conductance upon depolarization. In classical inward rectifiers, rectification is "strong," and currents decline steeply at voltages positive to the equilibrium potential for K^+ (Fig. 2). In other Kir channels, rectification is "weak," and currents decline only gradually at voltages positive to the equilibrium potential for K^+(Fig. 2).

Molecular Basis and Functional Diversity of Kir Channels

Seven subfamilies of eukaryotic Kir channels (Fig. 3), each sharing ~60% amino acid identity between individual members within each subfamily and ~ 40% identity between subfamilies, are



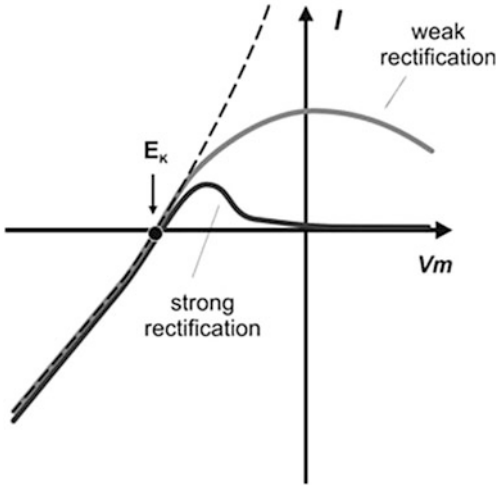
Inward Rectifier Potassium Channels, Fig. 1 The role of inward rectifier (Kir) channels in cardiac action potentials. Depolarization is generated and maintained by Na and Ca currents (I_{Na}, I_{Ca}). Voltage-gated K currents (K_v) and currents through Kir channels contribute to repolarization and maintenance of a negative resting potential

known (Hibino et al. 2010). In addition, multiple prokaryotic Kir channels (Kirbac 1.x-8.x) have been identified in bacterial genomes. We will focus on the eukaryotic channels.

Kir1 subfamily. Kir1.1 (ROMK1, gene *KCNJ1*) (Hibino et al. 2010) encodes a "weak" inward rectifier and is expressed predominantly in the kidney. Alternate splicing at the 5′ end also generates multiple Kir1.1 splice variants, Kir1.1a (ROMK2) through Kir1.1f (ROMK6), expressed in various tissues, including the kidney, brain, heart, liver, pancreas, and skeletal muscle. In the kidney the renal Kir1.1 channels control salt reabsorption.

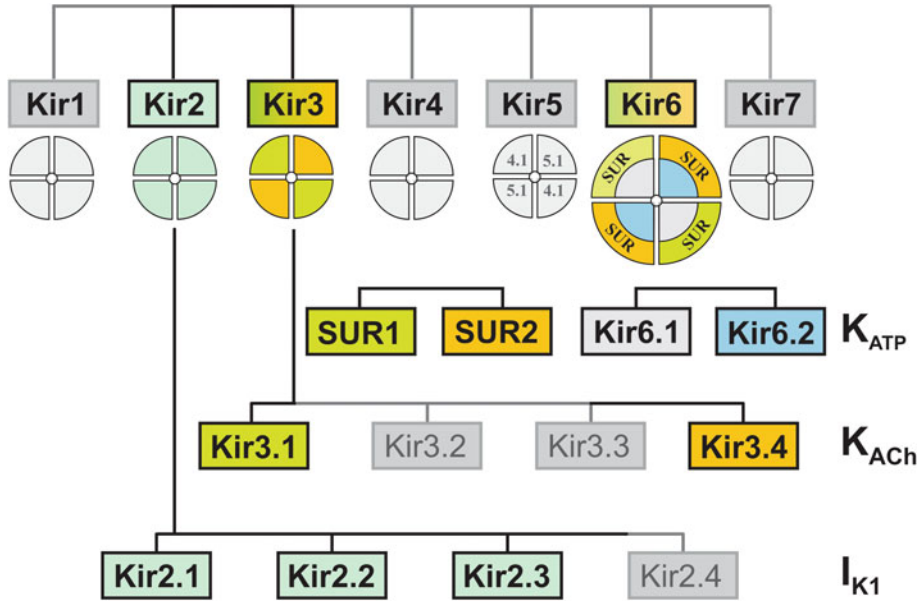
Kir2 subfamily. Six distinct Kir2 subfamily members (Kir2.1–Kir2.6; *KCNJ2*, *KCNJ12*, *KCNJ4*, *KCNJ14, KCNJ17, KCNJ18*) (Hibino et al. 2010), all encoding classical "strong" inward rectifiers, differ in single-channel conductance and in sensitivity to phosphorylation and other second messengers. Members of the Kir2 subfamily are highly expressed in muscles of all types but are also found in a number of other tissues (e.g., nervous system). Kir2 subunits are the key players in the cardiac inward rectifier current I_{K1} in atrial and ventricular myocytes. Kir2.1 is a predominant isoform in all species, while Kir2.2 and Kir2.3 may also contribute. Kir2.4 is believed to be restricted to neuronal cells within cardiac tissue.

Kir3 subfamily. Four members of the Kir3 subfamily (Kir3.1–Kir3.4: *KCNJ3*, *KCNJ6*, *KCNJ9*, *KCNJ5*) express G-protein-activated



Inward Rectifier Potassium Channels, Fig. 2 High $[K^+]$ inside cells relative to outside results in "normal" (outward-going) rectification (dashed line), whereby outward (positive by convention) potassium currents (I), when cells are depolarized (V_m is positive relative to equilibrium potential for K^+, E_K), are bigger than inward (negative) currents at membrane potentials (V_m) more negative than E_K. Conversely, inward (or "anomalous") rectifiers show "strong" or "weak" inward rectification whereby outward currents are smaller than inward currents

"strong" inward rectifier K^+ channels (GIRK channels) underlying G-protein-coupled receptor-activated currents in heart, brain, and endocrine tissues. Functional channels typically require co-assembly of two different subunits (e.g., Kir3.1 and Kir3.4 in atrial channels). Several studies have provided evidence for a



Inward Rectifier Potassium Channels, Fig. 3 The family of inward rectifier potassium channels. Kir channels may be homo- or hetero-tetrameric complexes of individual subunits, in some cases in tight association with beta-subunits (e.g., as in the K_{ATP} channel). SUR – sulfonylurea receptor. Modified from Anumonwo and Lopatin (2010)

promiscuous assembly between the various members of the Kir3 subfamily.

Kir4 and Kir5 subfamilies. These subfamilies of Kir channels (Kir4.1 and Kir4.2, *KCNJ10*, *KCNJ15*, Kir5.1, *KCNJ16*) are abundantly expressed in the brain, glia, and kidney. Kir4.1 forms "weak" inward rectifier K^+ channels when expressed alone. Kir5.1 does not form homomeric channels, but co-expression of Kir4.1 and Kir5.1 subunits results in formation of channels with novel properties: Kir5.1/Kir4.1 heteromeric channels are very sensitive to intracellular pH, and this property is conferred predominantly by the Kir5.1 subunits.

Kir6 subfamily. Two members (Kir6.1, Kir6.2, *KCNJ8*, *KCNJ11*) of this subfamily encode the pore-forming subunits of ATP-sensitive K^+ channels (K_{ATP}) that are found in most excitable tissues. Functional expression of channels that are inhibited by intracellular ATP and activated by ADP, thereby coupling cell metabolism to excitability (Nichols 2006), requires octameric assembly of four Kir6.x subunits with four sulfonylurea receptor subunits (SUR1 or SUR2) (Martin et al. 2017). K_{ATP} channels display "weak" rectification, allowing substantial outward current to flow at positive potentials, thus causing action potential shortening and reduced excitability when activated, for example, during metabolic inhibition.

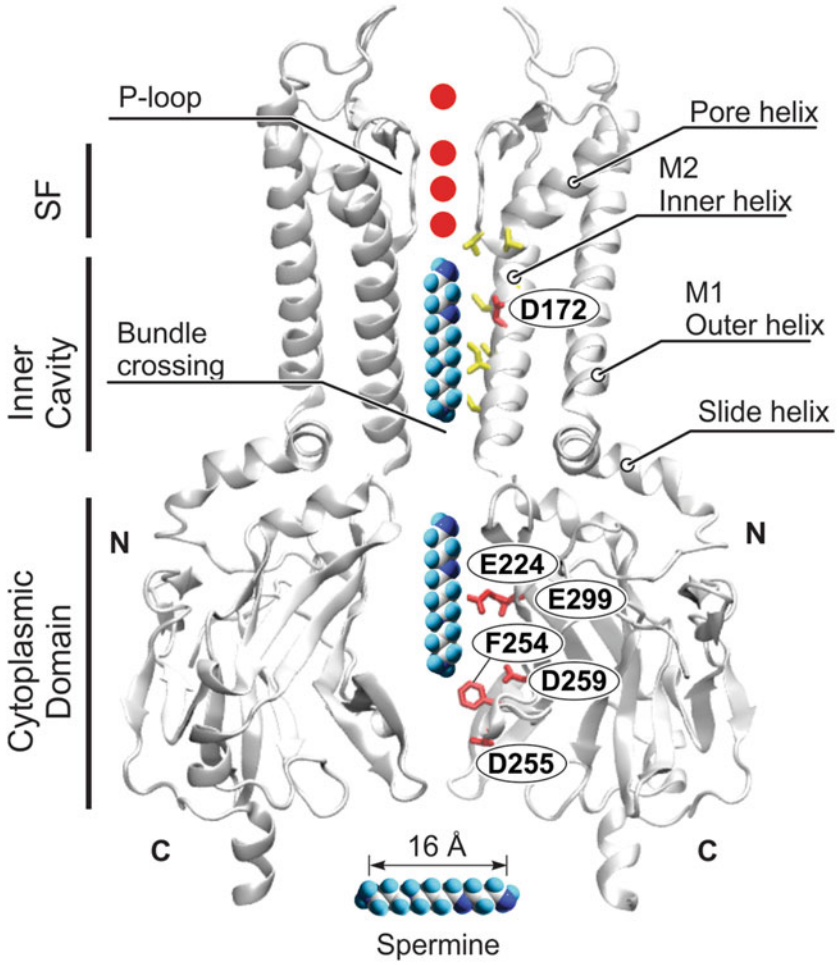
Kir7 subfamily. The only known member (Kir7.1, *KCNJ13*) is primarily expressed in the retinal pigment epithelium in the brain but is also found in a variety of other tissues, including the kidney and intestine. This weakly rectifying channel has an apparently very low single-channel conductance and very shallow dependence on external K^+ and is virtually insensitive to intracellular Mg^{2+}. The physiological role of this channel remains unclear.

Molecular Structure of Kir Channels

All Kir channels are tetrameric proteins (Fig. 3) of one-pore/two-transmembrane (1P/2TM) domain subunits which generate highly selective K^+ channels. Most Kir channels can be assembled as functional homotetramers, while some require heteromeric assembly (Fig. 3). For example,

functional GIRK channels underlying I_{KAch} (acetylcholine-activated) current in atria are obligate heteromers of two members of Kir3 subfamily: Kir3.1 and Kir3.4.

A feature of all K^+-selective channels is the signature G(or F)YG sequence within the P-loop (Fig. 4) that acts as a filter, to confer high selectivity to K^+ ions and to control single-channel conductance and kinetics. Two transmembrane domains with N- and C-termini facing the cytoplasm flank the P-loop (Fig. 4). The assembly of the Kir2.1 channel is supported by the presence of intrasubunit disulfide bonds between highly conserved cysteine residues at the outer surface of the channel which are absolutely required for proper channel folding. Scanning cysteine mutagenesis studies of relatively large stretches of N- and C-termini of Kir2.1 reveal that nearly half of them



Inward Rectifier Potassium Channels, Fig. 4 Kir channel subunits consist of two transmembrane helices (M1, M2), separated by a pore loop (P-loop) that contains the signature K^+-selectivity sequence (-GYG-), as well as a characteristic "Kir domain" formed by the extended cytoplasmic N- and C-termini that generates a long cytoplasmic extension to the pore. Only two (opposing) subunits are shown for clarity (transmembrane regions from a and c subunits, cytoplasmic Kir domains from b and d subunits). Several residues implicated in causing rectification are indicated (see text). Spermine may block the channel in the inner cavity and entrance to the selectivity filter (upper), and in the wider cytoplasmic vestibule (lower), potentially occupying both sites simultaneously. (●) K^+ ions. Structural data: Protein Data Bank code 5KUM; Kir2.2 channel at 2.8 Å resolution. Modified from Nichols and Lee (2018)

are water accessible, and potentially facing the pore, in addition to residues in the second transmembrane region. Crystal structures of eukaryotic Kir2.2 and Kir3.2 channels have been resolved, revealing the canonical K^+ channel pore structure (Hansen et al. 2011) in which the cytoplasmic "Kir" domain generates an additional wide cytoplasmic intracellular vestibule, large enough to accept multiple permeating and blocking ions. Multiple studies suggest that the Kir domains undergo subtle structural changes to open or close the channel via "gate" at the M2 helix bundle crossing point which generates the entrance to the inner cavity from the cytoplasmic vestibule.

The Mechanism of Strong Inward Rectification

Inward, or "anomalous," rectification of potassium permeability refers to increased potassium conductance under hyperpolarization and decrease under depolarization (Fig. 2), the effect being opposite to that of "normal" outward rectification resulting from physiological intracellular and extracellular [K^+]. It should be noted that not all Kir channels rectify strongly enough to fit the definition of classical rectification, such as observed in cardiac I_{K1} channels. In this regard, classical inward rectification is so strong that only small currents can be measured in the outward direction at voltages positive to the K^+ reversal potential (E_K), while large inward currents can be easily observed negative to it. This "strong" voltage-dependent rectification also depends on the concentration of external K^+ ([K_{OUT}]): increasing K_{OUT} relieves the rectification, so that the midpoint voltage of rectification shifts nearly perfectly with corresponding change in E_K. It is now established that strong inward rectification results primarily from voltage-dependent block by naturally occurring intracellular organic cations called polyamines (Hibino et al. 2010). Of the polyamines, spermine (Fig. 4) and spermidine are the most potent inducers of rectification, and micromolar concentrations of free spermine and spermidine are sufficient to reproduce the degree of rectification seen in native cells (Hibino et al. 2010), although putrescine and Mg^{2+} ions are also relevant. Importantly, total polyamine levels in cells are typically quite high (up to 10 mM), although most polyamines are bound to various intracellular targets such as RNA, DNA, ATP, and other, primarily phosphate-containing, molecules.

The varying degree of rectification between members of the Kir superfamily is fundamental to their respective functional roles. Kir2 and Kir3 encode classical "strong" inward rectifier channels, while other members encode channels with variably "weaker" rectification (Fig. 2). For example, because of weak rectification of the K_{ATP} channel, its activation can cause considerable shortening of the cardiac action potential, reducing entry of Ca^{2+} through voltage-dependent Ca^{2+} channels and hence conserving ATP under conditions of metabolic stress. Conversely, the strong inward rectification of Kir2.1 channels underlying the cardiac I_{K1} current results in very small currents flowing through these channels during the long depolarization phase of the action potential, while increased conductance once the cell hyperpolarizes makes the resting potential very stable, a combination that is essential to the normal pump cycle of the heart.

Structural Elements of Inward Rectification

Each Kir subunit consists of two transmembrane helices (M1, M2), with a pore-forming selectivity filter linking them, and cytoplasmic N- and C-termini (Hansen et al. 2011) (Fig. 4). The channel is formed as a tetrameric arrangement of these subunits, surrounding an external selectivity filter, an inner vestibule, and a cytoplasmic entrance to the pore (Fig. 4). Aspartate 172 located in the M2 region of Kir2.1 was the first residue implicated in the classical rectification of these channels and is sometimes referred to as the "rectification controller." A number of other residues in the C-terminus of Kir2.1 (e.g., E224, F254, D255, D259, and E299) also contribute to polyamine-induced rectification; neutralization of a few negatively

charged amino acids (D172, E224, and E299) can transform the strongly rectifying Kir2.1 channel into one that is nearly insensitive to blockage by polyamines and Mg^{2+}. The exact location(s) of the binding sites for polyamines remains controversial. Probably one spermine molecule is required to maximally block the channel, within the inner vestibule, or perhaps within the selectivity filter itself, and the charge movement through the electric field that underlies the voltage dependence of the block may arise from K^+ ions displaced from within the channel pore to the outside of the cell, or from movement of the spermine itself into the field within the selectivity filter, or a combination of both. Despite the relatively large size of the spermine molecule (~16 Å long) (Fig. 4), its diameter is close to that of a dehydrated K^+ ion, thus potentially allowing its head amine group to "squeeze" into the selectivity filter and block ion flow. Polyamines may also permeate Kir channels and can clearly permeate, as well as block, other nonselective cationic channels, consistent with such an interpretation.

Pharmacology of Kir Channels

Voltage-dependent block by external Ba^{2+} and Cs^+ ions, yet insensitivity to the Kv channel blocker tetraethylammonium (TEA), have been the classical tools to examine Kir channel activity. The honeybee venom tertiapin has been found to be an effective blocker of certain (Kir1, Kir3) inward rectifier subfamily members, and a spider toxin SpTx-1 is a potent blocker of Kir6.2 channels. Tight association of Kir6 family members with SUR subunits endows K_{ATP} channels with a rich pharmacology: channel activity is very specifically inhibited by sulfonylurea drugs such as tolbutamide and glibenclamide and is enhanced by a broad class of "potassium channel opening" (KCO) drugs such as pinacidil and diazoxide, all of which interact with the SUR subunits.

A potent antiarrhythmic drug RP58866 and its active enantiomer RP62719 (known as Terikalant) have been shown to block I_{KACh} (encoded by Kir3.x members) and I_{K1} (encoded by Kir2.x members) currents in the heart in the low micromolar range. Unfortunately, neither agent discriminates well between Kir and other K channels (e.g., underlying I_{Kr}) and thus has not received much attention as a selective blocker for Kir channels.

Kir channel-specific pharmacological tools also include chloroquine, mefloquine, tamoxifen, and quinacrine which inhibit Kir channels underlying cardiac I_{K1}, I_{KATP}, I_{KACh} currents. Chloroquine and quinacrine as well as pentamidine were also shown to effectively inhibit Kir4.1 channels with a number of serotonin reuptake inhibitors such as sertraline, fluoxetine, and fluvoxamine adding more to relatively rich pharmacology of this channel. An excellent review of Kir channel modulators can be found in Bhave et al. (2010).

Diseases Resulting from Kir Channel Mutations

Multiple channelopathies resulting from mutations in Kir channels are now recognized.

Kir1.1 Bartter syndrome. Several mutations in the core region as well as in the N- and C- termini of Kir1.1 are found in patients with hyperprostaglandin E syndrome (HPS; renal disorder resulting from impairment of tubular reabsorption), an antenatal form of Bartter syndrome. Some of these mutations result in the loss of function of Kir1.1 channels causing impaired renal K^+ secretion and NaCl reabsorption.

Kir2.1 Channelopathies. Dominantly inherited long QT syndrome (LQT), a disorder of cardiac action potential repolarization, is most commonly associated with mutations in cardiac Na^+ or voltage-gated K^+ channels, but multiple mutations in *KCNJ2* cause Andersen's syndrome (LQT7), a rare disease characterized by periodic paralysis, cardiac arrhythmias, and dysmorphic features. Mutations in *KCNJ2* associated with Andersen's syndrome were found to cause dominant negative suppression of the wild-type Kir2.1 channels when expressed in *Xenopus* oocytes or cultured cell lines, thus mimicking the effects of the *KCNJ2* gene knockout which is characterized

by prolonged QT interval. Alternatively, a gain-of-function mutation in the "rectification controller" of Kir2.1 channel (D172N mutation) causes a form of short QT syndrome (SQT3), which is characterized by a unique short QT interval on the ECG. Another gain-of-function mutation in human *Kir2.1* gene (V93I) was also found to underlie a familial atrial fibrillation. A number of mutations in *KCNJ2* gene linked to catecholaminergic polymorphic ventricular tachycardia (CPVT) have also been identified.

Kir3.2 Keppen-Lubinsky syndrome. A mutant mouse (the Weaver mouse) with cerebellar degeneration and motor dysfunction resulting from a serine for glycine substitution in the -GYG- sequence of the K^+ selectivity filter of Kir3.2 leads to loss of the K-selectivity of cerebellar G-protein-activated K^+ channels, a consequent Ca^{2+} overload, and cell death. Mutations in the same region of human Kir3.2, resulting in loss of K^+ selectivity, have been identified in Keppen-Lubinsky syndrome, a rare disease characterized by developmental delay and intellectual disability, facial dysmorphology, and severe movement disorder.

Kir4.1 SeSAME/EAST syndrome. Kir4.1 is critical for glial function, control of neuronal excitability, and systemic K^+ homeostasis. Homozygous or compound heterozygous loss-of-function Kir4.1 mutations are associated with EAST/SeSAME syndrome, characterized by mental retardation, epilepsy, ataxia, seizures, hearing loss, and renal salt wasting (Sala-Rabanal et al. 2010).

Kir6.2/SUR1 Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) and neonatal diabetes. Lowered blood glucose normally results in decreased ATP/ADP ratios in the pancreatic islet β-cells, triggering the opening of K_{ATP} channels, hyperpolarization, inhibition of Ca^{2+} entry, and cessation of insulin secretion. In PHHI, K_{ATP} channel mutations lead to abolition of activity and hence maintained depolarization and maintained Ca^{2+} entry and insulin secretion. Many mutations in the SUR subunit abolish ADP activation of channels, but point mutations in Kir6.2 are implicated in abolition of channel activity in some cases. Conversely, K_{ATP} channel mutations that lead to increased activity and hence maintained hyperpolarization and failure of Ca^{2+} entry block insulin secretion and cause neonatal diabetes. Many mutations in the Kir6.2 and SUR subunits have now been identified, and this has led to a change in therapy for the disease, from injected insulin to sulfonylurea pills (Nichols 2006).

Kir6.1/SUR2 Cantu syndrome. Kir6.1 and SUR2 subunits make up the K_{ATP} channels of smooth muscle. Cantu syndrome results from gain-of-function mutations that generally reduce the sensitivity to inhibition by ATP, in either subunit. This causes reduced smooth muscle electrical activity and reduced Ca^{2+} entry and hence vessel dilation and in turn leads to lymphedema and vasodilation, with secondary consequences of enlarged hearts, and persistent fetal blood flow. In addition, all Cantu syndrome patients have excess hair growth, explaining the hair growth-promoting effects of the K_{ATP} channel openers diazoxide and minoxidil (sold commercially as Rogaine©) (Nichols et al. 2013).

Definition

The *Ja*nus *k*inase-*s*ignal *t*ransducer and *a*ctivator of *t*ranscription (JAK-STAT) signaling pathway is activated in response to more than 50 cytokines, hormones, and growth factors. As their name implies, the STAT proteins exhibit the dual function of transducing signals from the cell surface into the nucleus as well as activating transcription of target genes, thus converting extracellular stimuli into a wide range of cellular responses. STATs have been identified as important regulators of a multitude of cellular processes, such as immune response, antiviral protection, and proliferation.

Basic Characteristics

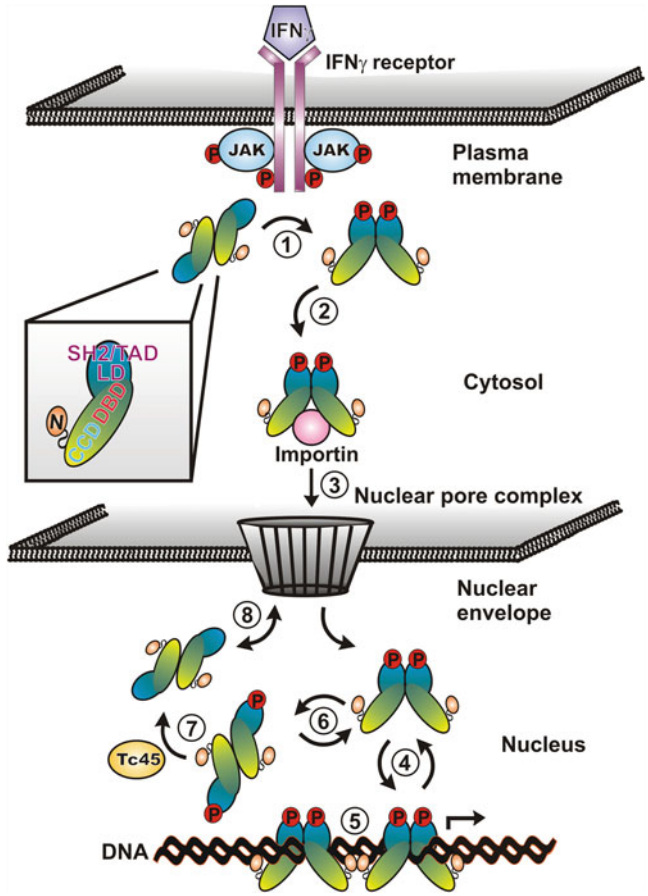
The JAK-STAT pathway is widely used by members of the cytokine receptor superfamily. Upon ligand binding and oligomerization of the cognate receptor chains, the receptor-associated JAKs themselves become tyrosine phosphorylated and consecutively phosphorylate critical tyrosine residues on the cytoplasmic domain of the receptors, thereby generating docking sites for STAT proteins and other intracellular signaling molecules (Levy and Darnell 2002). The STATs generally are recruited to specific phosphotyrosine-containing motifs located in the cytoplasmic part of the receptor through their Src-homology-2 (SH2) domain and in turn are phosphorylated by the activated JAKs at a single tyrosine residue in their C-terminus (Stark and Darnell 2012). Tyrosine phosphorylation, also called "STAT activation," induces a conformational change in the STAT molecules, which exist as preformed dimers (M_r ~ 180 kDa). Crystallographic and biochemical data indicate that the unphosphorylated STAT1 dimer is formed by mutual interactions between N-domains and the coiled-coil domain of one protomer and the DNA-binding domain of the other, a conformation referred to as "antiparallel." By virtue of reciprocal phosphotyrosine SH2 domain interactions, the activated dimer can adopt an equally stable "parallel" conformation. Phosphorylation-dependent conformation switching has important functional consequences. Unphosphorylated STAT dimers can shuttle in

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

and out of the nucleus without assistance from carrier proteins, while the activated STATs are barred from nuclear export and require the canonical carrier-facilitated mechanism for nuclear import. The phosphorylated STATs are also capable of binding to palindromic gamma-activated site (GAS) elements with the consensus sequence 5′-TTC$(N)_{3-4}$GAA-′3 in the promoter regions of cytokine-responsive genes, where they function as cytokine-regulated transcription factors. STATs are susceptible to enzymatic tyrosine dephosphorylation, which is the main mechanism to inactivate their transcription activity (Fig. 1).

Physiological Functions of JAKs

Named after the two-faced ancient Roman god Janus, the mammalian JAK family of protein tyrosine kinases consists of four members. While



JAK-STAT Pathway, Fig. 1 Model of the JAK-STAT pathway, as exemplified by the founding member of the family of the STAT transcription factors, STAT1. The cartoon depicts the following steps in the activation/inactivation cycle of STAT1: JAK-induced STAT1 tyrosine phosphorylation and formation of parallel phospho-dimers (1), formation of an import-capable complex of phospho-STAT1 with importin (2) including its nuclear import (3), sequence-specific binding to a GAS site on DNA (4), polymerization on DNA through interdimeric amino-terminal interactions resulting in cooperative DNA binding as a requirement for full-fledged gene induction (5), tyrosine dephosphorylation of STAT1 catalyzed by the Tc45 phosphatase after its dissociation from DNA and switching to an antiparallel dimer conformation (6), followed by nuclear translocation of the dephosphorylated STAT1 (7) through the nuclear pore complex (8). The inlet depicts the domain structure of a STAT1 monomer with the amino-terminal domain (N) and the core domain which are connected by a flexible linker. The core domain is comprised of the coiled-coil domain (CCD), the DNA-binding domain (DBD), the linker domain (LD), and the SH2 domain, followed carboxy-terminally by the transactivation domain (TAD)

JAK1, JAK2, and TYK2 are being ubiquitously expressed, the expression of JAK3 is mostly restricted to cells of hematopoietic origin (Babon et al. 2014). These multi-domain proteins have a molecular mass of approximately 130 kDa and consist of an N-terminal FERM-domain, a SH2-like domain, a pseudokinase domain (JAK homology 2, JH2), and, the catalytically active, signaling PTK domain (JH1). The essential role of JAKs in mediating signal transduction via members of the cytokine receptor superfamily became apparent from studies of knockout mice. Targeted disruption of the mouse JAK1 gene results in perinatal lethality, obviously caused by defective neural function, and altered lymphoid development. JAK2-deficient mice exhibited an embryonic lethal phenotype caused by a block in definite erythropoiesis but showed intact lymphoid development, demonstrating the obligatory and non-redundant roles of JAKs in cytokine-induced biological responses. Mutant mice lacking JAK3 are viable but display severe defects in both cellular and humoral immune responses with profound reduction in mature B and T cells, resembling the clinical symptoms of patients suffering from an autosomal recessive form of severe combined immunodeficiency, in which inactivating mutations in the JAK3 gene have been identified (Hammarén et al. 2019).

Roles of STAT Proteins in Gene Induction

In Mammalia, seven different members have been identified, all of which are activated by a distinct set of cytokines. Diversity in signaling is provided by variants of STAT proteins derived from either alternative splicing of RNA transcripts or proteolytic processing (e.g., STATs 1, 3, 4, and 5) and the ability of certain STATs to form both homodimers and heterodimers with each other. For example, STAT1 homodimers mediate type 2 interferon responses, while type 1 interferons require STAT1:STAT2 heterodimers. Major structural features in STAT proteins are the N-terminal region involved in cooperative DNA binding of multiple STAT dimers, the central DNA-binding domain, the dimerization region containing the SH2 domain and the site of tyrosine phosphorylation, and the C-terminal transcriptional transactivation domain. Phosphorylation of a critical serine residue within the transactivation domain is necessary for maximal transcriptional activity of some STAT family members.

STAT1 knockout mice exhibit selective signaling defects in their response to interferons, including an impaired expression of MHC class II, complement protein C3, the MHC class II transactivating protein CIITA, interferon regulatory factor 1, and guanylate-binding protein 1. In humans, loss-of-function mutations in the gene encoding STAT1 have been identified causing susceptibility to a range of infections, including severe viral and bacterial infections, such as non-tuberculous mycobacterial diseases (Mendelian susceptibility to mycobacterial disease, MSMD) (Olbrich and Freeman 2018). Autosomal dominant gain-of-function mutations in the *STAT1* gene characteristically result in chronic mucocutaneous candidiasis (CMC), likely caused by impaired IL-17 immunity (van de Verdonk et al. 2011). Almost all monogenic point mutations conferring CMC have been identified in regions of the *STAT1* gene coding for the coiled-coil domain and the DNA-binding domain, which are both engaged in the formation of the antiparallel dimer (Toubiana et al. 2016).

STAT3, activated through binding of IL-6, leptin, EGF, PDGF, LIF, or other ligands to their cognate receptors, appears to have important roles in preventing apoptosis and promoting proliferative processes. A deficiency in STAT3 causes embryonic lethality in mice, indicating the essential role of STAT3 in growth regulation, embryonic development, and organogenesis. Patients with STAT3 gain-of-function mutations have been identified, too (Fabre et al. 2019). They present with early-onset autoimmune and lymphoproliferative disease. Besides the role as a cytokine-inducible transcription factor in the nucleus, STAT3 elicits nonclassical functions in mitochondria by augmenting the activities of complex I and II of the electron transport chain. Furthermore, STAT3 directs self-renewal of pluripotent embryonic stem cells and induces pluripotent stem cells downstream of the LIF-receptor/gp130 complex.

STAT4 is activated in T cells in response to IL-12 and stimulates the development of TH1 cells. The two ubiquitously expressed STAT5 proteins (STAT5a and 5b) are encoded by distinct genes and share more than 90% sequence identity. They are activated by many growth stimulatory cytokines, including interleukins, GM-CSF, GH, prolactin, EGF, as well as erythropoietin, and exert critical roles in anti-apoptosis and proliferation. STAT6 functions in response to IL-4 and IL-13 signaling to induce TH2 cell development, CD23 and MHC class II expression, immunoglobulin class switching, and B- and T-cell proliferation.

Originally discovered as a DNA-binding protein that mediates interferon signaling, recent data demonstrated that STAT1 can also exert constitutive functions in the nucleus, which do not require STAT activation with tyrosine phosphorylation. Cells lacking STAT1 are resistant to apoptotic cell death induced by tumor necrosis factor α (TNFα) due to an inefficient expression of caspase genes, while reintroduction of STAT1 in these cells restores protease expression and sensitivity to apoptosis. For the transcription of certain target genes, a phosphorylation of the critical tyrosine residue 701 is not necessary, suggesting that unphosphorylated STAT1 can also bind to DNA. Recent data indicate that unphosphorylated STAT1 can either positively or negatively regulate the constitutive expression of a wide range of different genes.

Besides the cytokine receptors that lack intrinsic kinase activity but have associated JAK kinases, STAT proteins can be activated by a variety of G-protein-coupled receptors and growth factor receptors with intrinsic tyrosine kinase activity (e.g., EGF, PDGF, CSF-1, and angiotensin receptor). Increasing evidence suggests a critical role for STAT family members in oncogenesis and aberrant cell proliferation. Constitutively activated STATs have been found in many transformed cell lines and a wide variety of human tumor entities. Numerous non-receptor tyrosine kinases and viral oncoproteins, such as v-Src, v-Abl, v-Sis, and v-Eyk, have been identified to induce DNA-binding activity of STAT proteins.

Several mechanisms that negatively regulate the JAK-STAT pathway are known. The SOCS proteins (suppressor of cytokine signaling), also named as CIS (cytokine-inducible src homology 2-domain containing protein), JAB (JAK-binding protein), or SSI (STAT-induced STAT inhibitor), are induced by cytokine signaling and act in a negative feedback loop to inhibit JAK kinase activity. Another important negative regulatory mechanism involves the recruitment of tyrosine phosphatases containing tandem SH2 domains (SHP-1 and SHP-2) to the intracytoplasmic portion of receptor complexes, where they dephosphorylate and thus inhibit JAK activity. It was demonstrated that the activity of STAT1 is inhibited by conjugation of the small ubiquitin-like modifier (SUMO) to the lysine residue in position 703. Although only a disproportionately small fraction of the intracellular, unphosphorylated STAT1 pool is SUMOylated, the modification by SUMO interferes with the formation of paracrystalline arrays in the nucleus which sequester activated STAT1 molecules and protect them from being dephosphorylated (Droescher et al. 2011). Naturally occurring STAT variants lacking the transactivation domain can also suppress STAT signaling, but their role may be more complex. Likewise, PIAS proteins (protein inhibitor of activated STAT) have been shown to interact with STATs and to inhibit their DNA-binding activity, but they appear to play a limited role as physiological STAT regulators.

Drugs

Given the crucial role of the JAK-STAT signaling in autoimmune diseases and malignancies, it is not surprising that components of this pathway have become attractive therapeutic targets for pharmacological interventions (O'Shea et al. 2015). Small-molecule JAK inhibitors (i.e., jakinibs) that competitively bind to the ATP-binding site in the JAK kinases and thereby block their activity have been identified (Changelian et al. 2003). Such orally active JAK inhibitors have been marketed for rheumatoid arthritis and other immune system disorders, and these drugs have shown promising results in phase 2 and phase 3 clinical trials for other inflammatory conditions

and beyond. Approved compounds include ruxolitinib against JAK1/JAK2 for psoriasis, myelofibrosis, rheumatoid arthritis, and polycythemia vera and tofacitinib against JAK3 for psoriasis and rheumatoid arthritis. In addition, long-term treatment in CMC patients with ruxolitinib also showed good clinical responses in some patients.

In contrast, STAT protein inhibitors have not reached the clinic yet. However, given the high level of STAT activation in tumor cells and their contribution to malignancy, drugs specifically blocking STAT molecules could be highly beneficial in the treatment of cancer and autoimmune diseases. In contrast to the JAKs possessing a kinase domain, STATs do not have intrinsic catalytic activity, and their pharmacological targeting therefore is more challenging. Current approaches focus on STAT gene expression, SH2-mediated STAT dimerization, and DNA binding using a variety of chemical entities including small interfering RNAs, natural pharmacological inhibitors, peptides and peptidomimetics, non-peptidic small molecules, and decoy oligonucleotides.

Definition

Janus kinases transduce signals emanating from dozens of extracellular cytokines inside the cell by activating their downstream effectors such as STAT transcription factors. JAKs regulate critical cellular functions such as survival, proliferation, homeostasis, and immune and inflammatory responses. On the other hand, JAKs participate in the pathogenesis of several immunological and inflammatory diseases. Activating JAK mutations cause hematological diseases and cancers, and inactivating JAK mutations lead to immunodeficiencies. Currently, JAK inhibitors (JAKi) are used for the treatment of myeloproliferative neoplasms, rheumatoid or psoriatic arthritis, and inflammatory bowel disease, and clinical trials

are ongoing for a wide range of other autoimmune and malignant diseases.

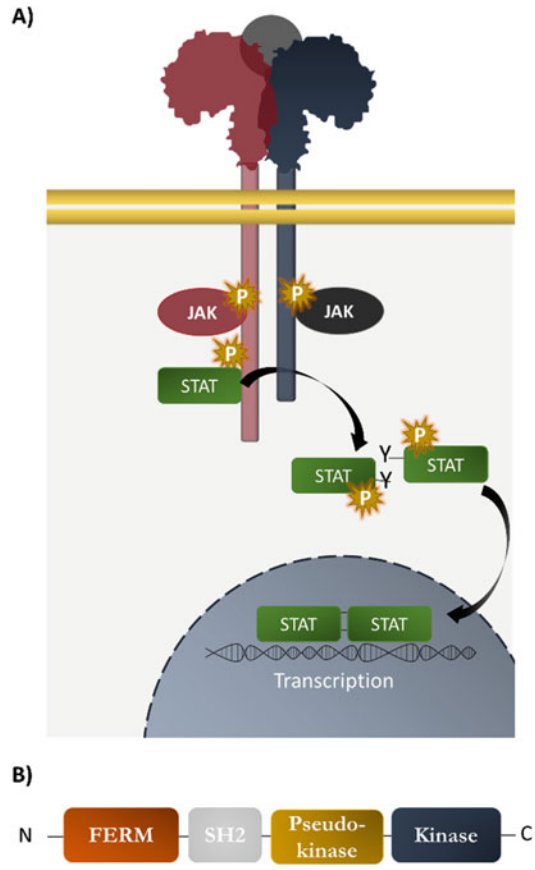
Basic Characteristics

Janus Kinases and the Cytokine Signaling

Janus kinases (JAKs) are nonreceptor tyrosine kinases that catalyze the transfer of ATP γ-phosphate within their active site to the substrate. JAKs mediate the signaling for approximately 60 small extracellular cytokines, particularly interleukins, interferons, hematopoietic growth factors, and some hormones by binding and activating their transmembrane receptors (Silvennoinen and Hubbard 2015).

Mammalian cells express four JAKs: JAK1-3 and TYK2 (tyrosine kinase 2). The JAK-family proteins are large cytoplasmic proteins (120–140 kDa) that constitute of N-terminal FERM (the band-4.1, ezrin, radixin, and moesin-domain) that forms the receptor-binding moiety with the adjacent Src homology 2 (SH2) domain. The kinase-domain resides in the C-terminus and shows the typical kinase characteristics with the nucleotide (ATP)-binding pocket and the activation loop with tandem tyrosine residues that become phosphorylated during activation. Between the kinase domain and SH2 resides the characteristic feature of JAKs, namely pseudokinase domain that shows structural homology to the kinase domain but lacks some of the conserved residues required for kinase transferase activity. However, the pseudokinase domain is a critical regulator of JAK activation.

Cytokine binding to the extracellular part of the receptors reorients or oligomerizes the receptors leading to conformational changes that bring the cytoplasmic JAKs in close proximity that allows the adjacent kinase domains to transphosphorylate each other and become activated (Fig. 1). Activated JAKs phosphorylate the specific tyrosine residues in the receptors that create docking sites for STATs. The seven STAT transcription factors (STAT1-6 including 5a and 5b homologs) are important downstream effectors of JAKs. Once phosphorylated by JAKs, STATs dimerize via their SH2 domains and translocate to nucleus, where they bind to their cognate promoter elements in cytokine-responsive genes to regulate the transcription of the cytokine-specific gene products.



Janus Kinase, Fig. 1 (**a**) Schematic presentation of the JAK-STAT signaling (illustrated here as heterodimeric receptor complex). Cytokine-binding induces conformational changes in the receptors, which draws the JAKs into proximity and allows their transphosphorylation and activation of downstream effectors such as STATs. Phosphorylated STATs translocate to the nucleus to regulate transcription. (**b**) The domain structure of JAKs

JAK1 associates with several cytokine receptors and is involved in several of cytokine-signaling pathways (see Table 1). JAK1 can form signaling complexes with all the other JAK family members. JAK1 is ubiquitously expressed throughout the tissues but is especially crucial for the development and function of the immune system. JAK1-deficient mice die perinatally

caused by severe defects in lymphoid development and neurogenesis.

JAK2 is critical for myeloid blood formation, although it also plays an important role in immune system together with other JAKs. JAK2 deficiency in mice leads to embryonic lethality due to impaired hematopoiesis. JAK2 is the only family member that signals as homodimeric complexes in, e.g., EPOR, TPOR, and GHR systems. JAK2 is ubiquitously expressed and also forms complexes with JAK1 and TYK2.

JAK3 has restricted expression pattern predominantly in the lymphoid cells. JAK3 binds specifically only to the common gamma chain (γc) receptor and plays a crucial role in the function of the lymphoid cell department in the immune system. JAK3 deficiency causes autosomal recessive form of severe combined immune deficiency (SCID).

TYK2 forms a complex with JAK1 and/or JAK2 to transduce signals emanating from the IFN type I family and gp130 family cytokines (Table 1). Consequently, TYK2 is important for immune function via its role in IL-12 and IL-23 signaling that regulates T and NK cells. Loss of TYK2 signaling is not lethal but causes immunodeficiency.

Function and Regulation of JAKs

Downstream Signaling

Cytokine receptors use different combinations of JAK and STAT family members to mediate signaling, which is based on binding specificity between a JAK FERM-SH2 domain with a cytokine receptor membrane proximal region (Table 1). The activated STATs form predominantly homodimers, but in some cases they form heterodimers (e.g., STAT1:STAT2). The dimeric STATs translocate from the cytoplasm to the nucleus with the help of importins and the Ran-GTP nuclear import pathway where they directly bind to the specific regulatory sequences in DNA. The specificity of a STAT for the promotor is a key determinant of the cytokine specificity and transcriptional outcome from a JAK kinase pathway. The canonical JAK-STAT-signaling pathway is relatively simple, but JAKs are triggering kinases for all downstream signaling and phosphorylate and activate substrates from several signaling pathways including MAPK and PI-3K pathways.

Intramolecular Regulation of JAK Kinases

JAK activation is tightly regulated at several levels to ascertain to suppression of signaling in the absence of ligand and to ensure rapid and transient signaling activation upon ligand binding to its receptor. Prior to stimulation, the JAK is maintained in an inactive state by a combination of inter-domain interactions within the JAK kinases as well as by the cell surface organization of receptor-JAK complex. The different JAK domains need to be correctly positioned to form a functional unit that allows inter-domain interactions and intricate regulation of activity. The interaction of the FERM domain with the receptor and membrane positions JAKs in an optimal orientation for interactions (Wilmes et al. 2020). The linkers connecting the domains are also critical for the regulation of the JAK domains. The key inter-domain regulation of JAK kinase is mediated by kinase-pseudokinase domain auto-inhibitory interaction where pseudokinase domain maintains kinase domain in an inactive state in the absence of ligand stimulation. Importantly, majority of the activating JAK mutations localize in this auto-inhibitory interphase (Babon et al. 2014; Silvennoinen and Hubbard 2015). Activation of JAK catalytic activity is initiated by the disruption of the auto-inhibitory interaction resulting in kinase domain trans/auto-phosphorylation. In addition to the negative regulatory role, the pseudokinase domain also has a positive regulatory role in JAK activation. This function is less well defined than the inhibitory role, but mutations in pseudokinase domain (of JAK3 and TYK2) can impair the catalytic activity as in SCID mutations. Furthermore, deletion of the pseudokinase domain in JAK2/3 abolishes cytokine-induced signaling. Thus, the pseudokinase domain serves as a key regulatory domain with dual functions and maintains JAK kinase in inactive state (or low basal activity) in the absence of cytokine and to stabilize the active conformation essential for kinase activity during cytokine

stimulation (Saharinen and Silvennoinen 2002; Ungureanu et al. 2011).

Intermolecular Regulation of JAK Kinases

It is important that JAK activation is transient, and this is achieved by negative regulator proteins at different levels: dephosphorylation, inhibition of transcription, and by internalization and degradation of the receptors (Rawlings et al. 2004; Babon et al. 2014). Initially, the activation is controlled by phosphatases that dephosphorylate JAKs as well as other phosphorylated effector proteins. The main phosphatases for JAK kinases are SHP1, SHP2, CD45, PTP1B, and TCPTP. Other main negative regulators which can bind to JAKs through their SH2 domains are SOCS and LNK family proteins. The SOCS family is composed of SOCS1-SOCS7 and CIS-1, and their transcription is activated by STATs thus creating a negative regulatory loop in cytokine signaling. Different SOCS proteins regulate JAK-STAT signaling by different mechanisms which can involve inducing ubiquitination and targeting JAKs for proteasomal degradation, block JAK catalytic activity or compete with the receptor interactions, and physically block STAT binding. The internalization of receptor complex and the Ubiquitin-proteasome pathway-mediated degradation terminates the signaling from JAKs. An additional negative regulation of JAK-STAT signaling is mediated by PIAS proteins which binds to the dimeric STATs and inhibits its binding to the DNA.

JAK-STAT Signaling in Disease

Cytokines play a central role in the pathogenesis of immunological and inflammatory diseases, and thereby JAK kinases and their regulation are clinically relevant in these diseases. Failure in regulation of JAK–STAT pathway is a common cause of myeloid and lymphoid disorders (Hammaren et al. 2019; Virtanen et al. 2019). Numerous JAK mutations have been identified in leukemia, myeloproliferative neoplasm (MPN), solid cancers, and SCID. Gain of function mutations in JAK1 and JAK3 is commonly found in lymphoid leukemias, while activating JAK2 mutations are more recurrent in myeloid leukemias and MPN. The best characterized example is somatic JAK2 V617F mutation that is highly prevalent in MPN and causes approximately 95% of polycythemia vera (PV), 50–60% essential thrombocythemia (ET), and primary myelofibrosis (PMF) cases. Although the pathogenic TYK2 mutations are infrequent, activating mutations have been identified in acute lymphocytic and myeloid leukemia patients, and defective mutants in a few primary immunodeficiency cases. Loss-of-function germline mutations in JAK3 cause autosomal recessive type of SCID: a disease resulting in complete lack of T- and NK-cells and reduced B-cell function. Approximately half of all JAK mutations locate in the pseudokinase domain, especially clustering in the auto-inhibitory interface that highlights the critical regulatory role of the domain.

The pathogenic JAK-STAT regulation failure may also be driven by mutations in other components or regulatory elements of the pathway (Hammaren et al. 2019). For example, the majority of the inherited SCID cases are covered by loss-of-function mutations either in JAK3 (10–18%) or in JAK3-associated receptors IL-7R (<10%) and IL-2RG (25–46%). Similarly, JAK2 V617F-negative MPN patients often carry mutations in either the thrombopoietin receptor (TPOR) gene MPL (1–5% of all PMF and ET cases), in a multifunctional endoplasmic reticulum protein calreticulin (CALR; ~13% of MPNs), or in the inhibitory adaptor protein LNK (5–7% of MPNs), which result in ligand-independent activation of JAK2 signaling (MPL and CALR mutants) or TPO hyperresponsiveness (LNK mutants). SOCS as inducible negative feedback regulators of cytokine signaling may also participate in various diseases, and decreased SOCS levels due to DNA hypermethylation have been observed in cancers, while elevated SOCS levels have been found in autoimmune diseases. Activating mutations also in STATs have been found in leukemia.

Drugs

JAKs as tyrosine kinases are traditionally targeted by ATP-competitive inhibitors. Currently, six JAK inhibitors have obtained a global approval

for clinical use: ruxolitinib and fedratinib for MPNs, tofacitinib for rheumatoid arthritis (RA), psoriatic arthritis (PsA) and ulcerative colitis (UC), and baricitinib, upadacitinib, and peficitinib (Japan only) for RA as listed in Table 2. The first JAK inhibitors, i.e., ruxolitinib, tofacitinib, and baricitinib, are so-called nonselective first-generation inhibitors that target at least two JAKs at high affinity. During the past decade, the research has focused more on so-called second-generation inhibitors with higher level of selectivity on particular JAK (Virtanen et al. 2019). All the approved JAK inhibitor drugs and vast majority of the ones currently in clinical trials are type-I inhibitors that target the active site of kinase domain. Few examples of non-type-I JAK inhibitors exist: A preclinical JAK inhibitor CHZ868 is a type-II inhibitor, which stabilizes the inactive kinase conformation, and clinical (Phase III) inhibitor BMS-986165 is an allosteric type-IV inhibitor, which targets TYK2 JH2 domain.

Approved JAKinibs

Ruxolitinib

Ruxolitinib (trade names Jakafi, Jakavi) was the first JAK inhibitor drug to enter the clinic. The potent JAK1/JAK2 inhibitor (IC50 2.8/3.3 nM for JAK2/JAK1; >115-fold selectivity over JAK3, and >5-fold over TYK2) was approved (11/2011 FDA; 8/2012 EMA) for treatment of intermediate or high-risk myelofibrosis (Table 2). Ruxolitinib also was the first drug to be approved for treatment of MF and, since, has been considered as the first-line therapy option. Phase III clinical trials with ruxolitinib (COMFORT-I and -II) have demonstrated reductions in splenomegaly and disease-related symptoms as well as improvements in quality of life measures and overall survival in patients with intermediate-2 or high-risk myelofibrosis despite the JAK2 mutational status (Vainchenker and Constantinescu 2013; Plosker 2014). Ruxolitinib is generally well tolerated. Anemia and cytopenias (thrombocytopenia, neutropenia), the most common hematologic adverse events, are dose-dependent and generally manageable with dosage modifications and/or red blood cell transfusions. The most common nonhematologic side-effects are generally mild and include bruising, dizziness, and headache. Ruxolitinib has also been approved for polycythemia vera (PV) patients when there has been an inadequate response to or intolerance of hydroxyurea, the best available therapy in PV. Currently, ruxolitinib is in clinical trials for coronavirus disease 2019 (COVID-19), AD, psoriasis, RA, cancers, and several other autoimmune and inflammatory diseases.

Tofacitinib

Pan-JAK inhibitor (IC50 1.6/3.2/4.1 nM for JAK3/JAK1/JAK2; >20-fold selectivity for JAK3 over TYK2) tofacitinib (trade names Xeljanz, Jakvinus, and Tofacinix) as the second JAK inhibitor drug was approved (FDA 11/2012, EMA 3/2017) for the treatment of moderate to severe active RA in patients who had an inadequate response to the first-line-therapy methotrexate (MTX) (Table 2). Efficacy and safety of tofacitinib monotherapy and combination therapy with MTX was demonstrated for RA in Phase III ORAL trials (Salgado and Gómez-Reino 2013). Using dosages applied in clinics approximately 50–65% of the inadequate responders or patients intolerant to MTX or other disease-modifying antirheumatic drugs obtained 20% enhancement of the symptoms (ACR20). The effects were generally sustained for at least 72 months. Tofacitinib treatment, although generally well tolerated, may cause infections that are typical also for biologics, as well as, decreases in CD4+ T cell count, elevated cholesterol levels, headache, and slight reversible increase in serum creatinine levels. In patient with increased risk for thrombosis, tofacitinib is contraindicated. Tofacitinib has also been approved for moderate or severe active UC (FDA 5/2018, EMA 8/2018) and active psoriatic arthritis (FDA 12/2017; EMA 6/2018) and is in clinical trials for ankylosing spondylitis (AS), psoriasis, alopecia areata (AA), and various other inflammatory and autoimmune diseases.

Baricitinib

Baricitinib (trade names Olumiant, Baricinix) is a JAK1/JAK2 inhibitor (IC50 5.7/5.9 nM for JAK2/JAK1; >70-fold selectivity over JAK3,

Janus Kinase, Table 2 Clinical JAKinibs, target JAKs, and main indications (Phase II and higher) (ClinicalTrials.gov 2020; Biggioggero et al. 2019; Virtanen et al. 2019)

Inhibitor	Target(s)	Disease	Clinical status
Ruxolitinib (Jakavi, Jakafi)	JAK1/2	MF, PV AD, COVID-19, vitiligo, GVHD, HLH AA, RA, psoriasis, leukemia, multiple myeloma, lymphoma, solid cancers, bone marrow fibrosis, HPS, HS, and HIV	Approved Phase III Phase II
Tofacitinib (Xeljanz, Jakvinus, Tofacinix, and others)	JAK1–3	RA, PsA, UC AA, AS, Takayasu arteritis psoriasis, SLE, JIA DLE, dermatomyositis, CD, and COVID-19	Approved Phase IV Phase III Phase II
Baricitinib (Olumiant, Baricinix)	JAK1/2	RA COVID-19 AD, SLE, JIA, uveitis psoriasis, giant cell arteritis, primary biliary cholangitis, AGS, IIM, and diabetic kidney disease	Approved Phase IV Phase III Phase II
Fedratinib (Inrebic)	JAK2	MF	Approved
Upadacitinib (Rinvoq)	JAK1	RA PsA, AS, CD, UC, giant cell arteritis, AD, Takayasu arteritis, and HS SLE	Approved Phase III Phase II
Peficitinib (Smyraf)	pan-JAK	RA UC, psoriasis	Approved (Japan) Phase II
Filgotinib	JAK1	RA, UC, CD, PsA AS, Sjögren syndrome, cutaneous lupus, lupus nephropathy, and uveitis	Phase III Phase II
Abrocitinib (PF-04965842)	JAK1	AD	Phase III
Momelotinib	JAK1/2	MF	Phase III
Pacritinib	JAK2	MF, COVID-19	Phase III
NS-018	JAK2	MF	Phase I/II
Gandotinib (LY-2784544)	JAK2	MPNs	Phase II
Cerdulatinib	JAK2	Vitiligo Lymphomas	Phase II Phase I/II
Decernotinib (VX-509)	JAK3	RA	Phase II/III
PF-06651600	JAK3	AA RA, UC, CD, vitiligo	Phase III Phase II
BMS-986165	TYK2	Psoriasis SLE, lupus nephritis, UC, and PsA	Phase III Phase II
PF-06826647	TYK2	UC, psoriasis, and HS	Phase II

MF myelofibrosis, *PV* polycythemia vera, *AD* atopic dermatitis, *COVID-19* coronavirus disease 2019, *GVHD* graft-versus-host disease, *HLH* hemophagocytic lymphohistiocytosis, *AA* alopecia areata, *RA* rheumatoid arthritis, *HPS* hemophagocytic syndrome, *HS* hidradenitis suppurativa, *HIV* human immunodeficiency virus, *PsA* psoriatic arthritis, *UC* ulcerative colitis, *AS* ankylosing spondylitis, *SLE* systemic lupus erythematosus, *JIA* juvenile arthritis, *DLE* discoid lupus erythematosus, *CD* Crohn's disease, *AGS* Aicardi Goutieres syndrome, *IIM* idiopathic inflammatory myopathies, *MPN* myeloproliferative neoplasm

and >10-fold over TYK2) structurally analogous to ruxolitinib. Baricitinib was approved for treatment of moderate-to-severe active RA in patients who have responded inadequately to, or who are intolerant to, one or more disease-modifying antirheumatic drugs (EMA 02/2017) or in patients

who have had an inadequate response to one or more tumor necrosis factor (TNF) antagonists (FDA 05/2018). Baricitinib has proven to be superior to placebo and TNF-blocker adalimumab in MTX background for RA patients with inappropriate response to MTX (Taylor et al. 2017). The improvements in baricitinib arm were statistically significant at week 1 compared to placebo and at week 2–4 compared to adalimumab, and the measures of efficacy maintained or improved through week 52. Adverse events were more frequent in baricitinib and adalimumab arms compared to placebo, and similar between baricitinib and adalimumab arms. Very common ($\geq$1/10) side effects for baricitinib are upper respiratory tract infections, hypercholesterolemia, whereas common ($\geq$1/100 to $<$1/10) side effects include other infections (herpes zoster, herpes simplex, urinary tract infections, and gastroenteritis), thrombocytosis, nausea, and hepatobiliary disorders. Anemia is a dose-dependent adverse event of baricitinib but has not been reported being an issue in RA patients at approved dosages (2 mg and 4 mg once daily). Baricitinib is in Phase IV clinical trials for COVID-19, and in Phase III trials for atopic dermatitis (AD), systemic lupus erythematosus (SLE), juvenile arthritis (JIA), and uveitis (Table 2).

Fedratinib

Fedratinib (trade name Inrebic) is a selective JAK2 inhibitor (IC50 of 3 nM for JAK2; 35-fold selectivity over JAK1, 135-fold over TYK2, and 334-fold over JAK3) (Wernig et al. 2008; Bewersdorf et al. 2019). Other primary targets of the inhibitor are kinases FLT3 (IC50 15 nM) and RET (IC50 48 nM). Fedratinib was recently (FDA 8/2019) approved for treatment of intermediate-2 or high-risk primary or secondary MF (Table 2). In Phase III JAKARTA trials, fedratinib was demonstrated significantly to reduce splenomegaly and symptom burden compared to placebo. More importantly, fedratinib was shown to be clinically effective in some ruxolitinib-resistant or intolerant patients. Three-fourth of common grade side effects include anemia (58%), fatigue (13%), gastrointestinal events, and nausea. Rare cases of Wernicke's encephalopathy resulted in a boxed warning for the drug.

Upadacitinib

Upadacitinib (trade name Rinvoq) is a so-called next-generation JAK inhibitor selective for JAK1 (IC50 45 nM for JAK1; 74-fold over JAK2, and 58-fold over JAK3). Upadacinib is a type-I inhibitor, the selective nature of which arises from utilization of differences in the nonconserved interactions outside the active ATP-pocket of JAK1 and JAK2 (Virtanen et al. 2019). Upadacitinib was recently approved (FDA 8/2019, EMA 12/2019) for the treatment of moderate to severe active RA, which is not controllable with methotrexate. In clinical trials, upadacitinib demonstrated fast response and efficacy shown by significant differences in ACR20 response rates compared to placebo already at week 2 after the start of the treatment. Upadacitinib treatment led to dose-dependent elevation of LDL and HDL cholesterol levels, while the LDL:HDL ratio remained unchanged. Dose-dependent reduction in hemoglobin levels also was observed, suggesting the possibility of JAK2 inhibition, especially at higher doses. Currently, Phase 2 and 3 trials are ongoing with upadacitinib for several indications, such as, AD, UC, CD, PsA, and SLE (Table 2).

Peficitinib

Peficitinib (trade name Smyraf) is pan-JAK inhibitor displaying moderate selectivity towards JAK3 (IC50 3.9/5.0/0.71/4.8 for JAK1/JAK2/JAK3/TYK2) (Markham and Keam 2019). Peficitinib was recently (3/2019) approved in Japan for treatment of moderate to severe active RA in patients who have an inadequate response to conventional therapies. In clinical trials, peficitinib showed statistically significant reduction of RA symptoms with similar responses as seen with nonselective JAKinibs. The adverse events also were similar to those displayed by nonselective JAKinibs, e.g., neutropenia, but increase rather than decrease in hemoglobin was observed. In a recent Phase 2b study for UC, peficitinib failed to show dose-response although at higher doses it displayed a trend for increased rates of clinical response and remission as well as mucosal healing. Peficitinib is currently assessed in Phase 2 for psoriasis and UC (Table 2).

JAKinibs in Clinical Trials

JAK1-Selective Inhibitors

JAK1 selective inhibitors target the broadest cytokine profile among the JAKs (Table 1). JAK1 has been suggested to dominate in IL-2-induced JAK1/JAK3 and IL-6-induced JAK1/JAK2/TYK2 signaling pathways, and either or both have been implicated in pathogenesis of most inflammatory or autoimmune diseases, implying that selective JAK1 inhibition provides efficacy in treatment of various inflammatory diseases. Although the JAK1-selective inhibitors target a broad cytokine spectrum and therefore the safety might be questionable, the inhibitors still spare JAK2-dependent EPO and TPO pathways responsible for side effects such as anemia, neutropenia, and thrombocytopenia. Upadacitinib was the first JAK1-selective inhibitor approved for the clinics, while filgotinib was the first JAK1-selective JAKinib to enter clinical trials (Virtanen et al. 2019). Filgotinib displays roughly 30-fold selectivity over JAK2 in whole blood assays, was efficacious in preclinical mouse model for arthritis, and was found not to interfere with JAK2 signaling in a Phase 1 study. In Phase II studies for RA, filgotinib demonstrated dose-dependent clinical efficacy with an early onset of action and was well tolerated with infections being the most frequent adverse event. Increase in hemoglobin was observed and attributed to reduced inflammation and lack of JAK2 inhibition. Currently, filgotinib is in Phase 3 trials for RA, UC, CD, and PsA. Other JAK1-selective inhibitors currently in clinical trials include abrocitinib, itacitinib, and solcitinib (Table 2).

JAK2-Selective Inhibitors

JAK2 signaling has critical roles in hematopoiesis, and therefore targeting JAK2 by inhibitors generally leads to dose-dependent hematological adverse events of anemia and cytopenias (Bewersdorf et al. 2019). However, hyperactive JAK2 signaling is in central role in pathogenesis of MPNs, which is the rationale for JAK2-selective inhibitors. Currently, JAK2-selective fedratinib has been approved for treatment of myelofibrosis, while pacritinib (56-fold selectivity over JAK1) is in Phase III clinical trials (Table 2). In addition to JAK2, pacritinib targets FLT3, IRAK1, and CSF1R. It has demonstrated significant improvements in efficacy compared to ruxolitinib, the best available therapy, as well as efficacy in some patients who previously had failed or were intolerant for ruxolitinib treatment. Thrombocytopenia, anemia, and gastrointestinal adverse events were the most common adverse events. Development of pacritinib was shortly placed on hold in 2016 due to few deaths caused by heart failure and intracranial hemorrhage. The hold was lifted after close review of the cases.

JAK3-Selective Inhibitors

JAK3 together with the signaling partner JAK1 has a central role in the regulation of immune responses, and therefore it is considered as a relevant target for immunosuppression. The expression of JAK3 is confined to hematopoietic cells, which implies that selective targeting of JAK3 in autoimmune diseases could escape the non-immunological side effects, e.g., neutropenia and anemia (Virtanen et al. 2019). Peficitinib, the approved JAKinib in Japan, and decernotinib assessed in Phase II/III clinical trials for RA have moderate JAK3 selectivity, whereas PF-06651600 currently in Phase III for AA targets JAK3 with high specificity (Table 2). PF-06651600 was developed by structure-guided design to covalently target JAK3. It is the only covalent, irreversible JAK inhibitor in clinical trials and acts through a nonconserved cysteine (Cys909) in the ATP-pocket of JAK3 kinase domain. PF-06651600 is potent and highly selective inhibitor with negligible potency toward other JAKs allowing a selective inhibition of signaling through γc cytokines. Kinome scans have revealed the only off-targets being TEC family of kinases, which share the cysteine in the same position in the active site as JAK3. PF-06651600 has demonstrated remarkable efficacy, in Phase II trials for AA, and was granted (Pfizer 2019) Breakthrough Therapy designation from US FDA. The most common side effects in the AA clinical study were the infections, gastrointestinal and skin/subcutaneous tissue-related. Herpes zoster reactivation was not observed.

TYK2-Selective Inhibitors

Biologics targeting TYK2 cytokine signaling pathways (IL-12/IL-23, IFNα, and IL-6) have proven efficacious in treatment of various autoimmune diseases including RA, UC, psoriasis, PsA, and AS, which gives rationale for development of TYK2-selective JAKinibs (Virtanen et al. 2019). BMS-986165 is an allosteric TYK2 pseudokinase-domain-binding inhibitor, which, despite strong binding to JAK1, via unique and mostly unknown mechanisms inhibits selectively TYK2-mediated cytokine signaling. The allosteric inhibitor currently is in Phase III for psoriasis, and in Phase II trials for SLE, lupus nephritis, UC, and PsA (Table 2). In Phase 2 study of 267 patients with moderate-to-severe psoriasis, BMS-986165 demonstrated greater clearance of psoriasis and improvements in quality of life compared to placebo. Most common treatment-related adverse events included nasopharyngitis, headache, diarrhea, nausea, and upper respiratory tract infections.

Kallidin (Lysyl-Bradykinin)

► Kinins

Kinins

Thomas Renné[1] and Heiko Herwald[2]
[1]University Medical Center Hamburg (UKE), Hamburg, Germany
[2]Lund University, Lund, Sweden

Synonyms

Bradykinin; DesArg^{10}-kallidin (Lys^{0}, desArg^{9}-bradykinin); DesArg^{9}-bradykinin; Kallidin (lysyl-bradykinin); T-kinin (Ile-Ser-bradykinin)

Definition

Kinins are a group of short-lived proinflammatory peptide hormones that bind to G-protein-coupled receptors and trigger Ca^{2+}-dependent nitric oxide and/or prostaglandin-dependent signaling pathways.

Inflammation
Nociception
Blood pressure
Edema

Basic Characteristics

Liberation of Kinins

Kinin hormones are locally produced on cell surfaces by limited proteolysis from their precursors, the kininogens (Fig. 1).

In humans, two types of kininogens are circulating in plasma, namely high-molecular-weight kininogen (H-kininogen, HK) and low-molecular-weight kininogen (L-kininogen, LK). The human kininogens result from alternative splicing of a single *KGN1*gene. A third type of kininogen, T-kininogen, is exclusively found in rats but not in other mammalians. Kininogens are predominantly expressed by the liver and secreted by hepatocytes into the circulation. The kidney and some secretory glands also express kininogens.

Kininogens are processed by kinin-liberating enzymes named kallikreins. Kallikreins are a group of serine proteases that are expressed by hepatocytes and glandular cells, neutrophils in their zymogen forms. Kallikreins are found in biological fluids such as plasma and urine. In humans, two types of kallikreins exist: tissue kallikrein and plasma kallikrein. Despite their similarities in name, the serine proteases differ in their structure, function, and expression. Tissue kallikrein (TK) mostly utilizes L-kininogen as the substrate to produce the kinin kallidin, whereas plasma kallikrein (PK) acts mostly if not exclusively on H-kininogen to generate the bradykinin (BK) hormone (Table 1). The substrate specificity of kallikrein for H-kininogen is due to the fact that

kallikrein is tightly bound to a substrate. The bimolecular complex circulates in the blood and attaches to cell surfaces (Weidmann et al. 2017). In addition to kallikreins, kinins can also be released by other proteases such as trypsin, elastase, or cathepsin D; however, the biological significance of these kininogenases has remained unknown. Apart from mammalian kininogenases, a large number of proteases derived from microorganisms have the capacity for liberating kinins

from host kininogens with implications for bacteria- and parasite-driven inflammatory and infectious reactions.

Kinins are short-lived peptide hormones with plasma half-lives in the second range that are rapidly proteolytically converted and/or inactivated. Active hormones bradykinin and kallidin are chopped at their carboxyterminal ends by carboxypeptidases of the N and M type, collectively referred to as kininases type I. Processing leads to desArg^9-bradykinin and desArg^{10}-kallidin, respectively (Table 1). Bradykinin and kallidin act on B_2 receptors, but desArg^9-bradykinin and desArg^{10}-kallidin activate B_1 receptors. Together, the proteolytic conversion of the kinins "switches" the relative binding affinity of the ligands for the two kinin B_1 and B_2 receptors, respectively (Fig. 1). DesArg^{10}-kallidin and des Arg^9-bradykinin are rapidly degraded by the dipeptidylpeptidase angiotensin-converting enzyme (ACE), also known as kininase type II, and neutral endopeptidase, respectively (Table 1). In humans and some other mammalian species, kininogens are modified by posttranslational hydroxylation of a proline residue within their kinin sequence, that is, position 3 in bradykinin or position 4 in kallidin. Hydroxylation does not affect the specificity, affinity, or intrinsic efficacy of the kinins.

Bradykinin

The best characterized kinin is bradykinin (from the Greek brady-, slow; −kinin, kīn(eîn) to move). The nine-amino acid peptide is mostly if not exclusively produced by the plasma contact system, comprising the proteases factor XII (FXII) and plasma kallikrein. The name "contact system" originates from the unique mode of FXII zymogen activation following binding ("contact") to negatively charged surfaces that induce a conformational shift leading to limited proteolytic activity. Initially, a small amount of active FXII (FXIIa) is formed that in turn converts plasma kallikrein to the active protease PKa. PK then reciprocally activates new FXII zymogens. The feedback loop amplifies FXII activation and initiates the intrinsic pathway of coagulation via FXIIa-mediated activation of Factor XI. Additionally, formed PKa cleaves H-kininogen to release bradykinin (Kallikrein-kinin system, Fig. 3). The bradykinin-forming contact system components bind to endothelial cells, platelets, and neutrophils with H-kininogen serving as a docking site for kallikrein. H-kininogen binds to cells via heparan and chondroitin sulfate glycosaminoglycans (GAG) of cell surface proteoglycan. FXII may also bind to GAGs, facilitating contact system protein assembly on endothelial cells. GAGs do not only assemble contact system proteins on cellular surfaces, the polysaccharide also regulates kinin generation. H-kininogen binding to GAGs interferes with contact system-driven bradykinin generation, indicating that H-kininogen needs to dissociate from GAGs to allow for efficient plasma kallikrein-mediated kinin formation (Maas and Renne 2018).

An array of synthetic polymers has the capacity for initiating FXII contact activation leading to bradykinin formation. Within the last decade, natural FXII contact activators have been identified including misfolded protein aggregates, DNA/RNA, collagens, and the inorganic polymer polyphosphate (polyP). Platelet- and bacteria-derived polyphosphate form insoluble Ca^{2+}-rich nanoparticles that potently initiate bradykinin formation in an FXII- dependent manner, and targeting polyphosphate ablates their proinflammatory activity, for example, in edema models. Furthermore, the FXII activator platelet polyphosphate has potent procoagulant activities with implication for thrombosis (Mailer et al. 2019).

Diagnostics of Kinins

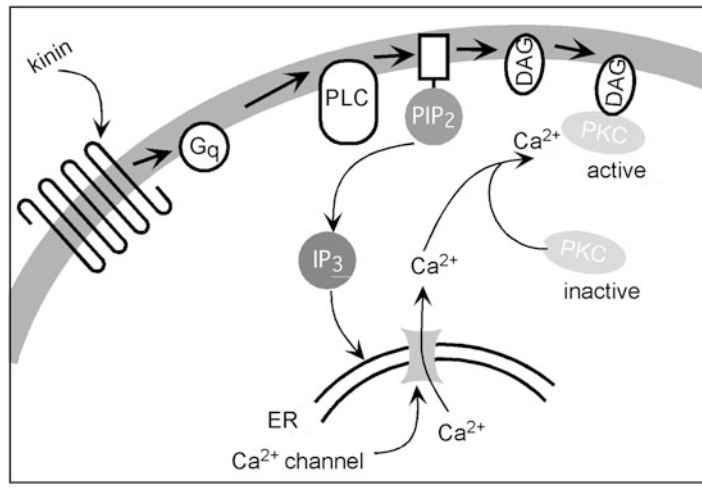
Analysis of kinins has remained challenging due to their short half-life and artificial contact-mediated production during sampling and storage. HPLC-based and RIA/capture-EIA measurements are established to determine kinins in human plasma, liquor, or urine in experimental studies. Most accurate kinin measurements are mass spectrometry-based methods that either determine the kinin hormones directly or indirectly via measuring H-kininogen/L-kininogen breakdown products. Furthermore, cleaved H-kininogen (cHK, that is devoid of the kinin moiety) has been established as a biomarker for

kinin generation with implications for clinical trials. Serine protease inhibitors targeting active FXII and plasma kallikrein need to be added to prevent artificial generation of kinins in vitro during sample preparation. Kinins and their degradation products have been studied in various biological milieus such as plasma/serum, urine, joint fluids, kidney, lung, and skeletal muscles. Under physiological conditions, the concentration of kinins in these compartments is low in the femtomolar and lower picomolar range. In contrast, plasma levels of kininogens are in the micromolar range, that is, the ratio of hormone to precursor is low and kinin release is tightly controlled. Kinin levels can rise considerably (>100-fold) in patients with diseases such as hereditary angioedema, rheumatoid arthritis, or sepsis and septic shock. Kinin levels correlate with the severity of the disease state (van der Poll and Herwald 2014).

Chromogenic substrates including H-D-prolyl-L-phenylalanyl-L-arginyl-*p*-nitroanilide and *N*-benzoyl-L-propyl-L-phenylalanyl-L-arginyl-*p*-nitroanilide are available for measuring the proteolytic activity of plasma kallikrein. Synthetic kallikrein inhibitors such as diisopropyl fluorophosphate (DFP), L-phenyl-L-phenyl-L-arginyl-chlormethylketone, or *p*-amidino-phenylmethylsulfonyl-fluoride (PMSF) covalently bind to the catalytic triad serine and thus completely block the proteolytic activity of the enzyme. The major inhibitor of kallikrein in human plasma is the C1 esterase inhibitor (C1INH), which belongs to the large family of serine protease inhibitors (serpins). In addition, α2-macroglobulin (α2M), antithrombin III, plasminogen activator inhibitor-1, and protein C inhibitor interfere with plasma kallikrein activity in plasma and on cell surfaces with implications for kinin formation.

Kinin Receptors

Cellular kinin functions are mediated by their interaction with cell surface receptors (Fig. 2). In humans, two types of kinin receptors have been identified, namely kinin B_1 and B_2 receptors. The two receptors are coded by two distinct genes on closely apposed loci in human chromosome 14q32. *Bdkr1* and *Bdkr2* genes likely arose from a common progenitor. Kinin B_1 and B_2 receptors belong to the large family of G-protein-coupled



Kinins, Fig. 2 Intracellular signaling cascades triggered by kinins. Following kinin binding the receptor, the associated heterotrimeric G protein complex dissociates. The α subunit stimulates phospholipase C (PLC), which in turn catalyzes the breakdown of phosphatidylinositol-4,5-bisphosphate (PIP_2) into 1,2-diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3). IP_3reacts with Ca^{2+} channels in the endoplasmic reticulum (ER) releasing Ca^{2+} into the cytosol. The increase in intracellular Ca^{2+} levels activates protein kinase C (PKC), which translocates to the plasma membrane, anchoring to DAG and phosphatidylserine

receptors characterized by seven transmembrane-spanning helices. Unlike B_2 receptors that are constitutively expressed in many cell types and tissues, the expression levels of B_1 receptors are very low under physiological conditions. However, inflammatory or noxious stimuli boost expression of the B_1 receptor. Several cytokines such as interleukin IL-1β, as well as growth factors and bacterial lipopolysaccharides, upregulate transcription of *Bdkr1* (Qadri and Bader 2018). B_1 and B_2 receptors are predominantly coupled to the pertussis toxin-insensitive G_q type of G protein leading to phospholipase C activation, mobilization of intracellular calcium by inositol-1,4,5-trisphosphate (IP_3), and activation of protein kinase C. Kinin receptors are stimulators of the biosynthesis of potent downstream effectors such as prostaglandins and leukotrienes due to phospholipase A_2 activation, and of nitric oxide via stimulation of the endothelial isoform of nitric oxide synthase (eNOS).

Kinin Receptor-Deficient Mice

Homozygous B_1 or B_2 receptor-deficient mice are healthy, fertile, and normotensive. In B_1-deficient mice, lipopolysaccharide-induced hypotension is diminished, recruitment of polymorphonuclear leukocytes to the sites of tissue injury is impaired, and the animals show signs of hypoalgesia. Deletion of the B_2 gene in mice leads to salt-sensitive hypertension and altered nociception. B_2 receptor-deficient embryos subjected to salt stress in utero show suppressed renin expression, an abnormal kidney phenotype, and develop early postnatal hypertension. Consistently, although basal bradykinin formation is reduced, tissue kallikrein-null mice have normal blood pressure and however suffer from cardiovascular abnormalities, which support a function of kinins during development. Mice deficient in both kinin receptors have been generated that are normotensive but protected from endotoxin-induced hypotension supporting a function for kinins in infectious and inflammatory disease states.

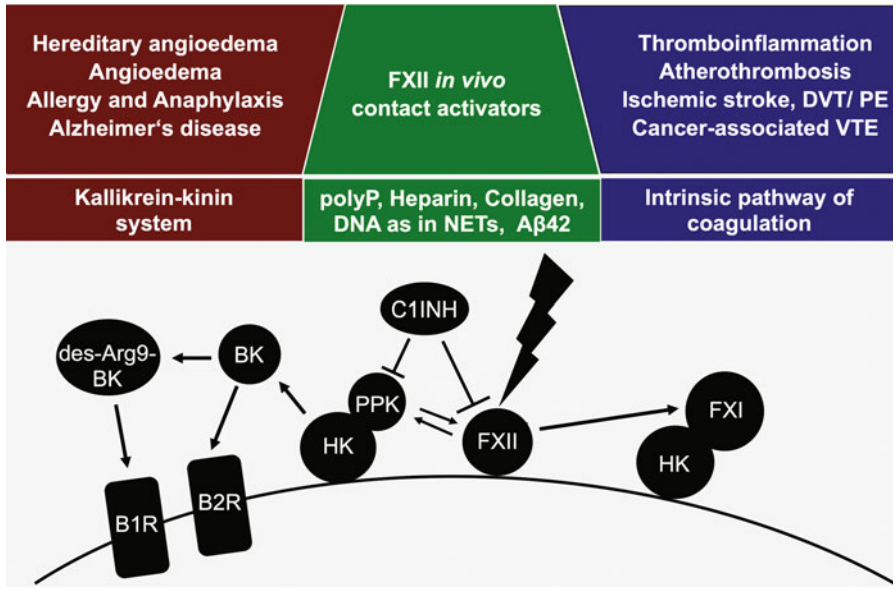
Biological Functions and Clinical Implications

Kinins are implicated in many physiological and pathological processes including the induction of pain and hypotension, contraction of smooth muscles, regulation of local blood flow, stimulation of electrolyte fluxes, activation of sensory neurons, and increase of vascular permeability. Many of these effects are triggered at least in part via the major downstream effectors prostaglandins, leukotrienes, the small GTPase Cdc42, and nitric oxide.

Bradykinin shows a variety of physiological and pathological effects. The hormone induces contraction of nonvascular smooth muscle in the bronchus and gut and relaxes vascular smooth muscle cells leading to hypotension, natriuresis and diuresis, and decrease in blood glucose level. It is a mediator of inflammation and causes an increase in vascular permeability, stimulation of nociceptors, and release of other mediators of inflammation (e.g., prostaglandins). It has a cardioprotective effect (directly via bradykinin action and indirectly via endothelium-derived relaxing factor action).

Uncontrolled activation of the FXII-driven contact system (Fig. 3) triggers massive formation of kinins under certain pathological conditions. The best-studied kinin-mediated disease is hereditary angioedema (HAE), a life-threatening swelling disorder. Three different types of HAE exist that are either due to deficiency in C1 esterase inhibitor (C1INH, the major inhibitor of PKa and FXIIa; Type I), defective C1INH function (Type II), or an FXII point mutation at Thr309 that causes loss of a single glycosylation site leading to excessive FXII contact activatability (Type III).

Angioedema (AE) has been associated with angiotensin-converting enzyme (ACE) inhibitor intake. ACE degrades kinins (Table 1) and interferes with kinin metabolism leading to kinin accumulation and kinin-mediated swellings and coughing. Furthermore, excess bradykinin formation is seen in patients with a systemic inflammatory response syndrome (SIRS) due to sepsis or trauma. SIRS progression is accompanied by depletion of contact system factors, and low levels of H-kininogen and plasma kallikrein are indicative of a fatal outcome. Other diseases associated with a massive, often systemic release of kinins are pancreatitis, Alzheimer disease (AD), allergic



Kinins, Fig. 3 The factor XII (FXII)-driven contact system and its roles in diseases. Polyphosphate (polyP), mast cell-derived heparin, collagen, nucleic acids (DNA and RNA), and misfolded protein aggregates such as Aβ42 induce FXII contact activation in vivo. Activated FXII (FXIIa) triggers fibrin formation through the factor XI (FXI)-mediated intrinsic coagulation pathway, contributing to thrombo-inflammation, atherothrombosis, ischemic stroke, venous thromboembolism such as deep vein thrombosis (DVT), pulmonary embolism (PE), and cancer-driven VTE. FXIIa also activates plasma kallikrein (PK) leading to release of bradykinin (BK) by active plasma kallikrein (PKa)-mediated cleavage of high-molecular-weight kininogen (HK). Both FXI and PK are bound indirectly to cells via HK. Bradykinin activates kinin B2 receptors (B2R), while the BK metabolite des-Arg9 BK binds to kinin B1 receptor (B1R), both of which activate proinflammatory signaling cascades that contribute to increased vascular leak in HAE and others such as angiotensin-converting enzyme (ACE) inhibitor-induced angioedema, allergic and anaphylactic reactions, and vascular dysfunction in patients with Alzheimer disease. Serpin C1 esterase inhibitor (C1INH) is the major inhibitor of both activated FXII and PK. (Adapted from (Nickel et al. 2017))

and nonallergic rhinitis, and asthma (Fig. 3). Notably, kinins are important endogenous mediators exerting acute protective effects in the ischemic myocardium via nitric oxide-dependent mechanisms.

Drugs

Aprotinin (Trasylol®) was the first drug to be used in the clinic to prevent the formation of kinins. However, due to aprotinin's anaphylactic potential, the use of Trasylol has raised serious concern worldwide and has been withdrawn from the market. To target plasma kallikrein activities, a specific inhibitor (Ecalantide ®) and neutralizing antibody (Takhzyro®) were introduced for acute and prophylactic treatment of hereditary angioedema of attacks. Furthermore, a variety of plasma-derived and recombinant C1INH are approved for interference with kinin formation in HAE types I and II. Alternatively, a peptide-based inhibitor of B2 receptors (Icatibant®) is used to prevent swellings of HAE patients and possible other kinin-driven alterations of vascular leak such as burn injuries.

In addition to this inhibitor, a large number of specific B_1 and B_2 receptor antagonists and agonists have been developed, and data from clinical trials suggest potential future use of these agents in SIRS, sepsis, ischemic and traumatic brain injury, hyperalgesia, and angioedema.

Angiotensin-converting enzyme (ACE) inhibitors represent a class of drugs that have proven

anti-hypertensive and anti-proteinuric effects. They delay the progression of renal disease in conjunction with the ability to reduce systemic blood pressure. Furthermore, they have been shown to reduce mortality and morbidity in myocardial infarction associated with chronic heart failure. The cardioprotective effect of ACE inhibitors is a combined result of the diminished conversion of angiotensin I and of the attenuated kinin breakdown leading to kinin accumulation in ischemic myocardia. Given their pleiotropic effects, ACE inhibitors may well use alternative mechanism(s) to exert their beneficial roles, for example, through the resensitization of kinin receptors.

Wall peptidoglycan inhibitors; Lactam β antibiotics

Definition

β-Lactam antibiotics are bicyclic or monocyclic azetidinone ring-containing compounds (Fig. 1). They kill bacteria by preventing peptide cross-linking in the assembly of peptidoglycan. This covalently closed net-like polymer forms the matrix of the cell wall by which the bacteria can grow and divide despite their high internal osmotic pressure.

Mechanism of Action

Peptidoglycan (Fig. 2) is comprised of glycan chains made of alternating β-1,4-linked *N*-acetylglucosamine and *N*-acetylmuramic acid residues (Vollmer et al. 2008). The D-lactyl groups on carbon C_3 of the muramic acids are substituted by L-alanyl-γ-D-glutamyl-L-diaminoacyl-D-alanine stem tetrapeptides. The peptides borne by adjacent glycan chains are cross-linked by the DD-transpeptidases (DD-TPases) through direct linkages or cross bridges (comprising one or several intervening amino acid residues) that extend from the D-alanine residue at position 4 of a stem peptide to the ω-amino group at position 3 of another stem peptide ((4–3) peptidoglycan). Lipid II (Fig. 3) is the immediate biosynthetic precursor. A disaccharide bearing an L-alanyl-γ-D-glutamyl-L-diaminoacyl-D-alanyl- D-alanine stem pentapeptide (the diamino acid residue of which can be either free, i.e., unsubstituted, or substituted by one or several amino acid residues, i.e., branched) is synthesized in the cytoplasm and transported to the outer face of the plasma membrane, linked to a C_{55}-undecaprenyl via a pyrophosphate. From this precursor, the formation of polymeric peptidoglycan relies on glycosyl transferases (GTases) ensuring glycan chain elongation and acyl transferases (DD-Tpases) ensuring peptide cross linking.

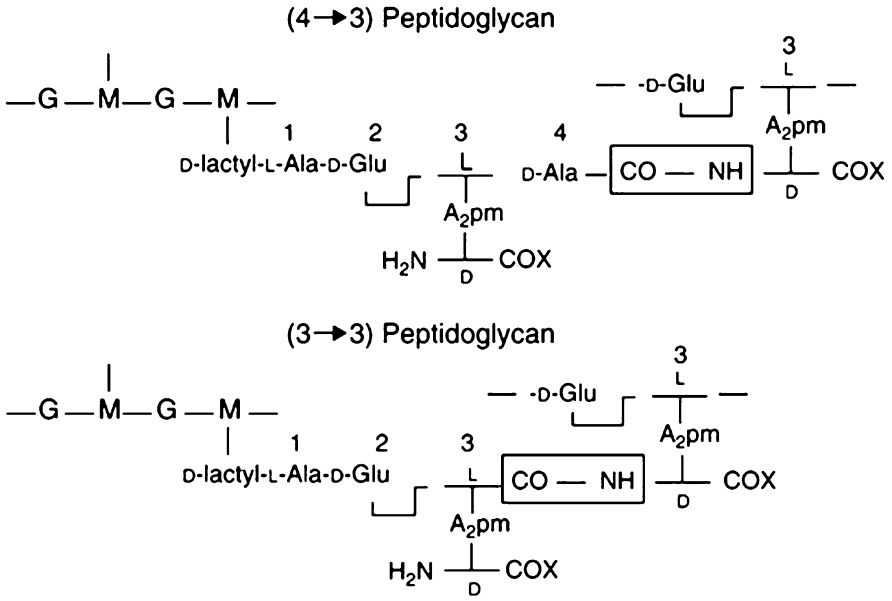
β-Lactam Antibiotics, Fig. 1 Bicyclic (penams, 3-cephems, oxacephems, and carbapenems) and monocyclic (monobactams, e.g., aztreonam) β-lactam antibiotics. In carbapenems, the methylene in the 5-membered ring can be substituted by a methyl group. Rupture of the scissile amide bond of the azetidinone ring (arrow) by the SXXK acyl transferases implicated in (4–3) peptidoglycan synthesis results in the formation of long-lived, serine-linked acyl ester derivatives. Thus, these enzymes behave as penicillin-binding proteins or PBPs

Acyl transferases of the SXXK superfamily (SXXK Acyl Transferases, also called DD-transpeptidases, with X denoting a variable amino acid residue) are implicated in cross-linking and they exhibit a specific bar code in the form of three motifs, SXXK, SXN (or analogue), and KTG (or analogue), occurring at equivalent distances along the polypeptide chains (Sauvage et al. 2008). As a result of the polypeptide folding, the motifs are brought close to each other at the immediate boundary of the catalytic center between an all-α and an α/β domains. SXXK acyl transferases identify *N*-acyl-D-alanyl-D-alanine sequences as carbonyl donors, produce an *N*-acyl-D-alanyl moiety linked as an ester to the serine residue of the invariant SXXK motif, and transfer the peptidyl moiety onto an amino group (DD-transpeptidation) or a water molecule (DD-carboxypeptidation). SXXK



β-Lactam Antibiotics, Fig. 2 (4–3) Peptidoglycan (the cross-linking of which, catalyzed by PBPs, is susceptible to β-lactam antibiotics) and (3–3) peptidoglycan (the cross-linking of which, catalyzed by LD-transpeptidase or LDTs, is resistant to most β-lactam antibiotics with the exception of carbapenems, see below, PBP-mediated resistance) in *Escherichia coli* and *Mycobacterium tuberculosis*. G: *N*-acetylglucosamine. M: *N*-acetylmuramic acid (i.e., *N*-acetylglucosamine with a D-lactyl substituent on carbon C_3). A_2pm: *meso*-diaminopimelic acid. In *E. coli* and *M. tuberculosis*, the stem peptides are unbranched. COX: COOH (in *E. coli*) or $CONH_2$ (in *M. tuberculosis*)

acyl transferases recognise penicillin (used as a generic term for β-lactam antibiotics) as a suicide carbonyl donor. Because the serine-ester linked penicilloyl enzymes formed by SXXK acyl transferases generally exhibit long half-lives, they remain immobilized in the form of penicillin-bound proteins, hence the DD-transpeptidases (and DD-carboxypeptidases) are usually called PBPs for Penicillin Binding Proteins (Sauvage et al. 2008). The inactivation reaction involves the formation of an acylenzyme as shown in Fig. 4 where E-OH is the enzyme with -OH the hydroxyl group of its active-site serine residue.

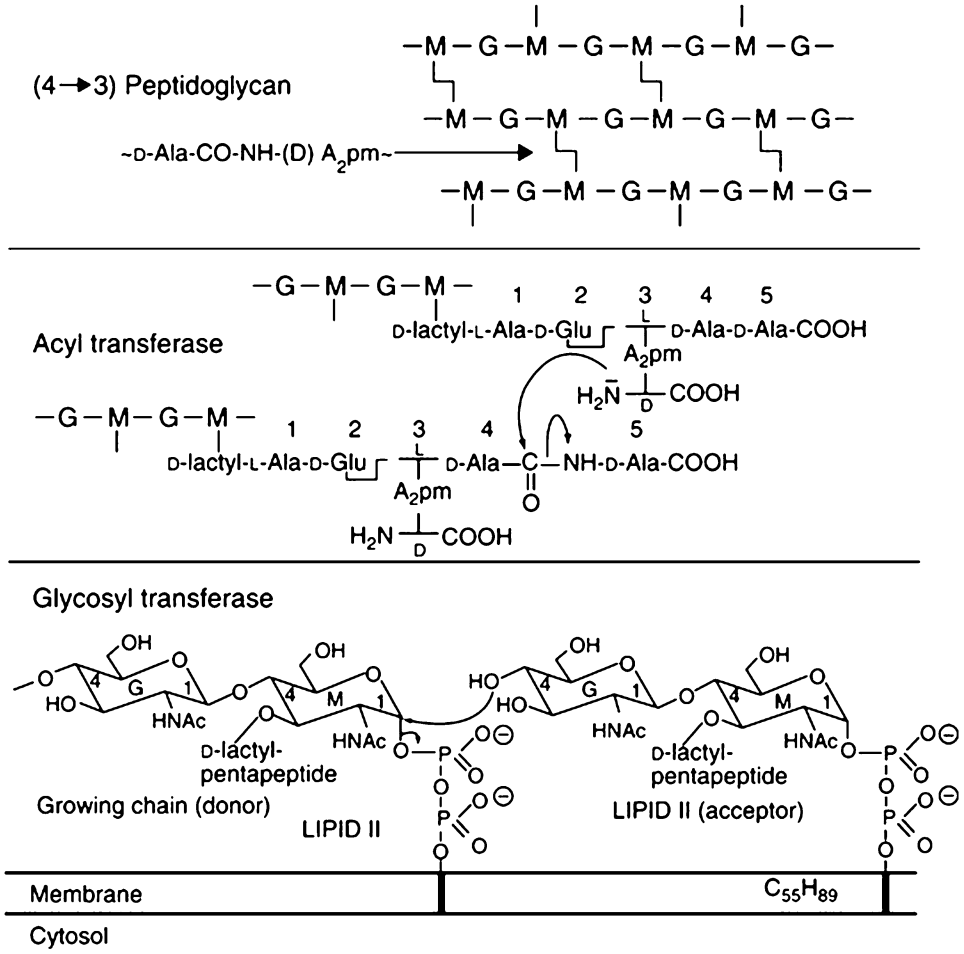
Kinetically, the interaction is described by a three-step model (Fig. 5) where E is the enzyme, I the β-lactam and P(s) the product(s) resulting from the very slow decay of EI*.

In all cases, k_3 has been found to be very small and K is generally large so that the sensitivity of a PBP to a β-lactam is best characterized by the k_2/K ratio (Frère et al. 1975). This ratio varies from 100,000 to 1,000,000 $M^{-1}s^{-1}$ for the most sensitive PBP to less than 1 for the most resistant.

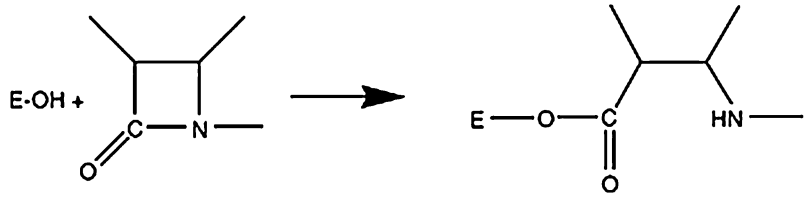
Lethal Target Proteins

A constellation of genes code for PBPs of varying amino acid sequences and functionalities. The PBP functional domain can be associated with additional domains whose exact function is not always clear. This combinatorial system of structural modules results in a large degree of diversity.

Penicillin-binding proteins are historically divided based on their molecular mass into two group known as high and low molecular mass (HMM, LMM) PBPs (Sauvage et al. 2008). HMW-PBPs are involved in the late stages of peptidoglycan polymerization while LMW-PBPs, also referred to as class C PBPs, are mainly peptidoglycan hydrolases (carboxypeptidases, endopeptidases) involved in the remodeling and recycling of peptidoglycan. Loss of these auxiliary proteins causes varying morphological aberrations but is not fatal, at least in the laboratory environment. As a result, HMM-PBPs are the primary targets of β-lactam antibiotics. HMM-PBPs are mostly multidomain enzymes divided

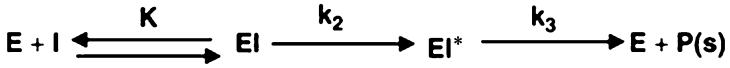


β-Lactam Antibiotics, Fig. 3 Lipid II precursor (bottom) and polymeric (4–3) peptidoglycan of *Escherichia coli* and *Mycobacterium tuberculosis*. Glycosyl transferase and acyl transferase-catalyzed reactions. G: *N*-acetylglucosamine. M: *N*-acetylmuramic acid. A $_2$pm: *meso*-diaminopimelic acid. (3–3) Peptidoglycan cross-linking (Fig. 2) may proceed via the formation, in a penicillin-resistant (but not carbapenem-resistant) manner, of an *N*-acyl-L-diaminoacyl moiety linked as an ester to the cysteine residue and the transfer of the peptidyl moiety to the ω-amino group of the diamino acid residue of another peptide



β-Lactam Antibiotics, Fig. 4 Inactivation reaction of PBPs (E-OH) by β-lactams. The covalent adduct (the acyl enzyme) is referred to as EI* in Fig. 5

in two classes A and B (aPBP and bPBP, respectively) based on their domain organization and function (Sauvage et al. 2008; Sauvage and Terrak 2016). In aPBPs the DD-TPase domain is invariably linked to an N-terminal GTase domain. The latter converts the disaccharide–pentapeptide units borne by lipid II precursor molecules into uncross-linked glycan chains. Peptide



β-Lactam Antibiotics, Fig. 5 Three-step kinetic model describing the interaction of a PBP enzyme (E) and a β-lactam (I). EI and EI* are respectively a non-covalent complex (dissociation constant: K) and a covalent adduct. EI* is the ester depicted in Fig. 4. k_2 and k_3 are first-order rate constants

cross-linking between elongated glycan chains is then carried out by the associated SXXK acyl transferase module. The PBPs of class B are comprised of an SXXK acyl transferase module, bound to the carboxy end of an N-terminal module devoid of enzymatic activity. These proteins are components of large morphogenetic complexes that control wall expansion, ensure cell-shape maintenance, and carry out septum formation (Derouaux et al. 2014; Typas et al. 2011). The GTase and TPase activities are coupled within the same aPBPs. The TPase activity of bPBPs act in concert with the GTase activity of aPBPs and SEDS (shape, elongation, division, and sporulation) protein partners (Egan et al. 2015; Taguchi et al. 2019).

Escherichia coli is killed in a number of ways (Sauvage and Terrak 2016); via cell lysis as a result of the selective inactivation of the class A PBP1a and PBP1b (which can substitute for each other) by cephaloridine and cefsulodin; via transformation of the cells into round bodies as a result of the selective inactivation of the cell-cycle subclass B2 PBP2 by mecillinam and thienamycin; via cell filamentation as a result of the selective inactivation of the cell-cycle subclass B3 PBP3 by mezlocillin, cefaperazone, cefotaxime, cefuroxime, cephalothin, and aztreonam; or via different combinations of these morphological alterations by ampicillin, benzylpenicillin, carbenicillin, and cefoxitin. In the end, all these defects result in cell lysis.

In addition to the catalytic GTase and TPase domains, some PBPs, such as the class A PBP1a and PBP1b of *E. coli*, exhibit small domains called ODD and UB2H, respectively, located between the GTase and the TPase domains (Typas et al. 2011). They have been shown to function as the binding sites of regulatory lipoproteins LpoA and LpoB which stimulate the activities of PBP1a and PBP1b, respectively (Typas et al. 2011). The bPBPs can also contain additional domains. The subclass B4-PBPs (e.g., PBP2x of *Streptococcus pneumoniae*), for example, have two additional C-terminal PASTA domains (PBP and Serine/Threonine kinase Associated). These domains have been found to play a role in β-lactam binding, protein stability, and bacterial morphogenesis (Sauvage et al. 2008; Sauvage and Terrak 2016).

Generally, two HMW-PBPs (one aPBP and one bPBP) are necessary for viability in most bacteria, but this paradigm has been challenged in *Bacillus subtilis* and enterococcus as the deletion of all aPBPs was tolerated (Arbeloa et al. 2004; McPherson and Popham 2003). This led to the discovery of new class of peptidoglycan transglycosylases, the SEDS protein family (RodA, FtsW). They require to be activated by a bPBP partner and their coupled activities were shown to produce cross-linked peptidoglycan (Meeske et al. 2016; Taguchi et al. 2019).

Bacterial cell wall growth and division is highly coordinated and regulated within specialized multiprotein complexes, the elongasome and divisome. Several protein-protein interactions between PBPs and between PBPs and the proteins in these complexes have been identified and shown to regulate the activities of the PBPs. In *E. coli*, the divisome proteins PBP3 and FtsW interact with each other and were shown to form a ternary complex with PBP1b (Leclercq et al. 2017). PBP3 regulates the interaction between FtsW and the lipid II substrate and its availability for the PBP1b synthase (Leclercq et al. 2017). Recently, the divisome proteins FtsBLQ were shown to directly interact with PBP1b and inhibit (via FtsL) its GTase activity (Boes et al. 2019). PBP1b also interacts with FtsN which stimulates its activities (Müller et al. 2007). The addition of the PBP1b activators, FtsN or LpoB, was found to suppress this inhibition by FtsBLQ and restore PBP1b activity (Boes et al.

2019). In addition, FtsBLQ (via FtsQ) were shown to inhibit the TPase domain of PBP3 but not of PBP1b (Boes et al. 2019).

The periplasmic steps of peptidoglycan synthesis and remodeling exhibit high level of redundancy (over 36 enzymes for 9 steps) (Pazos et al. 2017). Recent results show that bacteria use their redundant PBPs repertoire to cope with the variable environmental challenges. A compelling example is the presence in the pathogenic *Salmonella enterica* serovar Typhimurium of a second specialized penicillin-binding protein (PBP3sal) that is absent in nonpathogenic bacteria, in addition to the classical cell division specific PBP3. PBP3sal displays PG biosynthetic activity restricted to acidic conditions (it is inactive at neutral pH) and promotes cell division inside the host cells. In contrast, PBP3 that displays optimal activity at neutral pH is inactive at acidic pH (Castanheira et al. 2017).

Another example is the finding that the pH value can influence the fitness of *E. coli* cells with defects in PBP1a or PBP1b. Defects in these PBPs affect growth in alkaline and acidic condition, respectively. These results show that the virtually redundant PG synthases are required for optimal fitness across pH environments. Moreover, synthase specialization has consequences for intrinsic resistance to β-lactam antibiotics in nonstandard growth conditions (Mueller et al. 2019).

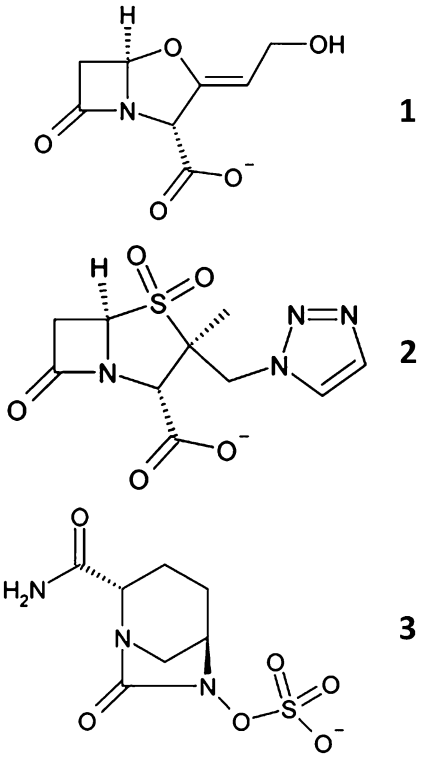
β-Lactamase-Mediated Resistance

The SXXK β- *lactamases* possibly result from the conversion of free-standing PBPs into β-lactam antibiotic-hydrolyzing enzymes, with loss of peptidase activity and conservation of the polypeptide fold. There are three classes of SXXK β-lactamases A, C, and D, which are easily distinguished on the basis of their sequences, although the tertiary structures are clearly similar and also related to those of the acyl transferase modules of PBPs. In particular, in addition to the characteristic SXXK, motifs reminiscent of the bar code SXN and KTG groups are found in nearly superimposable positions. The catalytic pathway of β-lactamases follows the three-step model shown above but with good substrates, the k_3 value can be higher than 1000 s^{-1} and the k_2/K value can be close to that of a diffusion-limited reaction (Matagne et al. 1999).

The class A enzymes have M_r values around 30,000. Their substrate specificities are quite variable and a large number of enzymes have emerged in response to the selective pressure exerted by the sometimes abusive utilization of antibiotics. Some of these "new enzymes" are variants of previously known enzymes, with only a limited number of mutations (1–4) but a significantly broadened substrate spectrum while others exhibit significantly different sequences. The first category is exemplified by the numerous TEM and SHV variants whose activity can be extended to third- and fourth-generation cephalosporins and the second by the NMCA, SME, and KPC enzymes which, in contrast to all other SXXK β-lactamases, hydrolyze carbapenems with high efficiency. Among the "extended-spectrum" enzymes, some β-lactamases whose genes are plasmid-borne are particularly worrying, for example, the CTX-M and KPC families. The first one hydrolyzes extended spectrum cephalosporins and monobactams and the second one many carbapenems and extended spectrum cephalosporins. Despite these specificity differences, the tertiary structures of all class A β-lactamases are nearly superimposable.

The class C enzymes have M_r values around 39,000 and exhibit more uniform properties. They hydrolyze benzyl- and phenoxymethyl penicillin relatively well (turn-over numbers of 20–70 s^{-1}), ampicillin and amoxicillin 10- to 20-fold less rapidly, and the other penicillins extremely slowly (generally due to low k_3 values). The early cephalosporins (cephalothin, cephalexin, cefazolin) are well hydrolyzed but the later generation compounds also exhibit low to very low k_3 values, as do imipenem and aztreonam. A few mutations are known to extend the spectrum of some enzymes but the most currently utilized bacterial strategy is overproduction by deregulation of the biosynthetic control mechanism, so that the MICs of poor or even very poor substrates can increase significantly (Lakaye et al. 1999).

Class D enzymes (M_r of 27–28,000) usually exhibit a high activity versus isoxazolyl



β-Lactam Antibiotics, Fig. 6 β-lacatamase inactivators: (1): clavulanic acid; (2) tazobactam; (3) avibactam

penicillins, such as oxacillin and are referred to as the OXA-family. Surprisingly, the amino group of the SXXK lysine residues is carboxylated in the most active forms of the enzymes (Vercheval et al. 2010). Penicillins are generally better substrates than cephalosporins but the number of identified OXA enzymes has significantly increased (and continues to increase) over the years and some of them hydrolyze extended spectrum cephalosporins, monobactams, and/or carbapenems.

Inactivators of class A β-lactamases (clavulanate, and sulphones such as sulbactam and tazobactam, Fig. 6) are themselves β-lactams and act as suicide substrates. They can be used in combination with β-lactamase-sensitive compounds (ampicillin, amoxicillin) but are not clinically useful against class C and class D producers. Some TEM mutants have also been selected that exhibit reduced sensitivity to these inactivators.

More recently, diazabiscyclo(3.2.1)octanones have been developed (e.g., avibactam, Fig. 6). They exhibit good inactivation properties against class A, class C, and some class D β-lactamases. Interestingly, with these compounds, the decay of the EI* adduct regenerates the EI complex containing the intact inactivator, but the k_{-2} step is generally too slow to be of physiological relevance (Ehmann et al. 2012).

The class B metallo-β-lactamases have emerged more recently as a clinical problem (e.g., the VIM, IMP, and NDM families whose genes are plasmid-borne). They are particularly dangerous since many of them hydrolyze all known β-lactams, with the exception of monobactams. In particular, they hydrolyze, although rather poorly, the suicide substrates mentioned above (to which they are not sensitive), as well as carbapenems that usually escape the activity of most the SXXK enzymes, with the exceptions mentioned above. Their genes also spread rather rapidly and are often associated, on the same plasmids, with genes encoding resistance properties to other classes of antibiotics.

Three subclasses B1, B2, and B3 can be distinguished on the basis of the sequences. B1 and B3 enzymes are optimally active with 2 Zn^{2+} ions, while a second Zn^{2+} ion inhibits the B2 enzymes. These B2 enzymes also exhibit a very narrow activity spectrum and only hydrolyze carbapenems. The 3D structures of representative members of each subfamily have been solved and they highlight a typical αββα fold, completely unrelated to that of the SXXK enzymes (Kerff et al. 2012).

The production of β-lactamases can be inducible or constitutive and the genes carried by the chromosome or plasmids, some genes being parts of integrons. A non-negligible number of clinical strains produce several distinct enzymes.

More information about β-lactamases (more than 1200 of them have been described so far) can be found in recent reviews by (Bush 2018; Bush and Bradford 2019).

PBP-Mediated Resistance

There are at least two modes of intrinsic resistance to β-lactam antibiotics. Determinants conferring a decreased susceptibility to β-lactam antibiotics evolve by the accumulation of point mutations in

genes that code for essential PBP fusions of classes A and/or B. The shuffling and capture of DNA sequences from commensal *Streptococci* having a reduced susceptibility to the drug give rise to *Streptococcus pneumoniae* pathogens in which mosaic genes code for mosaic PBP fusions of classes A and/or B of decreased affinity for the drug. Mosaic and wild-type PBP fusions of the same class (and the same subclass) differ by up to 15% amino acid residues (Calvez et al. 2017; Zapun et al. 2008). Mosaic PBPs occur also in *Neisseria meningitidis* and *Neisseria gonorrhoeae* strains.

Other strategies leading to an increased resistance are the transfer of a complete gene encoding a resistant PBP from a nonpathogenic-related species to yield the methicillin-resistant *Staphylococcus aureus* (MRSA) and the overproduction by *Enterococci* of a preexisting but minor resistant PBP, which can further mutate to even more resistant forms.

Some bacteria can also manufacture a peptidoglycan exhibiting 3–3 peptide cross-links (Fig. 2) with the help of structurally unrelated, penicillin-resistant LD-transpeptidases, which are not SXXK enzymes but active-cysteine enzymes that function according to the same general kinetic scheme as PBPs, with the cysteine -SH replacing the serine -OH group (Lecoq et al. 2013). In mycobacteria and *Clostridium difficile*, the proportion of (3–3) cross-links is large (70–80%). LDTs are also responsible for high levels of resistance to penicillins in laboratory mutants of *E. coli* and *Enterococcus faecium* (Triboulet et al. 2019). However, LDTs can be inactivated by carbapenems (Mainardi et al. 2007), and, in consequence, represent potential targets for the development of carbapenem-based therapies for multidrug-resistant tuberculosis.

However, LD-transpeptidases exclusively use acyl donor containing a tetrapeptide stem except LDT_{fs} from *Enterococcus faecalis,* which also uses a pentapeptide stem (Magnet et al. 2007). Consequently, hydrolysis of the C-terminal D-Ala of pentapeptide stems by a D,D-carboxypeptidase is essential to generate the tetrapeptide-containing substrate of the L,D-transpeptidases (Mainardi et al. 2002). This can be done by a metallo-DD-carboxy peptidase as in *E. faecium*, a resistant class C PBP as in *E. coli* or an "endopeptidase" that cleaves 4–3 cross-links to generate the tetrapeptide in *Mycobacterium smegmatis* (Baranowski et al. 2018).

Outer Membrane Permeability and Active Efflux Systems

In Gram-negative bacteria, diffusion of β-lactam antibiotics into the periplasm (where the activity of PBPs takes place) occurs via the channels that porins create in the outer membrane. The number and properties of the porin molecules are such that diffusion is relatively rapid in *E. coli* but much slower in *Enterobacter* and *Pseudomonas*. Mutants can be selected after the permeability of porin channels or their number has been decreased (Masi et al. 2019). A slow diffusion into the periplasm becomes a particularly important factor when it is combined with the presence of a β-lactamase (even in low concentration or when poorly active) in the same cellular compartment. Note that in *Mycobacteria*, the mycolic acid layer plays a role similar to that of the outer membrane in Gram-negatives.

Finally, β-lactams can be ejected from the periplasm by the active efflux systems of the RND family (e.g., AcrAB-TolC in *E. coli* and *Salmonella typhimurium* and MexAB-OprM in *Pseudomonas*). Compounds bearing a hydrophobic side-chain are particularly good substrates of these machineries whose overexpression can significantly increase the level of resistance but there are also pumps (AcrD and MexY) that can expel hydrophilic ligands (Nikaido 2018).

Clinical Use

Because the SXXK PBPs are specific to the prokaryotes, the β-lactam antibiotics have a high selective toxicity without marked side effects except for possible allergic reactions. Resistance is a problem of great concern. The use of antibiotics fuels the continuing emergence and spreading of novel β-lactamases and intrinsic resistance determinants among bacterial pathogens.

Eicosanoids; Lipid mediators

Definition

Leukotrienes (LTs) are produced by the enzymatic oxidation of arachidonic acid (AA) released from cellular membrane (Shimizu 2009; Nakamura and Shimizu 2011). The 5-lipoxygenase (5-LO) cascade is involved in the production of these lipid mediators. Structural differences divide leukotrienes into two groups:

(i) leukotriene B_4 (LTB_4), which contains two hydroxy groups, and (ii) cysteinyl-leukotrienes (Cys-LTs), i.e., LTC_4, LTD_4, and LTE_4, based on the cysteine residue in their structures. LTB_4 is synthesized from AA through formation of LTA_4. LTB_4 is well-known as one of the potent chemoattractants and activators of leukocytes and is involved in inflammatory diseases. LTC_4 is also produced via LTA_4 by glutathione conjugation of LTA_4 with opening of the epoxide at the allylic position C-6. Next, LTC_4 is converted to LTD_4 by elimination of glutamic acid. The remaining peptide bond in LTD_4 is further hydrolyzed by a dipeptidase to generate LTE_4. These mediators cause smooth muscle contraction, enhance mucus secretion, recruitment of eosinophils to the airways, and increase vascular permeability, producing edema. They have a relatively short half-life (seconds to minutes) and can be degraded enzymatically.

Basic Mechanisms

LTs play important roles in the regulation of cell proliferation and differentiation, as well as the reproductive, gastrointestinal, and cardiovascular systems. In contrast, the excessive production of these mediators is associated with pathological manifestations of various diseases, such as asthma, allergic inflammation, and innate immunity. These lipid mediators exert their effects by binding to cognate G-protein-coupled receptors (GPCRs): BLT receptors with affinity to LTB_4 and Cys-LTs receptor family for LTC_4, LTD_4, and LTE_4 (Yokomizo et al. 2018).

Pharmacological Relevance

Production of LTB_4

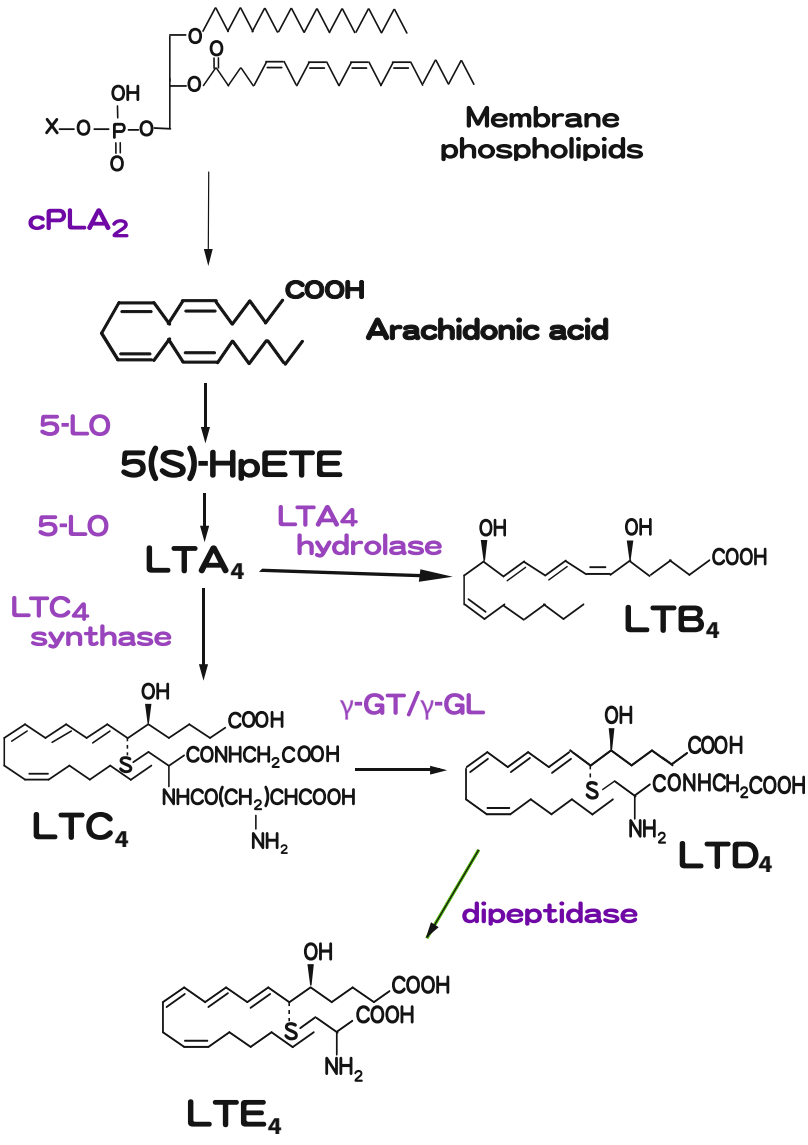
LTB_4 is one of the potent activators of leukocytes and is involved in various immune and inflammatory diseases. LTB_4 is produced from AA released from membrane phospholipids by the action of cytosolic phospholipase $A_2\alpha$ ($cPLA_2\alpha$) (Shimizu 2009; Nakamura and Shimizu 2011). Two enzymes, 5-LO and LTA_4 hydrolase, are implicated in the biosynthesis of LTB_4. 5-LO catalyzes the first two steps, i.e., conversion of AA to 5(*S*)-HpETE (hydroperoxyeicosatetraenoic acid) and 5(*S*)-HpETE to LTA_4 (Fig. 1). During the activation of the cells, 5-LO-activating protein (FLAP) serves as a scaffold protein for 5-LO on the nuclear membranes. AA is transferred to 5-LO by FLAP, followed by dehydration to the unstable epoxide LTA_4. Thus, FLAP is a prerequisite protein for the 5-LO cascade. Then, LTA_4 is hydrolyzed by LTA_4 hydrolase to produce LTB_4. Transport of LTA_4 from the synthetic cells into a completely different cell containing either LTC_4 synthase or LTA_4 hydrolase is also involved in the biosynthesis of LTs (Figs. 2 and 3). This is the process called transcellular biosynthesis. Thus, production of LTB_4 is enhanced in both leukocytes and other cells in inflammation. LTA_4 hydrolase is a bifunctional zinc-containing enzyme with epoxide hydrolase and aminopeptidase activities. Although the biological significance of aminopeptidase activity of LTA_4 hydrolase is under debate, one paper suggested that aminopeptidase activity of LTA_4 hydrolase is important in the inactivation of an inflammatory peptide PGP (proline-glycine-proline) derived from collagen (Snelgrove et al. 2010). This enzyme is inactivated by its substrate LTA_4 (suicide inactivation).

Metabolism of LTB_4

LTB_4 has a relatively short half-life and is degraded enzymatically. The metabolic fates of LTB_4 seem to differ among the cells and tissues where LTB_4 is synthesized.

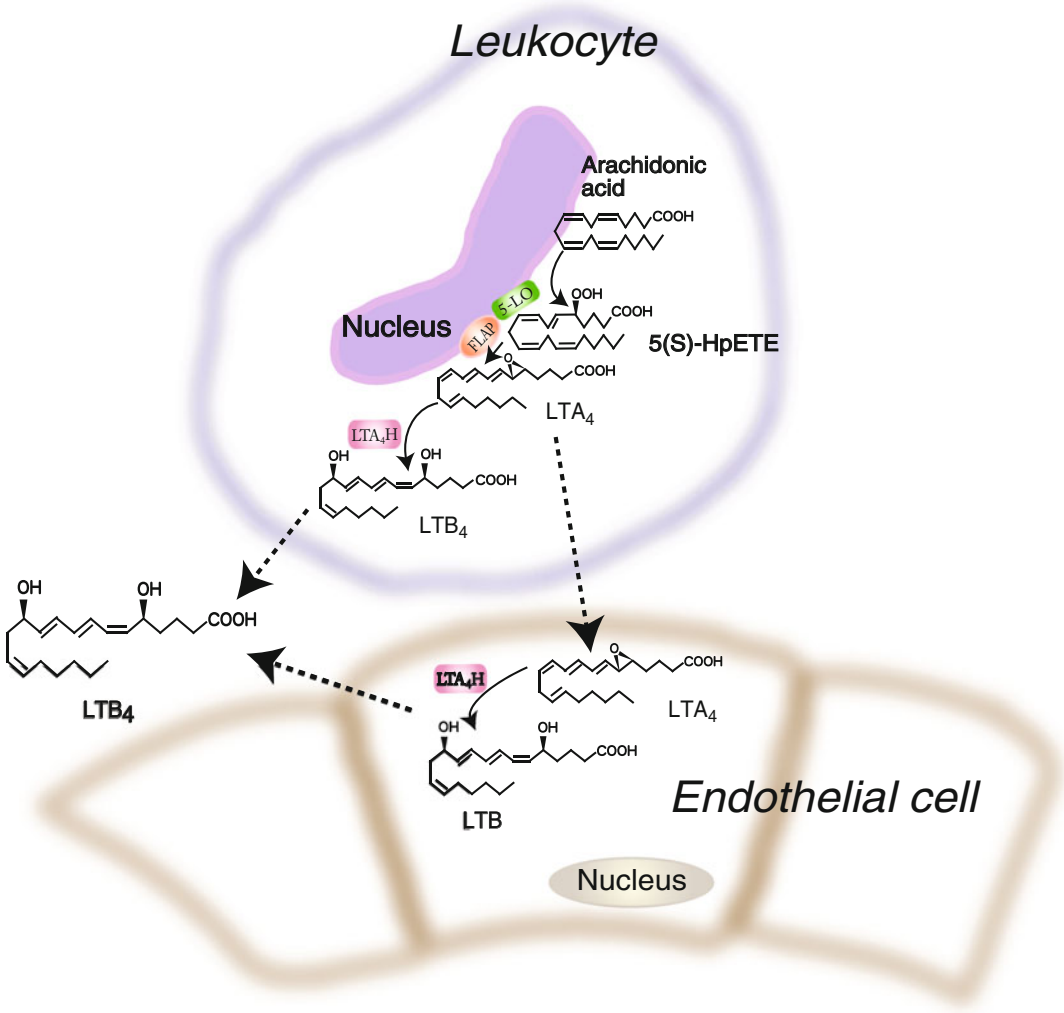
ω-Oxidation of LTB_4: Neutrophils metabolize LTB_4 into 20-hydroxy-LTB_4 (20-OH-LTB_4) by LTB_4 ω-hydroxylases and then 20-carboxy-LTB_4 (20-COOH-LTB_4). In neutrophils, one of the CYP4F isoforms, CYP4F3A, metabolizes LTB_4 with K_m values of 3.9 μM. Because 20-OH-LTB_4 binds to BLT1 with similar affinity to LTB_4, ω-oxidation itself does not inactivate LTB_4. An alternative pathway for subsequent ω-oxidation of 20-OH-LTB_4 was found to involve ADH (alcohol dehydrogenase) and AldDH (aldehyde dehydrogenase) in other tissues, e.g., liver.

β-Oxidation of LTB_4: For this metabolism, LTB_4 requires initial ω-oxidation to form ω-



Leukotrienes, Fig. 1 Biosynthetic pathways of leukotrienes. Enzyme names are also described: 5-LO, 5-lipoxygenase; $cPLA_2$, cytosolic phospholipase A_2

COOH-LTB_4, and CoA ester formation proceeds from the newly formed ω-carboxy group. 20-COOH-LTB_4 is metabolized via the peroxisomal and the mitochondrial β-oxidation pathways. The steps of chemical transformation that take place in peroxisomes start with 20-COOH-CoA esters, which are β-oxidized to a Δ^{18}-intermediate, catalyzed by acyl-CoA oxidase. This is followed by hydration of the C-18 double bond and then oxidation to form the 18-oxo-CoA ester by the peroxisomal bifunctional enzyme having both CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities. The penultimate carbon atoms of LTB_4 are then removed by 3-oxoacyl CoA thiolase, yielding the CoA ester of 18-COOH-LTB_4. This process is repeated for a second round of β-oxidation. The insertion of a new double bond adjacent to the 18-carboxy-CoA ester results in a conjugated diene involving the double bond at carbon atoms 14–15 in LTB_4. The peroxisomal enzyme 2,4-dieneoyl-CoA reductase reduces this diene to a monoene at C-16. The removal of the two terminal carbon atoms from 18-COOH-LTB_4 as acetyl-CoA leads to generation of the metabolites 16-COOH-tetranor-LTB_3.



Leukotrienes, Fig. 2 Biosynthesis pathways of LTB_4. AA is metabolized by 5-LO in the presence of FLAP first to 5(*S*)-HpETE then to LTA_4. LTA_4 is hydrolyzed by LTA_4 hydrolase (LTA_4H) to form LTB_4 in the cytoplasm. LTA_4 is converted to LTB_4 intracellularly and is exported for the transcellular synthesis

Metabolism by 12-hydroxydehydrogenase/15-oxo-prostaglandin-13-reductase: LTB_4 is also metabolized by the action of 12-hydroxydehydrogenase (12-HDH)/15-keto-prostaglandin 13-reductase (15-oPGR) (Yokomizo et al. 1993, 1996). The 12-HDH/15-oPGR cascade for the inactivation of LTB_4 is first discovered in porcine leucocytes, where several metabolites that did not retain the conjugated triene structure of LTs were found. This cascade had three separate structural conversions of the starting substrate. First, 12(*R*)-hydroxyl group of LTB_4 is oxidized by 12-HDH/15-oPGR, resulting in the generation of 12-oxo-LTB_4. The product of 12-hydroxy-oxidation is a conjugated ketone with a structural motif [R-CO-(*trans*)-CH=CH-R′] common to many LTs and PGs and as such is a structural unit that can be reduced in two steps to [R-CH(OH)-CH_2CH_2-R′]. 12-HDH/15-oPGR is known to perform the reduction of 15-oxo-PGs into 15-oxo-13, 14-dihydro-PG metabolites. However, it is still unclear whether this enzyme can reduce

12-oxo-LTB_4 to 12-oxo-10,11-dihydro-LTB_4 or whether a separate reductase carries out this step. Human keratinocytes metabolize LTB_4 to 10-HOTrE (10-hydroxyoctadecatrienoic acid) by the 12-HDH/15-oPGR cascade, suggesting that a C-1 CoA ester can be formed from 10,11-dihydro-LTB_4.

Characteristics of LTB_4 Receptors

Two LTB_4 receptors, BLT1 and BLT2, have been cloned (Table 1) (Yokomizo et al. 2018). BLT1, which is known as a high-affinity LTB_4 receptor, is expressed in various subsets of leukocytes and is responsible for LTB_4-dependent chemotaxis. BLT2 was originally identified as a low-affinity LTB_4 receptor and is now considered as a receptor for 12-hydroxyheptadecatrienoic acid (12-HHT). BLT2 is expressed in epidermal keratinocytes, epithelial cells of intestine, cornea, and lung, and is involved in wound healing and epidermal barrier function.

BLT1: BLT1 shows high affinity for LTB_4 with a *K*d value of 0.15 nM. In Chinese hamster ovary (CHO) cells expressing BLT1, this receptor is able to couple with both Gαi- and Gαq-like (Gα16) G-proteins. BLT1 is mainly expressed in various subsets of leukocytes, e.g., granulocytes, eosinophils, effector-type $CD4^+$ and $CD8^+$ T cells, dendritic cells, and macrophages. This receptor is further expressed in vascular smooth muscle cells and involved in atherogenesis and vascular injury. Docking study with LTB_4 and BLT1 demonstrates that LTB_4 would interact with the residues H96, R158, E187, and S243 of BLT1. These residues were predicted to be involved in the LTB_4 binding by the mutation study. Recently, the crystal structure of BLT1 with an antagonist BIIL260 was reported (Hori et al. 2018). The benzamidine moiety of BIIL260 interacted with the side chains of D66, V69, S106, W236, and S276, which are shared among most GPCRs. These residues bind water molecules as the sodium ion-centered water cluster, stabilizing the inactive form of BLT1. LTB_4 shows potent chemotactic effect on leukocytes because granulocytes and eosinophils from BLT1-null mice do not migrate toward LTB_4. BLT1 activation in leukocytes leads to degranulation through the production of phosphatidylinositol tris-phosphates (IP_3) by phosphatidylinositol 3-OH kinase (PI3 kinase). The receptor for advanced glycation end products (RAGE) was recently identified as a BLT1-binding protein and was determined as a molecular switch for BLT1, inhibits BLT1-dependent NF-κB activation, and stimulates BLT1-dependent chemotaxis. Recent study demonstrated that an LTB_4 gradient around inflammatory sites boosts BLT1 phosphorylation in a stepwise manner to facilitate the precise migration of leukocytes and initiation of local responses, including degranulation.

BLT2: BLT2 shares amino acid identities of 45% with BLT1. This receptor shows low affinity for LTB_4 with a *K*d value of 10–20 nM. Although BLT2 can be activated by 12(S)-HETE, 12(S)-HPETE, and 15(S)-HETE at micromolar concentrations, 12-HHT was identified as a high-affinity agonist for this receptor. 12-HHT activates BLT2 at lower concentrations than LTB_4 followed by the activation of Gαi- and Gαq-type G-proteins. Most classical BLT antagonists inhibit both BLT1 and BLT2, and a synthetic BLT2 specific agonist (CAY10583) is available. BLT2 is expressed in keratinocytes, epithelial cells of intestine and cornea, lung alveolar type 2 cells, and vascular endothelial cells.

Leukotrienes, Table 1 Characteristics of LTB_4 receptors

Receptor	BLT1	BLT2
Ligand	LTB_4 > 20-OH-LTB_4 > 12(*R*)-HETE	12-HHT > LTB_4 > 12(S)-HETE > 12(S)-HpETE > 15(S) HETE

LTB_4 in Health and Diseases

The binding of LTB_4 to its specific receptors on immune cells, e.g., neutrophils, macrophages, T cells, and DCs, evokes various cellular responses, such as chemotaxis, adhesion to vascular endothelial cells, release of lysosomal enzymes, and production of reactive oxygen species. For example, exogenous LTB_4 induces production of IL-2 and IFN-γ in $CD4^+$ T cells, and BLT1 antagonists block T-cell proliferation and IFN-γ production in vitro. The importance of LTB_4 in disease development has been determined from the detection of LTB_4 in inflammatory exudates and the efficacy of the receptor antagonists in abolishing or reducing the inflammatory condition. Recently, many studies have associated LTB_4 with various inflammatory events including asthma, atopic dermatitis, rheumatoid arthritis, septic peritonitis, psoriasis, and inflammatory bowel disease. The pathophysiological roles of LTB_4 are summarized in Table 2. In this regard, several blockers for LTB_4 receptors, as well as inhibitors of the LTB_4 biosynthesis, have been developed for clinical use.

Leukotrienes, Table 2 Pathophysiological roles of LTB_4

	Related diseases

Bone	Osteoporosis (confirmed in BLT1-null mice)

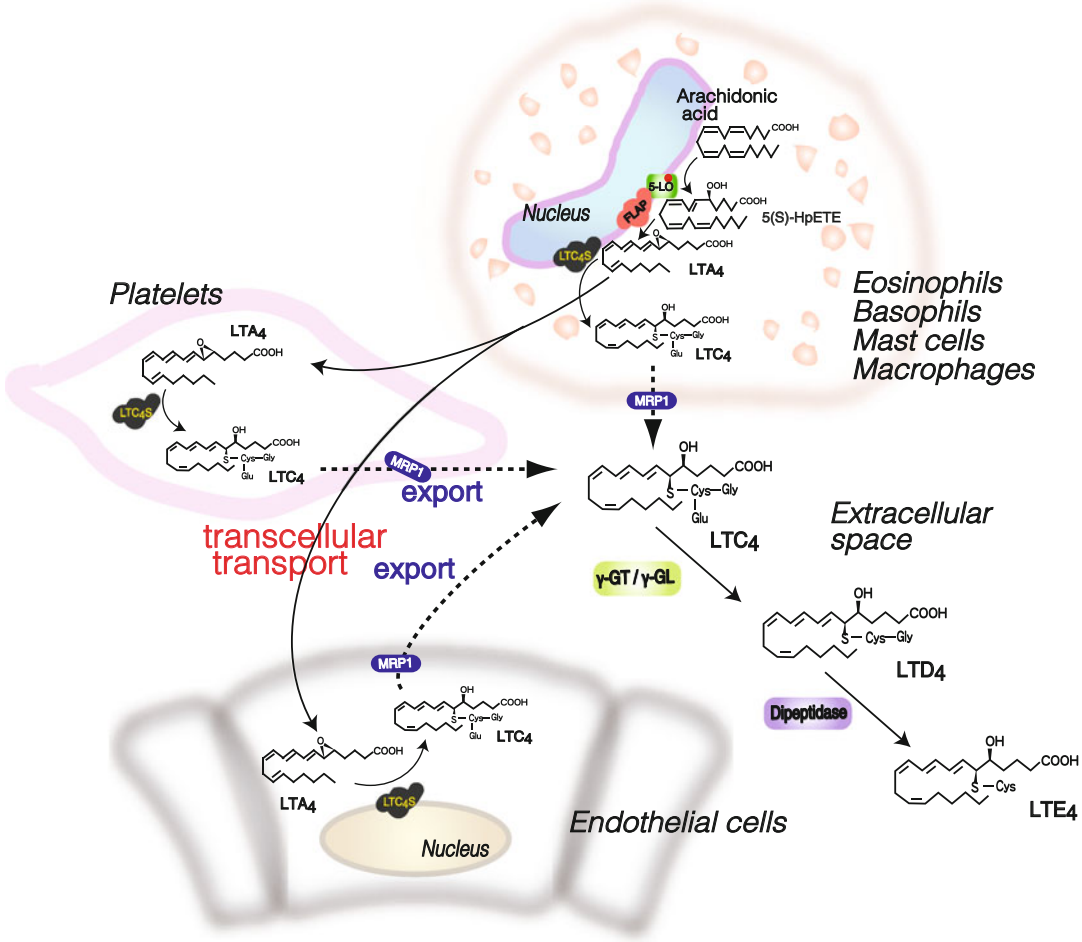
Characteristics of Cys-LTs

Production of Cys-LTs

As mentioned above, AA is converted to the intermediate 5(*S*)-HpETE and quickly to LTA_4 by 5-LO. In neutrophils, LTA_4 is hydrolyzed to LTB_4 by LTA_4 hydrolase, whereas eosinophils, basophils, mast cells, and macrophages preferentially produce LTC_4 through conjugation of a reduced glutathione to LTA_4 by LTC_4 synthase (Fig. 3) (Nakamura and Shimizu 2011). LTC_4 synthase is an integral nuclear membrane protein and is the key enzyme for the biosynthesis of this lipid mediator. Both FLAP and LTC_4 synthase constitutively localize to the perinuclear envelope, where LTC_4 synthesis is thought to occur. LTC_4 synthase is also expressed in platelets and endothelial cells, although these cells cannot synthesize LTA_4 on their own. However, these cells are able to synthesize LTC_4 using LTA_4 released by 5-LO-expressing cells via transcellular transport. The synthesized LTC_4 is exported to the extracellular space by multidrug resistance-associated protein 1 (MRP1). The transcellular metabolism of LTC_4 is associated with formations of LTD_4 and LTE_4. Namely, LTC_4 is converted extracellularly to LTD_4 by a γ-glutamyltranspeptidase (γ-GT) or γ-glutamylleukotrienase (γ-GL) and then to LTE_4 by a dipeptidase. LTE_4 is the most stable Cys-LT and can be measured after excretion into the urine. There were two important reports demonstrating the crystal structure of human LTC_4 synthase in its apo- and glutathione (GSH)-complexed forms. The LTC_4 synthase monomer has four transmembrane segments and forms a homotrimer as a unit with functional domains across each interface. The structure of the enzyme in complex with substrate revealed that the active site enforces a horseshoe-shaped conformation on GSH and effectively positions the thiol group for activation by a nearby Arg at the membrane-enzyme interface. These data provide new structural insights into the mechanism of LTC_4 formation and a structural basis for the development of LTC_4 synthase inhibitors for a pro-inflammatory cascade mediated by Cys-LTs.

Metabolism of LTE_4

LTE_4 is metabolized via similar pathways to LTB_4. After initial ω-oxidation to 20-COOH-LTE_4 and formation of the 20-CoA ester, metabolism proceeds through three steps of β-oxidation exclusively within the peroxisome. In rat hepatocytes, the most abundant metabolite observed is *N*-acetyl-16-COOH-tetranor-LTE_3. *N*-acetylation



Leukotrienes, Fig. 3 Biosynthesis pathway for the conversion of AA into Cys-LTs. AA is metabolized by 5-LO in the presence of FLAP first to 5(*S*)-HpETE then to LTA_4. LTC_4 synthase, which is a nuclear membrane protein, conjugates glutathione (GST) to this intermediate to form LTC_4. In the extracellular space, further generation to LTD_4 and LTE_4 takes place by γ-GT or γ-GL and dipeptidase, respectively

is a major metabolic step for LTE_4 in the rat even before ω/β-oxidation; however, it is not a major metabolic pathway in human tissues. Intact LTE_4 is also excreted into urine as a major metabolite due to its stability. Thus, LTE_4 levels are monitored in the urine, sputum, and exhaled breath condensate as an index of the Cys-LT synthesis in human diseases such as asthma, where its concentrations are markedly elevated.

Characteristics of Cys-LT Receptors

So far, five Cys-LT receptors have been identified: CysLT1, CysLT2, P2Y12, GPR99, and GPR17 (Table 3) (Yokomizo et al. 2018). CysLT1 is widely expressed in the spleen, leukocytes, lung, small intestine, colon, and skeletal muscle. CysLT2 exhibits 37.3% amino acid identity with CysLT1 and is exclusively expressed in the heart, adrenals, leukocytes, spleen, lymph nodes, and brain. CysLT1 is preferentially activated by LTD_4, whereas CysLT2 binds both LTC_4 and LTD_4 with equal affinity. Recently, P2Y12, GPR99, and GPR17 were reported as receptors for LTE_4. Furthermore, GPR17 has been proposed as a putative negative regulator of CysLT1.

CysLT1: CysLT1 is expressed in a variety of inflammatory cells, i.e., neutrophils, mast cells, and monocytes/macrophages, suggesting the

Leukotrienes, Table 3 Characteristics of Cys-LT receptors

Receptor	CysLT1	CysLT2	P2Y12	GPR99	GPR17
Ligand	$LTD_4 > LTC_4 >> LTE_4$	$LTD_4 = LTC_4 >> LTE_4$	$LTE_4 > LTD_4$, ADP	LTE_4, α-ketoglutarate	$LTE_4 > LTD_4$, UDP
Antagonist	Montelukast, zafirlukast, pranlukast, MK571, pobilukast	Zafirlukast, pranlukast, BAY-u9773, gemilukast	Clopidogrel

clinical effectiveness of the antagonists in asthma. Human CysLT1-expressing cells respond to Cys-LTs with rank order of potency: $LTD_4 > LTC_4 > LTE_4$. Activation of CysLT1 by LTD_4 results in the production of several second intracellular messengers through phospholipase Cβ. Several reports demonstrated that Cys-LTs elicit Ca^{2+} responses via a pertussis toxin (PTX)-sensitive G-protein (Gαi/o) in peripheral blood mononuclear cells or through two distinct G-proteins, PTX-sensitive and insensitive (Gαq/11), in monocyte/macrophage U937 cells, as well as a human epithelial cell line, suggesting the promiscuity of CysLT1 in G-protein coupling.

CysLT2: Although both CysLT1 and CysLT2 are highly expressed in spleen, CysLT2 exclusively existed in the heart and eosinophils. In situ hybridization analyses of human lung demonstrated that CysLT2 is expressed in interstitial macrophages and smooth muscle cells. Moreover, the presence of human CysLT2 mRNA was determined in atrium, ventricle, and intermediate coronary arteries. The potency ranking for the competition with $[^3H]LTD_4$ binding to human CysLT2 is $LTD_4 = LTC_4 >> LTE_4$. The CysLT1 antagonists are either weak (zafirlukast and pranlukast) or inactive (montelukast and pobilukast) at competing for $[^3H]LTD_4$ binding to human CysLT2, whereas full competition was observed with the dual CysLT1/CysLT2 antagonist BAY-u9773. LTC_4 and LTD_4 elicit a dose-dependent activation of Ca^{2+} flux through a PTX-insensitive G-protein (Gαq/11) in human CysLT2-expressing oocytes. In contrast, in human mast cells, the IL-8 production through the CysLT2 activation is completely blocked by PTX, suggesting it occurs via Gαi/o-protein. Recent reports demonstrated that CysLT2 negatively regulates the development of Th2 pulmonary inflammation by inhibiting the CysLT1 functions on dendritic cells. Furthermore, LTC_4, but not LTD_4 and LTE_4, activates mouse platelets via CysLT2, although these cells express both CysLT1 and CysLT2.

Other Receptors for Cys-LTs

Some of LTE_4-dependent responses are resistant in CysLT1/CysLT2-null mice, indicating the presence of other LTE_4 receptor(s). Based on the similarities of CysLT1 and CysLT2 with the nucleotide P2Y receptors, LTE_4 receptor seemed to be P2Y-like GPCRs. Human mast cells express P2Y12, an adenosine diphosphate receptor. Deficiency of this receptor impaired the LTE_4-elicited responses, e.g., productions of MIP-1β and PGD_2 in LAD2 cells without altering their responses to LTD_4. In the CHO cells expressing P2Y12, LTE_4 elicits the ERK1/2 activation which is sensitive to PTX. Furthermore, administration of LTE_4 to the airways of sensitized BALB/c mice induces eosinophilia, goblet cell metaplasia, and IL-13 production in response to low-dose aerosolized OVA. These responses are intact in CysLT1/CysLT2-null mice but are blocked by administration of clopidogrel, a P2Y12-selective antagonist. GPR99 belongs to the P2Y receptor subfamily and was initially identified as a receptor for α-ketoglutarate. Because the α-ketoglutarate-evoked response in the GPR99-expressing cells is insensitive to PTX, GPR99 seems to be coupled with Gαq/11. Recently, GPR99 was shown to be a high-affinity receptor for LTE_4 with a *K*d value of 2.5 nM. This receptor is highly expressed in the kidney, placenta, trachea, salivary glands, lung, and smooth muscle. GPR99 deficiency eliminated vascular leaks in response to Cys-LTs in the CysLT1/CysLT2-null mice. Because LTE_4 elicits airflow obstruction and lung inflammation in asthmatics, blockage of the GPR99 signaling may have therapeutic benefit in asthma. GPR17 also belongs to the P2Y receptor family and is activated by two unrelated ligands: uracil nucleotides and Cys-LTs. Activation of GPR17 leads to intracellular Ca^{2+} increase and inhibition of cAMP synthesis, indicating the coupling with Gαi/o proteins. Recent studies demonstrate that the administration of montelukast, a CysLT1 antagonist, leads to the reduced neuroinflammation, elevation of hippocampal neurogenesis, and improved learning and memory in old rats. These effects are impaired in GPR17-null mice, suggesting the involvement of this receptor in the rejuvenation of the aged brain. Recent reports demonstrated that GPR17 suppresses CysLT1-mediated signaling through heterodimerization. In IgE-dependent passive cutaneous anaphylaxis, vascular permeability is enhanced in GPR17-null mice. This response is blocked by administration of a

Leukotrienes, Table 4 Pathophysiological roles of cys-LTs

CysLT1 antagonist, proposing CPR17 as a negative regulator for CysLT1. This negative regulation was further confirmed in both the antigen presentation and downstream phases of allergic pulmonary inflammation, demonstrating physiological evidence for its negative regulatory role.

Cys-LTs in Health and Diseases

Generations of the mice deficient in Cys-LT receptors and development of receptor antagonists have expanded the scope of functions served by Cys-LTs. Cys-LTs participate in the inflammatory component of asthma by increased microvascular permeability, bronchoconstriction, recruitment of effector cells (especially eosinophils and mast cells), mucus and cytokines secretion, and fibrosis. The pathophysiological roles of Cys-LTs are summarized in Table 4. The importance of Cys-LTs in these diseases has been supported by animal models and awaits validation in humans.

Definition and Introduction

Relationships between plasma lipid levels and the risk of having an atherosclerotic cardiovascular

disease (ASCVD) event have been observed consistently in many human population studies. There is also support for a causal relationship between some plasma lipoprotein fractions and ASCVD risk, with overwhelming evidence from large, randomized, double-blind, placebo-controlled, clinical trials that interventions that reduce the level of low-density lipoprotein cholesterol (LDL-C) and its constituent apolipoprotein, apoB, also reduces the risk of having an ASCVD event (Cholesterol Treatment Trialists et al. 2010). This has led to a longstanding, major investment in the development of drugs that lower LDL-C and apoB levels. In recent years, the focus of these efforts has been extended to reducing the cholesterol content of all atherogenic lipoproteins, which is commonly referred to as non-high-density lipoprotein cholesterol (non-HDL-C).

Mechanisms of Action and Clinical Use

LDL-C, Non-HDL-C, and ApoB Lowering Drugs in Current Use

Evidence from epidemiologic studies, genetic studies, and randomized, double-blind, placebo-controlled clinical trials have established that the concentrations of LDL-C, non-HDL-C, and apoB are positively and causally related to the risk of having an ASCVD event (Cholesterol Treatment Trialists et al. 2010). Global guidelines support the use of multiple agents to lower LDL-C, non-HDL-C, and apoB levels for reducing ASCVD risk.

Statins

Statins in current clinical use are atorvastatin, rosuvastatin, pitavastatin, simvastatin, pravastatin, and fluvastatin. All statins inhibit hydroxymethyl-glutaryl-CoA (HMGCoA) reductase, the main rate-limiting enzyme in cellular cholesterol synthesis. The statin-induced inhibition of cholesterol synthesis reduces cell cholesterol concentrations. This activates a series of homeostatic processes that normalize cell cholesterol levels, including activation of sterol regulatory element binding protein-2 (SREBP-2), which increases synthesis of the LDL receptor. Upregulation of the LDL receptor accelerates uptake of LDLs from the circulation, which normalizes cell cholesterol levels and decreases the plasma concentration of LDL-C.

Treatment with a statin can reduce the concentration of plasma LDL-C by up to 50% and has been shown consistently in large, randomized, double-blind, placebo-controlled clinical outcome trials to reduce the risk of having a future ASCVD event in all patient groups (Cholesterol Treatment Trialists et al. 2010).

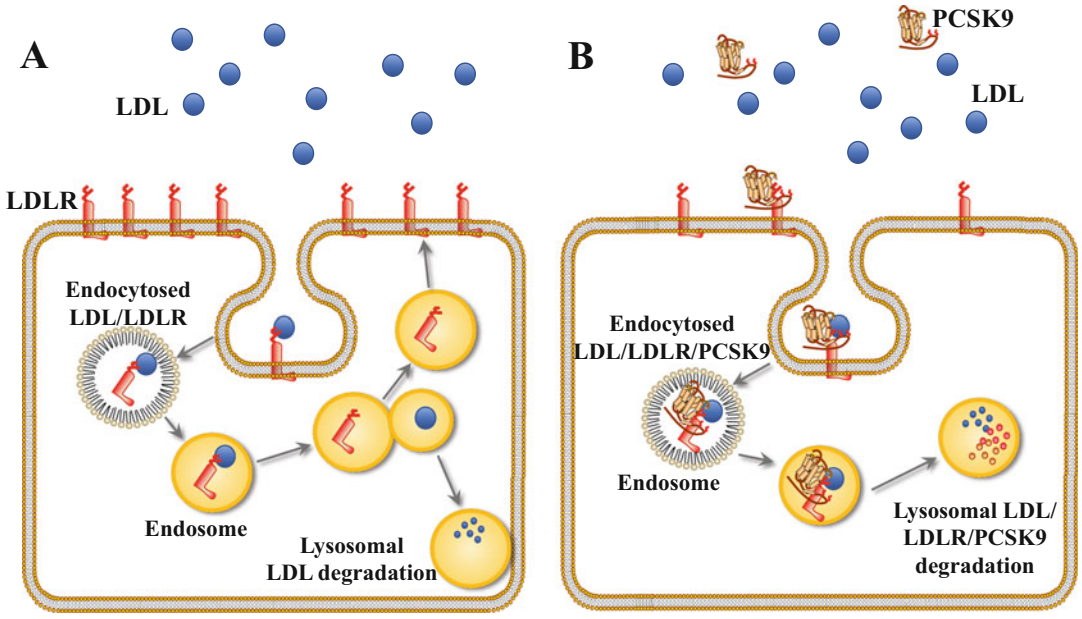
The statin-induced activation of SREBP-2 in response to a fall in cell cholesterol levels not only increases the number of cell surface LDL receptors but also increases the synthesis of proprotein convertase subtilisin/kexin type 9 (PCSK9) (Horton et al. 2007). PCSK9 maintains cholesterol homeostasis by degrading LDL receptors and inhibiting cellular cholesterol accumulation. While this is advantageous under conditions that lead to cellular cholesterol depletion, the ability of PCSK9 to degrade LDL receptors also limits the LDL-C-reducing action of statins.

As a class, when given at recommended doses, statins have few serious adverse effects. Adverse effects of statins that have been reported include myositis and an increase in new onset diabetes in those already at risk of developing type 2-diabetes. However, these adverse effects are greatly outweighed by the cardiovascular benefits of statin treatment.

PCSK9 Inhibitors

PCSK9 is expressed mainly in the liver and secreted into the plasma, where it binds to LDL receptors (Benjannet et al. 2004). In the absence of PCSK9, LDLs that bind to LDL receptors are endocytosed into lysosomes. The low pH within lysosomes causes LDLs to dissociate from the LDL receptor. The LDLs are then degraded, while the LDL receptor recycles back to the cell surface where it binds more LDLs (Fig. 1a). It has been estimated that each LDL receptor can recycle between intracellular compartments and the cell surface up to 150 times (Goldstein et al. 1985).

When a circulating LDL particle interacts with a cell surface LDL receptor to which PCSK9 is



Lipid-Lowering Drugs, Fig. 1 Degradation of the LDL receptor (LDLR) by PCSK9. Panel A: LDL binds to the LDLR on the cell surface and is endocytosed into lysosomes, where it dissociates from the LDLR and is targeted for degradation, freeing up the LDLR for recycling back to the cell surface. **Panel B**: In the presence of PCSK9, LDL and PCSK9 bind to the LDLR on the cell surface, forming an LDL/LDLR/PCSK9 complex that is degraded in lysosomes and inhibits the recycling of the LDLR back to the cell surface

already bound, a ternary complex containing PCSK9, the LDL receptor, and the LDL particle is formed (Fig. 1b). This complex enters the cell, where the PCSK9 prevents the LDL from dissociating from the LDL receptor and the entire complex (including the LDL receptor) is directed towards lysosomes for degradation (Benjannet et al. 2004). This stops LDL receptor recycling, reduces the number of LDL receptors on the cell surface, decreases the removal of LDLs from the circulation, and increases the plasma concentration of LDL-C, non-HDL-C, and apoB. Thus, PCSK9 partly negates the benefits of increasing LDL receptor expression with a statin.

Gain-of-function mutations in the *PCSK9* gene increase the plasma concentration of LDL-C and apoB, while loss-of-function mutations decrease LDL-C levels and are associated with reduced ASCVD risk. Preclinical studies in mice have furthermore established that overexpression of the *PCSK9* gene in mice increases susceptibility to atherosclerotic lesion development, while its inhibition reduces atherosclerotic lesion development (Rashid et al. 2005).

Inhibition of PCSK9 is thus a logical approach to reduce ASCVD risk. Inhibition of PCSK9 has been achieved with: (i) monoclonal antibodies that bind to and inactivate PCSK9 in plasma and (ii) inhibitors of PCSK9 synthesis. Fully human anti-PCSK9 monoclonal antibodies, including alirocumab and evolocumab, have been developed and approved for clinical use. These antibodies reduce the plasma concentration of LDL-C by more than 50%, including when given to people already taking a statin, and no major safety issues have yet been reported (Raal et al. 2012; Stein et al. 2012). Anti-PCSK9 monoclonal antibodies also reduce the risk of having an ASCVD event in large, double-blind, placebo-controlled clinical outcome trials (Sabatine et al. 2017) (Robinson et al. 2015).

Agents that inhibit the synthesis of PCSK9 are under investigation but are not yet available for clinical use. They include a PCSK9 antisense

oligonucleotide (ASO) that reduces plasma cholesterol levels by more than 50% (Graham et al. 2013) and a locked nucleic acid ASO that decreases PCSK9 mRNA levels and increases LDL receptor expression (Gupta et al. 2010). A PCSK9 siRNA that reduces LDL-C levels in nonhuman primates has also been reported (Frank-Kamenetsky et al. 2008). Clinical outcome trials with these agents are underway.

Inhibitors of Intestinal Cholesterol Absorption

Ezetimibe blocks the ability of the protein Niemann-Pick C1-Like 1 (NPC1L1) to promote the intestinal absorption of cholesterol. Inhibition of NPC1L1 by ezetimibe reduces intestinal absorption of cholesterol, thus reducing the hepatic uptake of dietary cholesterol. The resulting decrease in hepatocyte cholesterol levels increases the number of LDL receptors at the hepatocyte surface, lowers the plasma concentration of LDL-C by about 20% and significantly reduces the risk of having an ASCVD event (Cannon et al. 2015).

Bile Acid Sequestering Agents

Bile acid sequestering agents (including cholestyramine) have been used for many years to reduce the plasma concentration of LDL-C. They act by binding to bile acids in the intestine, thus preventing bile acid reabsorption. This increases the synthesis of bile acids from cholesterol in hepatocytes, which transiently reduces hepatocyte cholesterol levels and upregulates the synthesis and cell surface expression of the LDL receptor. Bile acid sequestrants reduce the plasma concentration of LDL-C by ~20% and, in the case of cholestyramine, reduced clinical cardiovascular events in the pre-statin era (Lipid Research Clinics Coronary Primary Prevention Trial 1984).

Inhibitors of ApoB Synthesis

ApoB is the main apolipoprotein component of very low-density lipoproteins (VLDLs) and LDLs. It is synthesized mainly in the liver. Inhibiting apoB synthesis has the potential to reduce the concentration of all apoB-containing lipoproteins. This is especially important in people with homozygous familial hypercholesterolemia (hoFH) who lack functional LDL receptors and do not respond to statins and PCSK9 inhibitors.

Mipomersen, an ASO that inhibits apoB synthesis in the liver, reduces apoB levels by 33–54% and LDL-C levels by 34–52% (Kastelein et al. 2006). While this is encouraging, Mipomersin has a high incidence of adverse effects, including severe injection site reactions in more than 70% of subjects, flu-like symptoms in more than 25% of subjects and headache in more than 15% of subjects.

Inhibitors of Microsomal Triglyceride Transfer Protein (MTP)

Another approach for reducing LDL levels in people who lack functional LDL receptors is to inhibit MTP. This protein is synthesized in the liver and intestine, where it transfers triglycerides to apoB to form apoB-containing lipoproteins.

Lomitapide is a small molecule that binds to MTP and blocks the transfer of triglycerides to apoB, thus preventing the formation of apoB-containing lipoproteins. Treatment with lomitapide reduces the concentration of LDL-C in humans with hoFH (Cuchel et al. 2013). Most patients taking lomitapide experience adverse effects, including gastrointestinal symptoms and elevation of liver transaminases. Lomitapide has been approved in some countries for treatment of people with hoFH.

Triglyceride-Lowering Drugs in Current Use

Evidence that the concentration of plasma triglycerides and triglyceride-rich lipoproteins are causally related to ASCVD risk has recently emerged. This indicates that agents that lower plasma triglycerides may reduce ASCVD risk.

Fibrates

Fibrates are agonists of the hormone-activated nuclear receptor, peroxisome proliferator-activated receptor alpha (PPARα) (Staels et al. 1998). Fibrates increase the oxidation of free fatty acids in the liver and reduce hepatic synthesis of triglycerides. Activation of PPARα also induces expression of lipoprotein lipase (LPL), the enzyme that hydrolyses triglycerides to glycerol and free fatty acids. LPL also hydrolyses the phospholipids in VLDLs and chylomicrons to

lysophospholipids and free fatty acids. Thus, as activators of PPARα, fibrates reduce plasma triglyceride levels by the combined effects of reducing its synthesis and increasing its hydrolysis. Activation of PPARα by fibrates also inhibits the synthesis of apolipoprotein (apo) C-III, an apolipoprotein that delays the catabolism of triglyceride-rich lipoproteins. Moreover, fibrates increase the plasma concentration of high-density lipoprotein cholesterol (HDL-C), possibly by increasing the synthesis of apolipoprotein (apo) A-I and apoA-II, the two main HDL apolipoproteins. The mechanism of this effect is not fully understood.

The results of clinical outcome trials of fibrates have varied, although in all of the human fibrate trials conducted so far, there has been a consistent finding that people with high plasma triglyceride and HDL-C levels have a reduction in cardiovascular events that is greater than what can be explained by the fall in plasma triglyceride levels, or the increase in HDL-C levels (Barter and Rye 2008). The mechanism of this cardiovascular benefit is not known.

Fibrates are relatively weak PPARα agonists and their efficacy is limited by dose-related adverse effects. New PPARα modulators that are more potent than fibrates, and may have fewer adverse effects, are currently under investigation. An insight into whether such agents will eventually play a significant role in the management of ASCVD risk may become more clear when the results of an ongoing human clinical outcome trial are reported.

Omega-3 Fatty Acids

Omega-3 fatty acids are dietary fats that inhibit lipogenesis and increase LPL activity, thus reducing the concentration of plasma triglycerides (Davidson 2006). There is also evidence that omega-3 fatty acids have anti-inflammatory effects and may improve the stability of atherosclerotic plaques (Thies et al. 2003).

Treatment with omega-3 fatty acids reduces the risk of having an ASCVD event (Bhatt et al. 2019), although it is not known whether the reduction in ASCVD risk relates to the fall in triglyceride levels or to some other action of these agents.

Niacin

Niacin (vitamin B3) has been used to modify plasma lipid levels for more than 50 years. When given in pharmacological doses, niacin reduces the level of plasma triglycerides by about 35%, reduces LDL-C levels by 10–15% and increases the concentration of HDL-C by up to 25%. The reduction in plasma triglycerides may be a reflection of the ability of niacin to inhibit the release of free fatty acids from adipose tissue. This decreases the plasma concentration of free fatty acids and the hepatic uptake of free fatty acids, leading to a reduction in hepatic triglyceride synthesis. The mechanism by which niacin decreases LDL-C levels and increases HDL-C levels is not known.

In a trial conducted in the pre-statin era, treatment with niacin significantly reduced ASCVD events. However, two recent large, randomized clinical outcome trials of niacin conducted in people taking statins did not reduce ASCVD events. The outcome of these trials suggest that it is unlikely that niacin will be used in future as a mainstream therapy for reducing ASCVD.

Lipid-Lowering Drugs Not Currently Used Clinically

Inhibitors of Cholesteryl Ester Transfer Protein (CETP)

CETP is a plasma protein that transfers cholesteryl esters from the non-atherogenic HDL fraction where they are synthesized to potentially the pro-atherogenic non-HDL fraction. Inhibition of CETP blocks this transfer, which decreases the concentration of cholesterol in the potentially pro-atherogenic non-HDL fraction and increases the concentration of cholesterol in the non-atherogenic HDL fraction. The mechanism by which CETP inhibitors lower the plasma level of LDL-C and apoB is not known with certainty. It may be the consequence of decreased transfer of cholesteryl esters from the HDL fraction into the LDL fraction. However, there is also evidence that rate of removal of LDLs from plasma is increased (Millar et al. 2015). This implies that the number of LDL receptors in the liver may increase when activity of CETP is inhibited.

The results of human genetic studies support the proposition that CETP is pro-atherogenic and that its inhibition may reduce ASCVD risk (Johannsen et al. 2012). Inhibition of CETP in rabbits protects against development of atherosclerosis (Sugano et al. 1998). Inhibition of CETP as a strategy to reduce ASCVD risk in humans has been disappointing, with no reduction in ASCVD events in trials with three inhibitors (torcetrapib, dalcetrapib, evacetrapib) but a significant reduction in events with a fourth inhibitor (anacetrapib) (Group et al. 2017).

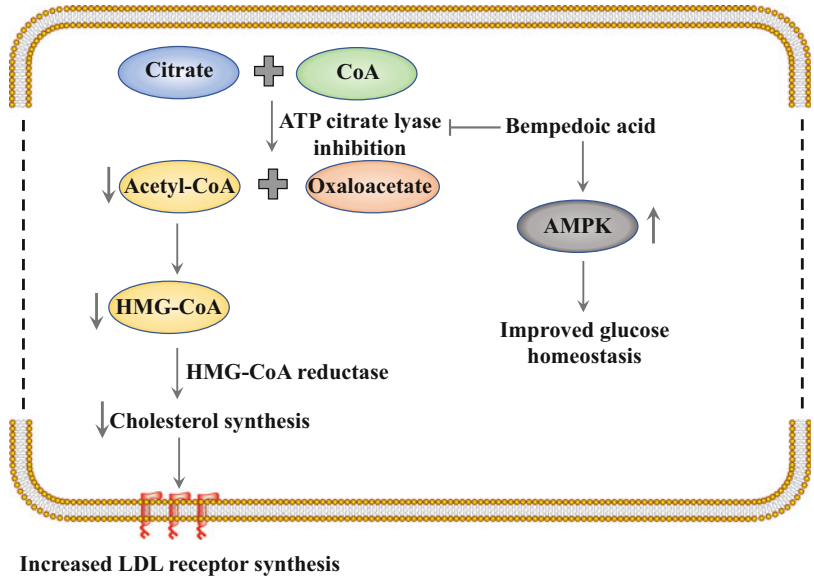
Inhibition of Adenosine Triphosphate Citrate Lyase with Bempedoic Acid

Adenosine triphosphate citrate lyase is a cytosolic enzyme expressed in liver and adipose tissue. It catalyzes the reaction in which citrate plus coenzyme A (CoA) are converted into acetyl-CoA and oxaloacetate (Fig. 2). Acetyl-CoA is an essential substrate in the pathway of cholesterol synthesis that acts upstream of HMG-CoA, the molecular target of statins. Pharmacological inhibition of adenosine triphosphate citrate lyase with bempedoic acid (also known as ETC-1002) reduces cytosolic acetyl CoA levels, decreases hepatic sterol synthesis, up-regulates the LDL receptor and reduces plasma LDL-C levels by up to 27%. Bempedoic acid also activates adenosine monophosphate (AMP), which can impact favorably on glucose homeostasis (Fig. 2). Effects of bempedoic acid on ASCVD risk are currently under investigation and it has been submitted for approval by the FDA.

Inhibitors of Lipoprotein (a) (Lp(a)) Synthesis

Lp(a) is an LDL particle to which an apolipoprotein(a) (apo(a)) molecule is attached via a disulfide bond. Lp(a) is pro-thrombotic, impairs fibrinolysis, and it activates endothelial cells (Kronenberg and Utermann 2013). It also transports pro-inflammatory, oxidized phospholipids that can increase cardiovascular risk. Elevated plasma levels of Lp(a) are genetically determined and associated with an increased risk of having an ASCVD event. Interventions that reduce the level of Lp(a) in plasma are therefore predicted to reduce ASCVD risk.

Inhibitors of PCSK9 reduce plasma Lp (a) levels by about 30% by an unknown mechanism. An almost 80% reduction in plasma levels of Lp(a) has been achieved with ASOs that inhibit apo(a) synthesis (Tsimikas et al. 2015). Apo(a) ASOs also reduce the levels of oxidized phospholipids that are associated with apoB-100-containing lipoproteins and Lp (a) (Tsimikas et al. 2015). Whether a therapeutic reduction in plasma levels of Lp (a) translates into a reduction in ASCVD events is currently not known.



Lipid-Lowering Drugs, Fig. 2 Bemedoic acid inhibits cholesterol biosynthesis and improves glycemic control. Bempedoic acid reduces cholesterol biosynthesis by inhibiting ATP citrate lyase, which is upstream of HMG-CoA reductase. Bempedoic acid also improves glucose homeostasis by upregulating AMPK

Inhibitors of ApoC-III Synthesis

ApoC-III is a pro-inflammatory protein that circulates in plasma as a component of VLDLs and HDLs. ApoC-III inhibits LPL and impacts adversely on HDL function. An elevated level of apoC-III in apoB-containing lipoproteins is an independent predictor of the risk of having an ASCVD event (Jorgensen et al. 2014). Transgenic overexpression of human apoC-III in mice increases both plasma triglyceride levels and susceptibility to atherosclerosis. Genetic studies in humans have shown that people with loss-of-function mutations in the *APOC3* gene have a significantly reduced risk of having an ASCVD event (Jorgensen et al. 2014), which makes the case for developing apoC-III inhibitors strong.

An apoC-III ASO that reduces the synthesis of apoC-III, decreases plasma triglyceride levels, and increases HDL-C levels in hypertriglyceridemic patients has been developed (Graham et al. 2013; Gaudet et al. 2015). The effects of inhibiting apoC-III synthesis on ASCVD risk remain to be established.

Synonyms

Local anesthetic drugs

Definition

Local anesthetics are drugs that reversibly prevent impulse generation and conduction in peripheral nerves. This action can lead to loss of sensation in

a limited area of the body without the loss of consciousness. Although local anesthetics are often used as analgesics, they may cause other physiological changes in autonomic, somatic, or muscle function.

Mechanism of Action

Chemistry

Most local anesthetics contain hydrophobic and hydrophilic moieties that are separated by an intermediate ester or amide linkage (Table 1). The hydrophobic group is usually an unsaturated aromatic ring, and the hydrophilic group is mostly a tertiary amine. Both groups are important for the drug binding to the target channel (voltage-gated Na^+ channel), and an ester or amide linkage affects the metabolism of the drugs. Since the ester bond is more prone to hydrolysis than the amide bond, esters usually show a shorter duration of action. The blocking potencies of the drugs range from a few micromolar to millimolar half-maximal blocking concentration and highly dependent on lipid solubility (Table 1).

Most local anesthetics are weak bases with pK_a values ranging from 7.5 to 9 and exist either as the charged form or the uncharged form at physiologic pH. The relative proportions of these two forms are shown in the Henderson-Hasselbalch equation:

$$\log [\text{charged form}]/[\text{uncharged form}] = pK_a - pH$$

According to this equation, the larger fraction of local anesthetics is the charged form at physiologic pH. An exception is benzocaine with a pK_a of 3.5 and benzocaine exists solely as the uncharged form under normal physiologic conditions.

The charged form is thought to be the active form at the receptor site, but the uncharged form is important for penetration of the cell membrane (Butterworth and Strichartz 1990; Courtney and Strichartz 1987; Hille 1977). Since the local anesthetic binding site is in the inner pore of the Na^+ channel, the uncharged form first penetrates into the cytoplasm, and after equilibration of the drug, the charged form binds to the Na^+ channel. The uncharged form may also reach the binding site laterally through the hydrophobic pathway of the cell membrane. In an acidic environment, like inflamed tissues, local anesthetics except benzocaine are highly protonated, therefore hardly penetrate the axonal membrane, and have little effect.

Sodium Channel Blockade

The major mechanism of action of local anesthetics is the blockade of voltage-gated Na^+ channels. Voltage-gated Na^+ channels are complexes of a large, about 2000-amino acid α-subunit, which contains the main channel functions, and one or two smaller β-subunits, which modulate membrane expression and channel function properties (Catterall 2000; Fozzard and Hanck 1996). The α-subunit is organized into four homologous, but not identical domains (I–IV), and each domain contains six transmembrane segments (S1–S6). The six transmembrane segments in each domain are further divided into a voltage-sensing unit (S1–S4) and a pore-forming unit (S5–S6), connected through the S4–S5 cytoplasmic linker. There are nine isoforms of α-subunits in mammals, which are 50–90% identical in amino acid sequence. Mutational studies allowed for the identification of the local anesthetic binding site on the α-subunit, which is formed by amino acid residues in the S6 segments in domains I, III, and IV (Ragsdale et al. 1994; Yarov-Yarovoy et al. 2001, 2002). Phenylalanine in domain IV, S6 is the most important residue for local anesthetic binding (Ragsdale et al. 1994).

Nerve fibers differ significantly in their susceptibility to local anesthetic block on the basis of differences in size and myelination. The relatively small and myelinated B fibers (autonomic preganglionic fibers) and the small and unmyelinated C fibers (mediating pain sensations or postganglionic sympathetic fibers) are blocked first, followed by the relatively small and myelinated Aδ fibers (mediating pain and temperature sensations) (Raymond and Gissen 1987). Then, the large and myelinated Aγ (mediating muscle tone) and Aβ fibers (mediating touch and pressure sensations) are blocked. The largest and myelinated Aα fibers (mediating proprioception and motor function) are blocked last.

Local Anesthetics, Table 1 Structure and properties of selected local anesthetics

Name	Structure	Potency (procaine = 1)	Duration of action	LogP	pK_a
Esters					
Cocaine		2	Medium	2.30	8.6
Procaine		1	Short	1.92	9.1
Tetracaine		16	Long	3.73	8.4
Benzocaine		–	–	1.86	3.5
Amides					
Lidocaine		4	Medium	2.26	7.9

Mepivacaine		2	Medium	1.95	7.8
Bupivacaine		16	Long	3.41	8.1
Ropivacaine		14	Long	2.90	8.2

Lipid solubility is given as the logarithm of the water/octanol partition coefficient, LogP

Another important factor determining the susceptibility of nerve fibers to local anesthetic block is the voltage-dependent effects of local anesthetics. Channels in the activated (open) and inactivated states, which predominate at more positive membrane potentials, have much higher affinities for local anesthetics than the rested channels, which predominate at more negative membrane potentials (Hille 1977). Therefore, local anesthetic blockade increases at higher frequencies of depolarizations (i.e., with an increased fraction of activated and/or inactivated channels) and with longer depolarizations (i.e., with an increased fraction of inactivated channels). Sensory fibers mediating pain sensations have a high frequency of firing and a relatively long action potential duration. Motor fibers fire with low frequency and have a shorter action potential duration. Since Aδ and C fibers exhibit high-frequency pain transmission, these fibers are blocked earlier with lower concentrations of local anesthetics than are Aα fibers (Drasner 2018).

Clinical Use

Local anesthetics provide regional analgesia and anesthesia. The routes of administration include a topical application (e.g., nasal mucosa), injection in the vicinity of peripheral nerve endings and major nerve trunks, and injection into the epidural or subarachnoid spaces surrounding the spinal cord. The patients usually stay awake under regional analgesia and anesthesia, but these can be combined with general anesthesia to reduce the requirement of narcotics and analgesics during major surgical procedures.

The choice of local anesthetic for a specific procedure is usually based on the duration of action required. Procaine is short-acting; lidocaine and mepivacaine have an intermediate duration of action; and tetracaine, bupivacaine, and ropivacaine are long-acting drugs (Table 1). The anesthetic effects of the drugs with short and intermediate durations of action can be prolonged by adding a vasoconstrictor agent (e.g., adrenaline) to reduce the absorption of local anesthetic molecules.

The clinical use of cocaine is restricted to topical anesthesia for ear, nose, and throat procedures because of its systemic toxicity and potential for abuse. Procaine was synthesized to reduce cocaine's toxicity and addictive nature and was the prototype for local anesthetics for nearly half a century. At present, procaine is not much used as a single entity. Tetracaine is widely used in spinal anesthesia when a drug of long duration is needed. Although tetracaine also is incorporated into several topical anesthetic preparations, tetracaine is rarely used in peripheral nerve blocks. Benzocaine is effective even under acidic conditions (e.g., gastric mucosa, infected tissues) because of its low pK_a and applied to topical anesthesia. Benzocaine, however, has a concern about its potential to induce methemoglobinemia. Lidocaine has a wide range of clinical uses as a local anesthetic. Lidocaine has utility in most applications except spinal administration where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic drug. Mepivacaine exhibits clinical properties resembling those of lidocaine. However, mepivacaine is more toxic to the neonate and more slowly metabolized in the fetus, and thus is not used in obstetrical anesthesia. Mepivacaine is not effective as a topical anesthetic, which is different from lidocaine. Bupivacaine is widely used in almost any application when prolonged anesthesia is needed. Ropivacaine is an *S*-enantiomar of one of the bupivacaine derivatives and expected to be less cardiotoxic than bupivacaine. Ropivacaine is suitable for both epidural and regional anesthesia.

All local anesthetics are not isoform-specific and are capable of blocking different isoforms of voltage-gated Na^+ channels in the different tissues and organs. The major unwanted side effects of local anesthetics are disturbances of brain and heart function occurring during high blood levels of the drugs after absorption from the site of administration or after accidental intravascular injection.

An early symptom of side effects in the brain is circumoral and tongue numbness. At higher concentrations, muscular twitching occurs and is followed by tonic-clonic convulsions caused by a depression of cortical inhibitory pathways. Such excitation is then followed by generalized brain depression, producing respiratory depression and coma at the highest concentrations.

Following systemic absorption, local anesthetics potentially block cardiac Na^+ channels and thus depress excitability and conduction. Local anesthetics except cocaine also depress the strength of cardiac contraction and cause arteriolar dilation, which leads to hypotention. Cardiovascular side effects are usually seen only after high systemic concentrations are attained and central nervous system symptoms are evident. However, bupivacaine is more cardiotoxic than other local anesthetics and induces serious arrhythmias. Both levobupivacaine and ropivacaine being *S*-enantiomars are expected to be less cardiotoxic than bupivacaine in clinical use.

In rare cases, hypersensitivity to local anesthetics occurs. The ester-type local anesthetics are metabolized to *p*-aminobenzoic acid derivatives, and these metabolites cause allergic reactions. Although allergic responses to the amide-type drugs are not common, the solutions of the amide-type drugs may contain preservatives such as methylparaben, and they may elicit allergic reactions.

Synonyms

ApoE receptors; Apolipoprotein E receptor family; Lipoprotein receptors; Low-density lipoprotein receptor-related proteins; LRP

Definition

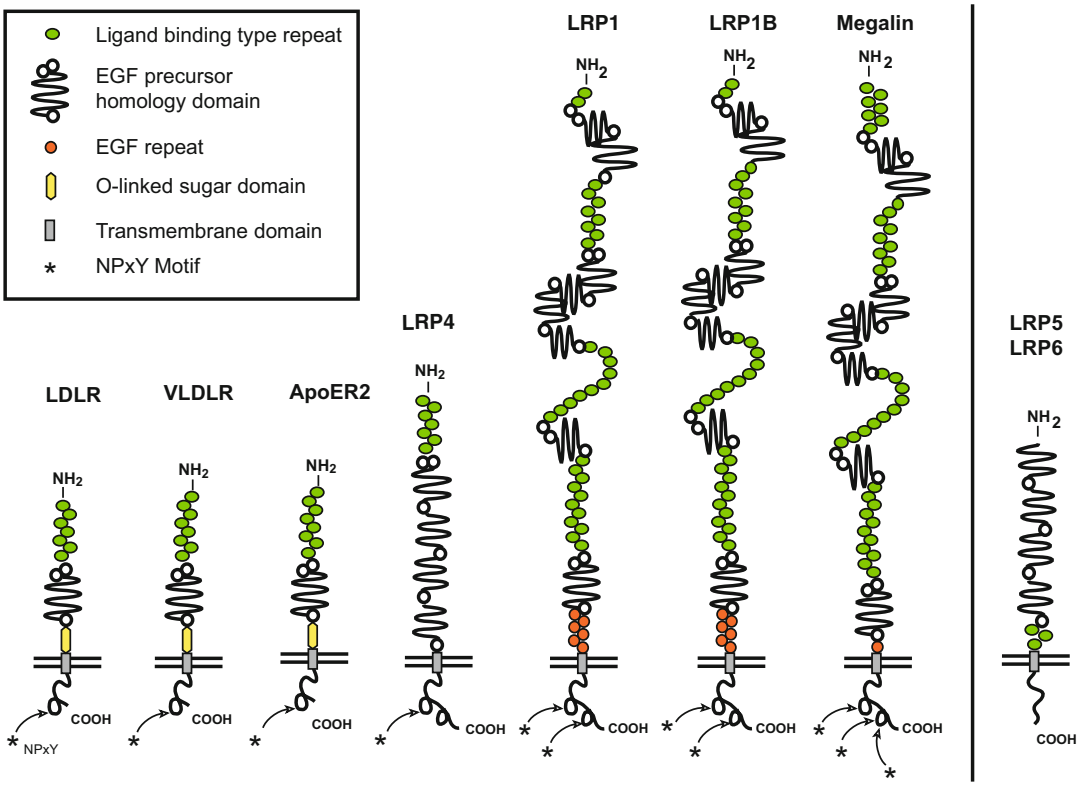
The low-density lipoprotein receptor gene family consists of structurally related cell surface proteins with diverse biological functions in numerous cell types and tissues. They are endocytic receptors that mediate binding and cellular uptake of extracellular cargo, including lipoproteins, complexes of lipids with lipid-binding proteins, proteases and protease-inhibitor-complexes, viruses, toxins, and extracellular signaling molecules. Several family members also participate directly in signal transduction processes by which cells communicate with each other and the extracellular environment. Members of the LDL receptor gene family fulfill essential roles in a number of biological processes, including lipid transport, regulation of protease activity, calcium homeostasis, cell migration, organ development, neurotransmission, and tumorigenesis.

Basic Characteristics

Structural Organization of the LDL Receptor Gene Family

The LDL receptor gene family (Fig. 1) consists of seven core members that share common structural elements in the extracellular and intracellular receptor domains, namely the family namesake LDL receptor, LRP1, LRP1b, LRP2 (megalin), LRP4 (MEGF7), LRP8 (APOER2), and very-low density lipoprotein receptor (VLDLR). They are type I transmembrane proteins with an extracellular domain that contains clusters of complement type repeats (= ligand binding type repeats), epidermal growth factor (EGF) precursor homology domains containing EGF repeats and 6 YWTD repeats that form a β-propeller structure, followed by a single transmembrane-spanning sequence and a comparatively short cytoplasmic domain that interacts with adapter and scaffolding proteins through various sequence motifs (Herz and Bock 2002; Nykjaer and Willnow 2002). The complement-type repeat clusters form calcium-dependent ligand-binding sites of different specificity, whereas the β-propeller domains allow the *pH*-dependent release of internalized ligands in the endosomes. The intracellular domains of all core members contain at least one Asn-Pro-X-Tyr (NPXY, where X designates any amino acid) tetra-amino acid motif, which is crucial for their involvement in receptor-mediated endocytosis and cellular signal transduction (May et al. 2003; Stolt and Bock 2006). The smaller members of the gene family (LDL receptor, ApoER2, and VLDLR) also contain an *O*-linked sugar domain, which may be absent due to alternative splicing and regulates proteolytic processing of the receptors. All core members of the LDL receptor gene family bind to the receptor-associated protein (RAP), an endoplasmic reticulum-associated chaperone that antagonizes binding of other lipoprotein receptor ligands. Moreover, all members of the receptor family can also interact with the cholesterol transport protein apolipoprotein E (ApoE), which exists in three major isoforms (ApoE2, 3, and 4) in humans (Lane-Donovan and Herz 2017). ApoE is the principal cholesterol-carrying apolipoprotein in the brain.

LRP5 and 6 are more distant members of the LDL receptor gene family. Their extracellular domains are arranged in a different order, with four β-propeller domains alternating with four epidermal growth factor (EGF) repeats and three complement-type repeats directly adjacent to the transmembrane-spanning segment. Moreover, their intracellular domains do not contain NPXY motifs.



Low-Density Lipoprotein Receptor Gene Family, Fig. 1 The LDL receptor gene family. The figure depicts the structural organization of mammalian members of the LDL receptor gene family

Receptor-Mediated Endocytosis and Signal Transduction

Members of this evolutionarily ancient gene family can be found in worms, insects, and vertebrates. This suggests that they evolved at an early stage of metazoan development. They can mediate the cellular uptake of extracellular cargo through a process known as receptor-mediated endocytosis, where a cell surface receptor binds a specific ligand from the extracellular space. The receptor-ligand complex is internalized via specialized regions of the plasma membrane called clathrin-coated pits and moves to an intracellular vesicle named endosome to release its cargo. The ligands are further directed to lysosomes for catabolism, while the unliganded receptor returns to the cell surface to initiate the next round of endocytosis. These concepts were first established for the LDL receptor and its role in cholesterol metabolism (Goldstein and Brown 2015).

Binding of some ligands to endocytic receptors may also trigger intracellular signaling cascades involved in the regulation of important (patho-)physiological processes such as embryonic patterning, neuronal cell migration, synaptic plasticity, or atherosclerosis. This is achieved by the interaction of conserved recognition motifs in the intracellular receptor tails with specific adaptor and scaffolding proteins, which functionally link the receptor tails to cellular trafficking, cellular signaling, and transcriptional regulation (Stolt and Bock 2006). Proteolytic processing of LRP family members offers an additional level of regulation. Soluble, released extracellular receptor domains may inhibit signaling by scavenging extracellular ligands. Sequential proteolytic cleavage of LRP family members by α- and γ-secretases can result in the release of a soluble intracellular receptor domain, which can translocate to the

nucleus and regulate transcription, as has been shown for LRP1 and LRP8.

Functions of LDL Receptor Gene Family Members

A number of human diseases are caused by sporadic or inherited forms of lipoprotein receptor deficiency (Table 1). In addition, animal models with spontaneous or induced receptor gene defects have been instrumental in elucidating the physiological roles of members of the LDL receptor gene family. The founding member of the gene family, the LDL receptor, was discovered as the gene that is defective in the autosomal-dominantly inherited disease called familial hypercholesterolemia (FH), characterized by high levels of low-density lipoprotein and premature cardiovascular disease.

LDL Receptor

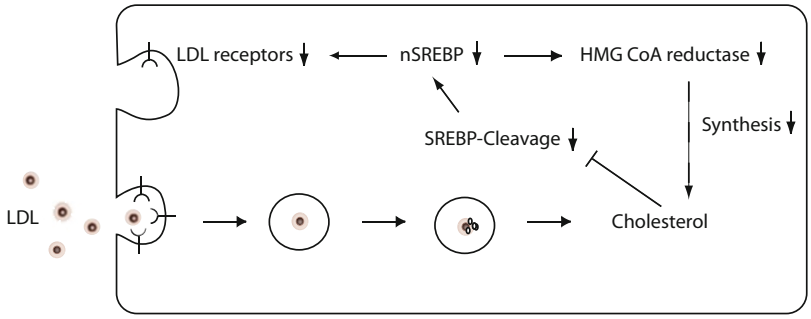
The LDL receptor (LDLR) is the founding member of the family (Goldstein and Brown 2015). It is the major endocytic receptor for cholesterol-rich lipoprotein particles. It binds lipoprotein particles that contain apolipoprotein B-100 (ApoB-100), which is the major structural apolipoprotein component of very low-density (VLDL), intermediate-density (IDL), and low-density lipoprotein (LDL) particles. In addition, LDLR binds to apolipoprotein E (ApoE), which is part of chylomicron remnants, VLDL and IDL, but not LDL.

After selective cellular uptake by receptor-mediated endocytosis in clathrin-coated vesicles, the internalized lipoprotein particle-receptor complexes are delivered to early endosomes where a decrease in *pH* allows the dissociation of the receptors from their cargo. The LDL receptors recycle back to the cell surface, whereas the lipoprotein particles are directed to lysosomes. Here, the apolipoproteins are broken down into amino acids while the cholesteryl esters are hydrolyzed and released into the cytosol for further metabolism (Fig. 2).

The uptake of lipoproteins by the LDL receptor serves two main functions. First, it delivers cholesterol to the cell which can be used for the formation of membranes, synthesis of steroid hormones and bile acids. Second, it regulates endogenous cholesterol synthesis. The importance of its regulating the concentration of cholesterol in the circulation is underscored by the phenotype observed in humans with LDL receptor gene defects, a syndrome called familial

Low-Density Lipoprotein Receptor Gene Family, Table 1 Human diseases of the LDL receptor gene family

Receptor	Type of mutation	Disease
LDL receptor	Loss-of-function (familial, autosomal dominant)	Familial hypercholesterolemia (impaired clearance of LDL)
LRP1B	Loss-of-function (somatic)	Esophageal squamous cell carcinoma, non-small-cell lung cancer
LRP4	Loss-of-function (familial, autosomal-recessive)	Cenani–Lenz syndrome (oligosyndactyly, metacarpal synostosis, phalangeal disorganization; variable facial dysmorphism)
	Loss-of-function (familial, autosomal-recessive)	Congenital myasthenic syndrome
VLDL receptor	Loss-of-function (familial, autosomal recessive)	VLDLR-associated cerebellar hypoplasia (ataxia, mental retardation, dysarthria, seizures)
LRP5	Loss-of-function (familial, autosomal recessive)	Osteoporosis-pseudoglioma-syndrome
	Gain-of-function (familial, autosomal dominant)	Increase in bone mass
	Loss-of-function	Polycystic liver disease
LRP6	Missense mutation (familial, autosomal dominant)	Hyperlipidemia, hypertension, diabetes mellitus, early coronary artery disease, osteoporosis
LRP2	Loss-of-function (familial, autosomal recessive)	Donnai–Barrow syndrome (brain and facial malformation, sensorineural hearing loss, renal tubular deficiency, diaphragmatic hernia)



Low-Density Lipoprotein Receptor Gene Family, Fig. 2 Regulation of cholesterol homeostasis by LDLR. Receptor-mediated uptake and lysosomal hydrolysis of LDL leads to accumulation of cholesterol in the ER membrane, which blocks SREBP cleavage and results in decreased nuclear SREBP (nSREBP) and decreased transcription of target genes including LDLR and HMG CoA reductase

hypercholesterolemia (FH). In patients with FH, lack of LDL receptor activity results in a massive increase in plasma LDL (approximately twofold in heterozygotes and six- to tenfold in homozygotes). As a consequence, FH patients suffer from premature atherosclerosis and coronary artery disease. To date, far more than 1000 different mutations have been identified in the human LDL receptor gene, which can be assigned to different classes: class I-mutations result in no detectable LDL receptor protein, class II-mutations prevent transport of the LDLR from the endoplasmic reticulum to the Golgi, class III-mutations result in defective ligand binding, class IV-mutations interfere with LDLR clustering in clathrin-coated pits, and class V-mutations result in defective receptor recycling to the cell surface.

Diet high in cholesterol leads to decreased transcription of the LDLR gene, which is mediated by the SREBP (sterol regulatory element-binding protein) pathway. SREBPs are membrane-anchored proteins that are transported to the Golgi and proteolytically cleaved when the cholesterol content of endoplasmic reticulum membranes drops, thus releasing a transcriptionally active fragment that translocates to the nucleus and activates genes involved in cholesterol synthesis and uptake (e.g., HMG CoA reductase, the rate-limiting enzyme in cholesterol synthesis, and LDLR itself; Fig. 2). Statins (HMG CoA-reductase inhibitors) block endogenous cholesterol synthesis in the cell. This leads to an increase in the production of LDL receptors and uptake of lipoproteins. The concomitant increase in HMG CoA reductase is inhibited by the statin. Therefore, statin treatment results in decreased plasma LDL concentrations, which reduces the risk for cardiovascular events and mortality.

The cytosolic adaptor protein ARH binds to the NPXY motif in the cytoplasmic tail of the LDLR and couples it to the endocytic machinery in hepatocytes. Mutations in the *ARH* gene cause autosomal-recessive hypercholesterolemia. An autosomal-dominant trait also causing familial hypercholesterolemia was linked to the *PCSK9* (proprotein convertase subtilisin/kexin type 9) gene, which encodes a secreted protein that binds to the extracellular domain of LDLR. PCSK9 binding to LDLR makes the receptor susceptible to enzymatic degradation by preventing a conformational change and directing it to the lysosome. Inherited gain-of-function mutations in the *PCSK9* gene cause familial hypercholesterolemia, whereas loss-of-function mutations result in low concentrations of plasma LDL cholesterol and protect against cardiovascular disease. Hence, pharmacological inhibition of PCSK9 has arisen as a novel therapeutic approach to lower LDL cholesterol to an unparalleled degree (Warden et al. 2020). Another pathway regulating lysosomal proteolysis of the LDLR and other members of the lipoprotein receptor family in various tissues involves the ubiquitin ligase IDOL (*inducible degrader of the LDLR*; a.k.a. MYLIP: myosin regulatory light chain interacting protein),

which is transcriptionally induced by activation of the sterol-responsive nuclear receptor LXR (liver X receptor).

LRP1

LRP1 (a.k.a. α2-macroglobulin receptor or CD91), one of the most versatile members of the LDLR family, is ubiquitously expressed (Herz and Strickland 2001). Conventional, constitutive inactivation of *LRP1* results in early embryonic lethality in mice. LRP1 binds more than 40 extracellular ligands including lipoproteins, protease/protease inhibitor complexes, coagulation factors, toxins, cytokines and growth factors, and has important functions both as an endocytic uptake and as a signaling receptor. The mature form of the receptor is derived from a large precursor protein of 600 kDa by proteolytic processing and consists of an 85-kDa membrane-spanning fragment including the intracellular domain and a noncovalently attached 515-kDa extracellular domain, which contains four ligand-binding domains. The intracellular domain can interact with a large number of cytoplasmic adaptor proteins, which contributes to its diverse roles in physiology and disease (May et al. 2007).

Together with the LDLR, LRP1 is the only other family member that is expressed at functionally significant levels in hepatocytes, where it mediates the uptake of ApoE-containing chylomicron remnants, lipoproteins that transport dietary lipids from the intestine to the liver. It also functions as a main uptake receptor for aggregated LDL in the vascular wall, a form of modified LDLs that promote foam cell formation and atherosclerotic lesion progression. By clearing proteases and protease inhibitor complexes from the extracellular space, LRP1 is an important regulator of extracellular proteolytic activity. This contributes to the regulation of cell motility and fibrosis, wound healing responses, tumor invasiveness, and vascular permeability, including that of the blood–brain barrier. In the lung and other tissues, LRP1 in conjunction with calreticulin can mediate the phagocytic uptake of apoptotic cells. Furthermore, bacterial toxins and viruses have been shown to use LRP1 (as well as other members of the gene family) as entry receptor on the cell surface. In the brain, neuronal LRP1 is a major receptor for astrocyte-derived ApoE-containing lipoprotein particles, and like APOER2 and VLDLR, it interacts with components of the postsynaptic density and regulates glutamatergic signaling.

In vascular smooth muscle cells, LRP1 acts as signaling receptor that suppresses the activity of the PDGF (platelet-derived growth factor) receptor-β (PDGFRB). Loss of LRP1 expression in vascular smooth muscle cells in mice enhanced activation of the PDGF receptor pathway, resulting in smooth muscle cell proliferation, hyperplasia of the aortic wall, and marked susceptibility to atherosclerotic lesion formation. Furthermore, LRP1 was shown to be identical to transforming growth factor-β (TGF-β) receptor V, which is coexpressed together with TGF-β receptors I and II. Thus, interactions between LRP1 and growth factor receptors in the vascular wall regulate signaling processes that are involved in aortic aneurysm formation and Marfan syndrome.

Another important function of LRP1 relates to the regulation of hepatic glucose and fatty acid metabolism in response to insulin, which regulates the cell surface translocation and endocytic function of LRP1 in various cell types. At the same time, LRP1 regulates the cell surface expression of the insulin receptor (IR). In consequence, loss of hepatic LRP1 attenuates insulin-dependent trafficking of glucose transporter 2 (GLUT2) to the plasma membrane, which ultimately leads to a state of insulin resistance. Thus, LRP1 is involved in the integration of hepatic lipid and glucose homeostasis and might be protective against development of the metabolic syndrome (van de Sluis et al. 2017).

Proteolytic shedding of LRP1 leads to release of a soluble form (sLRP1) that can be detected at nanomolar concentrations in human plasma. It contains the large extracellular α-chain and a 55 kDa fragment of the membrane-spanning β-chain (85 kDa subunit). The sLRP1 can act as a competitive inhibitor of ligand uptake by the uncleaved receptor. After shedding of sLRP1, the intracellular domain of LRP1 (ICD) can be released from the remaining receptor fragment by

a process called regulated intramembrane proteolysis (RIP). The ICD can translocate to the nucleus where it regulates transcription of target genes. RIP of LDLR family members has also been demonstrated for LRP8, VLDLR, and LRP2.

LRP1 also binds to amyloid precursor protein (APP), a transmembrane protein and precursor of amyloid-β (Aβ) whose fibrillar form is the major component of the neuritic plaques found in Alzheimer disease (AD). Their intracellular domains share common adaptor proteins, and processing and trafficking of APP is regulated by LRP1. Moreover, LRP1 is involved in the clearance of Aβ across the blood–brain barrier, which is modulated by ApoE in an isoform-dependent manner. Other ApoE receptor family members are also involved in APP- and Aβ-dependent processes to various degrees (Pohlkamp et al. 2017), linking them intrinsically to the pathophysiology of neurodegenerative disease.

VLDLR and APOER2 (LRP8)

Apolipoprotein E receptor 2 (APOER2, a.k.a. LRP8) and very low-density lipoprotein receptor (VLDLR) are the closest relatives of the LDL receptor (Dlugosz and Nimpf 2018). Both are expressed in the developing and adult nervous system and act as cell surface receptors of the secreted glycoprotein Reelin (Fig. 3). Binding of Reelin to LRP8 or VLDLR leads to receptor clustering and activation of an intracellular kinase signaling cascade, which is dependent on tyrosine phosphorylation of the intracellular adaptor protein Disabled-1 (DAB1) (Bock and May 2016). Defective Reelin signaling in mice or humans results in neurodevelopmental disorders with abnormal neuronal layering defects. In the adult brain, alterations in ApoE receptor-mediated Reelin signaling are involved in numerous neuropsychiatric disorders, including schizophrenia, bipolar disorder, and autism (Ishii et al. 2016).

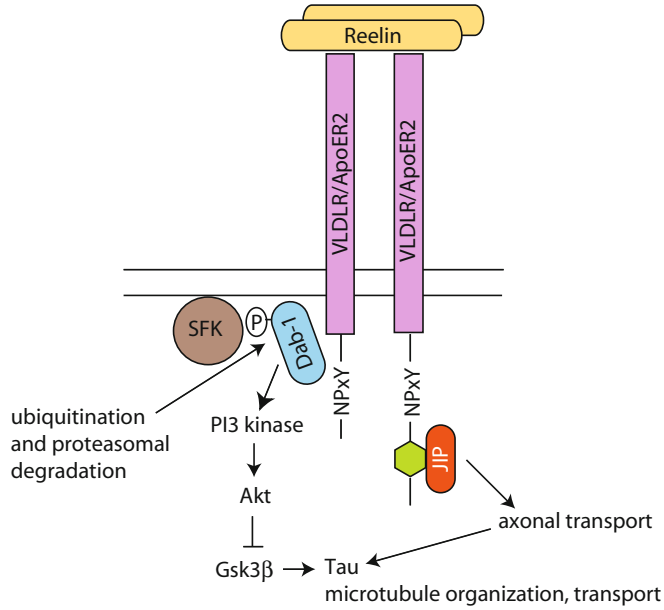
In humans, autosomal-recessive VLDLR-cerebellar hypoplasia is characterized by a predominantly truncal, nonprogressive congenital ataxia. Mice lacking VLDLR develop aberrant retinal neovascularization resembling age-related macular degeneration. This is caused by overactivation of Wnt signaling resulting in enhanced production of vascular endothelial growth factor. It was shown that the ectodomain of VLDLR inhibits Wnt signaling through heterodimerization with the LRP6 ectodomain.

In the brain, LRP8 and VLDLR associate with components of the postsynaptic density, including glutamate receptors. Reelin signaling modulates NMDA receptor function, thereby regulating synaptic plasticity. By antagonizing the synaptic suppression induced by oligomeric amyloid-β, Reelin and LRP8 may have a protective role in synaptic dysfunction associated with Alzheimer disease (Lane-Donovan and Herz 2017). The ε4 isoform of apolipoprotein E, ApoE4, constitutes a major genetic risk for the sporadic, late-onset form of Alzheimer disease. By preventing LRP8-glutamate receptor complexes from recycling to the cell surface, ApoE4 blocks Reelin's effect on synaptic plasticity.

In brain and testis, LRP8 functions as an endocytic uptake receptor for selenoprotein P (SEPP1) and contributes to the supply with selenium to these organs. Binding of SEPP1 to LRP8 occurs through the β-propeller domain and does not require the ligand-binding domain. *Lrp8*-deficient male mice display structural sperm defects and are infertile. LRP8 is also expressed in endothelial cells and platelets, where it can interact with dimerized β2-glycoprotein I bound to antiphospholipid antibodies, contributing to the pathophysiology of this autoimmune disorder.

LRP4

Various mutations of the human gene encoding LRP4 (a.k.a. *multiple epidermal growth factor-like domains 7*, MEGF7) are associated with Cenani–Lenz (C–L) syndrome, which is inherited in an autosomal-recessive manner. It is characterized by oligosyndactyly, abnormal limb development, and variable facial and systemic features (Al-Qattan and Alkuraya 2019), features that are shared by *Lrp4* mutant mice. In C–L syndrome, loss of function-mutations of *LRP4* release the antagonizing effect of LRP4 on LRP6, which is an essential coreceptor of frizzled in the canonical WNT signaling cascade (Niehrs 2006). This results in overactivation of the canonical WNT signaling pathway, ultimately leading to



Low-Density Lipoprotein Receptor Gene Family, Fig. 3 Signal transduction by members of the LDL receptor gene family: simplified scheme of Reelin signaling in neurons via lipoprotein receptors VLDLR and APOER2. Binding of Reelin induces clustering of DAB1 on the cytoplasmic receptor tails, which activates SRC family tyrosine kinases (SFKs) that phosphorylate the adaptor. Phosphorylated DAB1 activates phosphatidylinositol-3-kinase (PI3K) and protein kinase B (PKB). PKB inhibits the activity of glycogen synthase kinase 3β (GSK3β), resulting in reduced phosphorylation of Tau (τ) and stabilization of microtubules. A proline-rich region in the intracellular domain of APOER2, which is encoded by an alternatively spliced exon that is absent from other lipoprotein receptors, interacts with intracellular proteins including JNK-interacting protein (JIP) and postsynaptic density protein-95 (PSD95)

increased β-catenin stability and target gene transcription.

LRP4 is required for the formation and maintenance of the neuromuscular junction (NMJ) – a chemical synapse between skeletal muscle fibers and motor neurons – as well as for the signal transduction occurring there (Ohno et al. 2017). Autoantibodies against LRP4 have been reported in patients with seronegative myasthenia gravis, an autoimmune disease where inhibitory antibodies block acetylcholine receptor (AChR)-mediated neurotransmission. At the NMJ, LRP4 forms a heteromeric complex with muscle-specific receptor tyrosine kinase (MuSK). This complex functions as a transmembrane receptor for the motor neuron-derived proteoglycan agrin, which binds to the extracellular domain of LRP4 and indirectly activates the intracellular kinase domain of MuSK. MuSK phosphorylation leads to the recruitment and activation of downstream proteins, ultimately driving aggregation of the AChR-clustering scaffold protein rapsyn. Studies in gene-targeted mice suggest that LRP4 is also involved in synaptogenesis and neurotransmission in the central nervous system.

LRP5 and 6

LRP5 and 6 are distant relatives of the core members of the LDL receptor gene family (Fig. 1). Both receptors are highly homologous proteins that are integral components of the wingless (Wnt) signaling cascade by acting as coreceptors to a member of the Frizzled (Fz) family of seven-transmembrane proteins (Joiner et al. 2013). In the extracellular receptor domain, four β-propeller motifs, each connected by an EGF-like domain, are followed by three ligand binding type repeats (LBRs), which can mediate interaction with apolipoprotein E. In contrast to core members of the LRP family, the ligand binding domains and

β-propeller motifs are arranged in an inverse order, with the LBRs adjacent to the transmembrane-spanning segment rather than at the aminoterminal end, and the intracellular domain does not contain an *NPXY* tetraamino-acid motif.

Simultaneous binding of Wnt ligands to LRP5 or 6 and Fz induces canonical Wnt signaling, ultimately leading to increased β-catenin levels in the cytoplasm and nucleus, where it forms complexes with LEF/TCF family members to control transcription of target genes. Secreted proteins such as Dickkopf-1 (Dkk1), Wise, or sclerostin antagonize Wnt signaling by binding to LRP5/6, thereby disrupting the Wnt-induced Fz/LRP complex. In addition, Dkk1 binding to its coreceptor Kremen may inhibit Wnt signaling by promoting endocytosis of a ternary Kremen-Dkk1-LRP6 complex, removing LRP6 from the plasma membrane. Moreover, β-catenin independent LRP5/6 signaling has been reported.

Loss of LRP6 function in fruit fly, *Xenopus*, and mouse causes aberrant pattern formation and early embryonic lethality. A causal *LRP6* mutation in a family with early coronary disease, hypercholesterolemia, and glucose intolerance has been described. LRP5 activity is mainly required for the regulation of bone formation as concluded from loss- and gain-of-function mutations in humans. Sclerostin is produced by osteocytes and inhibits Wnt signaling by binding to LRP5/6. Its inactivation causes sclerosteosis, a rare disorder that is characterized by overgrowth of bone tissue. *LRP5* missense mutations were associated with polycystic liver disease. In mice, simultaneous inactivation of *Apoe* and *Lrp5* led to dyslipidemia and atherosclerosis.

LRP1B

LRP1B is a giant member of the LDL receptor gene family that shares extensive homology with LRP1. It was originally named LRP-DIT (*deleted-in-tumors*), because it was found to be frequently inactivated in non-small cell lung cancer (NSCLC) cell lines. Inactivation of the *LRP1B* gene has been observed in several types of human cancers. Therefore, it has been suggested to function as a tumor suppressor gene. Moreover, genome-wide association (GWA) studies have shown its genetic association with obesity. Mice carrying inactivating mutations of the *Lrp1b* gene display early embryonic lethality, whereas expression of a truncated allele predicted to allow secretion of the complete extracellular domain of LRP1b is sufficient to allow normal development without any obvious phenotype. Both LRP1 and LRP1B display an overlap in expression patterns and share common extracellular ligands, but in contrast to LRP1, LRP1B is not cleaved by furin and has a very slow endocytosis rate. This suggests that both receptors might partially antagonize each other's functions (May et al. 2007).

LRP2

LRP2 (a.k.a. megalin or gp330) is the largest member of the LDL receptor gene family. It was initially identified as the antigen giving rise to Heymann nephritis, a rat experimental model of human membranous nephropathy. It functions as an endocytic clearance receptor for a variety of extracellular ligands and is specifically expressed by absorptive epithelia in the kidney, brain, lung, eye, and reproductive organs (Willnow and Christ 2017). The interaction of the cytoplasmic receptor tail with different adaptor proteins governs the fate of internalized LRP2, which is either directed for lysosomal degradation or recycled back to the apical cell surface. In addition, trafficking from the apical to the basolateral plasma membrane enables transcytosis through polarized epithelia, e.g., in thyroid cells.

A major function of LRP2 in the kidney is its role as uptake receptor for plasma proteins from the tubular lumen, including low-molecular weight transport proteins for the vitamins D, A, and B_{12}. Lack of megalin in *Lrp2* deficient mice results in excessive urinary loss of filtered 25-OH vitamin D_3 bound to the vitamin D-binding protein (DBP), leading to osteomalacia due to vitamin D deficiency. In a similar manner, megalin is involved in vitamin A homeostasis by renal reuptake of retinol bound to retinol-binding protein (RBP).

Megalin interacts with cubilin (CUBN), a cargo protein that is mainly expressed in the kidney and small intestine. Because cubilin lacks a

transmembrane domain, the interaction with megalin is required for its endocytosis in proximal tubule cells. Mutations in *LRP2* and *CUBN* have been recognized as being involved in congenital forms of renal Fanconi syndrome, characterized by proximal tubular dysfunction with low-molecular weight proteinuria, phosphaturia, and renal tubular acidosis (Willnow and Christ 2017). Autosomal-recessive mutations in the *LRP2* gene give rise to the Donnai–Barrow syndrome, a rare human inherited disorder characterized by facial dysmorphology, agenesis of the corpus callosum (a form of holoprosencephaly), sensorineural hearing loss, developmental delay, progressive vision loss, and renal dysfunction. Despite the importance of megalin for renal reabsorption processes, including nephrotoxic drugs such as aminoglycoside antibiotics, and vitamin homeostasis, no therapeutic applications related to LRP2 have been developed yet.

Another important function of megalin is the control of morphogen signaling during organogenesis. By forming a receptor complex with the transmembrane protein Patched 1 (PTCH1), a receptor of the morphogen sonic hedgehog (SHH), on the apical surface of neuroepithelial cells, megalin facilitates binding and internalization of SHH bound to PTCH1. This in turn reduces the suppressive action of PTCH1 on Smoothened (SMO), which mediates the cellular effects of SHH signaling in the primary cilium. Consequently, inactivation of *LRP2* in mice results in holoprosencephaly resembling mice carrying mutations in components of the sonic hedgehog pathway.

Drugs

Statins

Statins lower plasma LDL cholesterol by inhibiting HMG CoA-reductase, the rate-limiting step of endogenous cholesterol synthesis in the cell (Goldstein and Brown 2015). The reduced cellular membrane cholesterol content activates SREBP-2, which results in increased LDLR cell surface expression and LDL uptake. HMG CoA reductase expression is also increased but cholesterol synthesis is inhibited by the statin. Lowering LDL-C by statins reduces the risk for cardiovascular events and mortality, and is a cornerstone of primary and secondary prevention of atherosclerosis and coronary artery disease (Boekholdt et al. 2014). There are six statins available, namely simvastatin, atorvastatin, fluvastatin, pravastatin, rosuvastation, and lovastatin, the latter being the first statin approved for medical use in 1987. Cerivastatin was withdrawn due to an increased risk of rhabdomyolysis. Other common side effects include myalgia and an increase in liver enzymes.

PCSK9 Inhibitors

Two monoclonal antibodies that bind to and inhibit PCSK9, thereby increasing cell-surface LDLR and reducing plasma LDL-C, have been approved for human therapeutic use both by the FDA and the European Union (EU) in 2015, namely alirocumab (Praluent™) and evolocumab (Repatha™). A third inhibitor, bococizumab, was withdrawn due to a relatively high incidence of neutralizing antidrug antibodies (Warden et al. 2020).

Alirocumab was approved as a second-line therapy for adults with familial hypercholesterolemia and people with atherosclerosis who require additional lowering of LDL cholesterol when diet and statin treatment alone have not worked, or when statins are not tolerated or are contraindicated. Evolocumab was the first PCSK9 inhibitor approved in the EU. Based on the results of two large-scale phase 3 trials, FOURIER (Further cardiovascular OUTcomes Research with PCSK9 Inhibition in subjects with Elevated Risk) for evolocumab, and ODYSSEY OUTCOMES (Evaluation of Cardiovascular Outcomes After an Acute Coronary Syndrome During Treatment With Alirocumab), both monoclonal antibodies also carry an indication for the reduction of cardiovascular events in patients with established atherosclerotic cardiovascular disease. Whether overall mortality reduction can be achieved by PCSK9 inhibition remains to be established. Side effects mainly included local injection site reactions. Adverse effects related to

cognitive impairment were not confirmed in the abovementioned trials.

Other approaches to lower PCSK9 that have not reached clinical practice (yet) include siRNA oligonucleotides (Inclirisan), vaccination or oral small-molecule inhibitors of PCSK9.

Romosozumab

The LRP5/6 antagonist sclerostin (SOST) is targeted by the inhibitory humanized monoclonal antibody romosozumab (Evenity™), which has been approved in the United States and EU for the treatment of osteoporosis in postmenopausal women with high risk of fracture in 2019 (Markham 2019). The drug is contraindicated in patients with hypocalcemia. In clinical trials, an increase in serious cardiovascular events in romosozumab-treated patients was observed. Therefore, the antibody is contraindicated in patients with a history of myocardial infarction or stroke.

Lipoprotein Receptors for Drug Delivery

In principle, lipoproteins or lipoprotein-like synthetic particles can be conceived as carriers to transport therapeutic or diagnostic agents (especially lipophilic compounds) to their cellular destination, making use of the highly efficient and specific ligand-receptor uptake systems provided by LDLR family members. To date, however, no such application has found its way into clinical practice yet.

Definition

The term lysophosphatidic acid describes a class of structurally related monoacyl-glycerol-3-phosphates which belong to the lysophospholipids.

Basic Characteristics

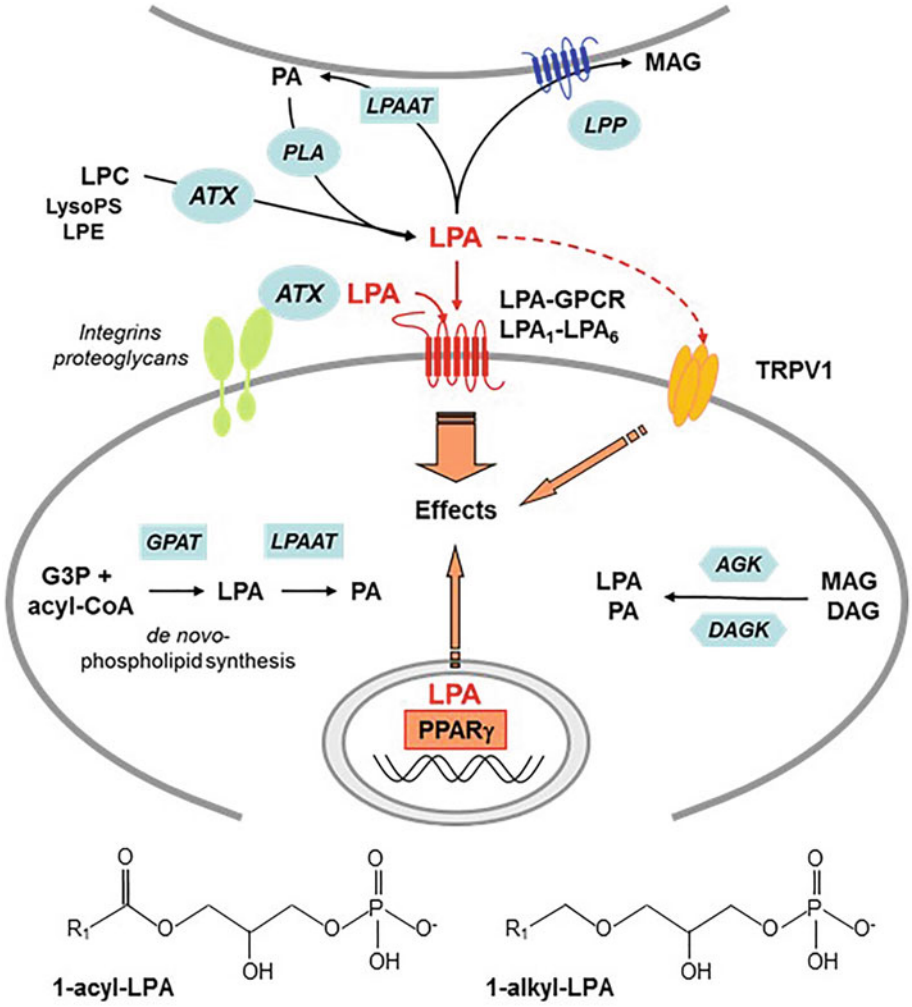
Metabolism

Lysophosphatidic acid (LPA) can be formed and degraded by multiple metabolic pathways (Fig. 1). Depending on the precursor molecule and respective pathway, the fatty acid chain in LPA differs in length, degree of saturation, and position (sn-1 or sn-2). LPA analogues with ether-bound alkyl or alkenyl chains are quantitatively less abundant than those with ester-bound acyl chains. LPA occurs in plasma (~200 nM), is formed during coagulation, and is present in serum in micromolar concentrations. Differences in the fatty acid composition of LPA in plasma and serum suggest that the sources of these LPA pools are different. LPA's chemical structure determines its interaction with LPA receptors and its biological activity (Yung et al. 2014).

Extracellular LPA is generated primarily from LPC by a lysophospholipase D named autotaxin (ATX; human gene name: *ENPP2*). LPA production by ATX is essential for embryonic development in mice and contributes most of LPA in plasma. In fact, ATX inhibitors can reduce plasma LPA by >95% (Yung et al. 2014; Benesch et al. 2018). Binding of ATX to cell surface integrins and proteoglycans facilitates the direct delivery of LPA to its GPCR (Peyruchaud et al. 2019). Extracellular LPA can furthermore be generated from surface-exposed phosphatidic acid by phosphatidic acid-selective PLA_1 or secretory type-II PLA_2. Intracellularly, LPA can be formed by glycerol-3-phosphate acyltransferases ($GPAT_{1-4}$) (Yu et al. 2018) or by phosphorylation of monoacylglycerol. Phosphorylation may be catalyzed by mitochondrial acylglycerol kinase (AGK) or by diacylglycerol kinase (DAGK) isoforms with partial monoacylglycerol kinase activity (Tigyi et al. 2019). Degradation of LPA occurs via dephosphorylation, catalyzed by lipid phosphate phosphatases (LPP_{1-3}; human gene names: *PLPP1-3*), or by acylation, catalyzed by LPA acyltransferases (LPAATα-ε; human gene names: *AGPAT1-5*) (Tang et al. 2015; Bradley and Duncan 2018). LPPs are integral membrane proteins with their catalytic activity directed to the extracellular space or to the luminal side of organelles. They can dephosphorylate diverse phospholipids and lysophospholipids and thereby regulate extra- and intracellular levels of both LPA and sphingosine-1-phosphate (Tang et al. 2015).

LPA Receptors

An overview of LPA receptors as listed in the IUPHAR/BPS Guide to Pharmacology is



Lysophosphatidic Acid, Fig. 1 The LPA signaling system. AGK, acylglycerol kinase; ATX, autotaxin; DAG, diacylglycerol; DAGK, diacylglycerol kinase; G3P, glycerol-3-phosphate; GPAT, glycerol-3-phosphate acyltransferase; GPCR, G-protein-coupled receptor; LPAAT, LPA acyltransferase; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; LPP, lipid phosphate phosphatase; LysoPS, lysophosphatidylserine; MAG, monoacylglycerol; PA, phosphatidic acid; PPARγ, peroxisome proliferator-activated receptor-γ; TRPV1, transient receptor potential cation channel subfamily V member 1

presented in Table 1. These receptors, $LPA_{1\text{-}6}$ (human gene names: *LPAR1-6*), are class A GPCR and widely expressed. $LPA_{1\text{-}3}$ belong to the EDG family of GPCR, while $LPA_{4\text{-}6}$ form a subcluster within the purinergic P2Y receptor family. LPA-GPCR differentially couple to $G_{i/o}$, $G_{q/11}$, and $G_{12/13}$ proteins, and LPA_4 and LPA_6 also couple to G_s (Table 1). Thus, they regulate classical signaling pathways such as adenylyl cyclase, phospholipase C, $[Ca^{2+}]_i$, protein kinase C, mitogen-activated protein kinases, Akt, Ras, Rac, and Rho. The LPA_2 receptor has a unique C-terminus which binds LIM domain-containing proteins and has a PDZ binding motif for G-protein-independent signaling (Tigyi et al. 2019). Non-GPCR targets of LPA comprise the nuclear transcription factor, peroxisome proliferator-activated receptor-γ (PPARγ), and diverse ion channels. While several ion channels are downstream targets of LPA-GPCR, direct binding of LPA to

Lysophosphatidic Acid, Table 1 G-protein-coupled LPA receptors

Receptor (previous names)	Signaling	Main biological effects
LPA_1 (EDG2, VZG1)	$G_{i/o}$, $G_{q/11}$, $G_{12/13}$	Cell proliferation, survival, migration, neurite retraction, brain development, olfaction, neuropathic pain −/− mice: 50% perinatal lethality, defective olfaction/impaired suckling, decreased body size, craniofacial dysmorphism
LPA_2 (EDG4)	$G_{i/o}$, $G_{q/11}$, $G_{12/13}$ PDZ binding	Cell proliferation, survival, migration, facilitation of DNA damage repair −/− mice: mostly normal
LPA_3 (EDG7)	$G_{i/o}$, $G_{q/11}$	−/− mice: defective embryo implantation and spacing
LPA_4 (P2Y9, GPR23)	G_s, $G_{i/o}$, $G_{q/11}$, $G_{12/13}$	Rho-mediated neurite retraction, cell motility ↓ −/− mice: enhanced LPA-induced cell migration, reduced numbers of hematopoietic stem/progenitor cells
LPA_5 (GPR92)	$G_{q/11}$, $G_{12/13}$	Neurite retraction, cell motility ↓, release of proinflammatory cytokines, neuropathic pain −/− mice: reduced pain sensitivity, faster recovery from inflammation, nocturnal hyperactivity and anxiety
LPA_6 (P2Y5)	G_s, $G_{i/o}$, $G_{12/13}$	Hair growth, neurite retraction, telencephalon development, vascular stability Human mutations: woolly hair, hypotrichosis

the transient receptor potential (TRP) ion channels, TRPV1 and TRPA1, may contribute to LPA-mediated pain and itch (Juárez-Contreras et al. 2018).

Biological Actions

The ATX/LPA receptor axis plays an important role in organismal **development**. In mice, ATX is required for vessel formation in yolk sac and embryos, neural crest development, and axial turning. *Lpar1* is highly expressed in the neurogenic ventricular zone of the embryonic cerebral cortex and important for neural development, olfaction, and craniofacial development in mice. *Lpar3* is expressed in the endometrial epithelium during embryo implantation and involved in cyclooxygenase-2-dependent implantation and embryo spacing in mice. Blood and lymphatic vessel development, also in extraembryonic vessels, depends furthermore on *Lpar4*. The LPA_6 receptor regulates hair growth and texture, and its mutation causes woolly hair with or without hypotrichosis in humans. In contrast to ATX knockout, deletion of single LPA receptors in mice is not fully lethal during embryonic development, indicating some redundancy. LPA/LPA_1 is furthermore involved in post-hemorrhagic fetal hydrocephalus (Yung et al. 2014; Sheng et al. 2015; Benesch et al. 2018).

In the adult organism, the ATX/LPA axis is involved in **tissue remodelling and wound healing** (Benesch et al. 2018). Platelets release high amounts of LPA during blood clotting. LPA in turn induces platelet aggregation, vasoconstriction, and proliferation and migration of fibroblasts. In endothelial cells, LPA promotes surface expression of leukocyte adhesion molecules. LPA is present in oxidized low-density lipoproteins (LDL) and accumulates in atherosclerotic plaques where it acts proinflammatory and promotes monocyte recruitment, macrophage-foam cell transformation, proliferation and migration of vascular smooth muscle cells, and neointima and thrombus formation. Therefore, LPA plays a role in atherosclerosis (Zhao et al. 2019; Zhou et al. 2019). A major source of ATX in plasma is adipose tissue, but the role of ATX/LPA in obesity remains contradictory. ATX/$LPA_{1,3}$ signaling impairs insulin sensitivity and deteriorates glucose tolerance (D'Souza et al. 2018). LPA furthermore regulates functions of T cells, macrophages, mast cells, neutrophils, and dendritic cells and is involved in **immunity, inflammation, and fibrosis**. ATX, LPA_4, and LPA_6 promote T cell entry into lymph nodes.

The role for ATX/LPA in fibrosis of the lung, kidney, liver, and skin is underlined by the clinical development of ATX inhibitors and LPA_1 receptor antagonists in these areas of indication. LPA is also involved in chronic inflammatory diseases such as bronchial asthma and rheumatoid arthritis (Yung et al. 2014; Ninou et al. 2018; Magkrioti et al. 2019). The ATX/LPA receptor axis plays an important role in the adult nervous system and has been implicated in numerous diseases of the central and peripheral nervous systems (Herr et al. 2019). ATX, LPA_1, LPA_3, and LPA_5 contribute to **neuropathic pain**. Different LPA receptor antagonists/ATX inhibitors were protective in mouse models of chemotherapy-induced or diabetic neuropathy (Velasco et al. 2017). Finally, ATX and LPA are secreted by many **cancers**, both by tumor cells and by cells of the tumor microenvironment. They promote invasion and metastasis and inhibit antitumor immunity. Furthermore, both ATX and LPA_2 play a role in DNA damage repair and counteract apoptosis-inducing therapies such as ionizing radiation or chemotherapy (Tigyi et al. 2019; Leblanc et al. 2018; Benesch et al. 2018).

Drugs

Several LPA_1 receptor antagonists and ATX inhibitors are in clinical development for treatment of fibrotic diseases (Table 2). SAR100842 is a negative allosteric modulator of the LPA_1 receptor and in phase II clinical trials for systemic sclerosis (Allanore et al. 2018). A phase II study with the LPA_1 antagonist, BMS-986020, for treatment of idiopathic pulmonary fibrosis, was terminated because of three cases of cholecystitis related to BMS-986020 (Palmer et al. 2018) (ClinicalTrials.gov Identifier: NCT01766817). An orthosteric LPA_1 antagonist, BMS-986202, is in phase I with the future indication psoriasis (ClinicalTrials.gov Identifier: NCT02763969). Several ATX inhibitors are listed in the clinical trial database. GLPG1690 (Maher et al. 2019) has been granted orphan drug designation for idiopathic pulmonary fibrosis and systemic sclerosis. Other ATX inhibitors, such as BBT-877 (future indication, idiopathic pulmonary fibrosis) and BLD-0409 (future indication, nonalcoholic steatohepatitis), are currently entering clinical development (Table 2).

Lysophosphatidic Acid, Table 2 Drugs targeting the LPA signaling system

Drug	Target	Indication	Stage
SAR100842	LPA_1 negative allosteric modulator	Systemic sclerosis	Phase II
BMS-986020	LPA_1 antagonist	Idiopathic pulmonary fibrosis (study terminated because of serious adverse events)	Phase II
BMS-986202 (AM152)	LPA_1 antagonist	Psoriasis	Phase I
GLPG1690	ATX inhibitor	Idiopathic pulmonary fibrosis Systemic sclerosis	Orphan drug
BBT-877	ATX inhibitor	Idiopathic pulmonary fibrosis	Phase I
BLD-0409	ATX inhibitor	Chronic liver disease, nonalcoholic steatohepatitis	Phase I

Lysophospholipids

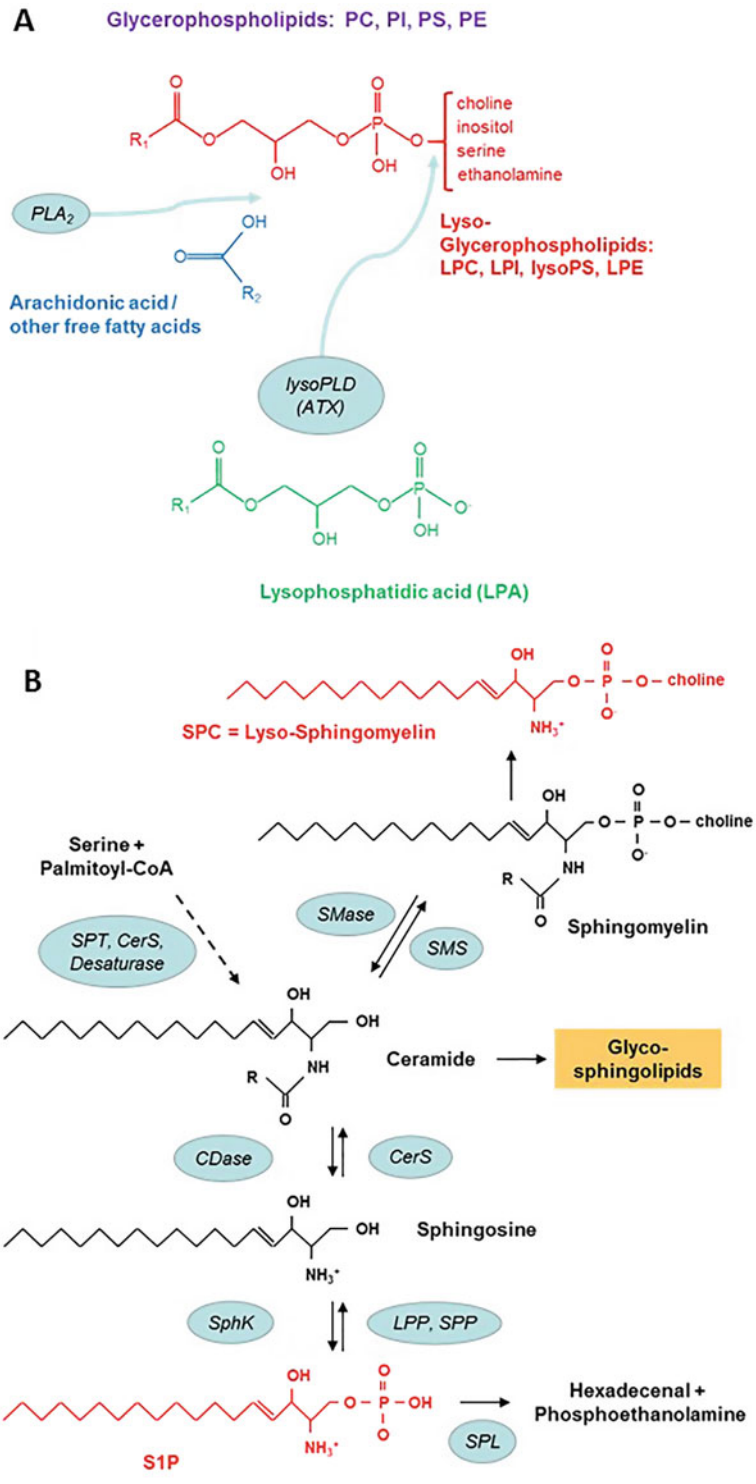
Dagmar Meyer zu Heringdorf
Institut für Allgemeine Pharmakologie und Toxikologie, Goethe-Universität Frankfurt am Main, Frankfurt, Germany

Synonyms

Lysoglycerophospholipids; Lysolipid mediators; Lysosphingolipids

Definition

Lysophospholipids are small bioactive lipid molecules characterized by a single carbon chain and a phosphate-containing polar head group. Two subgroups can be distinguished: molecules based on the glycerol backbone (lysoglycerophospholipids) and molecules based on the sphingoid base backbone (lysosphingolipids). The lysolipid structure renders these lipids more hydrophilic and versatile than their corresponding phospholipids. Cleavage



Lysophospholipids, Fig. 1 (**a**) Generation of lysoglycerophospholipids and arachidonic acid/other free fatty acids by phospholipase A_2 (PLA_2), and generation of lysophosphatidic acid (LPA) by autotaxin (ATX). LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; LPI, lysophosphatidylinositol; lysoPS, lysophosphatidylserine; PC,

of glycerophospholipids by phospholipases A_2 (PLA_2) simultaneously generates free fatty acids such as arachidonic acid, the precursor of eicosanoids, and lysoglycerophospholipids such as lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), lysophosphatidylserine (lysoPS), or lysophosphatidylinositol (LPI) (Fig. 1a). Further cleavage of their head groups results in lysophosphatidic acid (LPA), the simplest lysophospholipid (Fig. 1a). The lysosphingolipids, sphingosine-1-phosphate (S1P) and sphingosylphosphorylcholine (SPC), are products of sphingolipid metabolism as shown in Fig. 1b. Other lysosphingolipids, namely, psychosine (galactosylsphingosine) and glucopsychosine (glucosylsphingosine), lack a phosphate group.

Lysophospholipids may act as extracellular agonists at specific G-protein-coupled receptors (GPCR) and/or as versatile intracellular mediators. Bona fide lysophospholipid receptors as listed in the IUPHAR/BPS Guide to Pharmacology comprise the class A GPCR, $LPA_{1\text{-}6}$ (human gene names: *LPAR1-6*), and $S1P_{1\text{-}5}$ (human gene names: *S1PR1-5*) (Blaho et al. 2019a, b). Other lysophospholipid GPCR are still listed as orphan receptors. They comprise the potential LysoPS-GPCR, GPR34, GPR174, and P2Y10 (Kihara et al. 2015; Yatomi et al. 2018) and the potential LPI-GPCR, GPR55 (Alhouayek et al. 2018). Previous reports on G2A, TDAG8, OGR1, or GPR4 as SPC- and/or LPC-GPCR have in part been retracted; the role of these GPCR remains largely unclear.

Of all lysophospholipids, LPA and S1P have been characterized in greatest detail so far. They are auto- or paracrine regulators of cell proliferation and survival, cell migration and chemotaxis, cytoskeletal architecture, cell-cell contacts and adhesion, Ca^{2+} homoeostasis, and Ca^{2+}-dependent functions. By regulating these cellular responses, they play a role in organism development and homeostasis of many tissues within the cardiovascular, nervous, immune, and metabolic systems.

Serine/threonine protein kinase phosphorelay modules

Definitions

Mitogen activated protein kinase (MAPK) cascades are three kinase modules activated by phosphorylation. These modules are composed of a MAPK, a MAPKK, and a MAPKKK. Each component in the MAPK cascade is composed of multiple family members that are conserved from yeast to human. MAPK modules are selectively activated by different, specific stimuli including growth factors, cytokines, and cellular stresses. Activation of MAPK modules results in changes in gene expression and the control of diverse cellular functions such as growth, migration, and apoptosis.

Basic Characteristics

Characteristics of MAPK Cascades

MAPK cascades are signaling modules that mediate signal transduction of diverse, cellular stimuli to the nucleus to control gene expression (Widmann et al. 1999; Cuevas et al. 2007). These stimuli include growth factors, cytokines, and bacterial products. MAPK cascades are also activated by numerous cellular stresses such as irradiation, cold and heat shock, hyperosmolarity, and oxidative stress. Selective stimulation of MAPK modules leads to changes in cellular function, including proliferation, differentiation, survival, apoptosis, migration, and adhesion.

MAPK cascades are composed of three cytoplasmic kinases, the MAPKKK (MAP3K), MAPKK (MAP2K), and the MAPK that are regulated by phosphorylation (Fig. 1). The MAP3Ks are a large family of structurally diverse, serine/threonine kinases that are differentially activated by upstream stimuli. Activated MAP3Ks phosphorylate specific MAP2Ks, also called MEKs for MAP/ERK kinase. The MAP2K is phosphorylated by the MAP3K on two specific serine/threonine residues in its activation loop. The MAP2Ks are a family of seven, dual specificity kinases that phosphorylate threonine and tyrosine residues in the activation loop of specific MAPKs.

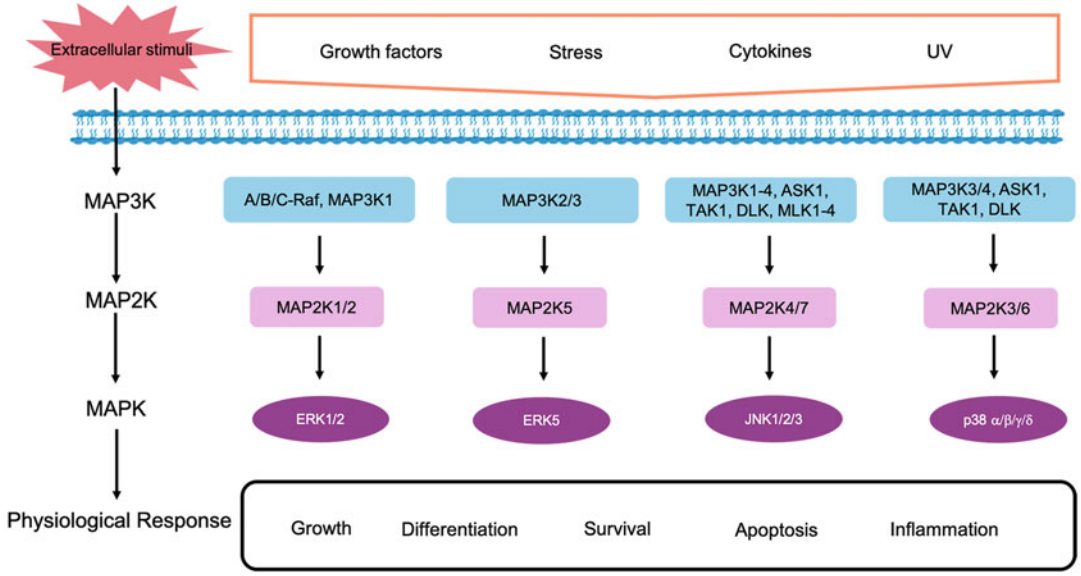
https://doi.org/10.1007/978-3-030-57401-7



MAP Kinase Cascades, Fig. 1 Organization of MAPK cascades. See text for details

The MAPKs are a family of 13 serine/threonine kinases. Phosphorylation and activation of MAPKs by MAP2Ks result in MAPK phosphorylation of specific cytoplasmic substrates. In addition, phosphorylated MAPKs translocate to the nucleus where they phosphorylate transcription factors and regulate gene expression. MAPKs are divided into the following six subfamilies: extracellular signal-regulated kinases (ERKs) 1 and 2, ERK5, Jun amino-terminal kinases (JNKs) 1, 2, and 3, p38 kinase members p38α, β, γ, and δ, atypical ERK3/4, and atypical ERK7/8. This review will focus on the four most characterized subfamilies, ERK1/2, ERK5, JNK, and p38 kinase (Fig. 1).

Characteristics of the ERK1/2 Pathway

Extracellular signal-regulated kinase (ERK) 1 and ERK2 are also called p44 MAPK and p42 MAPK, respectively. These MAPKs are expressed ubiquitously in most cell types. ERK1 and ERK2 play critical roles in the promotion of cell proliferation and survival, making them critical targets of anticancer therapies. ERK1/2s are the end components of several three kinase signaling modules that are activated in response to growth factors and cellular adhesion. These stimuli activate specific MAP3Ks, including RAF kinases and MEK kinase 1 (MEKK1/MAP3K1). MAP3K1 and RAF kinases phosphorylate and activate specific MAP2Ks called MAP2K1 and MAP2K2, more commonly called MAP/ERK kinase (MEK) 1 and MEK2. MEK1/2 dual phosphorylate threonine and tyrosine in a conserved threonine-glutamate-tyrosine (TEY) motif in the catalytic domain of ERK1/2. Active ERK1/2 phosphorylate many substrates in the cytoplasm, including ribosomal S6 kinase, phospholipase A2, and microtubule associated proteins. Further, active ERK1/2 translocate to the nucleus to promote the phosphorylation and transcriptional activity of several transcription factors, including ELK1, ETS1, and MYC. Dual specificity protein phosphatases (DUSP1 and DUSP2) dephosphorylate both threonine and tyrosine in the ERK1/2 catalytic domain, decreasing ERK1/2 activity (Widmann et al. 1999).

The selective deletion of ERK1 or ERK2 in mice has been used to define their biological functions. Although animals with the deletion of ERK1 are overtly normal, deletion of ERK2 results in early embryonic lethality due to defective placental development. Interestingly, deletion of one upstream activator of this MAPK cascade, the MAP3K CRAF, also results in early embryonic lethality due to placental defects. Knockout of the MAP3K BRAF or the MAP2K MEK1 results in

embryonic lethality due to vascular and angiogenesis defects (Pearson et al. 2001). These studies show the critical roles of the ERK1/2 MAPK cascades in cell proliferation, migration, differentiation, and angiogenesis during development. Further, aberrant activation of the ERK signaling module is responsible for the majority of cancers.

Characteristics of the ERK5 Pathway

ERK5 was originally named Big MAP Kinase (BMK1) owing to it being over twice the size of ERK1/2 (Nithianandarajah-Jones et al. 2012). This larger size is due to the presence of a long C-terminal extension not found in other MAPKs. Similar to ERK1/2, ERK5 is expressed in most cell types, tissues, and organs, and is activated in response to growth factors similar to ERK1/2. ERK5 is also activated by cellular stresses such as oxidative stress and hyperosmolarity similar to the MAPK members JNK and p38. Although ERK5 is activated by growth factors and cellular stresses, it is phosphorylated by distinct MAP3K and MAP2K family members. MAP3K2 and MAP3K3 are the sole MAP3Ks that activate MAP2K5 (MEK5). MAP3K2, MAP3K3, and MEK5 share a Bem1P (PB1) domain that is used for binding between the upstream components of this MAP3K/MAP2K module. MEK5 selectively phosphorylates the TEY motif in the catalytic domain of ERK5, and MEK5 is not used to activate other MAPKs. Active ERK5 phosphorylates many transcription factors, including MEF2A, C, and D, and increases their transactivation.

Individual components of the MAP3K2/3/MEK5/ERK5 pathway have been deleted in mice to determine the biological roles of these components. Although mice lacking MAP3K2 are overtly normal, MAP3K3 deletion results in early embryonic lethality due to defects in angiogenesis. Deletion of MEK5 is also early embryonic lethal due to defects in cardiac development, and increased apoptosis in several regions including the heart. ERK5 knockout results in early embryonic lethality due to defects in both the embryo and the placenta. Defects include defective heart development and angiogenesis. Deletion of MEF2C also results in death due to cardiac and vascular defects. Together, these studies demonstrate the critical function of this MAP3K3/MEK5/ERK5 signaling module in regulation of development. In addition to roles in blood vessel and cardiac development, ERK5 expression has been implicated in promoting several diseases including cancer.

Characteristics of the JNK Pathway

Jun amino-terminal kinases (JNKs) are a subfamily of MAPKs composed of three members, JNK1, 2, and 3 (Zeke et al. 2016). This family is named based on their shared ability to phosphorylate and activate the transcription factor Jun. They were also called stress-activated protein kinases (SAPKs) due to their activation in response to cellular stresses, including osmotic shock and irradiation. JNKs are also activated in response to stimulation by many growth factors and cytokines. Activation by these stimuli leads to JNK-mediated regulation of a diverse set of genes including growth factors, cytokines, extracellular matrix proteins, and matrix metalloproteinases. JNK activation is induced by over a dozen different MAP3Ks, including MAP3K1-4 and MLK1-4. These MAP3Ks selectively phosphorylate and activate MAP2K4 and 7, which in turn phosphorylate the threonine-proline-tyrosine (TPY) motif in the catalytic domain of JNKs. The presence of this proline is unique to JNKs. There are approximately 100 reported JNK substrates that include receptors, enzymes, cytoskeletal proteins, and transcription factors (Zeke et al. 2016).

JNKs play key roles in several cellular processes, most notably apoptosis. However, the biological roles of individual JNK family members have been difficult to determine. JNK1 and 2 are ubiquitously expressed in almost all cell types. In contrast, JNK3 expression is restricted mainly to the central nervous system with some expression in the heart and testis. The complexity of JNK signaling is increased by alternative splicing of JNK family members. For example, there are four isoforms each of JNK1 and 2, and eight different isoforms of JNK3. Individual deletion of JNK family members results in modest defects, suggesting their overlapping roles. For example, JNK1 knockouts show defects in metabolism, whereas JNK2 knockouts display epidermal hyperplasia. Individual deletion of JNK1 or JNK 2 also disrupts immune cell function. However,

co-deletion of JNK1 and JNK2 results in embryonic lethality due to failed neural tube closure. These studies have identified key roles for JNK in neuronal development and immune function. JNK dysfunction is associated with tumorigenesis, neurological disorders, insulin resistance and diabetes, and altered immune function.

Characteristics of the p38 Kinase Pathway

The p38 kinases are a subfamily of MAPKs identified by several groups as 38 kDa proteins that are phosphorylated in response to bacterial lipopolysaccharide (LPS) (Cuadrado and Nebreda 2010). The p38 kinase family is composed of four members, p38α, β, γ, and δ, based on a shared threonine-glycine-tyrosine (TGY) motif in their activation loop. The four p38 kinase family members are approximately 60% identical. They are found in both the cytoplasm and the nucleus where they phosphorylate and regulate a diverse set of proteins, including kinases, chromatin remodelers, and transcription factors. Similar to JNK family kinases, p38 MAPKs are activated in response to cellular stresses like hyperosmolarity, heat shock, and irradiation, and by growth factor stimulation. p38 MAPKs play critical roles in inflammation and cellular stress. p38 MAPKs are activated by several MAP3Ks, including MAP3K3, MAP3K4, ASK1, and TAK1. Active MAP3Ks phosphorylate MAP2K3 and MAP2K6, which phosphorylate the TGY motif in p38 kinases. MAP2K4 (MEK4) also phosphorylates p38. Interestingly, p38 kinases can also be activated by MAP2K independent mechanisms. Transient activation of p38 can lead to survival, whereas sustained activation of p38 often leads to cell death. Activation of p38 is terminated by both serine/threonine phosphatases like PP2A and by DUSPs.

The individual biological roles of p38 isoforms have been difficult to determine due to their overlapping expression and redundant substrate phosphorylation. The p38α isoform is expressed ubiquitously and at high levels in most cell types. In contrast, the other isoforms show reduced and more selective expression. p38β, p38γ, and p38δ show highest expression in the brain, muscle, and pancreas, respectively. Deletion of p38α in mice results in embryonic lethality due to placental defects. Although mice with individual deletion of MAP2K3 or MAP2K6 are viable, co-deletion of MAP2K3/6 results in embryonic lethality due to placental defects, demonstrating their key role in activating p38α during placental development. Mice with single deletion of MAP2K3 or MAP2K6 show immune function defects. In contrast to deletion of p38α, mice with deletion of p38β, γ, and δ are viable and overtly normal. Importantly, studies of adult knockout animals have revealed unique roles for these isoforms in muscle stem cells (p38γ) and in pancreatic beta cells (p38δ). Studies in mice have revealed key roles for p38 MAPKs during development and disease progression, especially inflammation.

Drugs

Due to the critical roles played by MAPKs in many pathological conditions including inflammation and cancer, MAPK modules have been very actively targeted for pharmacological intervention. Selective inhibitors for many of the MAPK family members have been created (Table 1). The most extensively targeted are the ERK1/2 and p38 MAPK modules. However, inhibitors have also been developed that target ERK5 and JNK MAPKs.

The RAF/MEK1/2/ERK1/2 MAPK signaling module is the most heavily mutated pathway in cancer. Aberrant activity of this MAPK cascade is responsible for the majority of cancers, making members of this MAPK cascade critical targets for drug therapy. Selective inhibitors have been developed for each component of the RAF/MEK1/2/ERK1/2 MAPK signaling module (Liu et al. 2018). First to be developed, PD98059 and U0126 inhibit MEK1/2 decreasing ERK1/2 activity at low concentrations that did not inhibit other MAPK cascades. Both act as allosteric inhibitors, binding at sites distinct from the ATP binding pocket. However, the pharmacological properties of these inhibitors made them unsuitable for clinical use. More recent work has developed new inhibitors for this cascade. RAF inhibitors that target the MAP3K

MAP Kinase Cascades, Table 1 Pharmacological inhibitors of MAPK cascades

Kinase	Inhibitors	Mechanisms of action	Biological consequences	Clinical trials
RAF	1. Sorafenib 2. Vemurafenib 3. Dabrafenib	ATP competitive	Reduces MAP2K1/2 activity and cancer growth	1. Phase IV liver cancer, Phase III kidney cancer 2/3. FDA approved for metastatic melanoma
MAP2K1/2 (MEK1/2)	1. PD98059 2. U0126 3. PD184352 4. PD0325901 5. Selumetinib 6. Binimetinib	Allosteric inhibitors bind to MAP2K1/2 at a site distinct from the ATP binding pocket	Reduces ERK1/2 activity and cancer cell growth	3. Phase II Cancer 4. Phase II neurofibromatosis type 1 5. Phase III cancer, FDA-approved low-grade glioma 6. Phase II metastatic colorectal cancer, FDA-approved melanoma
ERK1/2	1. SCH772984 2. VX-11e 3. BVD-523 4. GDC-0994	ATP competitive	Reduces ERK1/2 activity and cancer cell growth	3. Most advanced ERK inhibitor Phase I/II advanced solid tumors 4. Phase I melanoma and solid tumors
MAP2K5 (MEK5)	1. PD98059 2. U0126 3. PD184352 4. BIX02188 5. BIX02189	1-3. Allosteric MEK1/2 inhibitors that can also inhibit MEK5. 4/5. MEK5 selective ATP competitive	Reduces ERK5 activity	
ERK5	1. XMD8-92 2. ERK5-IN-1	Inhibit ERK5 kinase activity and EGF induced ERK5 autophosphorylation	Reduce ERK5 activity	
JNK1/2/3	1. SP600125 2. JNK-IN-8 3. JNK Inhibitor IX 4. XG-102	1. ATP competitive 2. Irreversible covalent modification of cysteine residue in ATP binding site 3. ATP binding site of JNK2/3 4. Cell-permeable peptide competes for docking site	1-3. Blocks JNK activity, including induction of TNFα and Jun phosphorylation 3. Selective for JNK2/3 4. Inhibit JNK interaction with substrates	4. Phase III in pain and inflammation
p38 kinase	1. SB203580 2. SB202190 3. Vertex 745 4. Vertex 702 5. BIRB-796 6. Ralimetinib 7. PH-797804	1-4, 6, 7. ATP competitive 5. Allosteric	Reduces activation of p38 and decreases production of inflammatory cytokines	3. Phase II Alzheimer's disease 4/5. Phase II rheumatoid arthritis 6. Phase I advanced cancers, phase I/II in adult glioblastoma 7. Phase II COPD, osteoarthritis, and rheumatoid arthritis

component of the cascade selectively inhibit RAF monomers. These inhibitors are in clinical trials to treat liver and kidney cancers, and have been approved for treating metastatic melanoma. Since the early development of PD98059 and U0126, multiple new inhibitors have been developed for

MEK1/2. These allosteric inhibitors are in clinical trials for several cancer types, and are approved for melanoma. Recently, ATP competitive ERK1/2 inhibitors have been developed. These inhibitors are in clinical trials to treat melanoma and advanced solid tumors. Several studies have shown an association of ERK5 expression in pathologies inducing cancer. Recent work has developed inhibitors specific for the MAP2K5 (MEK5) and ERK5 MAPK module (Table 1). These MEK5/ERK5 inhibitors have been tested in preclinical models of cancer, and may also be applicable to treat ischemia and chronic pain.

Similar to the ERK1/2 MAPK module, p38 kinases have been subjected to extensive development of pharmacological inhibitors, mostly due to the well-defined role of p38 kinase in inflammation. There are more than 20 candidate p38 kinase inhibitors in clinical trials, but no selective, p38 inhibitors have been approved (Haller et al. 2020). Inhibition of p38 kinase activity decreases the production of inflammatory cytokines and decreases inflammation. Several diseases strongly associated with inflammation including rheumatoid arthritis, osteoarthritis, and chronic obstructive pulmonary disease (COPD) have been targeted in clinical trials with p38 kinase inhibitors. Early p38 kinase inhibitors with pyridinyl imidazole compounds like SB203580 competitively inhibit p38 kinase by binding the ATP-binding pocket. Most of the new p38 inhibitors also act as ATP competitive inhibitors that bind to the ATP-binding pocket of p38 kinases. However, BIRB-796 is thought to function as an allosteric inhibitor that causes a conformational change in p38 kinase, preventing ATP binding and activation. Although p38 kinase inhibitors have been successful in preclinical trials, these inhibitors have failed in clinical trials due to poor efficacy and/or liver toxicity. Newer strategies include local application of p38 inhibitors and creation of inhibitors that block the interaction of p38 with specific substrates. In addition to targeting p38, there have been efforts to target JNK. For example, the JNK inhibitor SP600125 is an ATP competitive inhibitor, but it also inhibits several other kinases. Newer JNK inhibitors using a different strategy have recently been developed. For example, XG-102 acts by competing with the docking site, inhibiting the interaction of JNK with its substrates. XG-102 is currently in clinical trials to treat pain and inflammation.

In summary, MAPK cascades mediate the transduction of diverse cellular stimuli to the cytoplasm and nucleus. These cascades play critical roles during development, and their activity is altered during pathologies such as inflammation and cancer. Members of MAPK cascades have been actively targeted for pharmaceutical intervention with some success. However, key issues in the pharmacological targeting of the MAPK components include poor efficacy and organ toxicity. In addition, cross-talk between different MAPK modules has also resulted in issues. Further, compensatory activation of alternative kinase components or modules has frequently been observed. For example, initial targeting of MEK1/2 with inhibitors effectively decreases activation of ERK1/2 and blocks tumor cell proliferation. However, compensation by increased expression of ERK1/2 or activation of other kinases allows increased tumor cell proliferation and survival, and cancer recurrence. Approaches to mitigate these issues are actively being pursued.

Definition

Matrix metalloproteinases (MMPs) are zinc-dependent endopeptidases and belong to a larger family of proteases known as the metzincin superfamily. MMPs are a major group of enzymes that regulate cell–matrix composition. They require a zinc ion in their active site for catalytic activity and are critical for maintaining tissue allostasis. MMPs are active at neutral pH and can therefore catalyze the normal turnover of extracellular matrix (ECM) macromolecules. Members of the MMP family include the "classical" MMPs (extracellular proteolytic enzymes), the membrane-bound MMPs (MT-MMPs), the ADAMs (a disintegrin and metalloproteinase; adamlysins), and the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motif).

Basic Characteristics

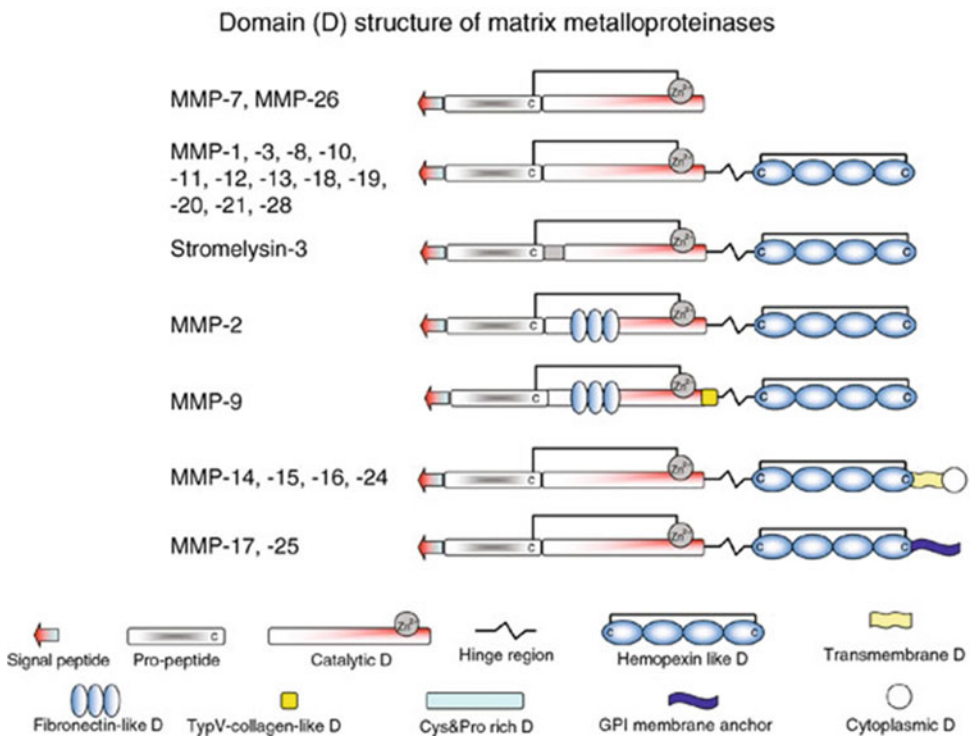
MMP genes show a highly conserved modular structure. They were first detected in vertebrates (1962), and human beings, but have since been found in invertebrates and plants as well. The MMP family consists of zinc-dependent proteolytic enzymes, which comprise at least 24 different members so far (Somerville et al. 2003) (Table 1). Although all of them exhibit a broad substrate spectrum, they are divided based on their main substrate into collagenases, gelatinases, stromelysins, matrilysins, metalloelastase, membrane-type MMPs (MT-MMPs), and others. MMPs are secreted as zymogens and become activated by cleavage of their propeptide. Figure 1 (domain structure) depicts an overview of the domain organization of different MMPs. They have several structural features in common that include a propeptide domain containing the "cysteine switch," the catalytic zinc-binding domain with the sequence HEXGHXXGXXHS, and a hemopexin-like domain. Although each MMP exhibits substrate specificity toward individual matrix proteins, there is considerable overlapping within the whole family. Collectively, they are capable of degrading all kinds of ECM proteins, such as the interstitial and basement membrane collagens, proteoglycans (e.g., aggrecan, decorin, biglycan, fibromodulin, and versican), as well as accessory ECM proteins such as fibronectin. MMPs can also process a number of bioactive molecules. They are involved in the cleavage of cell surface receptors, the release of apoptotic ligands (such as the FAS ligand), and chemokine (in-)activation. They also play a major role on cell proliferation, migration (adhesion/dispersion), differentiation, angiogenesis, apoptosis, and host defense.

In addition, MMPs influence endothelial cell function as well as vascular smooth muscle cell migration, proliferation, Ca^{2+} signaling, and contraction. MMPs play a role in vascular tissue remodeling during various biological processes such as angiogenesis, embryogenesis, morphogenesis, and wound repair. Alterations in specific MMPs might influence arterial remodeling and lead to various pathological disorders such as hypertension, preeclampsia, atherosclerosis, aneurysm formation, as well as venous dilation and lower extremity venous disease.

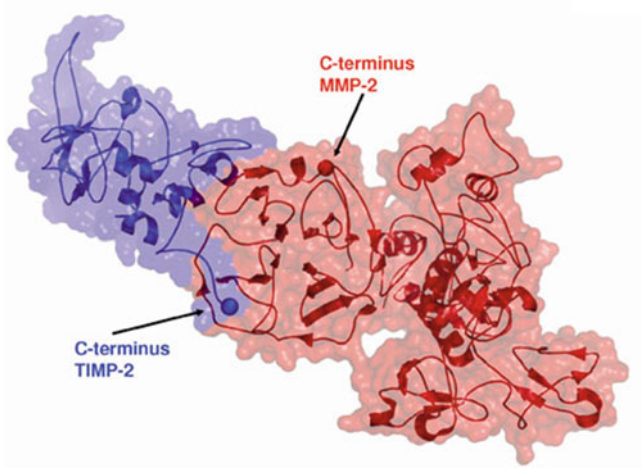
The enzymatic activity of these potentially harmful enzymes is tightly controlled. Once transcribed into protein, MMPs are expressed as inactive zymogens and require distinct activation processes to convert them into active enzymes. After secretion, MMP-activity is regulated by the noncovalent binding of tissue inhibitors of metalloproteinases (TIMPs) as shown in Fig. 2 for MMP-2 and TIMP-2. Four TIMPs have been identified so far: TIMP-1, TIMP-2, TIMP-3, and

Matrix Metalloproteinases, Table 1 MMPs and their genes known so far

Gene	Name	Location	Comments
MMP-1	Interstitial collagenase	Secreted	One of three collagenases that can degrade the interstitial collagens, types I, II, and III
MMP-2	Gelatinase-A, 72 kDa gelatinase	Secreted	
MMP-3	Stromelysin 1	Secreted	
MMP-7	Matrilysin, PUMP 1	Secreted	Smallest member of MMPs
MMP-8	Neutrophil collagenase	Secreted	
MMP-9	Gelatinase-B, 92 kDa gelatinase	Secreted	MMP-9 plays a regulatory role in angiogenesis not only through proteolytic activity but also through other downstream angiogenic factors
MMP-10	Stromelysin 2	Secreted	
MMP-11	Stromelysin 3	Secreted	MMP-11 shows more similarity to the MT-MMPs, is convertase-activatable and is secreted therefore usually associated to convertase-activatable MMPs.
MMP-12	Macrophage metalloelastase	Secreted	
MMP-13	Collagenase 3	Secreted	
MMP-14	MT1-MMP	Membrane-associated	Type-I transmembrane MMP
MMP-15	MT2-MMP	Membrane-associated	type-I transmembrane MMP
MMP-16	MT3-MMP	Membrane-associated	Type-I transmembrane MMP
MMP-17	MT4-MMP	Membrane-associated	Glycosyl phosphatidylinositol-attached
MMP-18	Collagenase 4, xcol4, xenopus collagenase	–	No known human orthologue
MMP-19	RASI-1, occasionally referred to as stromelysin-4	–	
MMP-20	Enamelysin	Secreted	
MMP-21	X-MMP	Secreted	
MMP-23A	CA-MMP	Membrane-associated	Type-II transmembrane cysteine array
MMP-23B	–	Membrane-associated	Type-II transmembrane cysteine array
MMP-24	MT5-MMP	Membrane-associated	Type-I transmembrane MMP
MMP-25	MT6-MMP	Membrane-associated	Glycosyl phosphatidylinositol-attached
MMP-26	Matrilysin-2, endometase	–	
MMP-27	MMP-22, C-MMP	–	
MMP-28	Epilysin	Secreted	Discovered in 2001, given its name due to have been discovered in human keratinocytes. Highly expressed in lung, placenta, salivary glands, heart, uterus, skin



Matrix Metalloproteinases, Fig. 1 Domain organization of different mammalian MMPs



Matrix Metalloproteinases, Fig. 2 ProMMP-2-TIMP-2 structure. (Adopted from Morgunova et al. 2002). TIMP-2 cartoon and transparent surface structure is shown in blue, MMP-2 in red. The C-terminal ends of both molecules are marked as spheres

TIMP-4. All known MMPs can be inhibited by at least one of the four known TIMPs. Nevertheless, individual differences with regard to bond strength and thus the magnitude of inhibition of a particular MMP do exist.

Drugs

Ample evidence exists on the role of MMPs in normal and pathological processes, including tissue remodeling associated with various

physiological and pathological processes such as morphogenesis, embryogenesis, angiogenesis, tissue repair, inflammation, cirrhosis (Hemmann et al. 2007), arthritis, cancer, and metastasis. The gelatinases MMP-2 and MMP-9 are thought to be important, e.g., in metastasis and MMP-1 in rheumatoid and osteoarthritis.

MMP inhibitor development constitutes an important branch of research in both academic and industrial settings and advances our knowledge on the structure–function relationship of these enzymes. Targeting MMPs for therapeutic interventions is complicated by the fact that MMPs are indispensable for normal development and physiology and by their multi-functionality, possible functional redundancy or contradiction, and context-dependent expression and activity. This complexity was revealed by previous efforts to inhibit MMP activity in the treatment of cancer patients that yielded unsatisfactory results. Doxycycline, at subantimicrobial doses, inhibits MMP activity and has been used in various experimental systems for this purpose. It is used clinically for the treatment of periodontal disease and is the only MMP inhibitor that is widely available clinically.

A number of rationally designed MMP inhibitors have shown some promise in the treatment of pathologies, which MMPs are suspected to be involved in. However, most of these, such as Marimastat (BB-2516), a broad spectrum MMP inhibitor, or trocade (Ro 32–3555), an MMP-1 selective inhibitor, have performed poorly in clinical trials. The failure of Marimastat was partially responsible for the folding of British Biotech, which developed it. The failure of these drugs has been largely due to toxicity (particularly musculo-skeletal toxicity in the case of broad-spectrum inhibitors) and failure to show expected results (in the case of trocade, promising results in rabbit arthritis models were not replicated in human trials). The reasons behind the largely disappointing clinical results of MMP inhibitors are still unclear, especially in light of their activity in animal models. New evidence suggests that MMPs may also generate angiogenesis inhibitors (Stetler-Stevenson 1999). Because of this dual role in tumor tissue, it is important to identify correctly the MMPs involved in function, activity, and origin as a prerequisite to creating highly selective MMP inhibitors as potential therapeutics.

Development of MMP null mice carrying specific MMP deletions has provided an opportunity to explore the role of MMPs in normal development as well as in such diverse conditions and diseases such as skeletal dysplasia, coronary artery and heart disease, arthritis, cancer, and brain disorders. MMP-28, e.g., the latest discovered MMP, has a role in promoting chronic lung inflammation and tissue remodeling induced by cigarette smoke and highlights a potential target to modulate COPD as has been seen in MMP-28$^{-/-}$ mice.

Adeno-associated virus (AAV) has emerged as a promising gene delivery vector. A protease-activatable AAV vector was developed, that responds to elevated extracellular protease activity commonly found in diseased tissue microenvironments. The provector is able to deliver transgenes site specifically to high-MMP-activity regions of the damaged tissue, with concomitant decreased delivery to many off-target organs, including the liver (Guenther et al. 2019). The AAV provector may be useful in the future for enhanced delivery of transgenes to sites of, e.g., cardiac damage.

Synonyms

5-Methoxy-N-Acetyltryptamine; N-Acetyl-5-methoxytryptamine

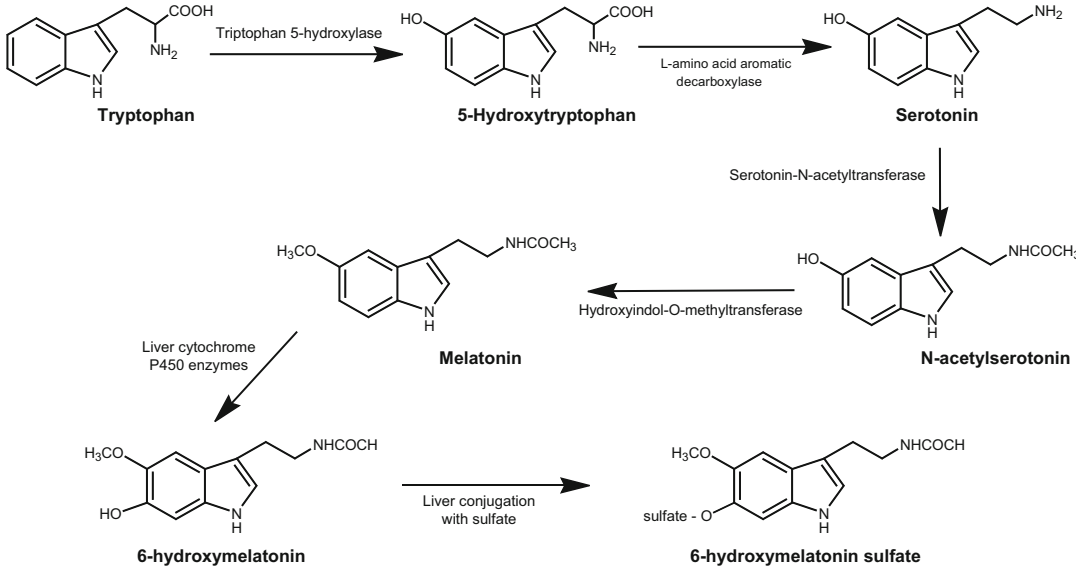
Definition

Melatonin (MLT, N-acetyl-5-methoxytryptamine) is a pleiotropic neurohormone primarily synthesized by the pineal gland during darkness that plays a key role in several physiological and biochemical functions including sleep, pain, thermoregulation, circadian rhythms, immunity, metabolism, and cardiovascular functioning (Reiter 1991). Notably, the synthesis of MLT is not restricted to mammalian species, but it is a unique universal substance with the molecular structure unchanged among non-mammalian vertebrates, some invertebrates, and plants. It was first isolated from bovine pineal tissue and structurally identified in 1958 by Aaron Lerner. Since this new molecule was blanching the melanophores in the skin of frogs and was derived from serotonin, it was named melatonin (i.e., melanophore-contracting hormone; Greek: μέλας, black; τόνος tension, in the sense of contraction).

MLT is also synthesized by several extrapineal organs among which the most important is represented by the gastrointestinal tract. Other organs include the retina, bone marrow cells, platelets, skin, lymphocytes, Harderian gland, and cerebellum (Acuna-Castroviejo et al. 2014).

MLT is synthesized from its precursor, the essential amino acid L-tryptophan, which is hydroxylated by the enzyme tryptophan-5-hydroxylase into 5-hydroxytryptophan that is then decarboxylated by the 5-hydroxytryptophan decarboxylase enzyme into serotonin. Two enzymes then transform serotonin into MLT: serotonin is first acetylated to form N-acetylserotonin by the arylalkylamine-N-acetyltransferase (AA-NAT) that is the rate-limiting enzyme for MLT synthesis, and then N-acetylserotonin is methylated by the N-acetylserotonin-O-methyltransferase (ASMT, also called hydroxyindole-O-methyltransferase or HIOMT) to form MLT. MLT is then mostly metabolized by cytochrome P450 enzymes in the liver to 6-hydroxymelatonin that is further conjugated and excreted with the urine as 6-hydroxymelatonin sulfate (Fig. 1). Degradation of MLT by deacetylation into 5-methoxytryptamine as well as by reaction with reactive oxygen and nitrogen species due to its important radical scavenging properties has been also reported.

MLT synthesis and secretion into body fluids including blood and cerebrospinal fluid is controlled by the external light/dark cycle. Its synthesis occurs during darkness and is inhibited by light in both nocturnal and diurnal species. Photosensory information is transmitted via a polyneuronal pathway which begins from the retina



Melatonin, Fig. 1 Biosynthetic and main degradation pathways of melatonin

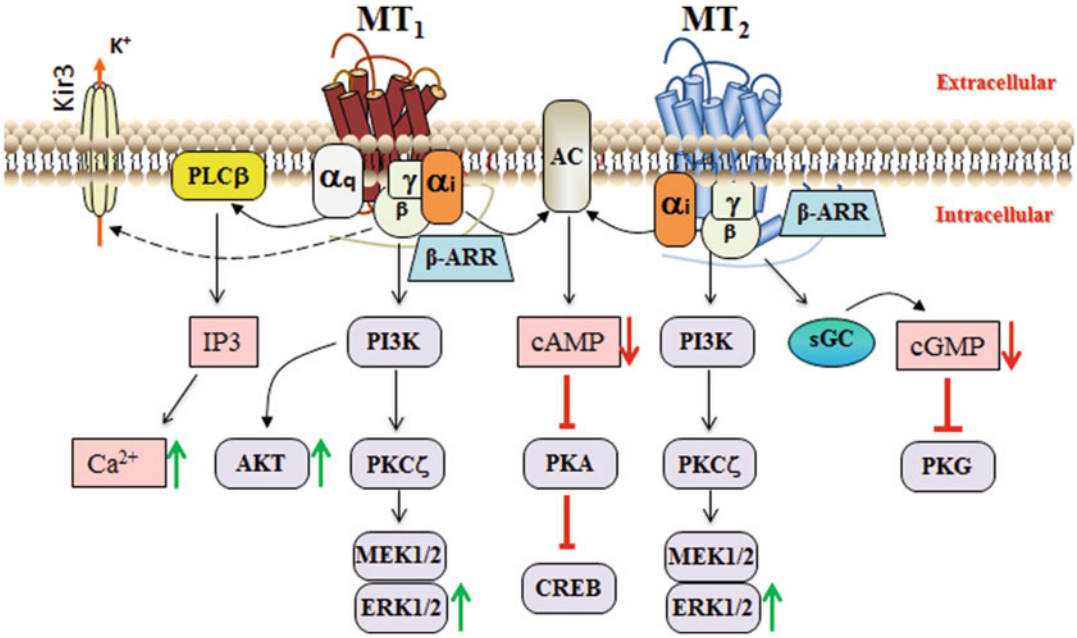
and terminates in the pineal gland and passes through the suprachiasmatic nucleus (SCN), the "master clock" that governs physiological circadian rhythms within the body. Postganglionic sympathetic nerve fibers that end in the pineal gland, when activated, stimulate the release of noradrenaline which produces a cascade of biochemical events within the pinealocyte. Noradrenaline binds to pinealocyte β-adrenergic receptors (and partially α-adrenergic receptors) and activates the adenylate cyclase through a GTP-binding protein in the cell membrane which leads to an increase in intracellular cyclic adenosine monophosphate (cAMP) levels. The increased cAMP levels stimulate the AA-NAT enzyme and finally the synthesis of MLT.

In humans, MLT secretion follows a well-defined circadian pattern with a peak (80–150 ng/mL) in the middle of the night – between 12 PM and 03 AM – that decreases gradually during the second half of the night, offset at 07–09 AM, reaching the level of 10–20 ng/mL during the day. Nearly 80% of MLT is synthesized during the night, with the peak of its serum concentrations decreasing with aging (Reiter 1991).

Basic Characteristics

Melatonin Receptor Types

MLT has been shown to bind to several proteins with various affinities. Most of its physiological effects are mediated through high-affinity MLT receptors belonging to the superfamily of the GTP-binding protein-coupled receptors (GPCR). In humans two MLT receptors exist, called MT_1 and MT_2, both binding MLT with high affinity (0.1–1 nM). A third protein called melatonin-related receptor or GPR50 belongs to the same family because of its high degree of sequence homology with MT_1 and MT_2, but this receptor is unable to bind to MLT or any other known ligand. The atomic structure of the human MT_1 and MT_2 has been solved in 2019. Among the low-affinity MLT targets, the best characterized target is the enzyme quinone reductase 2 (QR2), initially named MT3 or ML2. QR2 binds MLT with an affinity of 1 μM and has been suggested to participate in toxification/detoxification processes. The binding of MLT to QR2 has been confirmed in co-crystals (see Dubocovich et al. (2010) and Jockers et al. (2016) for reviews).



Melatonin, Fig. 2 Overview of main melatonin receptor signaling pathways

MT_1 and MT_2 are expressed in several brain regions (hypothalamic suprachiasmatic nuclei, ventrolateral preoptic nucleus, striatum, hippocampus, pituitary and pineal gland) in the retina and in several peripheral tissues (liver, adipose tissue, pancreas, kidney, etc.). Signaling of GPCRs is initiated by the activation of heterotrimeric GTP binding proteins and ß-arrestins followed by the activation of further downstream signaling cascades. MT_1 and MT_2 are coupling to GTP binding proteins of the Gi and Gq type. Coupling to Gi has been observed in many tissues, while coupling to Gq seems to be restricted to some tissues. Both receptors recruit also ß-arrestin1 and 2. Downstream effector pathways of MLT receptors include the cAMP/PKA, ERK1/2, PI3K/AKT, PLCß and soluble guanylate cyclase pathways, as well as calcium-activated Kir3 inward-rectifier potassium and the N-type calcium Cav2.2 channels. These signaling properties of MT_1 and MT_2 can be profoundly modified when they are engaged into heteromeric complexes with other receptors such as the serotonin $5\text{-}HT_{2c}$ receptor (Cecon et al. 2017). Figure 2 shows the main molecular signaling pathways activated by MLT receptors.

M

Physiology

Aging

The night peak of circulating levels of MLT varies according to aging. It is low during the first 6 months of life, it reaches the maximum between 1 and 3 years of life, and it remains almost constant until puberty from when it starts to decline progressively. During daylight hours, the serum concentrations of MLT are low (10–20 pg/ml) (Reiter 1991). Several potential mechanisms yet to be clearly elucidated may account for the decline in the peak of circulating MLT during senescence: a degeneration of the pineal gland which has a tendency to calcify with aging, altered clearance of MLT, and/or reduced activity of noradrenergic neurons stimulating the synthesis of MLT. In addition, during aging there is also a degeneration of the SCN that in parallel with the reduction of MLT synthesis may explain

the higher incidence and severity of circadian rhythm disturbances such as sleep disorders in elderly patients (Reiter 1991).

Sleep and Circadian Rhythms

The synthesis of MLT is under the control of the external light/dark cycle through the SCN. In turn, MLT by acting on MT_1 and MT_2 receptors present in the SCN synchronizes the circadian rhythm of the nucleus by affecting both the phase and amplitude of the rhythm. The MT_1 is highly expressed in the SCN and seems to control the circadian rhythm. Because of its ability to modulate the activity of the SCN and thus physiological circadian rhythms, MLT has the so-called chronobiotic properties. Indeed, it has shown efficacy for the treatment of disorders associated with abnormal timing of the circadian system including jet lag, shift work, and delayed sleep phase syndrome.

Among the many circadian rhythms, the sleep-wake cycle is governed by the Circadian process "C" and the Sleep homeostatic process "S." The "C" is the regulation of sleep by a light/night pattern, while the "S" is the regulation of sleep following the need of sleeping (i.e., if your sleep is of 7 h and yesterday you slept only 2 h, tonight you will need 9 h sleep to recover). For a long time it has been thought that MLT modulates sleep by acting on the SCN and thus on the circadian process. Research performed mostly during the last decade has instead been demonstrating that MT_1 and MT_2 receptors are located in several brain regions/nuclei involved in the homeostatic processes of sleep including the reticular thalamus, the lateral hypothalamus, and the ventrolateral preoptic nucleus. Therefore, MLT can directly affect sleep stages. In particular, preclinical research in rodents has shown that MLT by acting on MT_2 receptors modulates non-rapid eye movement (NREM) sleep whereas by acting on MT_1 receptors mostly controls REM sleep. Consequently, selective pharmacological activation of MT_2 receptors enhances NREM sleep duration, while that of MT_1 receptors increases REM sleep duration.

Overall, many studies have investigated the effects of MLT on sleep, and although hypnotic effects of MLT in humans have been reported, results are still controversial. Indeed, a meta-analysis has shown that MLT has soporific effects, thus helping people to fall asleep, rather than affecting sleep quality and maintenance. Selective MLT receptor agonists or antagonist may instead have more therapeutic effects on sleep disorders. See Gobbi and Comai (2019) for a review detailing the current knowledge on the MLT system and sleep.

Metabolic Regulation

The contribution of MLT in metabolic regulation occurs at different tissues and timescales (Karamitri and Jockers 2019). To better understand this diversity, it is helpful to recognize that MLT can mediate different types of effects, immediate effects that occur during the night, prospective or delayed effects that are typically primed during the night with functional consequences during the day, chronobiotic effects that rely on the direct effect of MLT on the circadian clock, and seasonal effects that depend on the duration of the night. Immediate effects of MLT are observed on glucose uptake and insulin secretion in insulin-sensitive tissues and insulin-producing pancreatic beta-cells, respectively. Important differences have been reported between nocturnal rodents and diurnal humans. Delayed effects have been observed on the expression of the glucose transporter type 4 (GLUT4) upon long-term MLT treatment and the modulation of diurnal insulin sensitivity via the regulation of PI3K expression by nocturnal MT_1 receptor activation. Most metabolic processes are under rhythmic regulation and desynchronization leads to metabolic dysfunction. MLT is involved in the synchronization of these processes. This chronobiotic effect of MLT can either occur by synchronizing peripheral tissue clocks by acting directly on the clock machinery in metabolic tissues or by acting on the biological master clock in the hypothalamic SCN. MLT plays a critical role in the photoperiodic control of reproduction in seasonal breeders by decoding the length of the night by means of the duration of MLT secretion. In this way, MLT can induce massive changes not only in gonad size but also in adipose tissue mass and associated metabolic adaptations in preparation of

hibernation in seasonal animals such as Siberian hamsters. Details can be found in Karamitri and Jockers (2019).

Non-receptor-Mediated Properties: Antioxidant and Anti-Inflammatory Effects

MLT is a high lipophilic compound that on top of binding to its receptors also has powerful free-radical scavenger and anti-inflammatory properties. As example, MLT has a greater efficiency in neutralizing the hydroxyl and the peroxyl radicals than reduced glutathione (GSH) and vitamin E, respectively (Acuna-Castroviejo et al. 2014). These effects likely derive by a non-enzymatic process of electron donation due to its chemical structure. MLT also seems to have the ability of regulating cytokine production, in particular to reduce the synthesis of pro-inflammatory cytokines, and of inhibiting cyclooxygenase 2 and the inducible nitric oxide synthase enzymes. Increased oxidative stress and inflammation, which may lead to cell and tissue damages, have been implicated in physiological aging and in a large number of pathologies including neurodegenerative, metabolic, and cardiovascular disorders and cancer (Acuna-Castroviejo et al. 2014). Many clinical trials have consequently studied the effects of MLT in these diseases, and despite some encouraging findings, the results are still contrasting and preliminary, and thus further work is necessary before validating a possible therapeutic use of the hormone.

Pathophysiology

Neuropsychiatric Disorders

Mood disorders including major depression (MDD) and bipolar (BD) disorders involve disruption of intrinsic biological rhythms, and therefore it is not surprising that several studies have demonstrated changes in MLT levels associated with MDD and BD. Low serum levels of MLT were shown to be a trait marker in BD, even though MLT levels did not show state-dependent changes across mania or depression states. A shift in the nocturnal MLT peak was also observed in BD patients. MDD was associated with an altered diurnal rhythm of MLT output, including a blunted nighttime surge. Indeed, MLT production may be lower in depression, and an enhancement in circulating levels of MLT has been correlated with effective antidepressant treatment. Interestingly, concerning MLT receptors, it was demonstrated a dysregulation of MT_1 but not of MT_2 receptors, namely, a high number of MT_1-immunoreactive cells, in the SCN of MDD and BD patients postmortem. Similarly to depression, anxiety disorders have been linked to MLT activity, but evidence is still limited. In preclinical paradigms of anxiety-like behavior, MLT has displayed anxiolytic-like effects. In human studies, MLT showed anxiolytic effects similar to benzodiazepines but without side effects including sleep disturbances (Comai and Gobbi 2014).

In patients with psychosis, most of the studies reported decreased nocturnal secretion of MLT. Interestingly, antipsychotic treatments ameliorating psychotic symptoms do not normalize the reduced levels of MLT. While MLT treatment alone is not effective for the therapeutics of psychosis, some studies have shown that in addition to antipsychotics, it is able to significantly improve sleep impairments often present in psychotic patients.

In age-related neurodegenerative disorders including Alzheimer's disease (AD) and Parkinson's disease (PD), the serum and cerebrospinal fluid levels of MLT are lower than in controls, and the loss of the diurnal rhythm of MLT synthesis is closely associated with the symptoms of these diseases. However, these impaired MLT levels are likely a consequence rather than a cause of the diseases. Reduced hippocampal MT_2 receptor expression was observed in AD patients. In PD, a significant decrease of both MT_1 and MT_2 receptor expression in both substantia nigra and amygdala, two brain regions affected by the disease, has been found.

Overall, several neuropsychiatric and neurodegenerative disorders are associated with reduced secretion and/or phase shift in MLT levels, but current knowledge does not allow to establish if circulating MLT could be a biomarker of disease, disease severity, or disease progression (Comai and Gobbi 2014).

Type 2 Diabetes Mellitus and Obesity

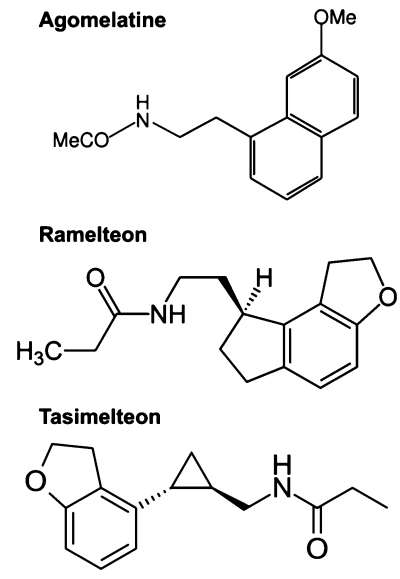
The role of MLT in the regulation of energy homeostasis implies a possible contribution to metabolic diseases like obesity and type 2 diabetes (T2D) (Karamitri and Jockers 2019). In rodents, MLT has a beneficial effect on body weight regulation by limiting body weight gain and the amount of adipose tissue. In humans, there is no strong support for a major role of MLT in body weight regulation and lipid metabolism in adults. However, notable effects of maternal MLT have been reported on fetal birth weight in humans.

The absence of MLT in rodents leads to glucose intolerance and peripheral and central insulin resistance. MLT treatment reverses these adverse effects. The absence of MT_1 receptors in mice induces systemic insulin resistance. The absence of MT_2 receptors reduces hepatic insulin sensitivity, but in contrast, MT_1 knockout mice show increased insulin release. In humans, the most convincing evidence for the role of MLT receptors in T2D development comes from genetic association studies of frequent and rare variants of the *MTNR1B* locus, encoding the MT_2 receptor, with T2D risk. Cumulative evidence indicates that the effect of the frequent intronic risk allele rs10830963 probably starts early during the development of prediabetic fasting hyperglycemia by affecting insulin secretion. Further contribution to T2D risk comes from multiple rare variants in the coding region of the *MTNR1B* gene that result in the expression of defective MT_2 receptors.

Drugs

The activation of the MLT system has shown to induce antidepressant, hypnotic, analgesic, and anxiolytic effects, although the results are not consistent among different preclinical and clinical studies. MLT's pharmacokinetic profile still limits its efficacy and applicability in therapy as a multipurpose drug. Indeed, although it is characterized by high lipophilicity which enables it to cross cell membranes as well as to distribute quickly also in the brain, when administered orally, MLT displays a poor bioavailability (due to first-pass metabolism) and short half-life (less than 30 min). One important aspect to consider when using MLT and selective or non-selective MLT receptors drugs is the time of administration due to the fact that (1) by acting on MLT receptors we may affect physiological circadian rhythms and (2) the pharmacological effect is dependent on the expression of MLT receptors which may vary according to the time of the day and endogenous levels of MLT (Atkin et al. 2018).

In many countries, MLT is classified as a dietary supplement to be used as a sleep inducer or for the treatment of irregular phase shifting, for example, in the case of jet lag. To overcome the pharmacokinetic problems of MLT when given orally, a long-release formulation of MLT (2 mg) has been approved in many countries as monotherapy for the short-term treatment of primary insomnia in patients aged more than 55 years (Atkin et al. 2018). During the past decades, other compounds targeting MLT receptors have been developed. One of them is agomelatine (Fig. 3), a structural



Melatonin, Fig. 3 Chemical structure of melatonergic drugs approved for use in humans: agomelatine, ramelteon, and tasimelteon

analog of MLT that acts as a non-selective MT_1/MT_2 agonist and as an antagonist for 5-HT_{2C} receptors and that is registered in Europe as an antidepressant drug. Ramelteon (Fig. 3) is another non-selective MT_1/ MT_2 agonist that has been approved only in the USA, in July 2005, for the treatment of insomnia, characterized by long sleep onset latency. Finally, tasimelteon (Fig. 3) is another non-selective MT_1/MT_2 agonist that has entered the clinical practice specifically for the treatment of non-24 h sleep-wake disorder in blind subjects (Atkin et al. 2018).

While very elevated doses of MLT that bring circulating levels of MLT up to 1000 times the physiological levels do not seem to induce a significant toxicity in either humans or rodents, except for headache, nausea, dizziness, and drowsiness (at doses higher than 10 mg/day), the use of agomelatine is associated with hepatotoxicity as well as with other common minor symptoms including drowsiness, headache, nausea, and dizziness.

The main adverse effects of ramelteon and tasimelteon include headache, elevated liver enzymes (likely due to an idiosyncratic issue similar to agomelatine), nightmares, and upper respiratory tract infections. Hepatic toxicity was instead not reported even after the administration of MLT for long periods of time and at high doses, likely indicating that the hepatic issues reported with MLT receptor agonists like agomelatine and ramelteon are probably not the consequences of the activation of MLT receptors (Atkin et al. 2018).

Despite the limited clinical efficacy of these non-selective MLT receptor agonists, MLT receptors seem to be a promising target in neuropsychopharmacology (Comai and Gobbi 2014; Gobbi and COmai 2019). As abovementioned, research is showing that the two MLT receptor subtypes may mediate complementary or opposite functions, and thus from a pharmacological point of view, selectivity toward either MT_1 or MT_2 receptors may enhance the therapeutic potential of targeting the MLT system. During the past decades, several selective ligands for the MT_2 receptors have been developed, some of which have been also tested for their pharmacological properties at preclinical level. Compounds including the selective MT_2 receptor agonist IIK7 or the partial agonists UCM765 and UCM924 have displayed in rodents hypnotic properties. In particular, they enhanced selectively NREM sleep. UCM924 also showed anxiolytic and analgesic effects at a dose lower than that inducing sleep. Research aimed at identifying MT_1-selective ligands has been not yet very successful, but with the very recent characterization of the crystallographic structure of both MT_1 and MT_2 receptors, it is plausible to think that MT_1 agonists/antagonists to be tested at preclinical level will be soon developed. In this direction, compounds such as the MT_1-selective partial agonist UCM871 and the MT_1-selective inverse agonist UCSF7447 seem to be promising. Some of the distinct physiological properties mediated by MT_1 and MT_2 receptors are reported in Table 1. Drugs that will be selectively developed to target MT_1 or MT_2 receptors may thus be endowed with peculiar and specific pharmacological activity (Gobbi and Comai 2019).

Melatonin, Table 1 Distinct pharmacological effects obtained following the selective activation of MT_1 or MT_2 receptors

	MT_1 receptor activation	MT_2 receptor activation
REM sleep	Increase duration	No effects
NREM sleep	Not investigated	Increase duration
Circadian rhythm	Deceleration of re-entrainment; phase advance when administered at subjective dusk[a]	Not investigated
Pain	Not investigated	Analgesia
Vascular level	Vasoconstriction	Vasodilatation
Body temperature	Increase	Decrease

[a]pharmacological effect shown in vivo by MT_1-selective inverse agonists

Not investigated: findings are yet too preliminary

Mitochondrial selective autophagy

Definition

Mitophagy is an evolutionary conserved cellular process that sustains mitochondrial homeostasis by mediating the elimination of superfluous and/or defective mitochondria. Mitophagy can be classified as basal, stress-induced, and programmed based on physiological context. Failure to properly carry out mitophagy deregulates mitochondrial metabolism and causes progressive accumulation of defective organelles leading to the deterioration of biological systems, often culminating in tissue collapse.

Basic Characteristics

Molecular Mechanisms of Mitophagy

Cells have evolved several molecular signaling pathways to eliminate defective organelles and adjust their mitochondrial pool in response to environmental and/or intracellular stimuli. Hence, different signals can promote mitophagy via multiple signaling cascades in distinct cellular contexts. Although mitophagy pathways are classified as ubiquitin-dependent or -independent, several studies highlight the intricate interplay between different signaling and execution mechanisms, and emphasize the conservation of mitophagy regulators in eukaryotes (Table 1) (Harper et al. 2018; Palikaras et al. 2018).

The PINK1/Parkin Pathway

The PINK1 (phosphatase and tensin homolog (PTEN)-induced putative kinase 1)/Parkin is the most well-studied molecular pathway known to mediate ubiquitin-dependent mitochondrial removal. Several aspects of mitochondrial metabolism, such as mitochondrial dynamics, biogenesis, transport, and recruitment of autophagic machinery, are associated with the induction of the PINK1/Parkin pathway to assure the degradation of damaged organelles.

In healthy mitochondria, the PINK1 kinase is transported into the inner mitochondrial membrane (IMM), where it is processed and cleaved by mitochondrial proteases. In turn, the truncated form of PINK1 is degraded by the proteasome system. Upon stress conditions, mitochondrial membrane is depolarized mediating the stabilization of PINK1 on the outer mitochondrial membrane (OMM). Subsequently, the enzymatic activity of PINK1 is enhanced by its auto-phosphorylation and promotes the recruitment of the E3 ubiquitin ligase Parkin to mitochondrial surface (Sekine and Youle 2018). PINK1 phosphorylates both Parkin triggering its E3 ligase activity and ubiquitin molecules or poly-ubiquitin chains on depolarized mitochondria. Inactive Parkin is translocated and bound to phopho-ubiquitin molecules or chains leading to its subsequent activation by PINK1. Then, Parkin mediates a feed-forward mechanism generating poly-ubiquitin chains, which are substrates for PINK1, amplifying mitophagy signal (Harper et al. 2018). In addition to its beneficial effects on Parkin activation and recruitment, PINK1-dependent phosphorylation of ubiquitin and poly-ubiquitin chains ameliorates hydrolysis by deubiquitinating enzymes (Harper et al. 2018). Several deubiquitinases, such as USP15, USP30, and USP35, block mitophagy by removing Parkin-generated ubiquitin chains from its mitochondrial substrates (Harper et al. 2018). Hence, a fine-tuned balance between ubiquitination and deubiquitination events regulates energy metabolism and underlines poly-ubiquitination as an "eat-me" signal for defective mitochondria.

Mitophagy, Table 1 Mitophagy components are evolutionary conserved

Model organisms

Following its translocation, Parkin mediates poly-ubiquitination of several OMM proteins leading eventually to their recognition by autophagy adaptors or proteasomal degradation. Parkin-dependent proteasomal turnover of mitofusins (MFN1/2) diminishes mitochondrial fusion mediating the isolation of damaged organelles from the healthy mitochondrial population (Harper et al. 2018). MFN2 is also phosphorylated by PINK1 and thereby functions as a scaffold protein for Parkin recruitment upon mitochondrial stress. Additionally, PINK1 influences indirectly DRP1 activity promoting fission of defective mitochondria for their autophagic elimination. Furthermore, mitochondrial motility is also reduced during energetic stress. Mitochondria Rho-GTPase (Miro), an OMM protein that anchors mitochondria to cytoskeleton, is degraded upon Parkin-driven ubiquitination. Miro turnover mediates inhibition of mitochondrial transport in response to mitochondrial membrane dissipation (Harper et al. 2018; Palikaras et al. 2018; Sekine and Youle 2018). Collectively, inhibition of mitochondrial motility and enhanced fission might promote mitophagy, presumably by generating smaller organelles that can easily be engulfed by autophagosomes.

Although Parkin is a major mitophagy regulator, mitochondrial elimination does not exclusively rely on its activity. Several ubiquitin E3 ligases, such as Gp78, SMURF1, SIAH, MUL1, and ARIH1, have been reported to ubiquitinate mitochondrial proteins facilitating mitophagy (Harper et al. 2018; Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Once poly-ubiquitin chains have been generated on mitochondrial surface, they stimulate the recruitment of autophagy adaptor molecules, including p62/SQST1, optineurin 1 (OPTN1), nuclear dot protein 52 (NDP52) among others. In turn, autophagy adaptors interact directly with the autophagosomal light chain 3 (LC3) protein via their LIR (LC3-interacting region) motifs promoting autophagosome biogenesis and sequestration of dysfunctional mitochondria (Harper et al. 2018; Montava-Garriga and Ganley 2019; Palikaras et al. 2018).

Receptor-Mediated Mitophagy

Multiple OMM proteins serve as mitophagy receptors interacting directly with autophagosomal machinery and fine-tuning mitochondrial number in response to various stimuli in mammalian cells. Mitophagy receptors bind directly to autophagosomal membrane proteins via their LIR motifs promoting mitochondrial degradation.

Genetic studies in *Saccharomyces cerevisiae* have identified Atg32 as an essential protein for mitochondrial removal. Atg32 is an OMM protein associating with cargo-specific protein Atg8 and Atg11 adaptor to facilitate autophagosome formation. The kinases Hog1 and CK2 (casein kinase 2) regulate Atg32 phosphorylation status promoting its association with Atg11 adaptor (Montava-Garriga and Ganley 2019). Interestingly, Atg11 recruits also Dnm1 (the homologue of DRP1 in yeast) to enhance mitochondrial fission leading to the isolation of damaged organelles. Hence, Atg32 mediate the formation of a multiprotein complex together with Atg8 and Atg11 regulating mitochondrial network morphology and mitophagy stimulation. Recently, BCL-2-like protein 13 (BCL2L13) has been characterized as a functional homologue of Atg32 in mammals. BCL2L13 is localized on the OMM and interacts directly with LC3 via its LIR motif upon mitochondrial stress (Sekine and Youle 2018; Montava-Garriga and Ganley 2019).

NIX has a pivotal role in the elimination of entire mitochondrial population during erythrocytes differentiation. Indeed, NIX-deficient cells display mitochondrial accumulation leading to elevated apoptotic events and subsequently to developmental deficits (Montava-Garriga and Ganley 2019; Palikaras et al. 2018). In addition to NIX, BNIP3 (BCL2 interacting protein 3) acts as a mitophagy receptor mediating mitochondrial removal. Interestingly, BNIP3 also regulates mitochondrial fission and fusion through its direct association with OPA1 and DRP1 in response to mitochondrial damage. Mutations in the LIR motifs of both NIX and BNIP3 disturb their physical interaction with autophagosomal proteins and deregulate mitophagy. Multiple lines of

experimental evidence indicate a complex interplay between mitophagy receptors and the PINK1/Parkin signaling pathway. Indeed, both NIX and BNIP3 require Parkin recruitment to preserve mitochondrial metabolism. Notably, Parkin targets and ubiquitinates NIX promoting its recognition by autophagy adaptors to enhance mitochondrial clearance (Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Recently, DCT-1, the mammalian homologue of BNIP3 and NIX in nematodes, is underlined as a key mediator of mitophagy sustaining cellular homeostasis and viability during challenged conditions. In congruent with its mammalian counterparts, DCT-1 is also ubiquitinated by PDR-1 (the nematode Parkin homologue) in a PINK1-dependent manner during stress-induced mitophagy. Interestingly, BNIP3 prevents PINK1 proteolytic cleavage and mediates its stabilization on the mitochondrial surface (Montava-Garriga and Ganley 2019; Palikaras et al. 2018).

FUN14 domain-containing protein 1 (FUNDC1) is a highly conserved OMM protein that facilitates the selective elimination of damaged organelles during hypoxic stress (Georgakopoulos et al. 2017; Montava-Garriga and Ganley 2019; Palikaras et al. 2018). The Sc and CK2 kinases regulate the activation of FUNDC1 by modulating the phosphorylation status of its LIR motif and thereby inhibiting the recruitment of autophagic machinery under non-stress conditions. FUNDC1 influences mitochondrial network morphology through its associations with both fission and fusion components in response to hypoxia. Indeed, the mitochondrial phosphatase PGAM5 dephosphorylates FUNDC1 promoting its dissociation with OPA1 and eventually preventing mitochondrial fusion. Then, FUNDC1 is recruited to ER-mitochondrial contact sites stimulating DRP1 translocation and subsequently mitochondrial network fragmentation. In addition to FUNDC1, both NIX and BNIP3 have been involved in the execution of mitochondrial removal upon low oxygen levels (Georgakopoulos et al. 2017; Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Interestingly, HIF1 (hypoxia inducible factor 1) regulates transcriptionally both BNIP3 and NIX enhancing mitophagy during hypoxic-like conditions (Palikaras et al. 2018).

Recent studies revealed an unexpected role of IMM proteins and phospholipids in mitochondrial turnover. OMM is disrupted in response to excessive stress conditions resulting in elevated ROS levels, mtDNA release, and cytoplasmic externalization of several IMM proteins. Notably, prohibitin 2 (PHB2) and cardiolipin, which are primarily distributed in IMM, are exposed to the cytoplasm and trigger mitophagy through the direct association with their LIR motifs with LC3 autophagosomal protein (Montava-Garriga and Ganley 2019; Palikaras et al. 2018).

Taken together, this experimental evidence underscores that the coordinated and compensatory action of OMM and IMM mitophagy receptors might assure the efficiency of mitochondrial surveillance and energy metabolism in response to multiple stimuli.

Basal, Stress-Induced, and Programmed Mitophagy

Until recently, information on basal mitophagy levels was limited. However, the generation of transgenic animals expressing mitophagy reporters endorsed the in vivo investigation of mitochondrial degradation under physiological conditions (Palikaras et al. 2018; Montava-Garriga and Ganley 2019). Although most cell types undergo continuously basal mitophagy during routine mitochondrial quality control, the extent differs across tissues or even between cells within the same tissue. Notably, mitophagy is highly induced in heart, skeletal muscles, brain, liver, and kidney, whereas thymus and spleen display low levels of mitochondrial removal (Palikaras et al. 2018; Montava-Garriga and Ganley 2019). Surprisingly, the PINK1/Parkin pathway does not regulate basal mitophagy both in mammals and flies, highlighting the existence of different mitophagy regulators under physiological and stress conditions (Montava-Garriga and Ganley 2019).

Mitochondrial homeostasis is impaired by extracellular and/or environmental stimuli that

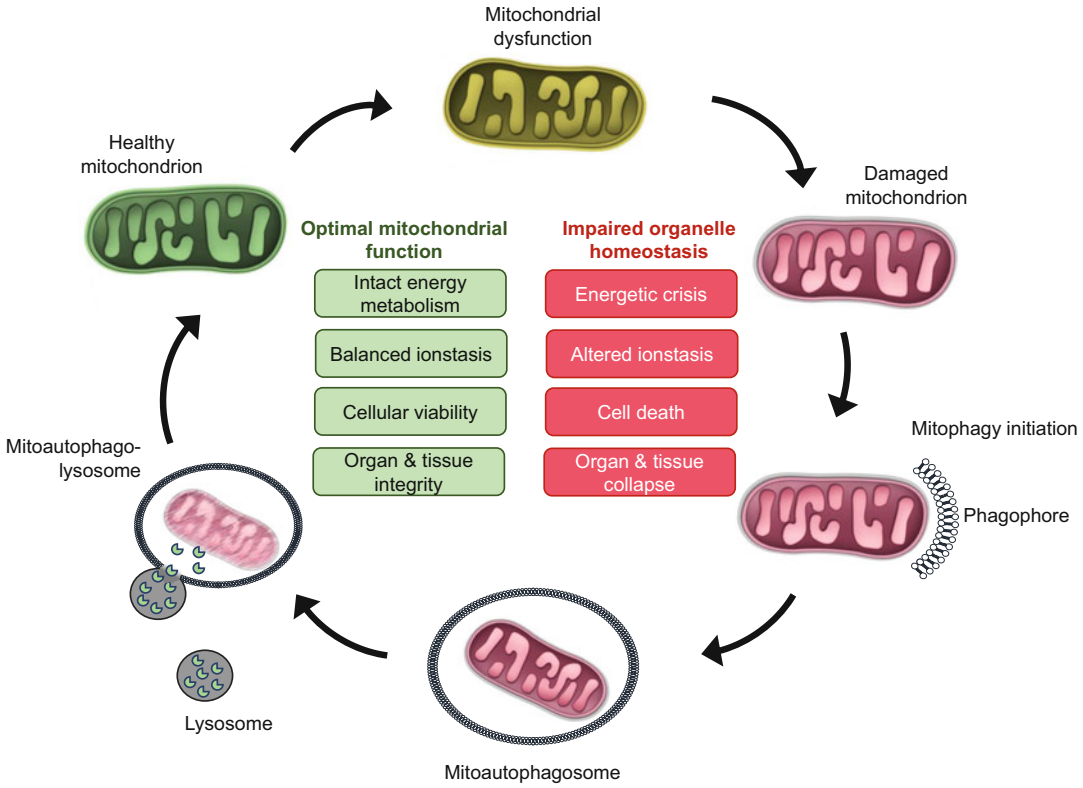
induce acute clearance of damaged mitochondria, by stress-induced mitophagy. Nutrient starvation, hypoxia, insecticides, and mitochondrial toxins deregulate electron transport chain (ETC) function and subsequently trigger energetic stress. In turn, stress-induced mitophagy facilitates mitochondrial quality control mediating the adjustment and adaptation of cellular metabolism to the external challenge. Nutrient deprivation promotes re-shaping of mitochondrial network and autophagy induction to degrade cytoplasmic materials and supply cells with building blocks for re-use and metabolism (Murphy and Hartley 2018; Palikaras et al. 2018; Montava-Garriga and Ganley 2019). Damaged and small sized mitochondria are initially removed through mitophagy to sustain a healthy mitochondrial pool during short period of starvation. Then, mitochondrial fission is prevented leading to unopposed fusion events. Elongated mitochondrial network is protected against autophagic degradation and display enhanced capacity of energy production (Montava-Garriga and Ganley 2019). On the other hand, prolonged starvation stimulates excessive mitochondrial elimination to renew and optimize mitochondrial population to the new environmental conditions. These observations underline the ability of eukaryotic cells to differentially regulate mitophagy under certain conditions of starvation. Indeed, yeast cells induce or inhibit mitophagy depending on carbon source in response to nitrogen starvation (Palikaras et al. 2018). General toxicants and mitochondrial uncouplers, including paraquat, valinomycin, oligomycin, and CCCP among others, have been widely used to induce mitochondrial depolarization and subsequently mediate PINK1/Parkin-dependent mitophagy (Georgakopoulos et al. 2017). Alternatively, hypoxia mainly engages receptor-mediated mitophagy to mediate mitochondrial quality and quantity (Georgakopoulos et al. 2017; Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Lack of oxygen results in defective mitochondrial respiration and energetic stress. Thus, a metabolic switch from oxidative phosphorylation (OXPHOS) to glycolysis is taking place attenuating the features of mitochondrial population. HIF1, the master regulator of hypoxic responses, orchestrates and coordinates both metabolic switch and mitophagy through the transcriptional regulation of glycolytic and mitophagic genes (Georgakopoulos et al. 2017; Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Cytoplasmic iron chelation is an alternative procedure to trigger hypoxic-like response (Georgakopoulos et al. 2017). Although the impact of iron deprivation on mitochondrial physiology is not well studied, iron chelating agents, such as deferiprone (DFP) and 2′,2-bipyridyl (BP), are potent mitophagy inducers both in vitro and in vivo. Interestingly, DFP and BP activate different molecular signaling pathways to mediate mitochondrial removal underlining the complexity and diversity of mitophagy induction even under similar cellular responses (Georgakopoulos et al. 2017).

The induction of programmed mitophagy is a critical event during organismal development. Erythrocytes maturation requires the removal of all the internal organelles from immature erythroblast. NIX-mediated mitochondrial elimination is essential for erythrocytes differentiation and organismal physiology, since NIX deficient mice retain mitochondria in their peripheral blood cells displaying defective erythroid maturation and anemia (Montava-Garriga and Ganley 2019; Palikaras et al. 2018). Furthermore, mitophagy regulates the degradation of sperm-derived mitochondria upon oocytes fertilization in nematodes, flies, and mice preventing paternal mtDNA inheritance (Palikaras et al. 2018). Mitophagy has a prominent role in cardiomyocyte maturation. Adult heart is an organ with enhanced metabolic demands that preferentially utilizes fatty acids for energy production in mitochondria. During cardiomyocyte maturation, programmed mitophagy is taking place to eliminate fetal mitochondria, which primarily use glucose for energy generation. Therefore, mitochondrial population is functionally and morphologically altered to meet the contractile demands of the adult heart (Palikaras et al. 2018). Re-shaping and re-adjusting mitochondrial network fine-tune the transition from OXPHOS to glycolysis and vice versa. Indeed, mitophagy-mediated glycolytic shift is pivotal both for retinal ganglion cells

differentiation and macrophage polarization (Montava-Garriga and Ganley 2019). Moreover, mitophagy-driven mitochondrial rejuvenation dictates several features of stem cell biology. Although stem cells rely on glycolytic metabolism and exhibit few spherical mitochondria, accumulating evidence underscores the impact of mitochondrial homeostasis and mitophagy on stem cells activation, fate, and senescence (Zhang et al. 2018).

Drugs

Mitochondria are cellular organelles specialized for energy production and critically influence several features of cell metabolism and physiology. The maintenance of healthy mitochondrial population is a prerequisite for cellular and tissue homeostasis. Compromised mitochondrial function results in the transformation of cellular powerhouses to "hotspots" of metabolic stress. Hence, it is not surprising that mitochondrial damage is associated with a broad spectrum of pathologies, such as ageing, myopathies, cardiovascular, metabolic and neurodegenerative diseases (Fig. 1). Given that the consequences of defective mitochondrial function can be detrimental for cellular viability, interventions modulating mitochondrial turnover hold a promise for considerable therapeutic potential and have been in the spotlight of scientific research. Pharmacological screenings are taking place to identify novel chemical compounds that may be used to manipulate the



Mitophagy, Fig. 1 Contribution of proper mitochondrial function to cellular and tissue homeostasis. In physiological conditions, intact mitochondrial population sustain energy metabolism, ionstasis, and cellular survival resulting in subsequent organ and tissue integrity. Excessive mitochondrial damage disrupts energy production and promotes ROS elevation and ionic imbalance, which trigger cell death pathways and often culminating in tissue collapse. Efficient elimination of dysfunctional organelles via mitophagy ensures mitochondrial homeostasis protecting against deterioration of biological systems

clearance of defective mitochondria and restore cellular energetic status. To this direction, several synthetic and natural chemical molecules have been utilized to modulate mitophagy (Georgakopoulos et al. 2017; Murphy and Hartley 2018; Palikaras et al. 2017).

Recently, mitophagy modulators, including general mitochondrial targeting agents, NAD^+ precursor molecules, and naturally occurring products among others, have been shown to enhance energy metabolism, healthspan, and organismal survival.

General Mitochondrial Targeting Agents to Manipulate Mitochondrial Turnover

Various pharmacological agents have been shown to interfere with mitochondrial ETC function and trigger mitophagy. Mitochondrial toxicants, such as paraquat, carbonyl cyanide *m*-chlorophenyl hydrazone (CCCP), and carbonyl cyanide-*p*-(trifluoromethoxy) phenyl hydrazone (FCCP), have been widely utilized to induce mitochondrial elimination through initiation of the PINK1/Parkin signaling cascade in mammalian cells and nematodes (Georgakopoulos et al. 2017). On the other hand, well-established ROS-generators, including rotenone, 6-OHDA (6-hydroxyldopamine) and MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), are not able to promote PINK1/Parkin-mediated mitophagy due to their moderate effects on mitochondrial membrane potential (Georgakopoulos et al. 2017). Notably, cardiolipin is released and binds to LC3 facilitating mitochondrial removal upon rotenone and 6-OHDA treatment. Despite the widespread application of general mitochondrial toxicants in basal research, their nonselective properties and off-target effects limit their use for therapeutic interventions (Fig. 2).

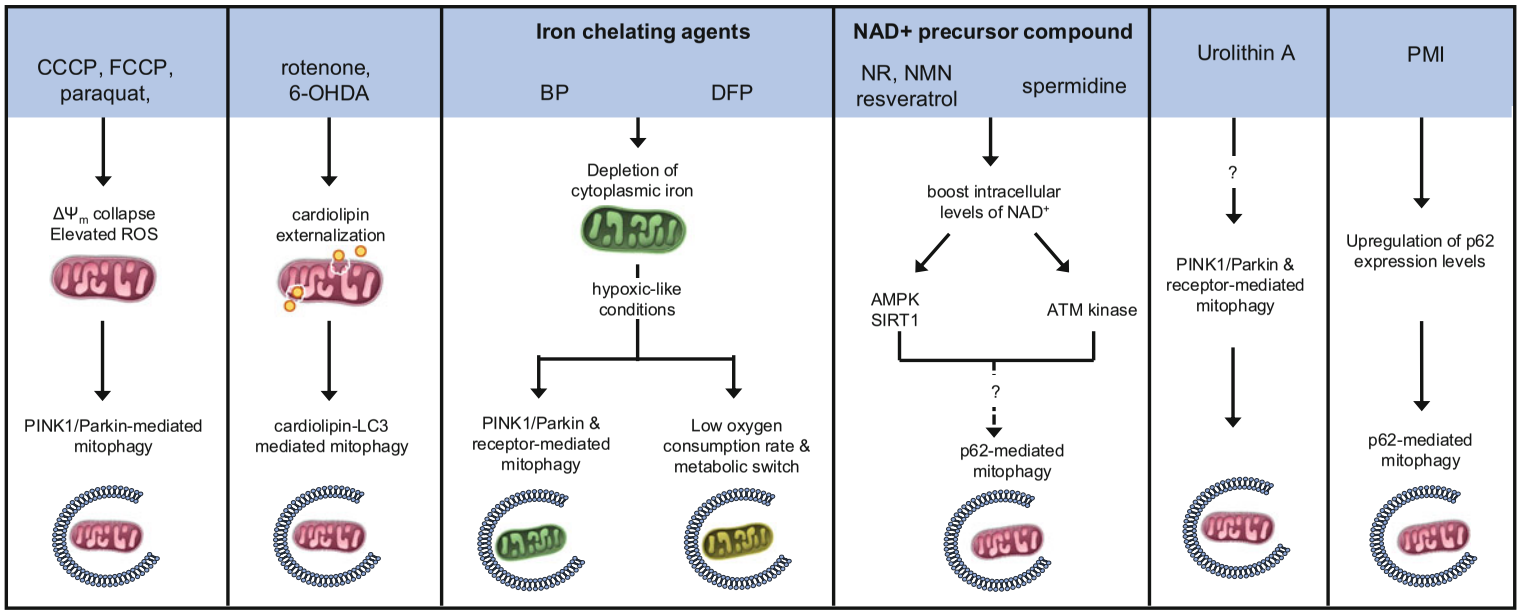
Kinetin triphosphate (KTP; 6-furfurylaminopurine) is a modified analog of ATP that binds and amplifies PINK1 catalytic activity both in vitro and in vivo. Supplementation of KTP diminishes mitochondrial motility, enhances Parkin translocation on depolarized organelles, and ameliorates apoptosis in a PINK1-dependent manner. Although KTP was initially identified and applied in clinical trials as mRNA splicing moderator, its safety and ability to cross the blood-brain barrier highlight its therapeutic potential in pathological conditions with defective PINK1 enzymatic activity, such as Parkinson's disease (Georgakopoulos et al. 2017).

To avoid nonspecific and toxic effects of uncontrolled mitochondrial membrane potential collapse by proton ionophores, a synthesized chemical compound called p62-mediated mitophagy inducer (PMI) was developed. PMI promotes the expression of p62/SQST1 adaptor protein forcing mitochondria to be sequestered and degraded by autophagosomes (Fig. 2). Interestingly, PMI does not affect mitochondrial bioenergetics and network morphology suggesting that its supplementation enhances the levels of basal mitophagy. This notion is further supported by the fact that PMI-induced mitophagy does not require the presence of PINK1 and/or Parkin (Georgakopoulos et al. 2017; Palikaras et al. 2017).

Maintenance of Mitochondrial Homeostasis Through the Regulation of NAD^+ Metabolism

Nicotinamide adenine dinucleotide (NAD^+) is an intracellular metabolite and a critical denominator of energy metabolism and organismal fitness. Age-dependent reduction of NAD^+ concentration is associated with premature ageing and several age-related pathologies, including cancer, metabolic syndrome, and neurodegeneration (Fang et al. 2017; Katsyuba and Auwerx 2017).

NAD^+ acts as a co-factor regulating the enzymatic activity of several proteins, including sirtuins and poly ADP-ribose polymerase 1 (PARP1) among others. Sirtuins are deacetylating enzymes and their activity relies mainly on NAD^+ intracellular levels. Sirtuins are involved in the regulation of multiple cellular processes, such as DNA damage responses, autophagy, and mitochondrial function (Katsyuba and Auwerx 2017). Supplementation of the NAD^+ precursor molecules, nicotinamide (NAM), nicotinamide



Mitophagy, Fig. 2 Overview of mitochondrial targeting agents that stimulates mitophagy. The molecular mechanisms and mitophagy-inducing properties of several synthetic and natural small molecules, such as CCCP, FCCP, paraquat, rotenone, 6-OHDA, iron chelating agents, NAD^+ precursors, spermidine, urolithin A, and PMI, are described

riboside (NR), and nicotinamide mononucleotide (NMN), boosts the intracellular NAD^+ levels enhancing energy metabolism, neuroprotection, and lifespan extension (Lou et al. 2019). Notably, NAM and NMN is recently documented to induce mitophagy in mammals and nematodes. The beneficial effects of NAD^+ replenishment on mitochondrial metabolism and organismal homeostasis are mediated, at least in part, by sirtuins (Fang et al. 2017). Indeed, NR and NMN treatment have been shown to induce NAD^+ – SIRT1 axis preventing protein aggregates accumulation and cognitive decline in Alzheimers' disease (AD) animal models via the restoration of mitochondrial activity and mitophagy (Lou et al. 2019). Moreover, administration of NR stimulates both the expression and activity of additional sirtuins, such as SIRT3 and SIRT6, ameliorating the hearing-loss defects in AD mouse models (Fang et al. 2017; Lou et al. 2019).

PARP1 is a NAD^+-consuming enzyme that is activated to maintain genome integrity through the recruitment of DNA repairing complexes during genotoxic stress. Accumulation of age-dependent DNA damage triggers the overstimulation of PARP1 resulting in diminished NAD^+ levels, reduced SIRT1 activity, and impairment of mitochondrial metabolism and mitophagy (Fang et al. 2017). Olaparib is a very well-studied inhibitor of PARP1 enzymatic activity. Interestingly, olaparib administration promotes mitophagy and restores mitochondrial homeostasis. Congruently, genetic ablation of PME-1 (the homolog of the mammalian PARP1 in *Caenorhabditis elegans*) enhances mitochondrial homeostasis and lifespan extension by augmenting intracellular NAD^+ content and sirtuins activity (Fang et al. 2017; Katsyuba and Auwerx 2017).

Altogether, these results underscore that genetic and chemical-induced modulation of intracellular NAD^+ pool might propel the development of novel therapeutic strategies to sustain energy homeostasis and cellular viability by stimulating the degradation of damaged mitochondria (Fig. 2). Although the beneficial outcome of NAD^+ replenishment methods has been investigated in several animal models, their off-target effects are questioned, highlighting the crucial and multifactorial role of NAD^+ in several cellular processes, including mitochondrial biogenesis, general autophagy, and tumorigenesis among others (Fang et al. 2017; Katsyuba and Auwerx 2017).

Natural Chemical Agents with Mitophagic Capacities

Mitophagy-inducing abilities of natural small-molecule drugs have been assessed in several model organisms, including yeast, flies, nematodes, and mice. Resveratrol, spermidine, urolithin A are first-in class mitophagy inducers that have been shown to adjust, preserve, and restore mitochondrial population and energy metabolism (Berman et al. 2017; Lou et al. 2019; Madeo et al. 2018; Palikaras et al. 2018).

Resveratrol is a natural phenol compound, which is highly concentrated in red grapes skin. Resveratrol has been characterized as a caloric restriction mimetic exerting anti-inflammatory and anti-ageing effects. This natural product has attracted the attention of scientific community due to its potential therapeutic properties against several human pathologies, such as neurological disorders, cardiovascular diseases, and diabetes (Berman et al. 2017). Experimental evidence indicates that resveratrol increases the intracellular NAD^+ concentration via AMP-protein kinase (APMK) activity resulting in the subsequent stimulation of SIRT1 (Fig. 2). Moreover, mitochondrial metabolism and biogenesis is upregulated in response to resveratrol treatment alleviating muscular and metabolic defects in obese mice (Palikaras et al. 2017).

Polyamines, putrescine, spermidine, and spermine, are involved in the regulation of multiple cellular processes, such as mitochondrial homeostasis, innate immunity, cell growth, and proliferation. Therefore, the biosynthetic and metabolic pathways of polyamines are tightly associated with organismal survival and viability. Indeed, the intracellular content of spermidine is gradually reduced in several cell types with age leading to the deterioration of biological systems

(Madeo et al. 2018). Chronic supplementation of spermidine enhances memory and lifespan in yeast, flies, nematodes, and mice, in an autophagy-dependent manner. Recent studies demonstrate that chronic administration of spermidine promotes also mitophagy sustaining heart function and renal homeostasis in aged rodents (Madeo et al. 2018). Ataxia telangiectasia mutated (ATM) kinase stimulates the PINK1/Parkin pathway upon spermidine treatment. ATM is involved in DNA damage responses preserving cellular physiology by altering mitochondrial activity and mitophagy upregulation. Notably, spermidine-induced mitochondrial membrane potential collapse leads to ATM activation and, in turn, PINK is stabilized on OMM and recruits Parkin on mitochondrial surface to initiate autophagosomal generation (Fig. 2) (Palikaras et al. 2018).

Urolithin A (UA) is the most abundant ellagitannin-derived metabolite in human body and is mainly generated by intestinal microflora upon consumption of fruits and nuts, such as pomegranate, raspberries, strawberries, walnuts, and almonds. Although the molecular mechanism of UA function is poorly understood, its antioxidant, anti-inflammatory, and anti-tumor properties are very well established (Palikaras et al. 2017). Recently, supplementation of UA is shown to improve muscle function and lifespan by stimulating mitophagy in both nematodes and mice (Palikaras et al. 2017, 2018). Furthermore, UA-induced mitophagy is shown to ameliorate cognitive defects, inflammatory responses, and protein aggregates in neuronal and microglia cells of AD nematode and mouse models (Lou et al. 2019). Interestingly, genetic studies in *C. elegans* uncovered that UA relies on BEC-1, PINK-1, SQST-1, and DCT-1 (the mammalian homologs of Beclin, PINK1, p62/SQST1, and BNIP3/NIX, respectively) to promote longevity, whereas PINK-1 and PDR-1 (the mammalian homolog of Parkin) are required for its neuroprotective effects indicating that there is an intricate communication between mitophagy regulators to sustain energy metabolism and cellular homeostasis in a cell-type and tissue-specific manner (Fig. 2). Moreover, the UA beneficial effects on cellular and organismal physiology are independent of dietary conditions and age. Thus, UA treatment could be used as a novel therapeutic strategy to rejuvenate mitochondrial metabolism and protect against age-dependent decline of muscular activity and mobility deficits (Palikaras et al. 2017, 2018). Indeed, the report of the first-in-human clinical study in which UA is orally administrated to healthy, sedentary elderly individuals highlights the successful translation of its benefits to humans, underlined by UA-mediated improvements on mitochondrial homeostasis and muscle activity together with its safety and bioavailability profile (Andreux et al. 2019).

Mitophagy Inhibitors

Despite the beneficial effects of mitophagy in mitochondrial metabolism and cellular homeostasis, runaway mitochondrial clearance promotes shrinkage of mitochondrial pool, overstressing the remaining organelles, triggering energetic crisis, and eventually leading to cell death (Kubli and Gustafsson 2012). Hence, several chemical substances have been identified and used to prevent mitophagy.

The most commonly used method to inhibit mitophagy relies on lysosomal inhibitors, such as bafilomycin, chloroquine, and berbamine, which could impair lysosomal acidification or the process of fusion between autophagosomal and lysosomal membranes (Georgakopoulos et al. 2017). An alternative indirect approach to block mitochondrial removal is via the regulation of fission/fusion machinery. Mitochondrial network fragmentation is a perquisite event for mitophagy under stress conditions. Administration of mitochondrial division inhibitor-1 (mdivi-1) disturbs mitochondrial morphology by preventing fission and subsequently mitophagy in yeast and mammalian cells (Georgakopoulos et al. 2017; Murphy and Hartley 2018). Mechanistically mdivi-1 disturbs enzymatic activity of DRP1 protecting against oxygen-glucose deprivation and glutamate driven neurotoxicity. Recently, a novel peptide inhibitor was generated to manipulate FUNDC1-meidated mitochondrial clearance. This specific peptide is

cell-permeable and associates directly with the LIR motif of FUNDC1. Indeed, this LIR mimetic peptide diminishes the physical interaction between FUNDC1 and LC3 preventing FCCP- and hypoxia-induced mitophagy (Georgakopoulos et al. 2017). Notably, general autophagy was not affected underlining peptide selectivity and endorsing the rationale for the designing of specific peptides mimetics to modulate mitophagy execution.

Molecular Modelling

Gerd Krause
Leibniz-Forschungsinstitut für molekulare Pharmakologie (FMP), Berlin-Buch, Germany

Synonyms

Biocomputing; Molecular dynamics; Molecular simulation; Structural bioinformatics

Definition

Molecular modelling itself can be simply described as the computer-assisted calculation,

modulation, and visualization of realistic three-dimensional molecular structures and their physical-chemical properties using *molecular mechanics/force fields*.

Moreover, molecular modelling is one key method of a wide range of computer-assisted methods to analyze and predict relationships between protein sequence, three-dimensional molecular structure, and biological function (sequence-structure-function relationships). In molecular pharmacology, these methods focus predominantly on analysis of interactions between different proteins and between ligands (hormones, drugs) and proteins as well gaining information at the amino acid and even to atomic level.

Description

The constantly increasing amount of data coming from high throughput experimental methods, from genome sequences, from functional and structural genomics has given rise to a need for computer-assisted methods to elucidate sequence-structure and function relationships.

Sequence Similarity

Protein sequences encoded by genome sequences encode biological functions.

There are two different dimensions, breadth and depth, used to reveal sequence-structure-functional relationships by computational methods (Luscombe et al. 2001).

The aim of the first dimension "breadth" is to reveal sequence-function relationships by comparing protein sequences by sequence similarity. Simple bioinformatics algorithms can be used to compare a pair of related proteins or for sequence similarity searches, e.g., BLAST (Basic Local Alignment Search Tool). Improved algorithms allow multiple alignments of larger number of proteins and extraction of consensus sequence pattern and sequence profiles or structural templates which can be related to some functions, see, e.g., under http://www.expasy.ch/tools/#similarity.

The aim of the second dimension "depth" is to consider protein three-dimensional structures to uncover structure-function relationships. Starting from the protein sequences, the steps in the depth dimension are structure prediction, homology modelling of protein structures, and the simulation of protein-protein interactions and ligand complexes.

Protein Structure Predictions

Starting from the protein sequence (primary structure), several algorithms can be used to analyze the primary structure and to predict secondary structural elements like beta-strands, turns, and helices. The first algorithms from Chou & Fasman occurred already in 1978. The latest algorithms are to find, e.g., under https://www.expasy.org/proteomics/protein_structure where also predictions of transmembrane and coiled coil regions just from the primary sequence are possible.

Approaches of de novo predictions, which try to calculate how the structural elements are folded into the three-dimensional structure (tertiary structure) of complete proteins, are under strong development (Marks et al. 2012) indicated by recent successful results at the contest for structural prediction methods in the Critical Assesment of Structure Prediction, CASP14 in 2020. With the fast growing number of experimentally solved 3D structures of protein and new promising approaches like artificial inteligence, threading tools combined with evolutionary and experimental structural constraints, one can expect increasingly reliable de novo predictions for 3D protein structures in the future.

Homology Models of Protein Structures

The primary sequence of proteins with identical function varies within different species by natural mutations of amino acids. With increasing distance in the evolutionary process, the number of variations between the sequences of proteins increase.

In the protein structure database PDB (http://www.rcsb.org/pdb), all experimentally solved three-dimensional protein structures are publicly accessible. Structural data from X-ray crystallography, NMR spectroscopy and cryo-electron microscopy are available. Homology model building for a query sequence uses protein

portions of known three-dimensional structures as structural templates for proteins with high sequence similarity.

If the sequence of a protein has more than 90% identity to a protein with known experimental three-dimensional structure, then it is an optimal case to build a homologous structural model based on that structural template. The margins of error for the model and for the experimental method are in similar ranges. The different amino acids have to be mutated virtually. The conformations of the new side chains can be derived either from residues of structurally characterized amino acids in a similar spatial environment or from side chain rotamer libraries for each amino acid type which are stored for different structural environments like beta-strands or alpha-helices.

The discrepancies between homologous protein sequences occur predominantly at the surfaces and in the so-called loop regions. With decreasing sequence identities, insertions and deletions of loop chains or modelling of completely different loop chains are necessary. Segmentation of the loop in overlapping sequence fragments (3–10 residues) and searching for sequence similarity using BLAST or FASTA in the PDB database was proven to be most successful in loop modelling. Web platforms for loop modelling are, for example, https://modbase.compbio.ucsf.edu/modloop/; https://bioserv.rpbs.univ-paris-diderot.fr/services/DaReUS-Loop/.

Those fragments occurring several times in different protein structures with a common backbone conformation have a high probability of adopting the same backbone conformation also in the query sequence. The overlap almost allows knowledge-based assembly of the fragments to a new loop conformation. This segmentation strategy is also part of the successful algorithm Rosetta (http://boinc.bakerlab.org/rosetta/) for predicting complete folds for new proteins.

Similar residues in the cores of protein structures, especially hydrophobic residues at the same positions, are responsible for common folds of homologous proteins. Certain sequence profiles of conserved residue successions have been identified which give rise to a common fold of protein domains. They are organized in the smart database (simple modular architecture research tool) http://smart.embl-heidelberg.de.

Natural mutation of amino acids in the core of a protein can stabilize the same fold with different complementary amino acid types, but they can also cause a different fold of that particular portion. If the sequence identity is lower than 30%, it is much more difficult to identify a homologous structure. Other strategies like secondary structure predictions combined with knowledge-based rules about reciprocal exchange of residues are necessary.

If there is a reliable assumption for common fold, then it is possible to identify intra- and intermolecular interacting residues by search for correlated complementary mutations of residues by correlated mutation analysis, CMA (https://biokinet.belozersky.msu.ru/visualcmat/). Analysis of multiple sequence alignments for proteins of known structure has revealed that pairs of alignment columns corresponding to residues in spatial contact often tend to show patterns of correlated mutations (when the amino acid in one column changes, the amino acid in the other column is also likely to change correspondingly). This covariation between alignment columns has been attributed to the need to preserve favorable residue-residue interactions such as hydrogen bonds or tight packing.

Predicting a likely conformation or fold of a particular region of a protein with less or no sequence similarity to protein structures recorded in the PDB is the main challenge for homology modelling of proteins. Depending on the molecule type, different kinds of online web servers are available to generate homology models of 3D structures. For protein structure predictions, three web servers should be mentioned here as examples: ITASSER (https://zhanglab.ccmb.med.umich.edu/I-TASSER/); PHYRE (http://www.sbg.bio.ic.ac.uk/phyre2/html/page.cgi?id=index) and RAPTORX (http://raptorx.uchicago.edu/). These servers take the primary sequence of the target protein as input. After the construction phase of a model follows the optimization of the geometrical structure utilizing force fields and provide as output the lowest energy 3D modeled structure of the protein. Thereby the contributions of force field terms to

an energy equation are minimized. A typical all atom form of a molecular force field is constituted by bonded (bond, angle, dihedral, and torsion) interactions and no bonded (electrostatic and van der Waal's) interaction energy terms. There are many all atom force fields available, such as CHARMM, AMBER, GROMOS, and OPLS among others. Each force field has a unique set of parameters that are optimized to reproduce experimental reference data of a particular molecule type (e.g., small molecules, peptides, proteins, glycans) and environment (solvent, membrane). For this reason, it is essential to ensure that the application of the corresponding force field is in accordance with the conditions to be investigated, especially in the case of online server use.

Sequence conservation is, in general, much weaker than structural conservation. There are proteins which are clearly not related in sequence but are closely related in 3D structure and fold, like hemoglobin and myoglobin, which have similar functions. In many proteins, fold elements like 4-helical bundles are repeated. Classifications of known structural folds of proteins are organized in the SCOP or CATH database, see, e.g., http://scop.mrc-lmb.cam.ac.uk/scop/.

Template-free modelling approaches can be applied to proteins without global structural similarity to a protein in the PDB. Lacking a structural template, these methods require a conformational sampling strategy for generating candidate models, as well as a ranking criterion by which native-like conformations can be selected. Advanced strategies are described in Kuhlman and Bradley (2019).

Taken together the procedure to build a starting protein structural model for a protein combines similarity searches by sequences and by folds in different 3D structure databases and filling in remaining unknown conformations by information resulting from bioinformatics, knowledge-based approaches, and overlapping segmentation of sequence fragments.

Molecular Simulation

Simulation in general describes calculations with models where different options and combinations of variables can be quickly played through. Molecular dynamics simulations allow the characterisation of molecular properties during the movements of the molecular models, over a period of time.

Starting with an energy for an unfavorable molecular geometry, the algorithm searches for the next local energy minimum at the energy hypersurface. Starting with different unfavorable geometries can lead to different conformations at other local energy minima. For larger molecular structures and especially for structural models built on templates with lower sequence identity, it is necessary to evaluate the geometrical stability.

Importantly, all biological procedures are operating at a temperature of 310 Kelvin, not at 0 Kelvin as the potential energy is calculated by the force fields. The kinetic energy must also be considered. Molecules and proteins at room temperature change the conformation at least at the surface and in the loop region. Molecular dynamics simulation (MD) is an approach to tackle these kinetic and stability problems. Simulations of biological systems are performed at multiple resolutions—atomistic, coarse-grained, and mesoscale. The all-atom simulations (MD engines GROMACS, NAMD, CHARMM, AMBER) are restricted to small time-steps to capture the intra- and intermolecular motion of atoms over time that result in detailed structural, thermodynamic, and kinetic data that can be compared to experimental data.

The coarse-grain (CG) resolution approach considers instead of all single atoms a group of atoms of an amino acid as one common interacting entity (e.g., CG force field MARTINI). Mesoscale models consider even clusters of amino acids as one common entity. These lower resolution approaches have the advantage of considering larger protein ensembles, but with the limitation of greater inaccuracy.

An approach to overcome the multi minima problem of proteins is the simulated annealing (SA) run. Besides global molecular properties such as structural and thermal motions, functional properties of fast biological reactions can also be studied by MD.

Docking

The goal of virtual docking is to calculate the binding of a large number of ligand-protein or of protein towards a binding site of a target protein and to predict their binding affinity. To solve the docking problem, both the flexibility of the ligand and the binding site at the target must be taken into account, as changes in the orientation of the amino acids involved can be induced during binding. This leads to a combinatorial explosion of possible binding modes of a single ligand, each of which must be evaluated for binding affinity to find the most likely one. For this reason, many of the currently available virtual docking programs neglect the conformational flexibility of the binding site.

Docking approaches are simple geometry-based methods in which large numbers of ligand-protein or protein-protein interfaces are generated via geometric rigidbody motions, followed by a scoring scheme that ranks the interfaces using scoring algorithms. Popular docking web server include among others SwissDock (http://www.swissdock.ch/) for small molecule docking and HADDOCK (http://www.bonvinlab.org/software/haddock2.2/) for protein-protein docking. The latter is an information-driven flexible protein-protein docking approach for the modelling of biomolecular complexes. It distinguishes itself from ab initio docking methods in the fact that it encodes information from identified or predicted protein interfaces in ambiguous interaction restraints (AIRs) to drive the docking process.

Accuracy and Limitations

Molecular models are only an approximation to reality, but experimentally guided good models can often closely approach reality.

The margin of error of a final structural model depends on the sequence or fold similarity to the starting structural template.

An important measure for quality is the verification by MD or SA of the stability of a molecular model. Other programs (e.g., PROCHECK) can also be used to check the globular geometrical quality of a structure to avoid serious defects in the geometry of proteins.

Even the most elaborate models are worthless if there is no experimental examination at all.

Functional insights based on structural relationships can only rise to the level of hypotheses, and these hypotheses must be tested by direct functional experiments.

The strongest verification for a 3D protein model comes from the experimental 3D structure. This is the objective of the Critical Assessment of Techniques for Protein Structure Prediction, CASP (http://predictioncenter.org), where the structural models are made in advance of the experimental structure of a particular protein. A similar contest is available for docking studies predicting protein-protein interaction, which is called Critical Assessment of PRediction of Interactions, CAPRI (http://www.ebi.ac.uk/msd-srv/capri).

In molecular pharmacology research, an indirect proof of a structural model is possible by functional examinations, e.g., by molecular biological experiments. Well-selected site directed mutagenesis and their functional characterization allows confirmation or rejection of a molecular protein model. The process is organized as an iterative procedure, where the biological answer of suggested mutations is used to refine the model. The iteration continues until the model is consistent with the biological experiments and the functional predictions of mutations are confirmed.

Pharmacological Relevance

In general the relevance of predictions of structure-function relationships based on molecular modelling and structural bioinformatics are threefold. First they can be used to answer the question of which partners (proteins) could interact. Second, predictions generate new hypotheses about binding site, about molecular mechanisms of activation and interaction between two partners, and can lead to new ideas for pharmacological intervention. The third aim is to use the predictions for structure-based drug design.

Common to all three aims is that in silico-derived predictions can rationalize experimental

efforts either by well-directed very specific molecular biological experiments like site-directed mutations or, e.g., by reducing the number of compounds to screen experimentally for drug design.

Structure-Function Prediction

From the human genome project, it is known that roughly 30,000 proteins exist in humans. Currently only the 3D structures of a few thousand human proteins or protein domains are known. Structures of membrane bound proteins are several magnitudes rarer. Beside efforts to solve further structures like structural genomics, there is a challenge for computational approaches to predict structures and function for homologous proteins.

This is eminently necessary for large protein classes with important functions, e.g., the G-protein coupled receptors (GPCR), where several hundred different human GPCR are known. Out of this large family of seven transmembrane helix proteins, there are currently crystal structures of approx. 60 different GPCRs stored in the PDB database with a constantly growing number. Of the more than 200 structural entries for GPCRs, there are fragments as well as dimers/oligomers (https://alf06.uab.es/dimerbow/) and different activation states of the receptors including bound antagonists, agonists, and G-proteins.

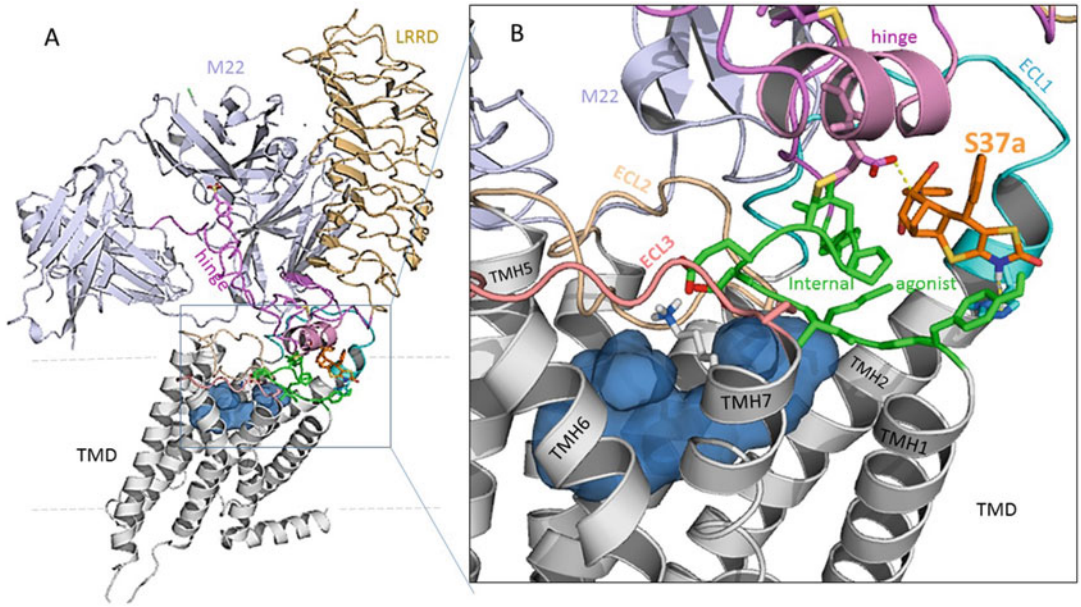
These crystal structures can be used as templates for various homologous receptor models. There are popular online servers for modelling GPCR structures, GPCR- ITASSER (https://zhanglab.ccmb.med.umich.edu/GPCR-I-TASSER/about.html), GPRM (http://gpcrm.biomodellab.eu/), and GPCR-Db (https://www.gpcrdb.org/) among others.

Most of them do not distinguish between the activation states or consider only inactive states of bound antagonists such as SSFE (http://www.ssfa-7tmr.de/ssfe2/). As with the selection of the force field, it is important that the selection of the template must be made according to the question to be investigated. The majority of the structure templates for GPCRs are in the inactive or intermediate state. For generating GPCR models in the active state, for example, to dock agonists, one should select such crystal structure as template, in which both an agonist and the corresponding G-protein or mimicking nanobodies are bound.

Incorporation of further experimental results like scanning accessible cysteines, cross linking, spin labelling, ligand binding, and site-directed mutations, etc. allowed molecular modelling to predict successfully ligand-binding sites and local activation mechanisms of diverse GPCR. In general the inactive conformation of GPCR is constrained by interaction of complementary residues in the interior side of the receptors which can be observed in the rhodopsin structure.

Activation mechanisms of homologous GPCRs can be revealed by molecular simulations and characterized by molecular experiments as in the following example.

The molecular activation mechanisms of the thyroid stimulating hormone receptor (TSHR), a homolog of glycoprotein hormone receptors (GPHR), LHR, and FSHR (web resource http://www.ssfa-gphr.de/) appear to be distinct from that of other GPCRs of family A, owing to its uniquely large N-terminal extracellular domain (ECD) in terms of overcoming its inhibitory function. The ECD of TSHR is comprised by a leucine-rich repeat domain (LRRD) and a hinge region. Molecular models of SHR indicate that the hormone TSH binds between the LRRD and hinge region and activates the transmembrane domain (TMD) indirectly via an internal agonist (Fig. 1a). TSHR-stimulating autoimmune antibodies (TSAb) such as M22 bind to TSHR at a similar site as TSH itself and cause deregulated TSHR hyper-activation in the thyroid and in the eye in pathogenic conditions of Graves' disease (GD) and Graves' orbitopathy (GO) respectively. Combined modelling and mutagenesis has shown that the intramolecular activation pathway is blocked by a recently identified highly TSHR-selective small molecule antagonist S37a (Marcinkowski et al. 2019) that binds allosterically between the hinge and the internal agonist (Fig. 1b). This binding site is distinct from a canonical transmembrane-binding site of GPCRs, wherein TSHR allosteric small molecule agonists are bound.

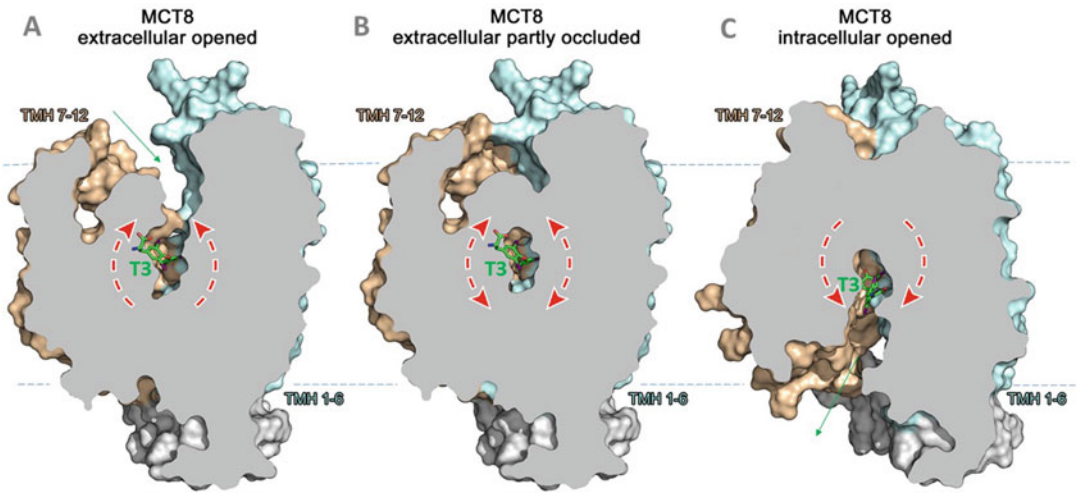


Molecular Modelling, Fig. 1 Homology model of the TSH-Receptor. (**a**) Autoimmune stimulating antibody M22 (light blue) binds to the extracellular leucine-rich repeat domain LRRD (beige) delocalizing the hinge region (magenta) that triggers the internal agonist sequence (green) to activate indirectly the transmembrane domain (TMD, grey), which contains a canonical allosteric binding pocket (blue surface), where also small molecule agonists can bind. (**b**) The antagonistic small molecule S37a (orange) binds into an alternative and distinct binding site between internal agonist (green), extracellular loop 1 (ECL1, cyan), and hinge region (magenta) and locks the inactive state of the TSHR (Marcinkowski et al. 2019)

Simulation of Functional Properties

With growing computer power, the abilities to simulate functional properties and dynamics of fast biological reactions are increasing. Today molecular dynamics (MD) can be traced over a time range of about 1 millisecond. Relevant dynamics of fast biological processes (vision and photosynthesis) like electron transfer reactions, proton translocation (e.g., bacteriorhodopsin, V-ATPase), ion transport (diverse ion channels), and hormone transport (e.g., thyroid hormone transporter) across the membrane via membrane proteins have been studied. MD simulations can provide a realistic molecular description of the actual reactive event. For example the dynamics and mechanisms of water permeation through biological membranes via pore proteins were studied using Aquaporin 1 (AQP1) and the homologous glycerol facilitator (GlpF). The selective pattern for transport of water at AQP1 and glycerol at GlpF could be identified. Also a fine-tuned water dipole rotation during the passage through the pores could be simulated by MD (de Groot and Grubmüller 2001).

Recently the molecular mechanisms of thyroid hormone (TH) transport across the plasma membrane via the transport protein Monocarboxylate transporter 8 (MCT8) were studied that comprises 12 transmembrane helices. Three new MCT8 homology models based on crystal structures of homologous sugar transporters XylE in the intracellular opened (PDB ID: 4aj4) and the extracellular partly occluded (PDB ID: 4gby) conformations as well as FucP (PDB ID: 3o7q) and GLUT3 (PDB ID: 4zwc) in the fully extracellular opened conformation allowed the identification of a membrane-traversing mechanism for THs such as T3 by MCT8 (Fig. 2). The N-terminal transmembrane six-helix-bundle undergoes a rigid body rotation around a central TH-interacting cavity with respect to the C-terminal transmembrane six-helix-bundle. This allows alternating extra- and intracellular accessibility of the TH recognition-sensitive residues His192, His415, Arg445, and Asp498,



Molecular Modelling, Fig. 2 Sliced MCT8 molecular models of (**a**) extracellular opened, (**b**) extracellular partly occluded, and (**c**) intracellular opened conformations are based on crystal structures of homologous sugar transporters in respective states (XylE, PDB:4aj4 & 4gby, GLUT3, PDB:4zwc and FucP, PDB:3o7q). The models indicate two revolving six–transmembrane helix (TMH)-bundles, one central substrate-recognition and membrane-traversing cavity, which is accessible by thyroid hormone (TH) T3 (green) from both sides. After extracellular TH recognition, T3 adheres to transport-sensitive residues during tilting (red arrows) of the N-terminal (TMH 1–6, cyan) and C-terminal (TMH 7–12, sand) six-TMH bundles around the central cavity and is thus lifted through the central traversing cavity and released towards the intracellular side and vice versa (Protze et al. 2017)

enabling MCT8 to transport TH into and out of the cell, depending on the concentration gradient (Protze et al. 2017).

Critical examinations of dynamic effects showed that they are rather unlikely contribute to processes with significant activation barriers. Even in cases of ion channels, it is found that the most important effects are associated with energies rather than dynamics.

The resulting insight of MD is crucial in studies of fast photo biological reactions and instructive in cases of slower processes. Very slow processes like folding of proteins can until now be traced only fragmentarily by MD, because folding takes a time range between 20 milliseconds and 1 h.

Depressive illness; Inhibitors; Monoamine oxidases; Neuroprotection-neurorescue; Parkinson's disease

Definition

Monoamine oxidase (amine:oxygen oxidoreductase (deaminating); EC 1.4.3.4; MAO) exists in two forms, named type A and type B. They are responsible for oxidative deamination of primary, secondary, and some tertiary amines, including the neurotransmitters, noradrenaline, dopamine, and serotonin (5-hydroxytryotamine; 5-HT), the hormone adrenaline, and trace amines, such as tyramine, tryptamine, and 2-phenylethylamine. Their nonselective and selective inhibitors are employed for the treatment of depressive illness and Parkinson's disease.

Reaction Mechanism of Monoamine Oxidase

The role of monoamine oxidase in terminating the action of the aminergic neurotransmitters and dietary amines has been extensively studied; less attention has been paid to the functions of the products formed in the MAO reactions that include aldehyde and acidic metabolites.

$$RCH_2NR'R'' + O_2 + H_2O \rightarrow RCHO + NR'R'' + H_2O_2$$

Each of the products of this reaction may have important metabolic and signaling functions, but they are also potentially toxic at higher concentrations. In the presence of Fe(II), hydrogen peroxide may form highly toxic species, such as hydroxyl radicals, in the Fenton reaction. It has been suggested that the aldehydes derived from serotonin and noradrenaline deamination may be involved in the regulation of sleep. The aldehyde derived from dopamine, which is rapidly removed by aldehyde dehydrogenase and does not accumulate in normal brain, is thought to be highly toxic to dopamine neurons of substantia nigra in ▶ Parkinson's disease, since the levels of that enzyme are very low in parkinsonian substantia nigra pars compacta and also in the 6-hydroxydopamine model of that disease. Such aldehydes may also form adducts with amine groups, to yield compounds such as *N*-methyl-R-salsolinol and tetrahydropapaveroline as well as peptide adducts, which may have pathophysiological roles.

Basic Characteristics of Monoamine Oxidases

MAO is tightly bound to the mitochondrial outer membrane. The active site contains covalently bound FAD (flavin adenine dinucleotide) as cofactor. The existence of two forms of MAO was first identified by differences in sensitivity to some inhibitors in presence of different substrates. The irreversible inhibitor clorgyline inhibits serotonin oxidation at low concentrations, in a sigmoidal fashion, whereas it is a poor inhibitor of benzylamine and 2-phenylethylamine oxidation. However, with dopamine and tyramine, a double sigmoidal inhibition is observed. This was interpreted as indicating the involvement of two enzymes, termed MAO-A and MAO-B, where the

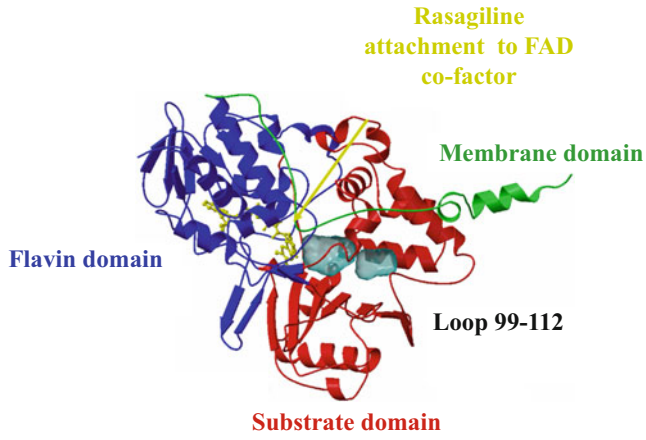
substrates for MAO-A include serotonin and clorgyline is a selective inhibitor of that enzyme. In contrast the irreversible inhibitor selegiline (*l*-deprenyl) is a potent inhibitor of MAO-B, which metabolizes benzylamine and 2-phenylethylamine. The responses to these inhibitors indicate that dopamine and tyramine are substrates for both enzymes (Tables 1 and 2). MAO-A and MAO-B have been purified and cloned. They have been shown to be different proteins, with MAO-A having about 70% identity to that of MAO-B form, with each enzyme containing FAD bound to a cysteine residue (Fig. 1). An important structural difference is the size of the entrance cavity that restricts the accessibility of bulkier substrates and inhibitors to the active site of MAO-B but allows them to access MAO-A. Comparisons of the three-dimensional structures of the enzymes from rat and human have shown the active site of the human MAO-A to comprise a single cavity, which is smaller than that of MAO-B from that

Monoamine Oxidases and Their Inhibitors, Table 1 Substrate specificity of the two forms of rat liver and brain monoamine oxidase

Rat liver and brain		
Substrates of the A form	Substrates of both forms	Substrates of the B form
A. Rat liver and brain		
Adrenaline	Dopamine	Benzylamine
Noradrenaline	Tyramine	2-Phenylethylamine
3-*O*-Methyladrenaline	3-Methoxytyramine	Phenylethenolamine
3-*O*-Methylnoradrenaline	p-Synephrine	O-Tyramine
Serotonin		1,4-Methylhistamine
		N-tele-Methylhistamine
		n-Pentylamine
B. Human brain		
	Adrenaline	Benzylamine
Serotonin	Noradrenaline	2-Phenylethylamine
	Dopamine	
	Tyramine	

Monoamine Oxidases and Their Inhibitors, Table 2 K_m values of the two forms of monoamine oxidase

Substrate	Source	Type A	Type B
		K_m (μM)	K_m (μM)
Serotonin	Rat liver	160	2000
Serotonin	Rat brain	180	1200
Serotonin	Human platelet	–	1800
Serotonin	Bovine chromaffin	–	2100
Noradrenaline	Bovine chromaffin	–	1750
2-Phenylethylamine	Human platelet	–	16
2-Phenylethylamine	Bovine chromaffin	–	21
Tyramine	Rat liver	110	580
2-Phenylethylamine	Rat liver	280	20
Dopamine	Human cerebral cortex	212	220
	Human striatum	180	210
Noradrenaline	Human cerebral cortex	284	238



Monoamine Oxidases and Their Inhibitors, Fig. 1 The crystal structure of human MAO-B. There are three functionally distinct domains, as shown. In red, the substrate domain contains two "cavities" shown in cyan. The outer space is the entrance cavity leading to the inner space, substrate binding cavity, closer to the flavin cofactor. The flavin-binding domain is shown in blue with the FAD molecule in yellow. In green, the C-terminal helical region which attaches the protein to the mitochondrial membrane. Rasagiline covalently links to the flavin via its propargylamine group (yellow arrow) and the indan ring and then extends into the substrate-binding cavity, blocking access for substrates

source but larger than that of rat MAO-A. Such differences suggest that the substrate specificities and sensitivities to inhibitors may show species differences. This structural difference may explain why adrenaline and noradrenaline have been reported to be a preferred substrate for MAO-A in rat liver and brain, but substrates for both enzymes in human brain.

The propargylamine-derived irreversible MAO-A and MAO-B inhibitors, clorgyline, *l*-deprenyl, and rasagiline, have been shown to form covalent adducts with the N-5 isoalloxazine moiety of covalently bound flavin (Fig. 1).

The separate genes for MAO-A and MAO-B are located on the X chromosome. Disruption of the MAO-A gene has been shown to result in a compulsive-aggressive phenotype, which is associated with some mental retardation. Similar responses have been observed in MAO-A knockout mice and in rats treated with clorgyline during the early postnatal period. The association with elevated serotonin levels in these subjects suggests the importance of maintaining low levels of this amine for normal brain development, a process which has been shown to be mediated by 5-HT-6 receptors. The effects of deletion of MAO-B are more modest but may be associated with reduced resistance to stress.

Drugs

The inhibitors clorgyline and deprenyl have been employed to identify the presence of each form in different tissues and species (Table 3) and also to determine the substrate specificities of MAO-A and MAO-B (Table 1) as well as their kinetic parameters (Table 2). A number of other inhibitors that are selective toward one or the other MAO have since been identified (Table 4, Fig. 2). The selective propargylamine inhibitors (clorgyline, selegiline, rasagiline, *N*-(2-propynyl)-2-(5-benzyloxy-indolyl) methylamine, aliphatic *N*-methyl propargylamine) may lose their selectivities at higher concentration in vitro and may do so after prolonged administrations in vivo. In contrast, the reversible inhibitors (Table 4) appear to retain their selectivity in vivo.

The effects of in vivo treatment with irreversible MAO inhibitors can be quite long-lasting, since regain of activity requires the synthesis of new enzymes. The rates of recovery from a single dose of an irreversible inhibitor show half-lives of about 2.5 and 3.5 days for MAO-A and MAO-B, respectively, in rat liver, 9 and 13 days in rat brain, and 2.2 and 7.7 days in rat intestine. A very much slower recovery rate has been reported for

MAO-B in human brain, with a half-life of about 40 days.

Neuropharmacology of Monoamine Oxidases and Their Inhibitors

Acute treatment of nonselective MAO inhibitors (e.g., iproniazid, tranylcypromine, phenelzine) increases brain levels of all monoamines including the neurotransmitters dopamine, noradrenaline, and serotonin as well those of 2-phenylethylamine, tryptamine, and methylhistamine. In contrast, selective inhibitors of MAO-A (e.g., clorgyline) increase serotonin, whereas MAO-B inhibitors (e.g., selegiline, rasagiline) increase brain levels of 2-phenyethlamine and related amines. Neither classes of the selective inhibitors greatly affect brain levels of dopamine, since that neurotransmitter can be metabolized by either enzyme. Thus, when one form is inhibited, the other continues its degradation. A combination of MAO-A plus MAO-B inhibitors has the same effect as the nonselective inhibitors. As shown in Table 2, the substrate specificities of MAO-A and MAO-B are not absolute, in that MAO-B is able to oxidize higher concentrations of serotonin. Indeed, it has been shown, both in vitro and in vivo, that when the concentration of serotonin is high enough to satisfy the K_m of MAO-B, it can be metabolized by that enzyme. For this reason, selective MAO-A inhibitors do not increase the brain levels of serotonin to the same extent as nonselective inactivators. Although the changes in amine levels occur rapidly after treatment with nonselective inhibitors, the antidepressant effects are manifested more slowly, typically only after 2–3 weeks of chronic treatment. This has been attributed to system's responses to the elevated

Monoamine Oxidases and Their Inhibitors, Table 4 Nonselective and selective monoamine oxidase inhibitors

Compound	MAO selectivity	Inhibitor type	Application
Iproniazid	A + B	Irreversible	Antidepressant
Phenelzine	A + B	Irreversible	Antidepressant

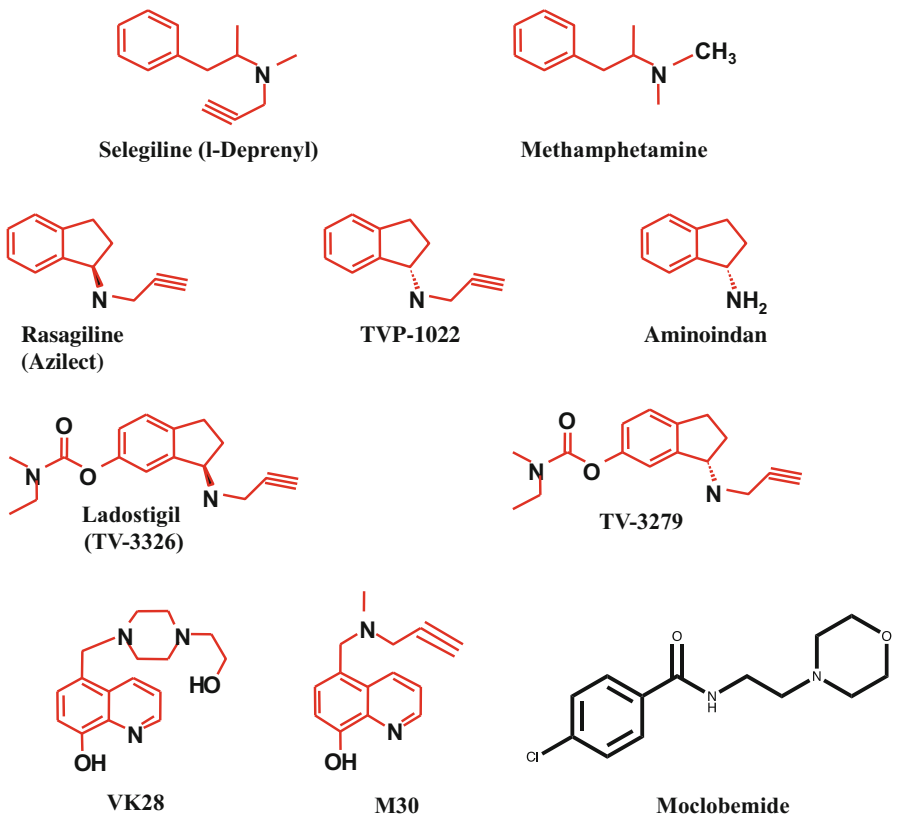
amine levels, including suppression of the synthetic enzymes, tyrosine hydroxylase, and tryptophan hydroxylase, as well as inhibition of aminergic neuronal firing, resulting from downregulation of presynaptic receptors alpha 2 receptors. Long-term postsynaptic adaptive changes include desensitization of postsynaptic beta receptors and subsensitivity of 5-HT1 receptors.

The Cheese Reaction

Iproniazid was among the first of the psychotropic antidepressants to be discovered and introduced into the clinic. Although this inhibitor and others that followed (tranylcypromine, phenelzine) demonstrated antidepressant activity, they also had a major side effect that became known as the "cheese reaction". This reaction (Fig. 3) is induced by tyramine and other indirectly acting sympathomimetic amines present in some foodstuffs (commonly in certain cheeses, hence the name) and fermented drink, such as beer and wine. Under normal circumstances, such dietary amines are extensively metabolized by MAO-A in the gut wall and in the liver and are, thus, prevented from entering the systemic circulation. If MAO is inhibited, this protective system is inactivated, and tyramine and other monoamines that are ingested are not metabolized and may enter the circulation, where they have access to, and induce a significant release of noradrenaline from, peripheral adrenergic neurons. This release results in a severe hypertensive response which, in some cases, can be fatal. This side effect stimulated a search for antidepressants that did not



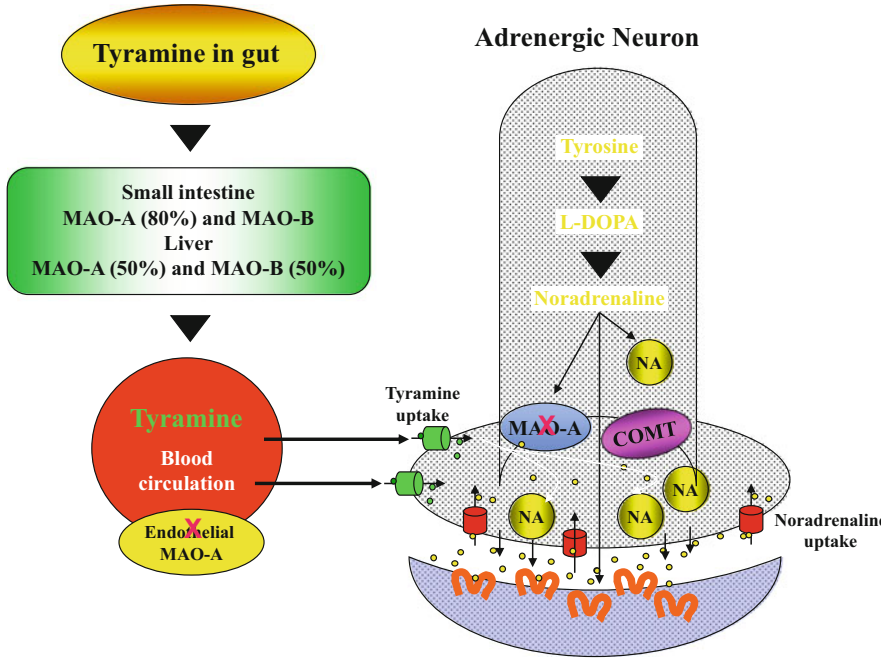
Monoamine Oxidases and Their Inhibitors, Fig. 2 Structures of some MAO inhibitors. In the top row, the structural similarity between selegiline/l-deprenyl and methamphetamine is shown. Below are the aminoindan series of propargylamine compounds such as rasagiline. Next, the bifunctional MAO and cholinesterase inhibitor (ladostigil) and the iron chelator-MAO inhibitors. The reversible MAO-A inhibitor moclobemide is shown in black

inhibit MAO. The amine uptake inhibitors, the tricyclic antidepressants, and, more recently, the serotonin selective reuptake inhibitors (SSRI), such as Prozac, have largely superseded MAO inhibitors as antidepressants. Better understanding of MAO-A and MAO-B distribution had led to the demonstration that the cheese reaction is the property of irreversible MAO-A inhibition in the gut and peripheral adrenergic neurons, where that enzyme resides. The irreversible MAO-B inhibitors, such as *l*-deprenyl (selegiline) and rasagiline (Azilect), do not induce a cheese effect and have limited cardiovascular potentiation at their MAO-B inhibitory dosage. However, at inhibitor concentrations where selectivity is lost and MAO-A is inhibited, the cheese reaction is prominent. Reversible and competitive MAO-A inhibitors (such as moclobemide) were developed as antidepressants that would not give a cheese reaction. The logic being that tyramine can compete with the reversible MAO-A inhibitor at the active site of MAO, allowing its metabolism before it can induce release of noradrenaline.

Monoamine Oxidase Inhibitors as Therapeutic Agents

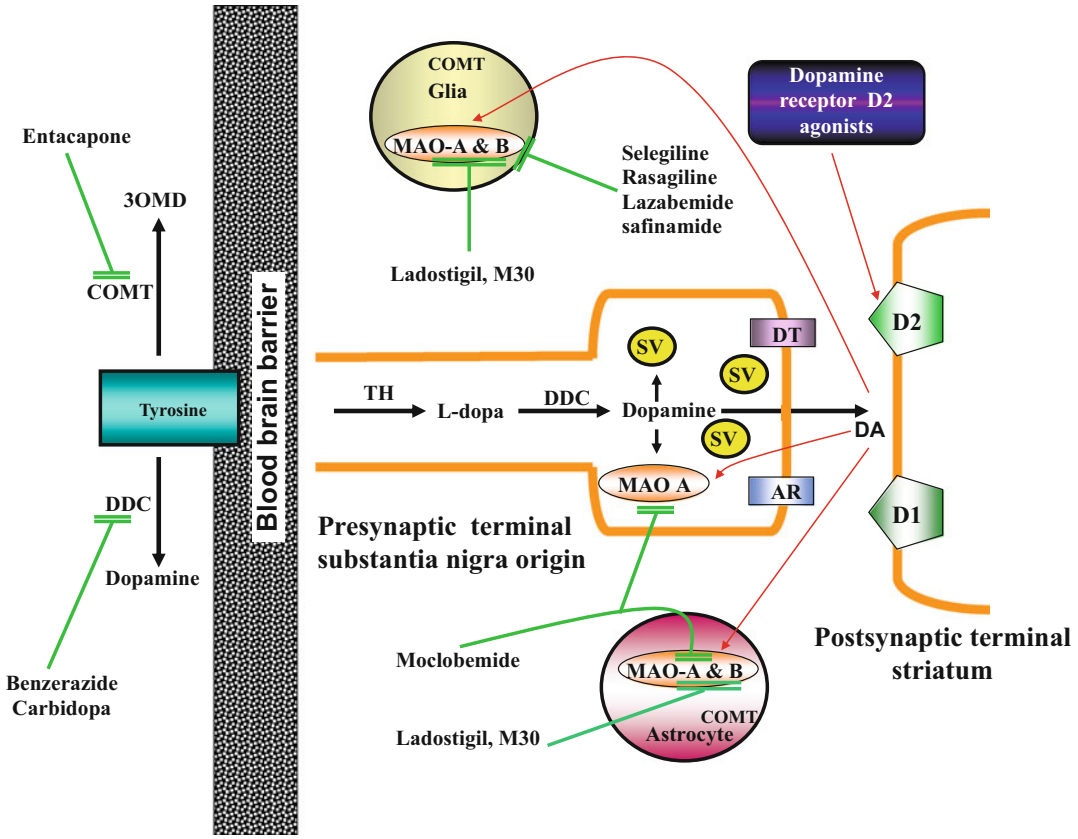
Parkinson's Disease

As early as 1961, the first generation of MAO inhibitors (iproniazid, isocarboxazid) was employed for the treatment of Parkinson's disease (PD). However, because of the severe side effects,



Monoamine Oxidases and Their Inhibitors, Fig. 3 The "cheese reaction" – potentiation of cardiovascular effects of tyramine (or other indirectly acting sympathomimetic amines) by irreversible inhibitors of MAO. Normally, dietary tyramine undergoes extensive "first pass" inactivation by the MAO-A and MAO-B types in gut wall and then in the liver. The tyramine that survives to enter the systemic circulation is further inactivated by the MAO in vascular endothelial cells and lung. At the adrenergic neuron, uptake of tyramine initiates the release of noradrenaline, which accounts for its sympathomimetic effects. Irreversible inhibition of MAO-A, the predominant form in the periphery adrenergic neurons, allows greatly increased tyramine entry in the systemic circulation and, from there, adrenergic neurons, consequently increasing noradrenaline release and effect. By contrast, reversible inhibitors of MAO-A (RIMAs) are displaced from the enzyme by tyramine which is then metabolized normally by the enzyme. Thus, circulating tyramine never attains the high levels resulting from irreversible inhibition of MAO

such as "cheese reaction," they were abandoned. The realization that the basal ganglia (extra pyramidal region) of human brain contained mostly MAO-B, which metabolized dopamine, and that the MAO-B inhibitor *l*-deprenyl did not potentiate the sympathomimetic actions of tyramine in vivo led to its employment as adjuvant to L-dopa therapy in 1975. Confirmation of these early results and the demonstration of its effectiveness in monotherapy led to its introduction into the clinic. The realization that MAO-B inhibitors had symptomatic activity and antiparkinson effects resulted in the development of other such MAO-B inhibitory drugs, many of which were subsequently abandoned because of toxicity or lack of effectiveness. A spur for such developments was the finding that *l*-deprenyl could be metabolized to *l*-amphetamine. The second-generation MAO-B inhibitor, rasagiline, which is not metabolized to amphetamine, is now in widespread use. The mechanism of the antiparkinson action of MAO-B inhibitors is not fully known but may be related to increased dopamine or to the ability of elevated 2-phenyethylamine to release dopamine. Since dopamine is metabolized both by MAO-A and MAO-B, it might be expected that MAO-A inhibitors and nonselective inhibitors would also have antiparkinson activity (Fig. 4), but these have not been employed because of the cheese reaction. However, some

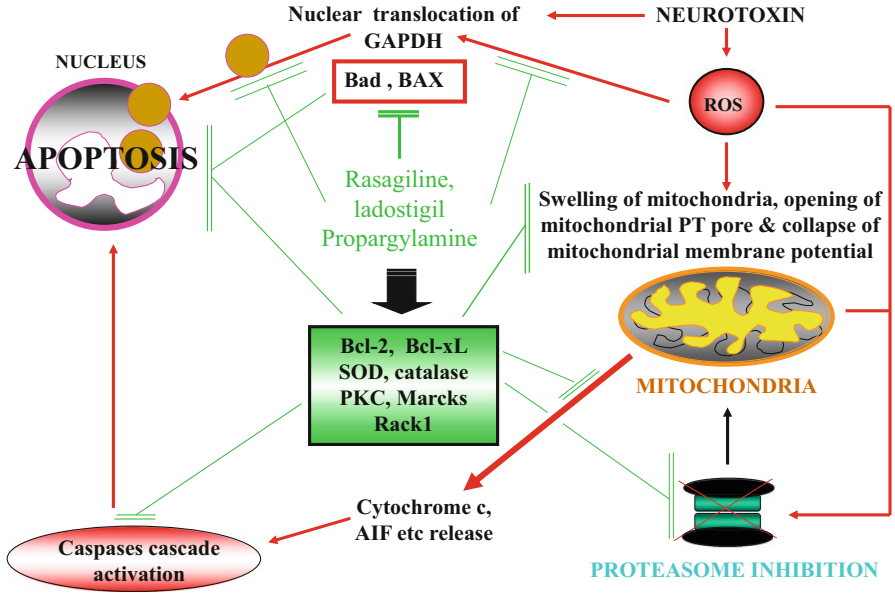


Monoamine Oxidases and Their Inhibitors, Fig. 4 Pathways of dopamine synthesis in dopaminergic neurons and metabolism by MAO-A and MAO-B in the brain. Tyrosine passes through the blood-brain barrier and is hydroxylated by tyrosine hydroxylase (TH) to DOPA and then decarboxylated by DOPA decarboxylase (DDC) to dopamine (DA) within the neuron. Dopamine is taken up into synaptic vesicles (SV) or metabolized by neuronal mitochondria MAO-A. After release from the terminal, extracellular dopamine is cleared by uptake into astrocytes and glia also containing MAO-A and MAO-B. Selective inhibition of one MAO isoform allows the other to metabolize dopamine effectively and does not greatly affect the steady-state levels of striatal dopamine. On the other hand, nonselective inhibition of MAOs induces highly significant increase in striatal dopamine and in other brain regions. D1 and D2, dopamine receptors. On the other hand, in adrenergic and serotonergic neurons, MAO-A and not MAO-B inhibition results in increased levels of these amines

clinical studies with the reversible MAO-A inhibitor, moclobemide, have shown that it does possess dopamine-sparing antiparkinson activity, without inducing a cheese reaction.

Neuroprotection in Neurodegenerative Diseases

The neurotoxin MPTP (*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) can cause parkinsonism in humans, nonhuman primates, and rodents by its ability to cause degeneration of nigrostriatal dopamine neurons. MPTP is an inert tertiary amine which is oxidized by MAO-B to the neurotoxin MPP^+ (1-methyl-4-phenylpyridinium). MAO-B inhibitors prevent this and the neurotoxic effects of MPTP in animals and neuronal cell cultures. Since MPTP is a synthetic compound, it was suggested that PD could be a result of an environmental neurotoxin; however, no such neurotoxin has yet been discovered. Nevertheless, propargyl-derived

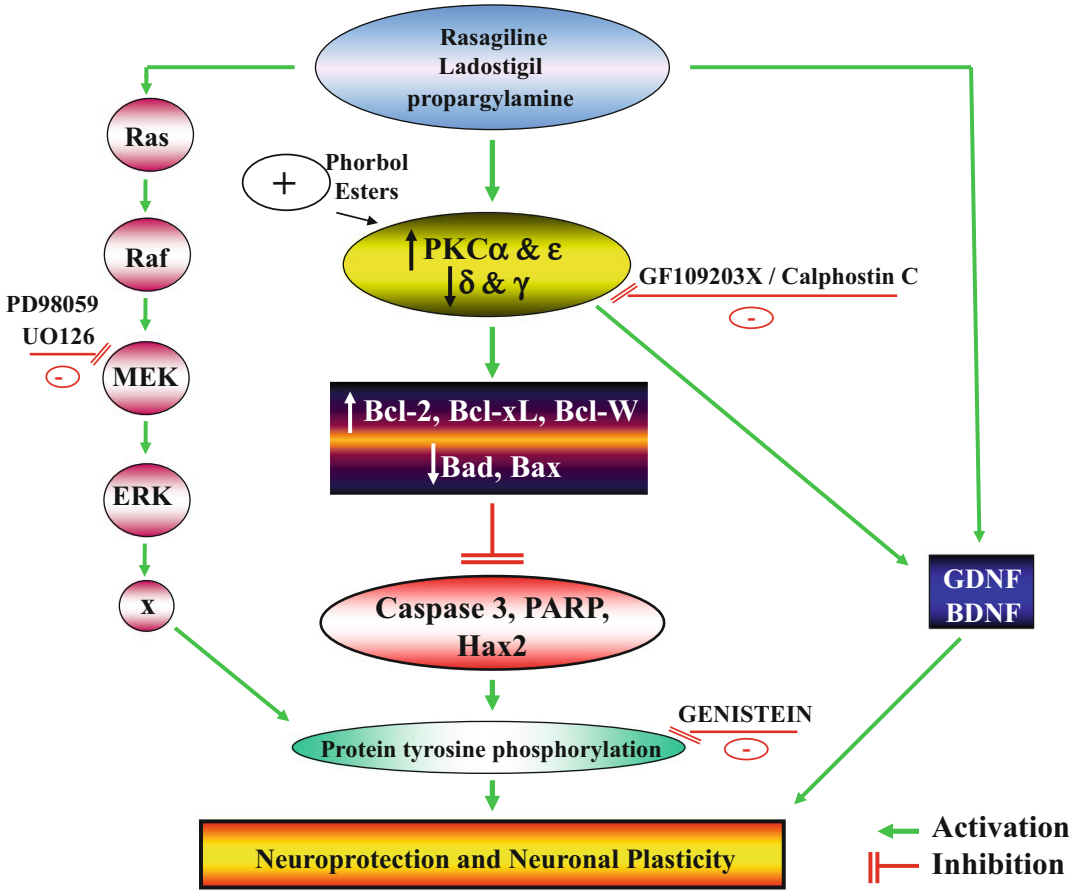


Monoamine Oxidases and Their Inhibitors, Fig. 5 The interactions of irreversible, propargylamine-based, MAO-B inhibitors with apoptotic pathways. Mitochondria are responsible for cell survival and death through the regulation of the B-cell leukemia/lymphoma 2 (BCL2) family anti-apoptotic (BCL2) and pro-apoptotic (BCL-associated death promoter, BAD, and BCL2-associated protein X, BAX) proteins. Rasagiline, selegiline, ladostigil, and propargylamine have been shown to induce cell survival in response to serum withdrawal or neurotoxins in neuronal cell cultures (SHSY-5Y and PC-12), through the activation of BCL2 and BCL-XL, and the downregulation of BAD and BAX. These propargylamines exert their neuroprotective activity by interacting with the mitochondrial outer membrane. The propargylamine moiety in these inhibitors prevents neurotoxin-induced collapse of mitochondrial membrane potential, mitochondrial permeability transition, and the opening of the voltage-dependent anion channel, as a consequence of the upregulation of anti-apoptotic BCL2 family proteins, which also leads to disinhibition of proteasome function. In addition, these propargylamines prevent the nuclear localization of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) in response to neurotoxins and reactive oxygen species (ROS). *AIF* apoptosis-inducing factor, *PKC MARCKS* myristoylated alanine-rich protein kinase C (PKC) substrate, *RACK1* receptor of activated PKC, *SOD* superoxide dismutase

MAO-B inhibitors such as selegiline and rasagiline have received much attention as neuroprotective drugs. However, their neuroprotective activity appears to be independent from MAO-B inhibition, since several propargylamines, including propargylamine itself, that do not inhibit MAO also show neuroprotective properties. These drugs upregulate anti-apoptotic Bcl-2 while down-regulating pro-apoptotic Bcl-2 family proteins (Fig. 5) and activate PKC-MAP kinase pathways (Fig. 6). The result is prevention of mitochondrial impairment and cell survival. Some propargylamines have also been shown to be capable of causing regeneration of dying neurons (neurorescue). A delayed-start study where rasagiline was given to two groups of parkinsonian subjects, 6 months apart, has shown that subjects treated with rasagiline for 12 months showed less functional decline than subjects whose treatment was delayed for 6 months. This was interpreted as indicating a disease-modifying action.

Depressive Illness

Although the cheese reaction seen with non-selective and irreversible MAO inhibitors curtailed their use, two of them, phenelzine and tranylcypromine, are still prescribed, with patients being instructed about foods and beverages that



Monoamine Oxidases and Their Inhibitors, Fig. 6 The mechanism of neuroprotection and/or neurorescue by propargylamine MAO inhibitors. The propargylamine monoamine oxidase (MAO) inhibitors (such as rasagiline and ladostigil) activate the protein kinase C (PKC)-dependent mitogen-activated protein (MAP) kinase pathway 185,187 and mitochondrial B-cell leukemia/lymphoma 2 (BCL2) family cytoprotective proteins and downregulate pro-apoptotic BCL-associated death promoter (BAD), BCL2-associated protein X (BAX), caspase 3, poly (ADP-ribose) polymerase 1 (PARP1), and H2AX (a phosphorylated mammalian histone H2A) 141. One direct consequence is the processing of amyloid precursor protein (APP) through the activation of α-secretase, resulting in increased release of the neuroprotective/neurotrophic soluble APPα (sAPPα). The activation of PKCα and PKCε might explain the ability of these propargylamines to induce expression of glia cell line-derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF) mRNAs and stimulate the release of GDNF. Inhibitors of PKC (such as GF109203X and calphostin C), extracellular signal-regulated kinase 1/2 (ERK1/2) (e.g., PD98059 and UO126), and tyrosine kinase (for instance, genistein) prevent APP processing and release of GDNF and block BCL2-dependent neuroprotective pathways, supporting a mechanism by which propargylamines operate at different levels and suggesting a direct link between PKC and BCL2 family protein expression. MEK, MAP kinase kinase; Raf, Ras, small G proteins; X represents a phosphorylated protein that activates tyrosine kinase

they should avoid. In comparison with the tricyclic antidepressants, it has been reported that monoamine oxidase inhibitors were less effective in endogenous depressive conditions involving melancholia whereas they were particularly effective in the so-called atypical depressions. With the reversible MAO-A inhibitor, moclobemide (Figs. 2 and 4), dietary restriction is unnecessary

since it has highly limited capacity to induce the cheese reaction. Because of its mild antidepressant activity, it is generally considered to be more suitable for elder subjects, who react poorly to standard antidepressants.

Definition

Bipolar disorder (BD) is a common, chronic, heritable, recurring mood disorder that involves manic, depressive, and mixed episodes. It is often comorbid with other medical conditions and is also associated with high morbidity and mortality. Without adequate maintenance treatment with mood stabilizers, the frequency and severity of BD episodes typically increases over time.

Mood stabilizers are highly effective for preventing mood episodes and improving manic and/or depressive symptoms; these medications are used as long-term prophylactic treatment based on their ability to prevent the recurrence of depression and mania. Mood stabilizers are also expected to prevent and treat switches between depression and mania, a feature that distinguishes these agents from other pharmacological approaches in mood disorders, such as antidepressants (Manji et al. 2009; Machado-Vieira et al. 2017; Goodwin 2015).

No mood stabilizer has ever been developed based on the known molecular pathophysiology of BD (Manji et al. 2009; Machado-Vieira et al. 2017; Goodwin 2015). To date, all FDA-approved mood stabilizers were either serendipitous discoveries or medicines initially developed for other clinical indications. These agents include lithium and several anticonvulsants, namely, valproate,

lamotrigine, and carbamazepine. Atypical antipsychotics have also been approved to treat mood episodes and for maintenance therapy (alone or in combination); these include aripiprazole, asenapine, cariprazine, lurasidone, olanzapine (+ fluoxetine), paliperidone, quetiapine, risperidone, and ziprasidone. More detailed information on these second-generation antipsychotics is provided in a different chapter of this series.

Mechanism of Action

With regard to the biological effects potentially related to their clinical efficacy in BD, mood stabilizers have been shown to reverse impaired cellular resilience and neuroplasticity pathways across biological systems in both clinical studies and preclinical models. Numerous studies exploring these effects have been conducted in humans – including in postmortem brain tissue, neurons, and other brain cells derived from human pluripotent stem cells – as well as in experimental animal models to explore the underlying pathophysiology of BD (Manji et al. 2009; Machado-Vieira et al. 2017; Goodwin 2015).

Despite a wide range of studies, neither the precise biological underpinnings of this disorder nor the mechanisms of action underlying the mood stabilizing effects of available agents are fully understood. Nevertheless, numerous direct targets of these agents have been identified. In this context, lithium has been and continues to be the gold standard and proof of concept agent used to study neurobiological targets and pathways related to the therapeutics of mood episodes in BD. Mood stabilizers in general target inflammation, neurotrophic factors, mitochondrial function, calcium metabolism, neurotransmitter systems, and HPA axis/stress pathways, all of which are factors closely implicated in BD (Teixeira et al. 2016). For example, lithium is known to inhibit: (1) inositol monophosphatase, (2) inositol polyphosphate 1-phosphatase, (3) glycogen synthase kinase-3 (GSK-3), (4) fructose 1,6-bisphosphatase, (5) bisphosphate nucleotidase, (6) phosphoglucomutase, and (7) neuronal calcium sensor-1 (NCN-1) (Manji et al. 2009; Teixeira et al. 2016). Another widely used mood stabilizer is valproate. This agent targets different proteins, enzymes, and neurotransmitters, including: (1) succinate semialdehyde dehydrogenase, (2) succinate semi-aldehyde reductase, (3) gamma aminobutyric acid (GABA) transaminase, and (4) histone deacetylase (HDAC) (Manji et al. 2009). With regard to other mood stabilizers, the known targets of carbamazepine include: sodium/calcium channels, adenosine receptors, and adenylate cyclase (Manji et al. 2009), and lamotrigine blocks voltage-sensitive sodium channels as well as L-, N-, and P-type calcium channels (Manji et al. 2009; Machado-Vieira and Zarate 2011).

Given the polygenic basis of BD and its complex neurobiological basis, it is likely that additional targets and systems that underlie mood stabilization will be identified. Indeed, the breadth of targets listed above underscores a major problem central to mechanistic research, namely the difficulty of attributing therapeutic relevance to any observed biological finding. One fruitful approach is to identify convergent mechanisms and targets in the brain produced by drugs that possess distinct chemical structures but belong to the same therapeutic class. As a relevant example, lithium is a monovalent cation and valproate is an eight-carbon branched fatty acid, but both are mood stabilizing agents that yield similar effects when administered in a "therapeutically relevant" paradigm (that is, the same plasma drug levels and treatment duration in human and experimental animals). This approach has led to the identification of several key signaling and downstream pathways regulated by different classes of mood stabilizers. These pathways include: (1) phosphoinositol/protein kinase C (PKC); (2) cyclic adenosine monophosphate (cAMP) and cAMP response element binding protein (CREB); (3) arachidonic acid (AA); (4) neurotrophic factor signaling (such as brain-derived neurotrophic factor (BDNF)) signaling; (5) glycogen synthase kinase 3 (GSK-3); and (6) Wnt signaling (Machado-Vieira et al. 2017; Manji et al. 2009). Through their effects on these pathways and downstream, mood stabilizers stabilize intracellular calcium homeostasis, protect and enhance mitochondrial function,

stimulate outgrowth, and regenerate neuronal processes (Machado-Vieira et al. 2017; Manji et al. 2009).

Overall, mood stabilizers target a wide range of biological systems in the limbic, striatal, and fronto-cortical neurotransmitter neuronal circuits that directly affect synaptic function, neurotransmitter activity, and related downstream targets at the cellular and molecular level. These targets and systems regulated by mood stabilizers play a key role in regulating mood states, cognition, and other functions such as autonomic and circadian systems (Machado-Vieira et al. 2017). Recent efforts to develop personalized medicine approaches in BD also hold considerable promise for identifying specific biomarkers that may help define the most effective therapeutic agent for each patient (Henter et al. 2017).

Clinical Use, Efficacy, and Side Effects

Maintenance therapy with mood stabilizers is recommended for all individuals with BD, preferably early in the course of the illness. Early intervention with mood stabilizers prevents the recurrence of new mood episodes, reduces the risk of suicide and violent behaviors, prevents substance abuse, and improves psychosocial functioning (Fazel et al. 2014).

With regard to choice of mood stabilizer, the ability to effectively treat different types of mood episodes is key. For instance, five mood stabilizers are recommended for the treatment of acute bipolar depression, alone or in combination with monotherapy: lamotrigine, lurasidone, lithium, quetiapine, and cariprazine (Grunze et al. 2018). In acute and long-term treatment of mixed states in BD, manic symptoms seem to respond to therapy with several atypical antipsychotics, with the best evidence supporting the use of olanzapine. Besides olanzapine and quetiapine, valproate and lithium should also be considered for preventing recurrences (Grunze et al. 2018).

During ongoing treatment, monitoring individuals with BD using standardized rating scales may identify outcomes such as suicidal ideation, self-harm behavior, and mood switches, as well as help identify nonresponders earlier and adjust pharmacotherapy. While monotherapy usually increases adherence and tolerability and also minimizes adverse effects, combination treatments are commonly required due to high rates of partial response as well as the emergence of undesirable side effects or comorbidities (Grunze et al. 2013; Post 2019). Below, we briefly review the most commonly prescribed mood stabilizers.

Lithium

Lithium is the best studied of the mood stabilizers and the only one whose initial FDA approval was specifically for BD (all other mood stabilizers were first tested as anticonvulsants or antipsychotics). Lithium is also the most studied and effective add-on therapy (at lower doses) for unipolar depression and is sometimes used in combination with one of the anticonvulsant mood stabilizers (e.g., valproate or lamotrigine) (Machado-Vieira 2018). Often referred to as the "classic" treatment for BD, lithium can be used alone or in combination with antipsychotics to treat mania, alone or in combination with antidepressants to treat bipolar depression, and as monotherapy for maintenance treatment (American Psychiatric Association 2002), where it has been shown to prevent relapse significantly better than placebo (Machado-Vieira 2018). Lithium has also been found to have significant anti-suicidal ideation/self-harm effects (Grunze et al. 2013). For adults with BD, a standard lithium serum level ranges from 0.60 to 0.75 mmol/L, with the option to reduce it to 0.40–0.60 mmol/L in case of good response but poor tolerance or to increase it to 0.80–1.00 mmol/L in case of insufficient response and good tolerance (Nolen et al. 2019). However, marked clinical improvement to lithium only appears after weeks of treatment (American Psychiatric Association 2002).

The side effects of lithium can include polyuria, polydipsia, weight gain, edema, gastrointestinal distress, hair loss, acne, benign leukocytosis, cognitive problems, tremor, sedation or lethargy, thyroid function alterations, and impaired coordination (American Psychiatric Association 2002). These side effects can typically be alleviated by changing lithium dose or treatment schedule. Most patients experience varied toxic effects with lithium levels above 1.5 meq/L, and levels above 2.0 meq/L are associated with life-threatening

side effects (American Psychiatric Association 2002). To minimize toxicity at higher lithium levels, hemodialysis may be needed. Lithium levels are regularly monitored after treatment has begun, as well as after every dosage change (American Psychiatric Association 2002).

Valproate

The anticonvulsant valproate is used alone or in combination with antipsychotics to treat bipolar mania as well as mixed episodes. When used as a maintenance treatment, valproate also significantly reduces the number of recurrent mood episodes in individuals with BD, especially depressive episodes (Grunze et al. 2013). Therapeutic serum levels are between 45 and 100 ug/ml (Grunze et al. 2013). As with lithium, significant clinical improvement only appears after weeks of treatment (American Psychiatric Association 2002).

Common side effects associated with valproate include gastrointestinal distress, benign hepatic transaminase elevations, osteoporosis, tremor, and sedation (American Psychiatric Association 2002). Some patients may also experience hair loss, increased appetite, and weight gain (Cipriani et al. 2013; American Psychiatric Association 2002). There is increased risk for hepatotoxicity in patients taking valproate with past or current hepatic disease. As with lithium, monitoring blood levels of valproate helps maximize efficacy and minimize side effects. Finally, valproate inhibits the metabolism of lamotrigine; therefore, lamotrigine must start from less than half of its usual dose when used in combination.

Lamotrigine

The anticonvulsant lamotrigine is typically used during depressive episodes and thus is often recommended for use as an initial or add-on treatment for bipolar depression (American Psychiatric Association 2002); it appears to be particularly effective in a subset of patients with bipolar depression (Prabhavalkar et al. 2015). However, it has shown no efficacy in treating acute mania (Osser 2019). Advantages to lamotrigine monotherapy include that the drug is superior to placebo in improving symptoms in both unipolar and bipolar depression, is generally well-tolerated, is not associated with weight gain, and is less likely to cause sedation (Osser 2019). For the treatment of bipolar depression, lamotrigine appears to be as effective as lithium, olanzapine+fluoxetine, citalopram, or inositol (Solmi et al. 2016). It has also been shown to be effective as a maintenance treatment, though its ability to reduce risk of relapse is modest compared to lithium and valproate (American Psychiatric Association 2002; Shelton and Bobo 2019).

Lamotrigine is usually well tolerated and has a benign metabolic profile. Common side effects include headache, nausea, and diarrhea. One key disadvantage to lamotrigine monotherapy, however, is that initial doses need to be titrated slowly in order to reduce the risk of life-threatening skin rashes. The starting dose is usually 25 mg once per day for 2 weeks; this is then increased to 25 mg twice per day (Shelton and Bobo 2019). Rashes occur in approximately 0.3% of adults and in 1% in children at any time during treatment but are more likely early in treatment (American Psychiatric Association 2002). Lamotrigine should be discontinued if rashes are accompanied by fever or sore throat, are diffuse and widespread, or have prominent facial and mucosal involvement (American Psychiatric Association 2002). Notably, case reports show that concomitant use of lamotrigine with valproate – which delays the clearance of lamotrigine (Zaccara and Perruca 2014) – increases the risk of rashes, including Stevens–Johnson syndrome and toxic epidermal necrolysis.

Quetiapine

An option for treating mania and for maintenance therapy in BD is the atypical antipsychotic quetiapine. Multiple randomized trials found that time to recurrence of mood symptoms was longer with quetiapine than lithium (Weisler et al. 2011). Furthermore, quetiapine is often used in combination with lithium or valproate as a first-line treatment and for successful maintenance therapy (Yatham et al. 2018). Quetiapine's efficacy in double-blind, randomized, controlled trials was the basis for its FDA approval in treating bipolar mania and bipolar depression, as well as its use as a maintenance treatment for BD and as either monotherapy or as an add-on treatment for major depressive disorder (Sanford 2011). As a result, quetiapine has become one of the most commonly

prescribed mood stabilizers in BD for all phases of the disorder (Plosker 2012) and is sometimes recommended if polarity is predominantly depressive or if there is no predominant polarity (Fountoulakis et al. 2017). Common adverse effects include constipation, dizziness, drowsiness, headache, sedation, increased serum cholesterol/triglycerides, increased thyroid stimulating hormone level, and weight gain.

Other Treatment Options

Many national and international guidelines suggest that lithium should continue to be the first-line choice for maintenance therapy in BD, and most recommend atypical antipsychotics to rapidly control severe manic symptoms and to treat psychotic symptoms (National Institute for Health and Care Excellence 2020; Goodwin et al. 2016). However, other treatment options for BD include the atypical antipsychotics aripiprazole, asenapine, cariprazine, lurasidone, olanzapine, paliperidone, risperidone, and ziprasidone, as well as the anticonvulsants carbamazepine and oxcarbazepine. The reader may wish to refer to treatment guidelines for more information regarding the circumstances under which any of these agents might ideally be prescribed (American Psychiatric Association 2002; Fountoulakis et al. 2017; Goodwin et al. 2016; Grunze et al. 2013, 2018; National Institute for Health and Care Excellence 2020; Yatham et al. 2018). In general, however, the clinical choice of prophylactic agents is considered on an individual basis rather than on explicit guidelines and can depend on efficacy and tolerability. For instance, aripiprazole, paliperidone, and risperidone are recommended for predominantly manic polarity, while aripiprazole plus a mood stabilizer might be recommended for frequent mixed episodes (Fountoulakis et al. 2017). Likewise, for depressive symptoms, adding ziprasidone to treatment as usual may provide additional benefits; however, the evidence is much more limited than for manic symptoms (Grunze et al. 2018).

Aripiprazole, which is also FDA-approved for the treatment of unipolar depression (Keck et al. 2007), has been shown to be an effective maintenance treatment for BD; it is also used adjunctively to treat bipolar mania. Long-acting injectable (depot) aripiprazole has increasingly been used but does not necessarily improve compliance. For BD, the FDA approved a new once-monthly, long-acting injectable form of aripiprazole for maintenance monotherapy treatment of BD-I in adults.

Similarly, several studies have shown that olanzapine is a more effective treatment than placebo for BD and prevents relapses more effectively than placebo. It is sometimes recommended if polarity is predominantly depressive or if there is no predominant polarity (Fountoulakis et al. 2017). Despite its robust results, it is typically considered a second-line therapy because of its metabolic effects (Yatham et al. 2018).

The atypical antipsychotic cariprazine has also been approved to treat BD, including mania with or without depressive symptoms as well as depression with or without manic symptoms. Specifically, post-hoc analyses of individuals with BD found that those with and without manic features improved following treatment with cariprazine (Stahl et al. 2020). Maintenance studies in BD are ongoing.

Based on long-term studies (Lindstrom et al. 2017), the long-acting injectable (depot) form of risperidone was FDA-approved for maintenance treatment in BD; however, no randomized trial has evaluated oral risperidone for this indication. Other atypical antipsychotic treatment options include ziprasidone, asenapine, and paliperidone, all of which are FDA-approved for maintenance therapy in BD.

Finally, the anticonvulsant carbamazepine and its analogue oxcarbazepine are also recommended for maintenance therapy in BD as alternatives to lithium and valproate (American Psychiatric Association 2002). The most common side effects associated with these agents include fatigue, nausea, diplopia, blurred vision, and ataxia. Skin rashes, mild leukopenia, mild liver enzyme elevations, mild thrombocytopenia, hyponatremia, and (less commonly) hypoosmolality can also occur. In addition, agranulocytosis, aplastic anemia, thrombocytopenia, hepatic failure, exfoliative dermatitis (e.g., Stevens–Johnson syndrome), and pancreatitis are rare and idiosyncratic but serious and potentially fatal side effects associated with their use. Oxcarbazepine has a superior side effect profile to carbamazepine.

Disclosures Funding for this work was supported in part by the Intramural Research Program at the National Institute of Mental Health, National Institutes of Health (IRP-NIMH-NIH; ZIAMH002927). Dr. Zarate is listed as a co-inventor on a patent for the use of ketamine in major depression and suicidal ideation; as a co-inventor on a patent for the use of (2*R*,6*R*)-hydroxynorketamine, (*S*)-dehydronorketamine, and other stereoisomeric dehydro and hydroxylated metabolites of (*R,S*)-ketamine metabolites in the treatment of depression and neuropathic pain, and as a co-inventor on a patent application for the use of (2*R*,6*R*)-hydroxynorketamine and (2*S*,6*S*)-hydroxynorketamine in the treatment of depression, anxiety, anhedonia, suicidal ideation, and post-traumatic stress disorders. He has assigned his patent rights to the US government but will share a percentage of any royalties that may be received by the government. Drs. Chen and Manji are full-time employees of Janssen Pharmaceutical Research & Development, Johnson & Johnson. Dr. Machado-Vieira has received consulting fees from Eurofarma Pharmaceuticals and BioStrategies group and has research contracts with Janssen Pharmaceuticals. Dr. Machado-Vieira has also received speaker fees from Otsuka and Cristalia and is a member of the scientific board of Symbinas Pharmaceuticals.

Acknowledgments The authors thank Ioline Henter (NIMH) for invaluable editorial assistance.

Mechanistic/mammalian target of rapamycin complex 1 signaling network

Definition

mTOR: A master regulator protein kinase hub which controls a variety of anabolic or catabolic cellular processes, such as protein synthesis, ribosomal biosynthesis, and autophagy, among others.

Basic Characteristics

*M*echanistic (or *m*ammalian) *t*arget *o*f *r*apamycin (mTOR) is a highly conserved Ser/Thr protein kinase that governs versatile cellular signaling networks to regulate a wide range of anabolic and catabolic processes. It plays central roles in maintaining normal cellular functions and, when dysregulated, in diverse diseases. mTOR forms two quite distinct types of multiprotein complexes (mTOR complexes 1 and 2). The complexes are activated by different signals and exert their physiological effects via the distinct downstream substrates which it phosphorylates (Xie and Proud 2014).

Both mTORC1 and mTORC2 contain the core component mTOR, plus mLST8 (*m*ammalian ortholog of *l*ethal with *s*ec *t*hirteen) and DEPTOR (*DEP* domain-containing m*TOR* interacting protein). The specific components of mTORC1 include the proteins RAPTOR (regulatory-associated protein of mTOR) and PRAS40 (*P*ro-*r*ich *A*kt *s*ubstrate of *40* kDa). mTORC2-specific components are RICTOR (rapamycin-insensitive companion of TOR), mSIN1 (*m*ammalian *s*tress-activated protein kinase *in*teracting protein 1) and PROTOR (protein observed with RICTOR) [reviewed in (Xie and Proud 2014; Xie et al. 2018), also see Fig. 1].

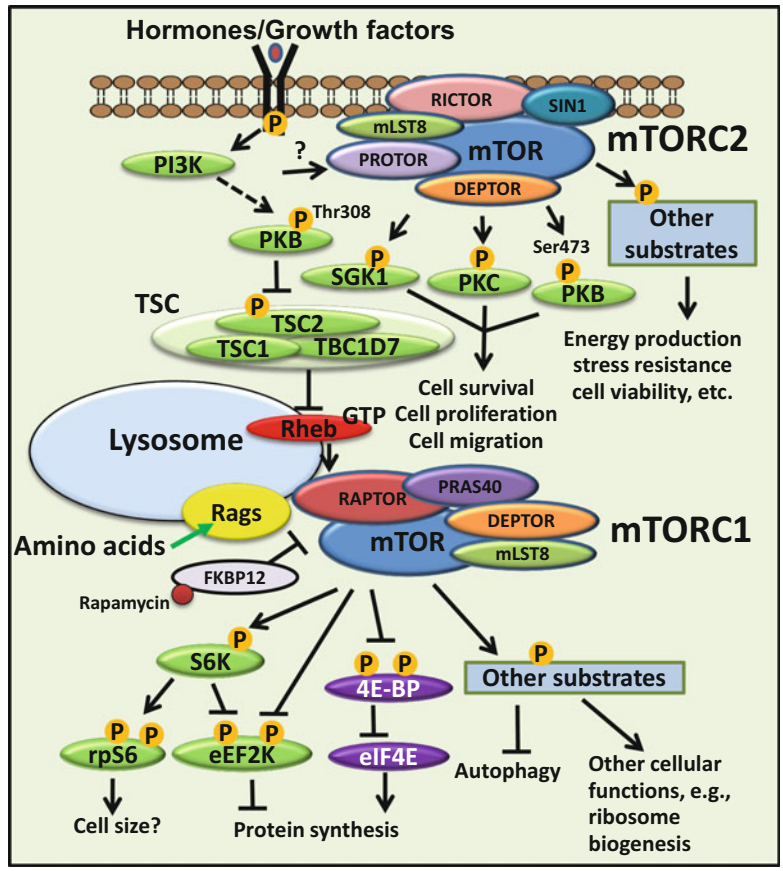
Upstream of mTORCs

mTORC1 indirectly senses a variety of environmental and other cues and integrates these signals to regulate a range of anabolic or catabolic processes. The small G-protein Rheb (*R*as *h*omolog *e*nriched in *b*rain) mediates the activation of mTORC1 by hormones and growth factors. When in its GTP-bound (Rheb-GTP) state, Rheb activates mTORC1. Rheb is regulated through the activity of its GTPase-activating protein TSC (*t*uberous *s*clerosis *c*omplex; comprising TSC1 or hamartin; TSC2 or tuberin, and TBC1D7), which negatively regulates mTORC1 by promoting the formation of inactive GDP-bound Rheb. Several upstream signaling pathways converge on TSC1/2 through downstream kinases that phosphorylate TSC1/2, thereby affecting its activity. Examples include the PI 3-kinase or PI3K (*p*hospho*i*nositide 3-*k*inase)/PKB (*p*rotein *k*inase *B*, also known as Akt) and classical MAP kinase pathways. These pathways are activated by many hormones and growth factors, and by phosphorylating and inactivating TSC1/2, bring about the activation of mTORC1 [reviewed in (Xie and Proud 2014)]. On the other hand, AMP-activated protein kinase (AMPK), which is activated when cellular energy [ATP] levels are low, phosphorylates TSC1/2 or other proteins to switch off mTORC1.

Lysosomes are the cellular sites of autophagy, a degradative process that, among other substrates, breaks down faulty or misfolded proteins thereby generating free amino acids. The surface of the lysosome is a major location where mTORC1 is activated; when phosphorylated via pathways that promote activation of mTORC1, TSC1/2 moves away from the lysosome, allowing Rheb to remain in its active GTP-bound state. Once it has been activated on the surface of the lysosome, mTORC1 is able to dissociate from the lysosome surface, remain active, and reach substrates at other locations in the cell (Fig. 1).

Certain amino acids are essential for the activation of mTORC1, which makes physiological sense since mTORC1 drives protein synthesis, which requires a constant supply of amino acids. Activation of mTORC1 by amino acids, including leucine and arginine, occurs on the surface of the lysosome, and involves the Rag GTPases, which are controlled by a rather complex set of proteins, including the Ragulator and GATOR multiprotein complexes [reviewed in Kim and Guan (2019)].

In contrast to mTORC1, the mechanism by which mTORC2 is regulated is much less well understood. The activity of mTORC2 towards one of its best-known substrates, PKB, is also acutely stimulated by insulin and serum, via PI 3-kinase. This is at least partially due to the fact that both PKB and mSIN1, an essential component of mTORC2, contain a PH (*P*leckstrin *H*omology) domain, that allows them to be recruited to the plasma membrane by interacting with phosphatidylinositol-3,4,5-trisphosphate (Xie et al. 2018), the product of Class I PI 3-kinases.



mTOR Signaling Pathways, Fig. 1 mTOR complexes and their substrate networks. Schematic summary representation of the pathways leading to mTOR activation, and of the main established targets and physiological processes specifically associated with each mTOR complex. The components of mTOR complex are shown. Rapamycin inhibits mTORC1 by binding to FKBP12. mTORC1 is activated by hormones and growth factors via the PKB-TSC pathway. mTORC2 phosphorylates PKB and PKC. Note that although mTORC2 is responsible for the phosphorylation of PKB (at Ser473), this does not contribute to the activation of mTORC1 (Frias et al. 2006; Jacinto et al. 2006). PKB phosphorylates and inhibits the TSC complex which acts as GAP for Rheb, while Rheb-GTP activates mTORC1 at the surface of lysosomes. Amino acids also activate mTORC1 by recruiting it to the surface of lysosomes via the Rag GTPases. S6K-rpS6 and 4E-BP1 are the best-characterized substrates for mTORC1; other substrates are responsible for controlling several anabolic effects driven by mTORC1 or for suppressing autophagy

Downstream of mTORCs

As protein kinases, mTORC1 and mTORC2 regulate cell function by phosphorylating a number of substrate proteins. They phosphorylate distinct substrates, because of the presence of different "substrate-targeting" subunits within mTORC1 and mTORC2, i.e., RAPTOR and RICTOR, respectively. In general, two main types of sites are phosphorylated by mTOR: some are followed by a proline residue, as in 4E-BP1 [eIF*4E* (*e*ukaryotic *i*nitiation *f*actor *4E*)-*b*inding *p*rotein 1, also referred to as PHAS-I], while others have hydrophobic residues at positions −4, −1, and +1 relative to the residue that is phosphorylated; such sites are typified by Thr389 in S6K1 (ribosomal protein *S6 k*inase *1*) or Ser473 in PKB/Akt.

RAPTOR, encoded by *Rptor*, is essential for the integrity of mTORC1 and is responsible for recruiting mTOR substrates, such as S6Ks and 4E-BPs, to mTOR. RAPTOR interacts with their TOS (*TO*R *s*ignaling) motifs, which comprise five amino acids including an N-terminal

phenylalanine (Schalm and Blenis 2002). Both S6Ks and 4E-BPs contain a TOS motif.

mTORC2 phosphorylated and promotes the activation of several members of the so-called "AGC" family of protein kinases, including PKB, SGK1 (*s*erum- and *g*lucocorticoid-induced protein *k*inase 1), conventional PKC (*p*rotein *k*inase *C*) isoforms (including α, βI, βII, and γ); ε, a novel PKC; and ζ, an atypical PKC (Fig. 1). Two types of phosphorylation sites ("turn" and "hydrophobic" motifs, both towards the C-termini of these enzymes) within these enzymes are targets for mTORC2 [reviewed in (Xie et al. 2018)]. These kinases play diverse roles in cellular regulation, placing mTORC2 at the center of a web of intracellular control processes.

Drugs

Rapamycin and "First Generation" mTOR Inhibitors

Given the role of mTORC1 in cell growth and proliferation, processes that are important in diseases such as cancers, there have been extensive efforts to develop compounds that inhibit mTORC1 function. Rapamycin was first isolated from the bacterium *Streptomyces hygroscopicus* found on Easter Island. The local name for this island is Rapa Nui, hence "rapamycin." Rapamycin was first studied as an antifungal agent and was later shown to block immune cell activation. It was subsequently found to impair the activity of mTORC1. Rapamycin forms a complex with the immunophilin protein, FKBP12 (*FK*506-*b*inding *p*rotein of *12* kDa), which interacts with mTOR through the FRB (*F*KBP12-*r*apamycin *b*inding) domain.

The binding of the rapamycin-FKBP12 complex to mTORC1 restricts access of substrates to its active site. Rapamycin inhibits the phosphorylation of some mTORC1 substrates, such as S6K, but not all of them (Thoreen and Sabatini 2009). In general, rapamycin prevents mTORC1 from phosphorylating "weak" substrates but not "strong" ones, although the sensitivity of different substrates to rapamycin seems to differ between cell types (Kang et al. 2013).

Rapamycin does not affect mTORC2 in the short term, as a consequence of occlusion of the FKBP12-binding site by RICTOR and mSIN1 (Chen et al. 2018). However, rapamycin can interfere with mTORC2 over longer time periods (after 24 h) in certain cell types, by preventing the formation of new mTORC2 complexes (as a consequence of the competition between rapamycin-FKBP12 and RAPTOR/Sin1 for binding to mTOR). Thus at least some of the long-term effects of rapamycin probably reflect inhibition of mTORC2.

The pharmacological properties of rapamycin itself are not ideal, leading to the development and application of rapamycin analogs (rapalogs, e.g., sirolimus, temsirolimus, everolimus; Table 1) with superior characteristics. Several such compounds have been developed and evaluated for their efficacy in treating diseases, including cancers (Table 1). These are semisynthetic rapamycin analogues which have typically been derivatized at the C-43 position on the cyclohexane outside the macrolide ring in order to improve aqueous solubility and permit oral administration. This also provides a more advantageous intellectual property position than for rapamycin itself. Notably, rapalogs have been successfully used in the clinic against acute renal allograft rejection and in preventing restenosis after angioplasty. Since 1999, rapalogs have also been approved by the FDA (U.S. Food and Drug Administration) against several types of cancer including renal cell carcinoma, tuberous sclerosis, pancreatic neuroendocrine tumors, and neurofibromatosis.

However, rapalogs are ineffective against other cancers, potentially for two major reasons. Firstly, rapalogs only partially inhibit mTORC1, and secondly, the inhibition of mTORCs triggers several feedback loops potentially (re)activating upstream oncogenic signaling pathways such as PI 3-kinase (Xie and Proud 2013, 2014). Furthermore, inhibition of mTORC1 promotes autophagy, which can aid the survival of cells within poorly vascularized solid tumors.

In addition, and probably not surprisingly given the key role of mTORC1 in cell physiology, rapalogs do exert a number of adverse "side-effects," as do mTOR kinase inhibitors. In the

mTOR Signaling Pathways, Table 1 Examples of inhibitors to the mTOR pathway and their effects on human diseases

Generation	Compound name	Approved year/ current phase	Developer	Examples of indications in completed clinical trials and other features

CRPC = castration-resistant prostate cancer; *DI* = dual mTOR/PI3K inhibitors; *HCC* = hepatocellular carcinoma; *MBC* = metastatic breast cancer; *NSCLC* = non-small cell lung cancer; *pNET* = pancreatic neuroendocrine tumors; *RCC* = advanced renal cell carcinoma

case of treating restenosis, the use of drug-eluting stents ensures local rather than systemic delivery of the rapalog, thus reducing unwanted effects.

Dual PI3K/mTOR Inhibitors

The kinase domain of mTOR (Fig. 1) is widely conserved in a group of protein kinases which display prominent structural similarities to PI 3-kinase-related kinases. As a result, it has been discovered that several PI 3-kinase inhibitors (including derivatives of the early inhibitors LY294002 and wortmannin) developed during drug discovery programs can also effectively suppress the activation of both mTOR

complexes. These are consequently classified as dual PI 3-kinase/mTOR inhibitors (Table 1). Unlike the rapalogs, this class of catalytic site-directed inhibitors blocks the activities of both mTOR complexes. Also, as anticancer agents, they offer superior benefits in comparison to the first class of mTOR inhibitors, because of inhibiting simultaneously both PI3K and mTOR, two crucial signaling hubs that promote cancer cell growth. Arguably the best successful example in clinical trials from this class of inhibitors is the imidazoquinoline derivative NVP-BEZ235 (Maira et al. 2008), developed by Novartis. NVP-BEZ235 exerts potent anti-tumor activity in vivo, and its effect can be further enhanced by combining it with inhibitors of other mitogenic pathways.

Second-Generation mTOR Inhibitors

Given the inability of rapamycin to affect all functions of mTORC1, and its frequent inefficacy in anticancer therapy, several academic and pharmaceutical laboratories have developed compounds that inhibit the catalytic activity of mTOR itself (which include the compounds described in the previous section). This yielded a second generation of mTOR inhibitors which are designed to act as ATP-competitive inhibitors of mTOR. This means they can potentially inhibit all phosphorylation events catalyzed by mTORC1 but will also affect mTORC2. These inhibitors (Table 1) exhibit a much lower IC_{50} against mTORCs than against PI3K.

The first such compound to be reported was PP242. INK128 (later renamed as MLN0128) is a PP242-derivative developed by Intellikine and has or is being tested in 42 clinical trials according to clinicaltrials.gov (searched on 19/20/20). Torin 1 and Torin 2 were synthesized by Nathanael Gray's lab and developed by AstraZeneca. Ku-0063794 and Ku-0068650, developed by KuDOS Pharmaceuticals (now AstraZeneca), are also examples of early ATP-competitive mTOR inhibitors which exhibit strong antiproliferative potential against cancer cells in vitro. AZD8055 and AZD2014 are two orally bioavailable compounds derived from the Ku compounds.

Third Generation of mTOR Inhibitors

The efficacy of mTOR inhibitors can be severely compromised by a wide range of clinical-relevant mutations in mTOR that can increase in catalytic activity of mTOR. To try to tackle this issue, careful analysis of the molecular model of mTOR revealed a juxtaposition of the rapamycin and AZD8055 binding sites, prompting to creation of a powerful bivalent mTOR inhibitor, named as RapaLink (1 and 2; Table 1, (Rodrik-Outmezguine et al. 2016)). RapaLink contains structural elements of both rapamycin and an mTOR kinase inhibitor within the same molecule, connected by a cunningly designed non-perturbing, strain-free cross-linker with optimum length, which allows the compound to interact with the FRB domain of mTOR through binding to FKBP12, as well as reaching the kinase domain of mTOR so that it can act as an ATP-competitive inhibitor at the same time (Rodrik-Outmezguine et al. 2016). RapaLink prevented growth of breast cancer xenografts bearing rapamycin and/or AZD8055-resistant mTOR mutations (Rodrik-Outmezguine et al. 2016). This landmark study gave thus birth to a new generation of mTOR inhibitors.

mTOR Complex-Specific Inhibitors

Most of abovementioned mTOR inhibitors unavoidably inhibit both mTOR complexes, at least in some types of cells (in the case of rapalogs). As noted, this would promote a number of feedback loops that (re)activate upstream signaling pathways (Xie and Proud 2013) and which may result in undesirable secondary effects. There have therefore been attempts to develop mTORC1/2-specific inhibitors that only affect one, but not both, mTOR complexes (Table 1).

In 2016, a small molecule called NR1 was discovered, which specifically targets Rheb (Mahoney et al. 2018). In particular, NR1 bound to the switch II domain of Rheb, which is crucial for binding to, and hence activating, mTORC1.

The following year, Gera's group discovered a compound named CID613034 which interferes with the mTOR-RICTOR interaction. It therefore selectively inhibits mTORC2 activity in glioblastoma xenografts while leaving mTORC1 activity intact (Benavides-Serrato et al. 2017). Dudley Lamming's group reported a rapalog named DL001 which is highly specific for mTORC1 (40 times more selective for mTORC1 than rapamycin) (Schreiber et al. 2019). DL001 exhibited remarkably reduced side effects in mice relative to rapamycin, i.e., it did not affect, or had smaller effects, on lipid metabolism, glucose homeostasis, and the immune system. Nevertheless, it is yet to be determined whether NR1, DL001, or CID613034 represent safer and more effective clinical options compared to other aforementioned mTOR inhibitors.

Given the manifold roles of mTOR signaling in human diseases, one can expect further intensive research will identify, develop, and test novel inhibitors of the mTOR complexes and/or their downstream effectors.

MS

Definition

Multiple sclerosis (MS) is the most frequent chronic neuroinflammatory disorder of the central nervous system and a cause of severe disability in adults. Globally, MS affects about two million people and two to three times more females than males. Its prevalence varies markedly between geographic regions with an overall tendency to increase with latitude. A hallmark of the disease is the dissemination of inflammatory lesions, both in time and space. In most patients (about 85%), the disease follows a relapsing-remitting course. Typical symptoms of attacks include visual disturbance of one eye (optic neuritis), double vision, ataxia, sensory disturbance (tingling, numbness), paresis, and sphincter dysfunction. First, symptoms typically remit after weeks to months. Over time, some residual disability remains after attacks and the disease follows a secondary progressive course. In the primary progressive variant of the disease affecting about 15% of patients, the disability slowly deteriorates from the beginning. Eventually, many MS patients suffer from impaired mobility or cognition. However, the clinical course of MS is highly variable, and a considerable proportion of patients do not experience severe disability.

Diagnosis relies on evidence for the spatial and temporal dissemination of the inflammatory process. As magnetic resonance imaging (MRI) provides a sensitive technique to detect acute and chronic lesions, including asymptomatic ones, it has become a cornerstone for diagnosis and follow-up studies. With the help of MRI, it is nowadays possible to diagnose MS after the first attack. Typically, oligoclonal IgG bands are found in CSF but not in blood. Other blood tests are normal in MS.

Basic Mechanisms

The cause of MS is still unknown. There is a polygenetic component as shown by a concordance rate in monozygtic twins of about 25% (Baecher-Allan et al. 2018). Genome-wide association studies have identified numerous loci that overlap with other autoimmune diseases (Farh et al. 2015). The genetic evidence points toward immune mechanisms, involving T and B lymphocytes, NK cells, and microglia, but provides little information on the neural response to the immune attack (International Multiple Sclerosis Genetics Consortium 2019). In addition to genetics, environmental factors influence the disease risk as illustrated by the observation that migrants acquire the risk of their new home after a while. Specific factors include UV irradiation, vitamin D supply, and Epstein-Barr virus infections.

Lesions often surround blood vessels and are characterized by inflammatory cell infiltrates, demyelination, axonal loss, and glial activation. In acute lesions, the blood-brain barrier is disrupted as shown by the contrast enhancement in MRI. With ongoing disease, atrophy of the cortex, optic nerve, spinal cord, or other parts of the CNS becomes evident. Detailed neuropathological investigations have defined subtypes of lesions that differ in respect to immunoglobulin and complement deposition as well as oligodendrocyte apoptosis (Reich et al. 2018). Interestingly, individual patients tend to have lesions of the same subtype, but, because of a lack of clinical biomarkers, this information does not yet influence therapeutic decisions.

According to current concepts, autoreactive T cells migrate into the CNS. Upon reactivation by antigen-presenting cells, they produce various cytokines that attract additional T cells and macrophages. Essential are $CD4^+$ Th1 and Th17 cells releasing IFNγ and IL-17. In addition to $CD4^+$ helper T cells, human MS lesions contain numerous $CD8^+$ effector T cells that also release IFNγ

and IL-17 and may induce death of oligodendrocytes and axonal damage. The suppressive capacity of regulatory Treg and Tr1 cells or $CD56^{bright}$ NK cells seems to be impaired in MS patients.

Recent studies highlighted the importance of B cells, especially $CD20^{+}$ memory B cells, in MS (Baecher-Allan et al. 2018). In addition to their role in autoantibody production, they present antigens to T cells and release inflammatory factors. The cellular network activated in MS encompasses myeloid cells, such as neutrophils (Liu et al. 2010). Monocyte-derived and dendritic cells present antigens to lymphocytes, while microglia seem to synthesize inflammatory factors and remove debris (Jordao et al. 2019).

The animal model experimental autoimmune encephalomyelitis (EAE) has greatly influenced understanding of the basic mechanisms and drug development of MS. Although this disease model deviates from the human disease in several aspects (Lassmann et al. 2012), it has allowed the discovery of several clinically effective drugs, such as glatiramer acetate and natalizumab.

Pharmacological Intervention/ Pharmacotherapy

Since the early 1990s, numerous drugs that ameliorate the course of relapsing-remitting MS have been introduced in routine clinical practice. Therapeutic options for primary or secondary progressive MS are more restricted. The following drugs allow for a disease-modifying therapy (DMT) but do not cure MS.

Parenteral Drugs

Interferon β (IFNβ)-1a and IFNβ-1b were the first drugs in the 1990s that became available as DMTs. The two variants of human IFNβ differ slightly in the amino acid sequence, in the pharmaceutical production mode, and consequentially in their glycosylation. IFNβ-1a is administered i.m. or s.c. and IFNβ-1b s.c. Being the standard of care for long time, they served as active comparator against which newer drugs were tested in trials. These studies confirmed that IFNβs are less effective in reducing the relapse rate than ocrelizumab, fingolimod, or alemtuzumab.

As a type-I interferon, IFNβ binds to a hetero- or homodimeric membrane receptor consisting of the subunits IFNAR1 and IFNAR2 that are present on virtually all cell types. IFNβ effects are mediated by several intracellular pathways that include tyrosine kinases JAK1 and TYK2, the transcription factors STAT1 and STAT2 (Chow and Gale 2015), the small G protein RAC1, and the inflammasome. Subsequently, it stimulates a large set of genes, so-called INFβ-stimulated genes (ISGs). Immunomodulation in EAE and multiple sclerosis involves several mechanisms. One of the ISGs is CD69 that inhibits S1P1 and the egress of lymphocytes from lymph nodes, mimicking the effect of pharmacological S1P inhibitors (Shiow et al. 2006). In patients with MS, IFNβ treatment elevates plasma levels of soluble VCAM-1 that may interfere with the penetration of immune cells across the blood-brain barrier (Calabresi et al. 1997). Moreover, IFNβ inhibits Th1 and promotes Th2 polarization; it counteracts the disruption of the blood-brain barrier in EAE and downregulates the induction of MHC II molecules. Which of these effects are essential for the disease-modifying activity in patients is still unclear. In experimental EAE, myeloid cells mediate the protective effect of endogenous IFNβ (Prinz et al. 2008). In some patients, IFNβ is inactive. This may be due to the formation of neutralizing antibodies (Rommer et al. 2019) or to a form of MS that is resistant to IFNβ treatment (Inoue et al. 2016).

Glatiramer acetate was discovered during attempts to induce EAE in animals with copolymers of amino acids that frequently occur in myelin basic protein. In contrast to expectations, Cop-1, one of the copolymer preparations, reduced the incidence and severity of EAE (Arnon and Aharoni 2019). It turned out that glatiramer acetate binds to various MHC II molecules on antigen-presenting cells and modulates the response of dendritic cells, monocytes/macrophages, and the polarization of B and T lymphocytes into an anti-inflammatory and neuroprotective direction. Glatiramer acetate is effective against relapsing-remitting multiple sclerosis. Its safety

profile is favorable and it is the only DMT that is licensed during pregnancy.

Natalizumab is a humanized antibody against integrin α4 on leukocytes. By inhibiting the interaction of α4 integrin with the endothelial adhesion factor VCAM-1, natalizumab restricts the access of T lymphocytes and other immune cells to the brain. This mechanism translates into a high efficacy against relapsing-remitting MS. However, its widespread use is limited by its safety profile. Natalizumab is responsible for progressive multifocal leukoencephalopathy in up to 1 out of 1,000 patients treated with the antibody (Major et al. 2018). This potentially lethal demyelinating disease in the brain is caused by an insufficient immune control of a JC virus infection. In patients receiving natalizumab, the risk and the prognosis of the infection can be mitigated by monitoring anti-JC virus titers and MRI.

Alemtuzumab is a humanized antibody targeted against CD52, a surface protein on T and B lymphocytes, monocytes, and eosinophiles. The drug is administered in a 3- to 5-day course once a year leading to the depletion of circulating T and B cells and monocytes. Despite a subsequent repopulation, lymphocyte counts remain low for a considerable time. Moreover, the nadir is followed by a change in lymphocyte subpopulations, including an increase in Treg cells. Alemtuzumab is more effective than INFβ-1 in reducing relapses and other activity markers of MS. However, its use is limited by a considerable rate of autoimmune diseases, such as Graves' disease or idiopathic thrombocytopenic purpura (Katsavos and Coles 2018).

Ocrelizumab is a humanized antibody targeting CD20 on B cells. It depletes B cells, both immature and mature, but not CD20-negative plasma cells or hematopoietic stem cells by complement-dependent cytotoxicity and antibody-mediated cellular cytotoxicity (Sellebjerg et al. 2020). Depletion is most efficient in blood but less so in lymphoid tissues or the brain. Ocrelizumab is effective in relapsing-remitting MS, and, importantly, ocrelizumab is the only drug that has been approved for primary progressive MS following the placebo-controlled phase III trial ORATORIO (Montalban et al. 2017).

Mitoxantrone was discovered as an analogue of the antibiotic doxorubicin with enhanced cytotoxic effects and less cardiotoxicity. Like the parent compound, mitoxantrone intercalates into DNA and inhibits topoisomerase II. Currently, mitoxantrone is used for the pharmacotherapy of acute myeloid leukemia, prostate cancer, and for MS therapy. The death of lymphocytes explains its immunosuppressive effects. Beyond cytotoxicity, immunomodulatory effects of mitoxantrone have been reported, such as inhibiting the migration of mononuclear cells (Kopadze et al. 2006). Although cardiotoxicity is less than with doxorubicin, it limits the application of mitoxantrone to a fixed cumulative lifetime dose. Mitoxantrone was the first drug to be approved for secondary progressive MS. However, with the advent of other effective drugs, it has become second choice.

Oral Drugs

Dimethyl fumarate is a prodrug that is converted into monomethyl fumarate in the gut after oral ingestion. The latter is the active compound and has three molecular targets that may potentially explain its clinical activity. It is an agonist of the G protein-coupled membrane receptor HCA2 on neutrophils, monocytes/macrophages, and microglia. By activating HCA2, monomethyl fumarate inhibits the migration and modulates the function of myeloid cells and microglia. HCA2 is required for the protective effect of dimethyl fumarate in EAE (Chen et al. 2014). In addition, monomethyl fumarate is able to react with cysteine residues in GAPDH and KEAP1, thereby inhibiting glycolysis and activating the anti-oxidative transcription factor NRF2 (Kornberg et al. 2018; Linker et al. 2011). Both mechanisms are able to modulate immunity. Dimethyl fumarate is used for the treatment of relapsing-remitting MS. Adverse effects include transient gastrointestinal effects and flushing. Rarely, it causes progressive multifocal leukoencephalopathy.

S1P receptor modulators antagonize the effects of sphingosine-1-phosphate (S1P) receptors. S1P receptors consist of five subtype (S1P1–S1P5) and are expressed on lymphocytes, on neural cells, and on atrial myocytes. As a prodrug,

fingolimod is converted to fingolimod-phosphate that binds to S1P1, S1P3, S1P4, and S1P5 receptors. It stimulates the internalization and degradation of S1P1. S1P1 mediates a key signal for T and B lymphocytes to egress from thymus and lymph nodes. Blocking the S1P phosphate effect interferes with the migration of lymphocytes to the CNS. As a side effect, fingolimod lowers heart rate and can cause atrioventricular block. Siponimod is a more selective modulator of S1P1 and S1P5 receptors, but it also transiently induces bradycardia (Gergely et al. 2012). S1P receptor modulators are highly efficacious in MS. Fingolimod has market authorization in relapsing-remitting MS and siponimod in the relapsing-remitting and secondary progressive phase of the disease.

Teriflunomide is the active metabolite of leflunomide, a drug that is approved for the treatment of rheumatoid arthritis. Teriflunomide reversibly inhibits dihydro-orotate dehydrogenase, a key mitochondrial enzyme for pyrimidine synthesis. Pyrimidines are required for the rapid proliferation of T and B lymphocytes. Notably, inhibition of dihydro-orotate dehydrogenase by teriflunomide specifically targets the differentiation and polarization of Th1 cells, apparently by interfering with oxidative phosphorylation and glycolysis (Klotz et al. 2019). In relapsing-remitting MS, teriflunomide is equally effective as IFNβ-1. The pharmacokinetic profile of teriflunomide is characterized by its long elimination half-life (about 19 days).

Cladribine is a purine analogue that enters cells by nucleoside transporters. The rate of phosphorylation to cladribine-triphosphate determines the cellular sensitivity to the drug. Cladribine-triphosphate is incorporated into DNA during replication or repair and inhibits cell proliferation and gene expression. It is able to induce apoptosis (Jacobs et al. 2018). These mechanisms lead to a depletion of both B and T lymphocyte as well as innate immune cells including NK cells and monocytes. Beyond depletion, cladribine inhibits chemokine release and chemotaxis. Cladribine is effective in relapsing-remitting MS. It is teratogenic and possibly increases the malignancy rate.

Future Directions

In the last decades, efforts to prevent attacks in relapsing-remitting MS have been successful. There is a now an impressive therapeutic armamentarium to treat this phase of MS. Future research will deal with the questions which drug (s) to use first and how to escalate therapy if the disease progresses. To answer these questions, controlled clinical trials that compare the long-term effect of different DMTs or of different treatment strategies are required. Such studies are currently underway (Ontaneda et al. 2019). Even more difficult will be attempts to reverse disability by enhancing remyelination or halting axonal loss. Existing therapies target the immune system and not the neural response to the immune challenge. However, there are promising approaches at the preclinical level, and clinical trials have started investigating remyelinating and neuroprotective principles (Faissner et al. 2019).

Molecular Signaling Section, Laboratory of Bioorganic Chemistry, National Institutes of Health (NIDDK), Bethesda, MD, USA

Synonyms

Muscarinic acetylcholine receptors

Definition

Muscarinic acetylcholine receptors (mAChRs) form a class of cell surface receptors that are activated upon binding of the neurotransmitter, acetylcholine. Structurally and functionally, mAChRs are prototypical members of the superfamily of G protein-coupled receptors. Following acetylcholine binding, the activated mAChRs interact with distinct classes of heterotrimeric G proteins, resulting in the activation or inhibition of distinct downstream signaling cascades.

Basic Characteristics

The neurotransmitter acetylcholine (ACh) exerts its diverse pharmacological actions via binding to and subsequent activation of two general classes of cell surface receptors, the nicotinic and the mAChRs. These two classes of ACh receptors have distinct structural and functional properties. The *nicotinic receptors*, which can be selectively activated by the alkaloid nicotine, represent ACh-gated ion channels. In contrast, the mAChRs, which can be selectively activated by the alkaloid muscarine, are members of the *G protein-coupled receptor* (GPCR) superfamily.

General Structural Features

Molecular cloning studies have revealed the existence of five molecularly distinct mammalian mAChRs (M_1–M_5; Table 1). All five receptor subtypes are members of the so-called class A GPCR subfamily (rhodopsin-like receptors) with which they share about 20 highly conserved amino acids (Wess 1996). These highly conserved residues play important roles in proper receptor folding and receptor activation (Wess 1996). The structural hallmark of mAChRs (and GPCRs in general) is the presence of seven α-helically arranged transmembrane domains (TM1–7) which form a tightly packed transmembrane core. The N-terminal portion of the receptor protein is located extracellularly, whereas the C-terminal segment protrudes into the cytoplasm.

During the past decade, high-resolution structures have been obtained for four of the five mAChR subtypes (M_1–M_4) (Haga et al. 2012; Kruse et al. 2012, 2013; Thal et al. 2016). These structures show that the classical (*orthosteric*) binding site for muscarinic agonists and antagonists is highly conserved among the different mAChR subtypes (Kruse et al. 2014; Thal et al. 2016).

Distribution and Physiological Functions of mAChRs

mAChRs are found in virtually all organs, tissues, and cell types. All five mAChRs are expressed in both the central nervous system (CNS) and the body periphery. Whereas the M_2 and M_3 receptor subtypes are the predominant mAChRs found in

Muscarinic Receptors, Table 1 Summary of key features of the five human mAChRs (M_1–M_5)

Receptor subtype	M_1	M_2	M_3	M_4	M_5
Amino acids (number)	460	466	590	479	532
Chromosomal localization	11q12	7q35–36	1q43–44	11p12–11.2	15q26
GenBank/EMBL accession number	X15263	X15264	X15266	X15265	M80333
		M16404		M16405	
G protein-coupling selectivity	$G_{q/11}$	$G_{i/o}$	$G_{q/11}$	$G_{i/o}$	$G_{q/11}$
Subtype-preferring antagonists (examples)[a]	VU0255035	Tripitramine	Darifenacin	PD102807	ML381
	MT7[b]		MT3[b]		

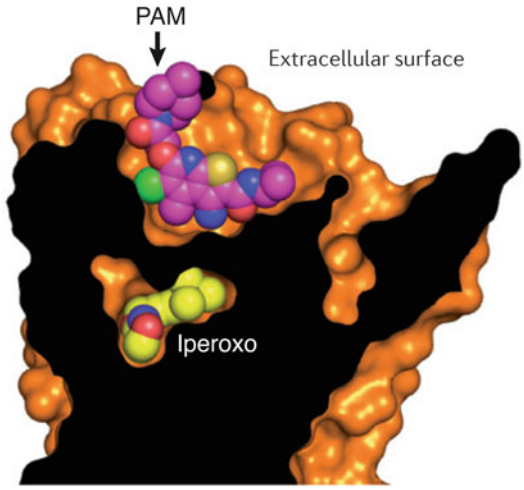
[a]Except for certain snake toxins, such as MT3 or MT7, the degree of subtype preference of so-called "subtype-selective" muscarinic antagonists is usually rather limited (for more details, see https://www.guidetopharmacology.org/GRAC/FamilyDisplayForward?familyId=2)
[b]MT3 and MT7 are toxins isolated from the venom of the green mamba and act as allosteric inhibitors

peripheral tissues, the M_1 and M_4 mAChRs are abundantly expressed in the CNS, specifically in higher brain regions. The M_5 mAChR is expressed at rather low levels in various central and peripheral tissues. Characteristically, most tissues or organs express multiple mAChR subtypes. Peripheral mAChRs are known to mediate the well-documented actions of ACh at *parasympathetically* innervated effector tissues (organs) including the heart, endocrine and exocrine glands, and smooth muscle tissues (Caulfield and Birdsall 1998; Wess 2004). The most prominent peripheral actions mediated by activation of these receptors are reduced heart rate and cardiac contractility, contraction of smooth muscle tissues (e.g., smooth muscles of the eye, gastrointestinal system, lung, and urinary bladder), and stimulation of glandular secretion (e.g., lachrymal, salivary, and gastrointestinal glands). Whereas the cardiac muscarinic actions of ACh are mediated by M_2 receptors, the M_3 receptor subtype plays a major role in mediating ACh-dependent stimulation of glandular secretion and smooth muscle contraction (Caulfield and Birdsall 1998; Wess 2004).

Central mAChRs are involved in modulating a very large number of behavioral, autonomic, sensory, and motor functions. For example, central muscarinic mechanisms play important roles in the control of body temperature, cardiovascular and pulmonary functions, learning and memory, emotional responses, arousal, attention, rapid eye movement (REM) sleep, and stress modulation. Moreover, increased or decreased muscarinic cholinergic neurotransmission has been implicated in the pathophysiology of several important disorders of the brain, including *Alzheimer's* and *Parkinson's disease*, depression, schizophrenia, and epilepsy (Kruse et al. 2014; Wess et al. 2007). The roles of the individual mAChRs in mediating the diverse central muscarinic functions of ACh are not well understood at present, primarily due to the lack of muscarinic ligands endowed with a high degree of receptor subtype selectivity (see below). However, recent studies analyzing newly developed mutant mouse strains deficient in specific mAChR subtypes have led to many new insights into the physiological roles of the M_1–M_5 receptors (Kruse et al. 2014; Wess et al. 2007).

Ligands and Mechanisms Involved in Ligand Binding and mAChR Activation

ACh is predicted to bind to the M_1–M_5 receptors within a cleft enclosed by the ringlike arrangement of TM1–7, about 10–15 Å away from the membrane surface (Fig. 1) (Kruse et al. 2014). This orthosteric muscarinic binding site consists of a cavity lined by amino acid chains located on several of the seven transmembrane (TM) helices (TM1–7) (Kruse et al. 2014; Thal et al. 2016). A key ligand/receptor interaction involves a charge-charge interaction between the tertiary or quaternary nitrogen of the orthosteric muscarinic



Muscarinic Receptors, Fig. 1 Agonist-induced conformational changes on the cytoplasmic surface of the M_2 mAChR. After agonist binding to the M_2 mAChR, the cytoplasmic end of TM6 rotates outward in the active M_2 receptor structure (orange), relative to the inactive state of the receptor (blue). This conformational change allows the activated receptor to bind to and activate heterotrimeric G proteins. (This figure has been modified based on recently published images Kruse et al. 2013)

ligands (agonists and antagonists) and a conserved TM3 aspartic acid chain (Kruse et al. 2014). This ion pair is surrounded by a cluster of tyrosine residues, thus creating a charge-stabilized aromatic cage. A TM6 asparagine residue that is characteristic for the mAChR family is also important for the binding of orthosteric muscarinic ligands (Kruse et al. 2014). Structural studies with the M_2 mAChR have shown that agonist binding leads to a contraction of the ligand-binding pocket, an effect that is not observed with muscarinic antagonists which are usually larger in size (Kruse et al. 2013; Thal et al. 2016).

The agonist binding pocket partially overlaps with that of competitive muscarinic antagonists such as tiotropium or quinuclidinyl benzilate (Kruse et al. 2014; Thal et al. 2016). However, antagonists form additional interactions with hydrophobic receptor residues, thus stabilizing the inactive state of the receptor (Kruse et al. 2014; Thal et al. 2016).

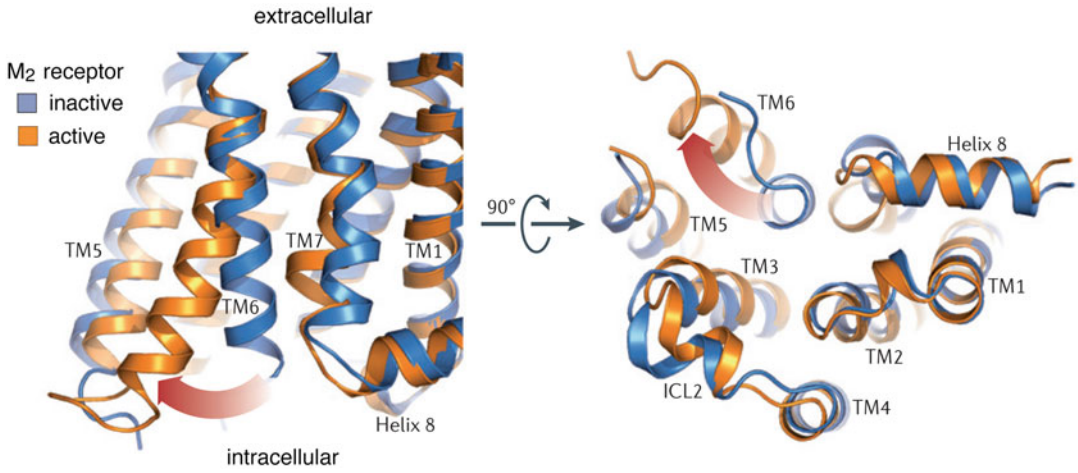
The amino acids lining the ligand-binding cavity are highly conserved among the M_1–M_5 mAChRs (Kruse et al. 2014; Thal et al. 2016). For this reason, the development of agonist or antagonist ligands that are able to interact with individual mAChR subtypes with a high degree of selectivity has proven to be a very difficult task. Except for so-called allosteric activators of M_1 mAChRs (see below), agonists that display a high degree of selectivity for a particular mAChR subtype are not available. Moreover, the degree of receptor subtype selectivity of so-called "selective" muscarinic antagonists, which are often used to distinguish between different mAChR subtypes, is generally rather modest. Representative mAChR subtype-preferring muscarinic antagonists are listed in Table 1.

However, several snake toxins have been identified that display an unprecedented degree of mAChR subtype selectivity. For example, the MT7 and MT3 toxins (Table 1) are highly selective antagonists for M_1 and M_4 mAChRs, respectively (Caulfield and Birdsall 1998). The binding of these polypeptide ligands is predicted to involve interactions with less well-conserved amino acids present on the extracellular surface of the mAChRs.

Structural studies with the M_1 and M_2 mAChRs have shown that agonist binding induces changes in the arrangement of individual TM helices that are transmitted to the intracellular surface of the mAChR proteins, enabling the receptors to productively interact with specific classes of *heterotrimeric G proteins* (Kruse et al. 2013; Maeda et al. 2019). The key feature of the active-state mAChRs is an outward rotation of TM6 that creates a G protein-binding cavity on the cytoplasmic receptor surface (Fig. 2). The active-state structures of the M_1 and M_2 receptors are similar to those of most other GPCRs for which high-resolution structural information is available.

Allosteric Modulators of mAChR Function

mAChRs possess one or more topographically distinct allosteric binding sites formed by amino acid side chains located within the extracellular loops or the outer segments of different TM



Muscarinic Receptors, Fig. 2 Ligand binding sites on the M_2 mAChR. This figure shows that the orthosteric muscarinic agonist (iperoxo) binds to a cavity within the transmembrane receptor core (black). Shown in magenta is a mAChR PAM (LY2119620) that binds to the extracellular receptor surface, thus interfering with the dissociation of the orthosteric agonist from its binding pocket. (This figure has been modified based on recently published images Kruse et al. 2013)

helices (Burger et al. 2018; Kruse et al. 2014). Since these regions are not highly conserved among the M_1–M_5 receptors, considerable progress has been in developing so-called allosteric modulators with a high selectivity for distinct mAChR subtypes (Burger et al. 2018; Conn et al. 2009; Kruse et al. 2014). These agents act by altering the affinity or efficacy of orthosteric muscarinic ligands. While positive allosteric modulators (PAMs) enhance the activity of orthosteric agonists, negative allosteric modulators (NAMs) exert the opposite effect. Allosteric agents that can directly activate mAChRs are referred to as allosteric agonists. It is likely that the development of subtype-selective muscarinic allosteric agents will lead to novel, clinically useful drugs that are endowed with increased efficacy and an improved side effect profile. Currently, a major focus in the field is to develop allosteric muscarinic drugs for the treatment of several severe disorders of the CNS, including Alzheimer's disease and schizophrenia (Conn et al. 2009; Kruse et al. 2014).

An X-ray structure of the M_2 mAChR has revealed the molecular details of a PAM-mAChR complex, confirming that the binding pocket for allosteric muscarinic agents is located just above the orthosteric binding cavity (Kruse et al. 2013; Fig. 1). This binding mode enables the PAM to interfere with the dissociation of the bound orthosteric agonist from the receptor (Kruse et al. 2013). The development of bitopic orthosteric/allosteric ligands, which can interact with both orthosteric and allosteric sites, also represents a promising approach to obtain high-affinity muscarinic ligands endowed with a high degree of receptor subtype selectivity (Lane et al. 2013).

G Protein-Coupling Properties of mAChRs

Based on their G protein-coupling properties, the M_1–M_5 mAChRs can been subdivided into two major functional subclasses (Caulfield and Birdsall 1998; Wess 2004). The M_1, M_3, and M_5 mAChRs are preferentially coupled to G proteins of the $G_{q/11}$ family, which mediate the activation of different isoforms of *phospholipase Cβ* resulting in the breakdown of phosphatidylinositol and the generation of the second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol. In contrast, the M_2 and M_4 mAChRs are selectively linked to

G proteins of the $G_{i/o}$ class, which, at a biochemical level, reduce the accumulation of intracellular cAMP via inhibition of *adenylyl cyclase*. However, the G protein-coupling selectivity of the individual mAChRs is relative rather than absolute, as has been observed with most other GPCRs. Both mutagenesis and structural studies have shown that amino acids located within the i2 loop and the membrane-proximal portions of the i3 loop play key roles in determining the G protein-coupling profile of the individual mAChRs (Maeda et al. 2019; Wess 1996).

Recent cryo-electron microscopic studies carried out with M_1 and M_2 receptors complexed with their respective G proteins have revealed the structural details underlying the G protein-coupling selectivity of individual mAChR subtypes (Maeda et al. 2019). These new structures show that the C-terminal tail of the activated M_1 receptor, but not the active M_2 receptor, can also interact with heterotrimeric G proteins (Maeda et al. 2019).

Signaling Pathways Activated by mAChR Subtypes

At a cellular level, the activation of mAChRs leads to a wide spectrum of biochemical and electrophysiological responses (Lanzafame et al. 2003; Wess 1996). The precise pattern of responses that can be observed depends on the nature of the activated G proteins (receptor subtypes) and the specific components of different signaling cascades (e.g., effector enzymes or ion channels) that are expressed in a particular cell type or tissue. The observed effects can be caused by direct interactions of the activated G protein(s) with effector enzymes or ion channels or may be mediated by second messengers (Ca^{2+}, IP_3, etc.) generated upon mAChR stimulation. Activation of M_1, M_3, and M_5 mAChRs does not only lead to the generation of IP_3 followed by the mobilization of intracellular Ca^{2+} but also results in the stimulation of phospholipase A_2, phospholipase D, and various tyrosine kinases. Similarly, M_2 and M_4 receptor activation does not only mediate the inhibition of adenylyl cyclase but also induces other biochemical responses including the augmentation of phospholipase A_2 activity. Moreover, the stimulation of different mAChR subtypes is also linked to the activation of different classes of mitogen-activated protein kinases (MAP kinases), resulting in specific effects on gene expression and cell growth or differentiation. Stimulation of mAChRs also results in the activation or inhibition of a large number of ion channels (Lanzafame et al. 2003). For example, stimulation of M_1 receptors leads to the suppression of the so-called M current, a voltage-dependent K^+current found in various neuronal tissues. M_2 receptors, on the other hand, mediate the opening of cardiac $I_{K(ACh)}$ channels, and both M_2 and M_4 receptors are linked to the inhibition of voltage-sensitive calcium channels (Lanzafame et al. 2003).

Regulation of mAChR Activity

Like most other GPCRs, mAChRs are subject to desensitization, which is defined as diminished responsiveness of the receptor/effector signaling pathway upon prolonged exposure of the receptor to an activating ligand. The phenomenon of GPCR desensitization involves a complex series of events, including G protein uncoupling, receptor sequestration/internalization (removal of receptors from the cell surface), and receptor downregulation associated with the net loss of receptor protein (van Koppen and Kaiser 2003). Many of these processes are regulated by receptor phosphorylation catalyzed by various protein kinases including different members of the family of *GPCR kinases (GRKs)*, casein kinase 1α, or second messenger-dependent protein kinases. Phosphorylation occurs on threonine and serine residues located within the i3 loop and the C-terminal tail of the mAChRs. The phosphorylated mAChRs can interact with beta-arrestins that play a key role in mediating receptor desensitization and internalization. The individual mAChR subtypes differ in their ability to serve as substrates for phosphorylation by the kinases mentioned above. The rapid removal of mAChRs from the cell surface following agonist stimulation (referred to as receptor internalization/sequestration) occurs through multiple pathways, one of

which involves the targeting of receptors to *clathrin-coated pits* (van Koppen and Kaiser 2003). Long-term treatment of mAChRs with muscarinic agonists results in receptor downregulation, the extent of which depends on receptor subtype and cell type (van Koppen and Kaiser 2003).

Drugs

Current Clinical Uses of Muscarinic Drugs

Muscarinic agonists and antagonists are used for the treatment of a variety of pathophysiological conditions. For example, muscarinic agonists (pilocarpine, carbachol, or aceclidine) reduce intraocular pressure when applied locally to the eye and are therefore widely used for the treatment of glaucoma. Muscarinic agonists (carbachol or bethanechol) are also employed in certain cases of atonia of the stomach, bowel, or urinary bladder. The agonists pilocarpine and cevimeline are used to stimulate salivation under conditions where the function of the salivary glands is impaired. Methacholine, an ACh analogue, is administered by inhalation for the diagnosis of bronchial airway hyperreactivity.

Centrally acting muscarinic antagonists (e.g., trihexyphenidyl, procyclidine, or biperiden) are useful for the treatment of Parkinson's disease or Parkinson-like symptoms caused by the administration of antipsychotic drugs, probably due to their ability to reduce excessive striatal muscarinic neurotransmission resulting from the lack of striatal dopamine. Muscarinic antagonists are also of considerable value in the treatment of clinical disorders characterized by an increased tone or motility of the gastrointestinal and urogenital tract (e.g., overactive bladder) and in the local therapy of chronic obstructive pulmonary disease. Antimuscarinic agents are widely used in ophthalmology to produce mydriasis and/or cycloplegia, are effective in the treatment of peptic ulcer disease (e.g., pirenzepine) and certain forms of cardiac arrhythmias, and can be used as part of routine preoperative medication, primarily to reduce reflex bradycardia and excessive bronchial secretion. A transdermal preparation of scopolamine is highly effective in preventing motion sickness.

Potential Clinical Uses of Muscarinic Drugs

A major problem associated with the use of classical muscarinic drugs is the rather common occurrence of bothersome side effects, primarily due to the simulation or inhibition of cardiac, glandular, smooth muscle, or central mAChRs. It is likely that the development of muscarinic agonists and antagonists that can interact with individual mAChRs with a high degree of selectivity will lead to novel muscarinic drugs with reduced side effects and increased efficacy. For example, several studies suggest that selective activation of central M_1 receptors may prove useful for the treatment of Alzheimer's disease (Kruse et al. 2014). Selective M_5 receptor antagonists are predicted to have potential for treating drug abuse (Kruse et al. 2014). Moreover, accumulating evidence indicates that agents that can selectively activate central M_1 and/or M_4 receptors may prove beneficial as novel antipsychotic drugs (Kruse et al. 2014).

Definition

Myocardial infarction (MI) is defined as the death of myocardial cells due to a prolonged time of ischemia (Thygesen et al. 2018). Clinically, the term should be used when acute myocardial injury is detected by abnormal cardiac biomarkers (such as troponins, myoglobin, creatine kinase-MB isoform) in the setting of evidence of acute myocardial ischemia (Thygesen et al. 2018). If there is no conclusive evidence to support the theory of myocardial ischemia but elevated cardiac biomarkers are present, the term myocardial injury should be used according to the latest universal definition of myocardial infarction published in 2018 as a consensus statement of many major cardiovascular societies (Thygesen et al. 2018).

Historically, MI is one of the most severe and furthermore most feared complication of progressive coronary artery disease (CAD). CAD refers to an atherosclerotic process taking place in the coronary vessels and represents a localized subset of the generalized process of atherosclerosis (Nabel and Braunwald 2012). Due to its widespread prevalence, the disease bears an enormous socioeconomic burden (Fryar et al. 2012). In the USA alone, over 1 million coronary events occurred in 2019 alone, meaning that every 42 s an US American will have a myocardial infarction (Mozaffarian et al. 2016). Worldwide, CAD causes over 7.4 million deaths annually making it the leading cause of death (WHO 2018). However, since the mid-1990s, there has been a steady decline in mortality from coronary heart disease and most notably in ST-segment elevation myocardial infarction (STEMI), owed substantially to refined evidence-based therapies especially due to advances in pharmacological, reperfusion, and preventive strategies (Nichols et al. 2013).

Pathophysiologic Mechanisms

General

MI is generally grouped into two major entities: ST segment elevation myocardial infarction (STEMI) and non-ST segment elevation myocardial infarction (NSTEMI). Unstable angina, meaning typical chest pain without exertion and negative cardiac biomarkers, is usually also considered an acute coronary syndrome (ACS), because it is believed to occur imminently before myocardial infarction. Since NSTEMI and

unstable angina share a similar pathophysiological principle, they are grouped together as so-called non-ST-segment elevation ACS (NSTE-ACS) to help clinicians streamline management pathways. In our current age, about 60–75% of all patient presenting with ACS are classified as NSTEMI whereas the proportion of STEMI is declining in the past decades (Yeh et al. 2010; McManus et al. 2011).

Furthermore, MI can be classified into five types depending on pathophysiological characteristics, prognosis, as well as clinical presentation (Thygesen et al. 2018). *Type I MI*, or spontaneous MI, is defined as myocyte necrosis due to atherothrombotic coronary artery disease (CAD) and usually precipitation by atherosclerotic plaque disruption (rupture or erosion). *Type II MI* is defined by an imbalance of myocardial oxygen supply and demand. The presence of CAD is specifically not required (but can be present) in type II MI. From a pathophysiological view, type II MI is a very heterogeneous group with many possible underlying causes such as coronary artery spasm, coronary microvascular dysfunction, severe bradyarrhythmia, respiratory failure with severe hypoxemia, severe anemia, and hypotension/shock, increased myocardial oxygen demand due to sustained tachyarrhythmia or severe hypertension. Notably, it has been shown that type II MI can present with (mostly transient) ST segment elevation in 3–24% of cases. The diagnosis of *type III MI* is reserved for patients who suffer cardiac death with symptoms suggestive of myocardial ischemia but who decease before cardiac biomarkers can be evaluated or MI is detected postmortem by autopsy. *Type IV and V MI* is designated for patients suffering from procedure-related myocardial infarctions in a PCI setting (IVa), related to acute stent thrombosis (IVb), related in-stent restenosis or after coronary artery bypass grafting (V). The diagnostic criteria for type IV MI is arbitrarily defined by an elevation of cardiac specific biomarkers values more than five times the 99th percentile upper reference limit in patients with normal baseline values up to 48 h after the index PCI procedure. Additionally, either new ischemic ECG changes, development of new pathological Q waves, imaging evidence of new loss of viable myocardium, or angiographic evidence of flow limiting procedural complications (such as coronary dissection) must be present. In the setting of coronary artery bypass grafting (Type V MI), the elevation of cardiac specific biomarkers must be larger than ten times the upper reference limit in addition to the development of new pathological Q waves, angiographic documentation of new graft or native coronary artery occlusion, or imaging evidence of loss of new loss of viable myocardium. For both type IV and V MI, the development of new pathological Q waves regardless of biomarker elevation meet the criteria for the respective MI. For an overview of MI Types, see Table 1.

Coronary Artery Disease

Coronary artery disease (CAD) is the underlying condition precipitating ischemic heart disease and thereby most cases (or all cases within MI type I) of myocardial infarction. CAD itself is only a subset of the generalized process of atherosclerosis localized in the coronary vasculature. Plaques in CAD usually consist of a fibrous cap covering a lipid rich core. Since the fundamental work of R Ross, the process of plaque development is understood as a systemic inflammatory process rather than a bland lipid storage in the artery walls (Ross 1999). For details on plaque composition, development, and formation, see the corresponding chapter on atherosclerosis. The risk factors of developing CAD are subsequently also shared with arteriosclerosis and include high blood pressure, smoking, diabetes, lack of exercise, adipositas, genetic factors, systemic rheumatologic diseases, high blood cholesterol, and high levels of lipoprotein (a) (Wilson 1994).

Over time, atherosclerotic plaques can develop further and grow to a size that the lumen of a coronary artery is reduced beyond a critical threshold (usually >80–90% considered hemodynamically relevant). This in turn limits the blood flow to the dependent myocardial cells which causes ischemia and exposing the cells to an ischemic environment with anaerobic metabolic homeostasis (Olivier 2011).

Myocardial Infarction, Table 1 Classification of Types of Myocardial Infarction

Type	Classification	Characterization
I	Spontaneous MI	Primary event caused by atherothrombotic coronary artery disease and usually precipitated by atherosclerotic plaque disruption (rupture or erosion)
II	Supply/demand mismatch	Myocardial infarction secondary to ischemia other than coronary artery disease due to a mismatch between oxygen supply and demand.
III	Death suspected to be related to MI	Cardiac death suggestive of an ischemic process without definitive biomarker evidence of myocardial infarction
IVa	MI associated with percutaneous coronary intervention	Rise in cardiac biomarkers (>5 times URL) up to 48 h after index PCI with evidence of new myocardial ischemia
IVb	MI associated with stent/scaffold thrombosis	Myocardial infarction fulfilling the same criteria as type I MI but with evidence of stent or scaffold thrombosis after index PCI
IVc	MI associated with (in-stent) restenosis	Myocardial infarction due focal or diffuse restenosis, or a complex lesion after index PCI associated with a rise or fall of cardiac biomarker values above the 99th percentile URL applying the same criteria utilized for type I MI
V	MI associated to coronary artery bypass grafting	Rise in cardiac biomarkers (>10 times URL) up to 48 h after index coronary artery bypass grafting with evidence of new myocardial ischemia
Injury	Myocardial injury	Acute or chronic elevation in cardiac biomarkers (above 99th percentile URL) without overt ischemia due to multifactorial etiology but associated with averse outcome

Overview of MI types and myocardial injury according to the Fourth Universal Definition of Myocardial Infarction; MI: Myocardial infarction; URL: Upper reference limit; PCI: Percutaneous coronary intervention

Since oxygen demand is higher during exercise (as coronary flow can rise up to fourfold under exercise), stable angina pectoris develops in these patients under exertion. However, not all plaques resulting in a certain degree of stenosis inevitably cause limiting blood flow and thereby symptoms of stable angina. The severity of flow obstruction is determined by a multitude of factors including plaques size, vasospasms, arterial remodeling, and ultimately also collateralization.

With progression of CAD (also called stable CAD), whether symptomatic or not, the process of plaque progression can be complicated by plaque rupture. In case of a resulting total occlusion of the coronary artery, a type I MI occurs. However, more often a plaque rupture is clinically silent and does not result in occlusive thrombus formation or is removed naturally by a process of endogenous lysis and following migration of smooth muscle cells that migrate to the area and cover the surface with connective tissue. During this process, plaques can increase in size in a phasic manner rather than linear and produce complicated plaques with several possible rupture sites.

Stable Coronary Plaques

A severe stenosis is usually required to cause angina. It was shown that these types of lesions less commonly cause type I myocardial infarction. This is believed to be caused by plaques composition as these lesions often tend to have a dense fibrotic cap that covers a rather small lipid pool and is in turn less likely to rupture and thereby allows for formation of collateral circulation over time. Stable plaques hereby promote a "barrier" usually composed of collagen fibers and smooth muscle cells and in comparison low amount of inflammatory cells (especially macrophages and T-lymphocytes). This keeps the blood flow separated from the highly thrombogenic lipid core of the plaque, preventing the initiation of the thrombotic cascade and subsequently formation of an occlusive (or non-occlusive) thrombus.

Vulnerable Coronary Plaques

In contrast to stable coronary plaques, vulnerable plaques often tend to be only 30–50% in absolute luminal stenosis and a thus not flow limiting eluding diagnosis in conventional coronary angiography. These plaques often show thin fibrous caps and a high burden of inflammatory cells (especially macrophages). Additionally, these lesions often have a large lipid-rich (and often necrotic) core. Additional features can be positive signs of vascular remodeling (vessel enlargement), increased vasa-vasorum neovascularization, and intra-plaque hemorrhage. This characteristic lesion profile leads to a zone especially vulnerable to mechanical stress (for example, high blood pressure) and ultimately plaque rupture. Even though plaque rupture is believed to be the most common entity that causes ACS, several modes of action including superficial plaque erosion, erosion of calcium nodules, and intra-plaque hemorrhage have been studied over the recent years (Libby 2011).

In case of plaque rupture, the often-thin fibrous cap beaks up and exposes its thrombogenic contents to the blood stream. The fibrous cap itself can uphold its structural integrity if the smooth muscle cells (SMC) can shift the balance between collagen synthesis and degradation (mostly by inflammatory cells) in their favor. By infiltration of dendritic cells mostly in the shoulder region of the plaque and following secretion of T-lymphocyte recruiting chemokines, T-lymphocytes migrate to the site and begin to secrete interferon-γ and TNF-α. This not only reduces the ability of SMCs to uphold the fibrous cap but also activates macrophages. The resulting presentation of pro-inflammatory cytokines can promote apoptosis of SMCs. Furthermore, matrix metallopeptidases (MMP) are overexpressed in these lesions and produced by the attracted macrophages leading to further collagen degradation and thinning of the fibrous cap (Libby et al. 2019).

Acute Coronary Syndrome

Acutely decreased blood flow in the coronary arteries causes a set of symptoms (syndrome) commonly termed acute coronary syndrome (ACS). The most prevalent clinical symptom is chest pain, often with radiation to the left shoulder, jaw or left arm and commonly associated with nausea and sweating. The sensation is often subjectively felt as crushing or weighing in the chest area in addition to a feeling of acute illness. However, many patients with ACS can present differently. Particularly, women, patients with diabetes mellitus or older patients often show a plethora of symptoms (often called "atypical") that can delay diagnosis in the clinical setting. In the case of suspected ACS and normal cardiac biomarker values (<99th percentile upper reference limit), an alternative diagnosis or unstable angina should be considered.

Electrocardiogram

The electrocardiogram (ECG) with its rapid application and widespread availability plays a crucial role in the diagnostic workup of patients with suspected MI and should be acquired at best immediately and not later than 10 min after first medical contact. Acute myocardial ischemia is often associated with dynamic changes in ECG waveform and thus serial acquisition is recommended. Suspect of myocardial ischemia are new ST-elevation at the J-point in two contiguous leads with the cut-point: >1 mm in all leads other than leads V2–V3 (>2 mm in men >40 years; >2.5 mm in men <40 years, or >1.5 mm in women regardless of age). Furthermore, new horizontal or downsloping ST-depression >0.5 mm in two contiguous leads and/or T-wave inversion >1 mm in two contiguous leads with prominent R wave or R/S ratio >1 should be considered a correlate of myocardial ischemia. Additionally, a newly diagnosed complete left branch block can be a sign of myocardial ischemia.

On a pathophysiological level, when a complete blockage of a coronary artery occurs, ischemia will affect all three layers of the myocardium (transmural). The ECG leads facing the corresponding area of cardiac muscle cells will show an action potential as ST elevation during systole, while during diastole, there is a depression of the PR segment and the PT segment. Since those intervals are regarded as baseline when evaluation ECG waveforms, ST segment

elevation is regarded as a sign of myocardial ischemia and damage.

Cardiac Biomarkers

Over the last decade, the isoforms T and I of cardiac troponins (cTnT and cTnI) have emerged as the preferred diagnostic tool, owing this status to their high sensitivity and specificity for myocardial cell damage. Both enzymes are components of the contractile apparatus of myocardial cells and are expressed almost exclusively in the cardiac muscle (Vasile and Jaffe 2017).

Today, high sensitivity essays (hscTnT or hscTnI) are recommended in the first line for routine clinical use. Since the introduction of high-sensitive essays, there has been a significant reduction in the diagnosis of unstable angina corresponding to an increase in diagnosis of NSTEMI. In general, myocardial injury is defined as being present when blood levels of a cardiac troponin are increased above the 99th percentile of the upper reference limit (URL) of the corresponding essay. This may be described as acute, evident by a newly detected dynamic rising and/or falling pattern or chronic in case of persistently elevated levels of cardiac troponins. Despite having a high sensitivity and specificity, elevated levels of troponin do not reflect the underlying pathophysiological mechanism, and it is not yet possible for clinicians to distinguish from the blood work alone whether myocardial injury is ischemic or not. However, per definition, a rising and/or falling pattern of cardiac troponin values with at least one value above the 99th percentile URL and suspected myocardial ischemia by ECG changes, clinical presentation, or imaging is designated as an acute MI.

Other available biomarkers that were used historically to detect MI such as myoglobin, creatine kinase, or the myocardial isoform creatine kinase MB have fallen out of favor since they cannot produce comparable levels of specificity and sensitivity as high sensitive cardiac troponin.

Myocardial Cell Death

When myocardial ischemia occurs, a large number of cardiomyocytes die rapidly due to factors including acidosis, oxidative stress, and of course hypoxia with resulting lack of aerobic energy production. The myocardium is usually not affected equally with irreversible injury starting in the endocardium as this area is the furthest away from the vessels and gradually continuing to the epicardium. After about 30 s of non-perfusion, diastolic and systolic dysfunction can begin to occur followed shortly after by noticeable ECG changes that begin with large peaked and sometimes widened T waves followed later by the defining ST segment elevation. First evidence of necrosis can be seen as soon as 30 min after flow discontinuation. From this point forward, the cell death becomes exponentially rather than linear, heightening the importance of swift revascularization to prevent extensive myocardial damage ("time is muscle"). After about 6 h of no perfusion, all affected myocardium will become necrotic.

On the cellular level, myocardial cells are very prone to suffer from ischemia due to their lack of anaerobic metabolic alternative pathways. Adenosine triphosphate (ATP) depletion occurs comparatively fast. As a result, ATP gets degraded and produces hydrons (H^+) which in turn lower the intracellular pH levels (intracellular acidosis). This now causes inactivation of troponin C which disables contraction and an increased influx of sodium ions (Na^+) causing oncotic swelling of the cells. Furthermore, since ATP gets scarce, inactivation of ATP-dependent proteins such as calcium ATPases lead to increased intracellular levels of calcium. The death of cardiomyocytes can be finally caused by oncotic swelling, necrosis, or controlled apoptotic pathways which are believed to occur mainly in the border zones of the infarcted myocardium and are believed to benefit the most from swift reperfusion. Cell death itself leads to a massive inflammatory process with invasions of neutrophils and monocytes causing further swelling and cytokine production that is believed to further promote apoptosis. Anti-inflammatory treatment in the acute phase of myocardial infarction has therefore been the aim of pharmacological intervention in clinical trials to improve outcome. As part of the normal healing process inflammatory cells promote the invasion of fibroblasts and endothelial cells that in turn

create primarily vascularized granulation tissue that over time matures into noncontractile acellular scar tissue.

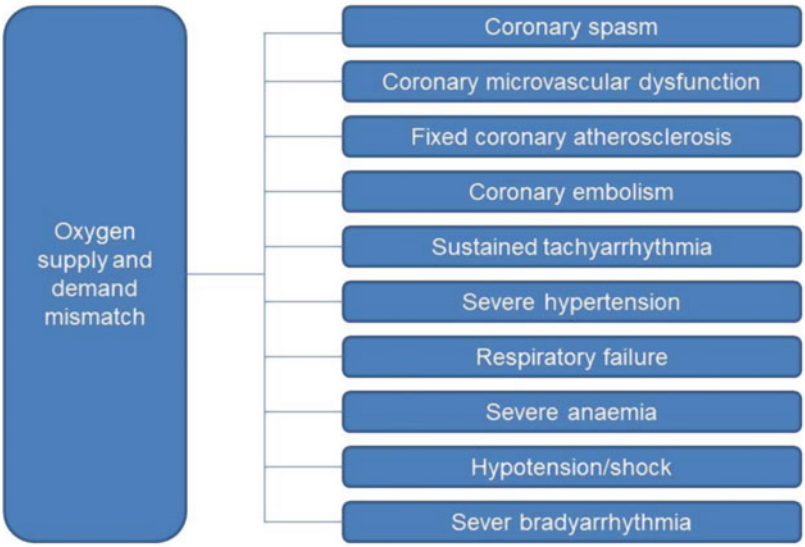
Reperfusion Injury

Even though swift reperfusion is the therapy of choice and is correlated with improved outcomes in patients with STEMI, the sudden reperfusion of the infarcted can prove to be problematic for the affected cells. With restoration of epicardial coronary flow, the extracellular pH is rapidly normalized, causing a significant H^+ gradient across the cell membrane. This in turn promotes further Na^+ influx via the Na^+/H^+ exchange protein and subsequently further calcium overload caused by activation of the NA^+/Ca^{2+} exchanger. In addition, the sudden shift to an again aerobic environment causes a high activity of the respiratory chain in the mitochondria resulting ultimately in high levels of reactive oxygen species (ROS) causing further oxidative damage. This process is usually called reperfusion injury and remains a field of inconclusive research concerning strategies (pre- and post-conditioning) to improve outcome beyond the lone revascularization of the epicardial coronary arteries.

Type II Myocardial Infarction

With an aging population and an increased prevalence of multimorbidity especially in developed countries, patients often show signs of myocardial injury as seen in elevated levels of cardiac troponins without signs of actual myocardial ischemia caused by acute atherosclerotic plaque disruption. Myocardial injury is in this case usually caused by a mismatch between oxygen supply and demand of the myocardium. From an epidemiological standpoint, type II MI might be even more common than type I MI. Such findings are common in several US studies where 57–75% of MIs were classified as type II MI. This subset of MI is a very heterogeneous entity which is also reflected in a highly variable clinical presentation of patients that often have less chest pain and more often have dyspnea or other atypical symptoms. Since patients can also often have CAD (obstructive or non-obstructive) distinction between type I MI, type II MI and acute myocardial injury can prove to be challenging especially when taking multiple comorbidities into account. Table 2 shows a list of possible clinical entities that can cause type II MI such as coronary spasm, coronary embolism, coronary, coronary endothelial

Myocardial Infarction, Table 2 Pathophysiology of Type II Myocardial Infarction



dysfunction, spontaneous coronary artery dissection, tachyarrhythmia, severe hypertension, bradyarrhythmia, severe hypoxia, severe anemia, or severe hypotension. Unfortunately, patients suffering from type II MI have similar all-cause mortality rates compared to patients with type I MI and are at high risk for cardiovascular mortality.

Pharmacological Intervention

After diagnosis of MI, the focus of clinicians should be on hemodynamic stabilization, pain control, decreasing myocardial oxygen consumption, increasing myocardial oxygen supply, and initiating antithrombotic therapy.

Following the immediate management of patients, coronary catheterization is indicated. The timing of the invasive strategy depends on multiple factors and also on the estimated complication risk. In patients with STEMI and very high risk NSTEMI, reperfusion should be initiated as soon as possible in less than 120 min if the time from symptom onset is less than 12 h. Reperfusion should be achieved by percutaneous coronary intervention (PCI), with a prompt initiation of fibrinolysis, or with a combination of both. Direct transport to the PCI center is indicated when PCI can be performed within 60–90 min. Patients presenting to a center without PCI capabilities with STEMI should be immediately transported to a PCI center, provided that reperfusion can be achieved in less than 120 min. If transport times are higher than 30–60 min, prehospital fibrinolysis is commended but must be followed by PCI within 3–24 h. High-risk NSTE-ACS patients require early PCI in the first 24 h. Intermediate-risk patients and patients with positive noninvasive ischemia tests should be referred to coronary angiography in a 72-h window.

Fibrinolysis

Even though primary PCI is the preferred method of reperfusion therapy, systemic fibrinolytic therapy by administering recombinant tissue plasminogen activators (rtPA) such as alteplase, reteplase, and tenecteplase can be performed in certain circumstances especially if PCI is not readily available. If the so-called door-to-balloon time exceeds 120 min, the benefit of primary PCI over primary fibrinolysis is lost and fibrinolysis should be administered within 30 min of first medical contact given that there are no contraindications. However, this is only applicable for patients with STEMI as bleeding risk outweighs the benefits in patients with NSTEMI.

Antiplatelet Agents

Patients should receive 150–325 mg acetylsalicylic acid to inhibit further platelet aggregation on first presentation. Additional inhibition can be achieved by blocking the P2Y12 receptor on the thrombocyte surface. Three substances with clopidogrel, ticagrelor, and prasugrel are readily available for oral administration. Whereas clopidogrel and prasugrel inhibit P2Y12 irreversible, ticagrelor is a reversible inhibitor.

Current guidelines recommend the use of the more potent prasugrel or ticagrelor in patients with acute MI; however, bleeding risk, reperfusion strategy, and local guidelines must be taken into account, as well as the results of emerging trials changing the landscape of antiplatelet therapy rapidly. The role of the only intravenously available reversible ADP receptor antagonist cangrelor is not yet well defined but might be useful in patients not adequately loaded with a P2Y12 inhibitor.

Glycoprotein IIb/IIIa inhibitors such as abciximab, tirofiban, and eptifibatide can provide additional very potent inhibition of platelet aggregation but confer a significant increased bleeding risk. In the area of a potent dual antiplatelet therapy, administration of glycoprotein IIb/IIIa seems to be reserved for patients with high-risk ACS or high thrombus burden shown in the initial coronary angiography.

Anticoagulant Agents

Inhibition of the thrombotic cascade is essential in initial management of ACS regardless if an invasive or conservative strategy is planned for the patient. Historically, unfractionated heparin is widely used to reduce thrombus formation and promote thrombolysis especially as a first-line treatment in a prehospital setting. In the past, trials could also show that the low-molecular-

weight heparin enoxaparin is non-inferior to unfractionated heparin if there is no immediate PCI planned. The use of direct thrombin inhibitors such as bivalirudin as the probably most widely studied substance remains controversial in acute myocardial infarction as pooled data suggest that bivalirudin monotherapy might increases the risk of acute stent thrombosis but on the other hand might reduce major bleeding when compared with unfractionated heparin or enoxaparin-based regimens depending on whether a glycoprotein IIb/IIIa inhibitor is given or not (Capodanno et al. 2016; Cavender and Sabatine 2014).

Secondary Prevention

As with all forms of degenerative vascular diseases, secondary prevention of patients suffered from myocardial infarction is as important if not more important than primary treatment itself. Next to lifestyle modification and specifically smoking cessation, a strict medical therapy is essential for lowering long-term mortality. Depending on bleeding risk, stent use, and type of myocardial infarction, a dual antiplatelet therapy should be continued for up to 12 months followed by lifelong single antiplatelet therapy with acetylsalicylic acid. Furthermore, recent studies suggest that selected high-risk patients might benefit from additional therapy with low dose directly acting oral anticoagulants such as rivaroxaban where the reduction in cardiovascular events outweighs the increased bleeding risk. Additionally, beta-blockers, angiotensin-converting enzyme inhibitors, and aldosterone antagonists in case of a left ventricular ejection fraction below 40% have been shown to improve long-term outcomes in selected patients after myocardial infarction.

Also, it is recommended that all patients after MI should be treated with lipid lowering agents namely statins to reduce events. Recent data suggest that even more aggressive control of LDL cholesterol with high-intensity statin therapy to LDL-C targets below 1.4 mmol/l improves cardiovascular outcomes in patients after ACS.

Definition

The plasma membrane Na^+/Ca^{2+} exchanger is a high-capacity and low-affinity ionic transporter that exchanges three Na^+ ions for one Ca^{2+} ion. When intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) rise and the cells require the return to resting levels, this exchanger couples the uphill extrusion of Ca^{2+} ions to the influx of Na^+ ions into the cells down their electrochemical gradient. This mode of operation, defined as forward mode, or Ca^{2+} efflux mechanism, keeps the 10^4-fold difference in $[Ca^{2+}]_i$ across the cell membrane. Under other physiological or pathophysiological conditions when the intracellular Na^+ concentrations ($[Na^+]_i$) rise, or membrane depolarization occurs and reduces the transmembrane Na^+ electrochemical gradient, the Na^+/Ca^{2+} exchanger mediates the extrusion of Na^+ and the influx of Ca^{2+} ions. This last mode of operation is defined as reverse mode or Ca^{2+} influx mechanism. The mode of operation of the antiporter depends on (i) the Na^+ gradient, (ii) the Ca^{2+} gradient, and (iii) the membrane potential. Therefore, NCX exerts a role in the maintenance of $[Ca^{2+}]_i$ and $[Na^+]_i$ homeostasis and plays a role in the regulation of physiological responses to increases of $[Ca^{2+}]_i$ and $[Na^+]_i$ (Annunziato et al. 2004; Philipson and Nicoll 2000).

Basic Characteristics

Molecular Biology and Topology

Three genes coding for the three different NCX1, NCX2, and NCX3 proteins are present in mammals. These genes appear to be dispersed, since *ncx1*, *ncx2*, and *ncx3* are localized in human

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

chromosomes 2, 19, and 14, respectively. At the posttranscriptional level, at least 15 NCX1 and 5 NCX3 proteins are generated through an alternative splicing of the primary nuclear transcripts. No alternative splicing was found in NCX2 transcript.

NCX1 mRNA encodes for 970 amino acids; however, the initial hydrophobic segment of 32 amino acids is a signal peptide cleaved during the initial processing in the endoplasmic reticulum. The role of this cleavage is still unknown. The mature protein of NCX1 on plasma membrane is composed of 938 amino acids. Similarly, NCX2 and NCX3 mRNA encodes for 921 and 927 amino acids, respectively, but because of the cleavage, the mature proteins NCX2 and NCX3 contain 899 and 896 amino acids, respectively. The most studied isoform of NCX is NCX1 with a theoretical molecular mass of 120 kDa. Regarding the topology of this exchanger, preliminary biochemical analyses have indicated the presence of nine transmembrane segments (TMS), but recent data strongly support a model of ten TMS and with both the amino- and carboxyl-terminus located in the extracellular space (Ren and Philipson 2013). The ten TMS can be divided into an N-terminal hydrophobic domain, composed of the first five, TMS 1–5, and into a C-terminal hydrophobic domain, composed of the last five, TMS 6–10. Two amino acid sequences, named α_1 and α_2 repeats, are located on the opposite site of the membrane where they form reentrant loops that interact within the protein. The α_1 repeat (106–145) comprises part of the TMS2 and TMS3 amino acid sequences and their connecting loop. The α_2 repeat (807–844) comprises part of the TMS7 and part of the connecting loop with TMS8. Since the putative α-helices of the α-repeats are amphipathic, the hydrophilic faces of these helices may form a portion of the ion translocation pathway. Indeed, these two hydrophobic domains are important for the binding and the transport of ions. Interestingly, just after the α_2 repeat sequence, there is a GIG amino acid sequence similar to the GYG sequence present in the P loop of K^+ channels (Philipson and Nicoll 2000). The first five TMS 1–5 are separated from the last five TMS 6–10 through a large hydrophilic intracellular loop of 550 amino acids, named f loop (Fig. 1).

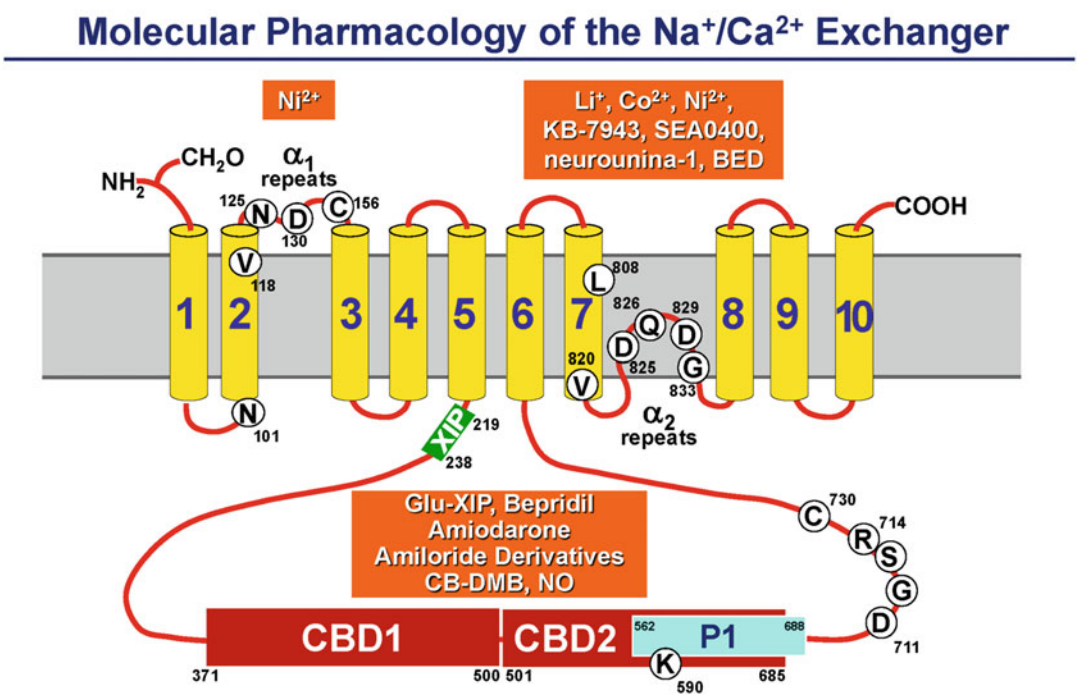
Although the f loop is not implicated in Na^+ and Ca^{2+} translocation, it is responsible for the regulation of NCX activity elicited by several cytoplasmic messengers and transductional mechanisms, such as Ca^{2+}, Na^+, and H^+ ions, NO (nitrergic systems, NO-synthases), sumoylation, phosphatidylinositol 4,5 bisphosphate (PIP_2), protein kinase C (PKC), protein kinase A (PKA), and ATP. Furthermore, in the f loop, there are two Ca^{2+} binding domains named Ca^{2+} binding domain 1 and 2 (CBD1 and CBD2, respectively) (Hilge et al. 2006; Ottolia et al. 2009). CBD1 is the primary Ca^{2+} sensor (371–500 aa) and detects slightest increases in cytosolic Ca^{2+}, and the associated large structural changes activate the exchanger. In contrast, CBD2 (571–685 aa) undergoes comparably modest structural alterations and binds Ca^{2+} only at elevated concentrations. These two different sensitivity thresholds may enable NCX to function dynamically over a wide range of Ca^{2+} concentrations and permit high Ca^{2+} fluxes in excitable cells.

At the N-terminal end of the f loop, in proximity with the membrane lipid interface, there is an autoinhibitory domain, rich in both basic and hydrophobic residues and consisting of a 20-amino acid sequence (219–238). This amino acid sequence, named exchange inhibitory peptide (XIP), is involved in the Na^+-dependent inhibitory effect on NCX activity through the binding to the amino acid sequence named P1 (562–688) near the C-terminal of the f loop (Molinaro et al. 2015).

The other two isoforms NCX2 and NCX3 are characterized by molecular masses of 102 and 105 kDa, respectively. NCX2 displays a 65% sequence identity with NCX1, whereas NCX3 possesses a 73% sequence identity with NCX1 and 75% sequence identity with NCX2. The high amino acid sequence homology indicates that all these three NCX gene products share the same membrane topology (Fig. 1).

Distribution

Na^+/Ca^{2+} exchanger activity is present in virtually every cell type examined. The NCX1 gene is almost ubiquitously expressed since it is found in many tissues, including brain, heart, skeletal



Na^+/Ca^{2+} Exchangers, Fig. 1 Molecular pharmacology of the Na^+/Ca^{2+} exchanger. The first five domains, TMS 1–5, are separated from the last five domains, TMS 6–10, by the f loop provided with regulatory functions. α_1 and α_2 regions are responsible for ion translocation. (Modified from Annunziato et al. (2004))

muscle, smooth muscle, kidney, eye, secretory, immune system, and blood cells. By contrast, NCX2 expression is found exclusively in neurons and glia, whereas NCX3 has been found in neuronal, glial, and skeletal muscle tissues. In addition, NCX1 and NCX3 give rise to several splicing variants that appear to be selectively expressed in different regions and cellular populations of the brain.

At the cellular level, all the three NCX proteins are present on the cell membrane; however, more recently, it has been reported that nuclear-encoded NCX3 isoform is located on the outer membrane of neuronal mitochondria and co-localizes with the protein kinase A anchoring protein (AKAP-121) (Scorziello et al. 2013). In addition, evidence has been provided on the presence of NCX1 in the nucleus at the level of the inner membrane where it contributes to the neuronal differentiation (Secondo et al. 2018). NCX2 was also found on neuronal neurotransmitter vesicles where it possibly participates in Ca^{2+} clearance and neurotransmitter release (Jeon et al. 2003; Takamori et al. 2006).

Regulatory Factors

Several factors are involved in the regulation of Na^+/Ca^{2+} exchanger activity: (i) the two transported cations, Na^+ and Ca^{2+}; (ii) the intracellular pH; (iii) the metabolic related compounds, ATP, PIP_2, PKA, and PKC; and (iv) reactive oxygen species, including NO.

The domains CBD1 and CBD2 are situated in the center of the intracellular f loop, and they regulate NCX activity but do not participate in Ca^{2+} transport. Indeed, nanomolar concentrations (20–50 nM) of intracellular Ca^{2+} are needed to activate the antiporter through the first Ca^{2+} binding site, CBD1, whereas submicromolar concentrations (0.1–0.3 μM) of intracellular Ca^{2+} are needed to increase the antiporter activity with the second Ca^{2+} binding site, CBD2 (Table 1).

An increase in $[Na^+]_i$ leads to an inactivation process of the exchanger. This inactivation

Na^+/Ca^{2+} Exchangers, Table 1 Regulatory mechanisms of Na^+/Ca^{2+} exchanger activity

Regulatory factors	Effect
$[Ca^{2+}]_i$	Increase Na^+/Ca^+ exchanger activity (low affinity, 0.1–0.3 μM; high affinity, 20–50 nM)
$[Na^+]_i$	$[Na^+]_i$-dependent inactivation of outward Ca^{2+} currents
NO	Stimulates NCX1 and NCX2 activity via a cGMP pathway Inhibits NCX3 activity via a direct nitrosylation
Sumoylation	Increases NCX3 protein half-life
Redox status	Oxidizing agents stimulate activity
PIP_2	Elimination of the $[Na^+]_i$-dependent inactivation
ATP	Increases $[Na^+]_o$-dependent Ca^{2+} efflux
PKC	Increases the affinity of $[Ca^{2+}]_i$ and $[Na^+]_o$ for the Na^+/Ca^{2+} exchanger
PKA	Increases exchange activity in splicing isoforms of NCX1 containing the exon 3 (namely, exon A)
PKT	Increases expression and activity of NCX1 and NCX3

process, very similar to the phenomenon occurring in voltage-dependent ionic channels, is named Na^+-dependent inactivation. In particular, this autoinhibition process seems to be mediated by the XIP domain that, in turn, might interact with a sequence of f loop including a portion of CBD2 (562–688), named P1. In accordance with this view, a synthetic peptide provided with the same sequence of XIP region binds the P1 region on the f loop and inhibits NCX activity. By contrast, a synthetic peptide provided with the same sequence of P1 domain binds the XIP sequence on the f loop and removes this latter from the inhibitory interaction with the P1 domain 562–688 on the f loop.

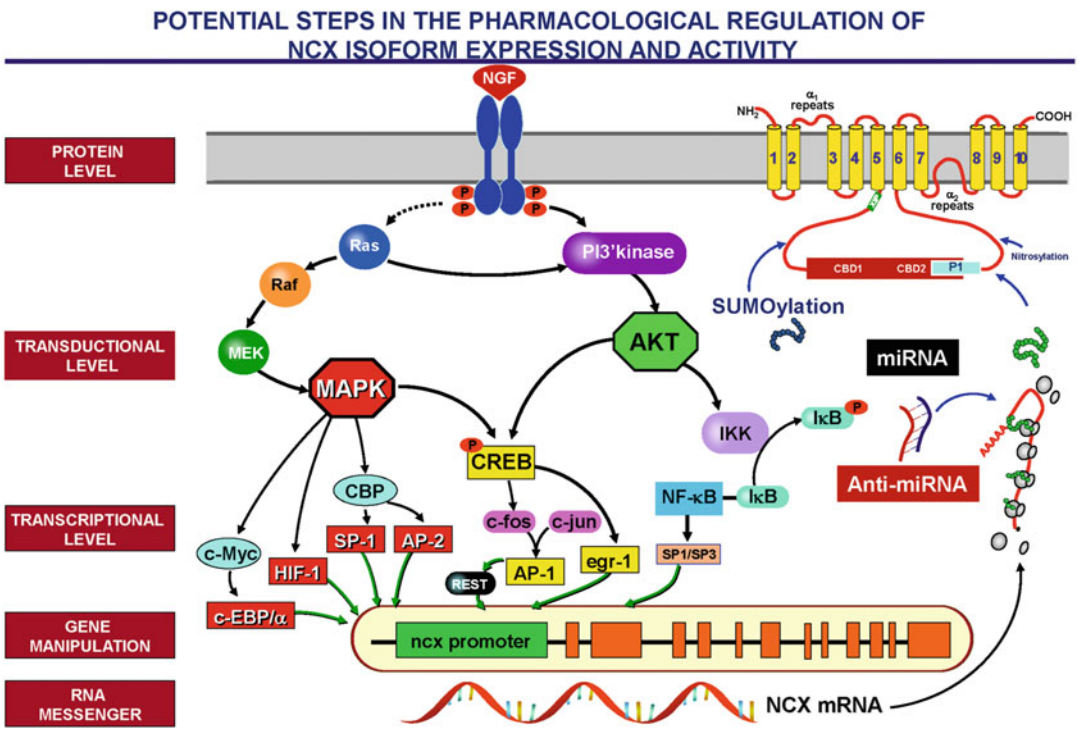
The intracellular pH can also regulate the exchanger. Indeed, reduction in $[pH]_i$ values, as little as 0.4, can induce a 90% inhibition of NCX activity under steady-state conditions. Such inhibitory action depends on the presence of intracellular Na^+ ions; hence, the action exerted by H^+ ions is pathophysiologically relevant with regard to brain and heart ischemia, two pathological conditions characterized by pH lowering.

ATP, acting as a phosphoryl donor molecule, may increase the activity of the exchanger in a number of ways. Firstly, ATP directly participates in the NCX molecule phosphorylation process by PKA and PKC. Secondly, it increases PIP_2 production. Finally, by activating G-protein-coupled receptors, via endogenous and exogenous ligands, ATP can stimulate the activity of the Na^+/Ca^{2+} exchanger through the pathway involving PKC or PKA activation. The mechanism underlying the phosphorylating effect on the exchanger is related to an increase in its affinity for both internal Ca^{2+} and external Na^+ and to a decrease in its inhibition by internal Na^+. Each of the NCX isoforms has distinctive putative phosphorylation sites; ATP cellular depletion inhibits NCX1 and NCX2 but does not affect NCX3 activity (Secondo et al. 2007; Linck et al. 1998). The other mechanism by which ATP can activate NCX occurs through the production of the lipid PIP_2. In fact, this lipid, binding the XIP region of the f loop, eliminates NCX inactivation and stimulates NCX function. In addition, Na^+/Ca^{2+} exchanger can be sensitive to reactive oxygen species, since modifications of the cellular redox state can cause an increase of NCX activity.

Transcriptional Factors Regulating NCX Expression

Several factors were identified to regulate the expression of NCX1 and NCX3 genes (Fig. 2), whereas no studies were reported on the transcriptional regulation of NCX2 gene.

Ncx1 gene expression appears to be directed by three alternative regulatory regions, named heart (Ht), kidney (Kd), and brain (Br) promoters. In cardiomyocytes, the expression of NCX1 is controlled by the Ht promoter that includes serum response factor (SRF), GATA-4, AP-1, and Nkx2.5 binding sites. In kidney, *ncx1* expression is controlled by the Kd promoter region that includes a typical TATA box preceded by two tandem GATA elements, NF-Y binding site, and two CAAT/enhancer binding protein-like (C/EBP-like) sites. Br *ncx1* promoter is a



Na^+/Ca^{2+} Exchangers, Fig. 2 Potential steps in the pharmacological regulation of NCX isoform expression and activity. This scheme reproduces the potential levels at which drugs can interfere with the transduction, transcription, translation, and activity of NCX

ubiquitous GC-rich TATA-less promoter, giving rise to the majority of *ncx1* transcripts in the CNS and also drives the expression of NCX1 in other tissues at lower levels. This region contains several putative binding sites for transcriptional factors including Sp1, AP1, AP2, nuclear factor kB (NF-kB), CREB, hypoxia-inducible factor 1 (HIF-1), and RE1-silencing transcription factor (REST). Recent data showed that NF-kB increases NCX1 protein expression in cortical neurons under hypoxic conditions (Sirabella et al. 2009). In addition, two epigenetic complexes also regulate NCX1 expression in stroke. The first complex comprises Sp3/REST/HDAC1/HDAC2 proteins and downregulates the expression of NCX1 in stroke. The second complex is composed of Sp1/HIF-1/p300 proteins and upregulates the expression of NCX1 in the stroke preconditioning. In addition, a number of microRNA were found to regulate NCX1 expression in several tissues (Table 2).

To date, the promoter of *ncx2* gene has not yet been identified, and moreover, no extensive data are available for its transcriptional regulation. The promoter of *ncx3* is located immediately upstream of the first exon and includes binding sites for AP-1, AP2, CREB, downstream regulatory element antagonist modulator (DREAM), Egr-1, KROX24, MyoD, GATA 2/3, and Sp1. Two of these transcription factors, CREB and DREAM, seem to be the most important regulators of *ncx3* gene transcription in response to changes in the intracellular concentrations of Ca^{2+} and cAMP.

Physiological Roles

Because of the limitations of pharmacological tools acting on NCX, several genetic modified mice were generated to identify the role of each isoform under physiological and pathophysiological conditions. Results showed that the genetic ablation of NCX1 is lethal, since it is essential for embryo development. By contrast, NCX2 and

Na^+/Ca^{2+} Exchangers, Table 2 Drug families inhibiting the Na^+/Ca^{2+} exchanger

Pharmacological class	Drugs
Amiloride derivatives	CB-DMB, DCB, DMB
Substituted pyrrolidines	Bepridil
Isothiourea derivatives	KB-R7943
Ethoxyanilines	SEA0400
Benzofuran derivatives	Amiodarone
Quinazolinone derivatives	SM-15811
Thiazolidine derivatives	SN-6
Phenoxypyridine derivatives	JP11092454
Nicotinamide derivatives	YM-244769
Piperidine derivatives	YM-252077
Ylacetamide derivatives	YM-270951
Benzamide derivatives	BED
Peptides	XIP, Glu-XIP, FMRFa, FRCRCF
Small interference RNA	siRNA-NCX1, siRNA-NCX1, siRNA-NCX3
microRNA	miR-103-1, miR-132, miR-135a, miR-206, miR-212-5p
Antisense oligodeoxynucleotides	AS-NCX1, AS-NCX2, AS-NCX3
Inorganic cations	Ni^{2+}, La^{2+}, Gd^{2+}

NCX3 knockout mice survive until the adulthood, and both mainly regulate neuronal Ca^{2+} clearance and synaptic plasticity with consequences on learning and memory processes (Jeon et al. 2003; Molinaro et al. 2011).

Pathophysiological Implications

In consideration of the relevant role played by the forward and reverse mode operation of NCX in the maintenance of $[Na^+]_i$ and $[Ca^{2+}]_i$ homeostasis in cells of the cardiovascular and central nervous system, alterations in gene structure, gene activation, protein expression, stability, and function may take part in the pathophysiology of several diseases. As matter of fact, homozygous overexpression of NCX1 in the heart results in mild cardiac hypertrophy and in a higher susceptibility to ischemia-reperfusion injury, whereas NCX1 gene deletion confers protection. In addition, NCX is widely recognized as a contributing factor to both impaired contractile performance and electrical instability like arrhythmia in human and experimental heart failure. It is also hypothesized that in salt-dependent hypertension, NCX1, operating in the reverse mode, may be involved in Ca^{2+} entry, thus resulting in vasoconstriction.

Recently, relevant roles have been attributed to NCX in brain disorders. In fact, several studies showed that NCX activation is desirable in numerous neurological disorders such as Alzheimer (Pannaccione et al. 2012; Sokolow et al. 2011), Parkinson (Sirabella et al. 2018), multiple sclerosis (Boscia et al. 2012; Casamassa et al. 2016), and stroke (Molinaro et al. 2008; Pignataro et al. 2004; Vinciguerra et al. 2014; Annunziato et al. 2007; Molinaro et al. 2016).

In particular, rats treated with NCX1 or NCX3 antisense and genetic modified mice lacking *ncx1* or *ncx3* display a remarkable enlargement of the infarct volume when subjected to stroke (Molinaro et al. 2016; Molinaro et al. 2008; Pignataro et al. 2004), whereas genetically induced NCX1 overexpression determines an amelioration of stroke (Molinaro et al. 2016). This evidence suggests that a pharmacological intervention aimed at increasing NCX expression and activity might be a promising perspective to reduce cerebral damage after ischemic insult.

More recently, the activity of NCX3 has been linked to myelination/demyelination processes occurring in multiple sclerosis. Indeed, silencing or knocking out NCX3 impairs the differentiation of oligodendrocyte precursor cells in mature oligodendrocytes producing myelin (Boscia et al. 2012), and the activation of NCX3 attenuates myelin damage and stimulates myelin repair (de Rosa et al. 2019).

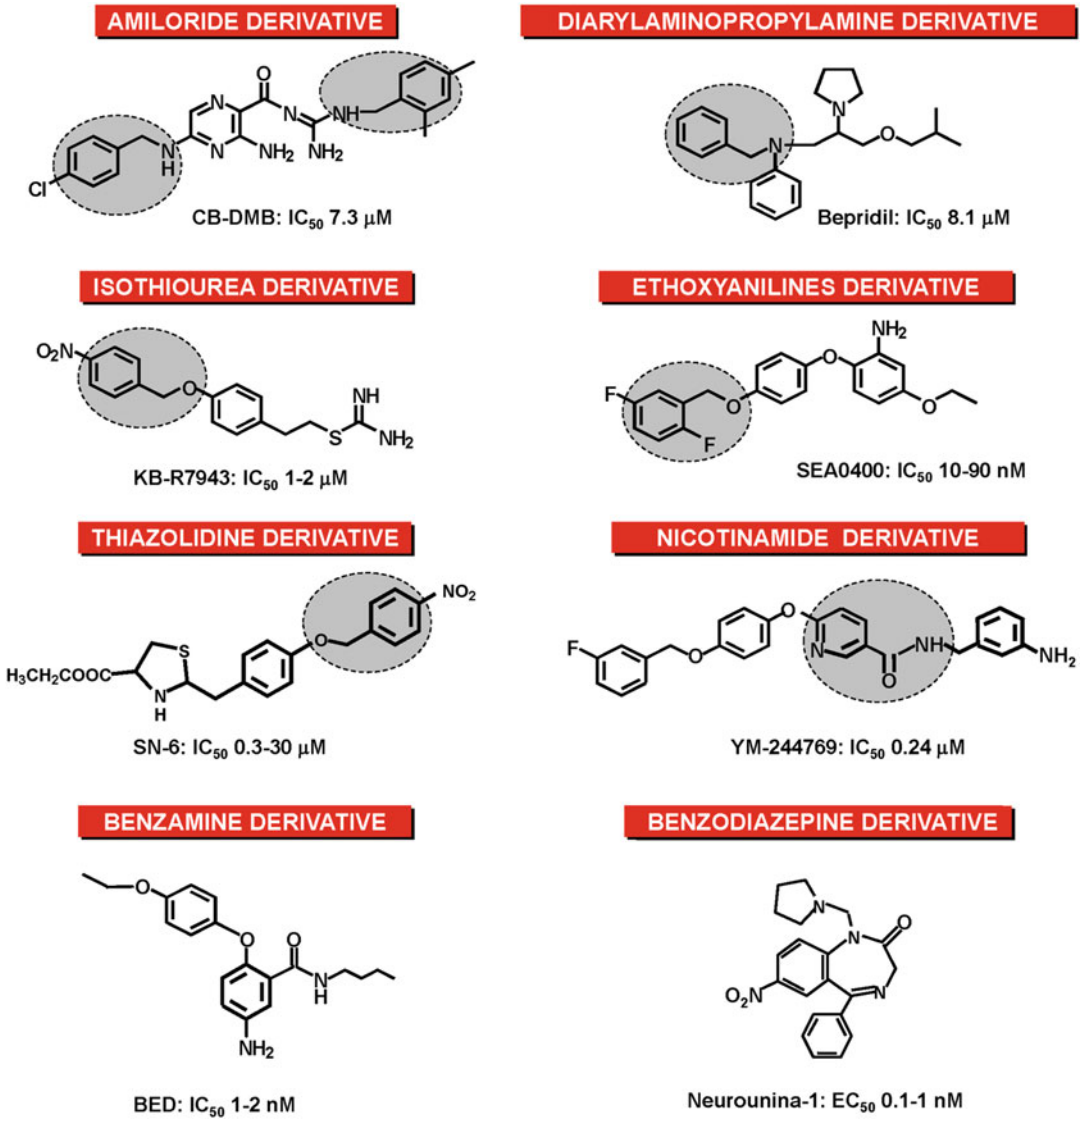
Drugs

Molecular Pharmacology of Na^+/Ca^{2+} Exchanger

The use of genetic-modified mice helped to discriminate the role played by each NCX gene product in several animal models mimicking human

pathological conditions. On the basis of results obtained, a great deal of interest has been devoted to find clinically effective drugs for those pathophysiological conditions, including cerebral ischemic disease, arrhythmias, heart failure, and hypertension, in which a stimulation or an inhibition of NCX might exert beneficial effects. To this aim, in the last 40 years, several inorganic and organic compounds have been reported to activate or to block NCX activity (Figure 3, Tables 2 and 3).

However, these compounds besides inhibiting NCX may also interfere with other cellular ion transporting mechanisms, i.e., Na^+ epithelial channels; K^+ channels; plasma membrane store-operated Ca^{2+} channels; VGCC-, NMDA-, and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid/kainate receptor-operated channels; Na^+/H^+ exchanger; Na^+/K^+ ATPase; and plasma membrane Ca^{2+} ATPase. In addition, other aspects that should be taken in consideration in the



Na^+/Ca^{2+} Exchangers, Fig. 3 Chemical structures of some NCX inhibitors. IC_{50}/EC_{50} values for NCX inhibition of drugs belonging to different chemical families. (Modified from Annunziato et al. (2004))

pharmacological modulation of NCX activity are (i) the existence of three different gene products NCX1, NCX2, and NCX3 that, although all share a high degree of amino acid sequence homology, display a different pharmacological sensitivity; (ii) the existence of at least 15 splicing variants for NCX1 and 5 for NCX3, each of them might be selectivity modulated by various compounds; and (iii) the double mode of operations of the exchanger, forward or reverse, that can be modulated in a differential manner by different drugs (Table 4). Thanks to site direct mutagenesis, a great advancement has been achieved in the last few years in the molecular pharmacology characterization of the domains, of the transmembrane segments, of the connecting loops, and finally of the single amino acids responsible of drug action (Fig. 1).

Na^+/Ca^{2+} Exchangers, Table 3 Compounds stimulating the Na^+/Ca^{2+} exchanger

Pharmacological class	Drugs
Redox agents	DTT, GSH, Fe^{2+}, O_2^- and of Fe^{3+}, H_2O_2
Heterocyclic compounds	Neurounina-1, CNPYB2
Inorganic cations	Li^+
Agonists of GPCRs	α, β agonists, histamine, 5HT $_{2c}$ agonists, endothelin-1, angiotensin-II
Peptides	Insulin, concanavalin A, tat-P1
Neurotrophic factors	NGF

Among the organic derivates, amiloride analogs were the first to be described as powerful inhibitors of NCX activity when the antiporter operates either in the forward or the reverse modes of operation. These compounds are reversible blockers and the inhibition is competitive with respect to Na^+ ions. The compounds of the amiloride family bearing substituents on the terminal guanidino hydrogen atom behave as a specific NCX inhibitor but are devoid of any effect on other antiporters such as Na^+/H^+ exchanger. Later, Shigekawa's and Iwamoto's groups identified an isothiourea derivative named KB-R7943 that is able to block the reverse mode operation of the antiporter in the low micromolar range, whereas concentrations 30 times higher are needed to

inhibit the forward mode. Another peculiarity of this isothiourea compound is the different ability to block NCX activity depending on the gene product involved. In fact, NCX3 inhibition requires concentrations that are threefold lower than those necessary to inhibit NCX2 and NCX1. KB-R7943 interacts with α_2 repeat of the exchanger molecule at the level of Ala809, Val820, Gln826, Gly833, and Asn839. In light of these peculiar pharmacological properties, KB-R7943 has aroused a great deal of interest among investigators working on NCX activity. However, an increasing number of reports have shown that KB-R7943 also exerts an inhibitory effect on several other transport mechanisms such as L-type voltage-gated Ca^{2+} channels and receptor-operated NMDA channels.

In 2001, a new compound belonging to the ethoxyaniline family, SEA0400, was reported as being the most potent NCX inhibitor available at the time, IC_{50} = 5–92 nM, with a predominant activity on NCX1, a lower affinity for NCX2, and no effect on NCX3. However, the specificity of SEA0400 on NCX activity has recently been questioned, since it can also interfere with Ca^{2+} movement across the cell membrane. In 2002, by screening benzyloxyphenyl derivatives, Iwamoto's group discovered the new compound SN-6, which differs from KB-R7943 only in the substituent of phenyl moiety. The presence of this phenyl group confers to this antiporter inhibitor a more selective action on NCX1 rather than NCX3. Using chimeric analysis and subsequent site-directed mutagenesis, some critical amino acid residues responsible for SN-6 inhibition in the XIP region of the antiporter have been identified. Interestingly, SN-6 preferentially acts on the exchanger under ATP-depleted conditions (Iwamoto 2004).

In addition, the further screening of new benzyloxyphenyl derivatives revealed a highly potent NCX inhibitor, named YM-244769. This orally bioavailable compound is more potent inhibiting NCX3 than NCX1 and NCX2 in the reverse mode, but it is not active on the forward mode of operation of the three antiporter isoforms (Table 4).

Finally, two new compounds have been synthesized, 7-nitro-5-phenyl-1-(pyrrolidin-1-ylmethyl)-1H-bezo[e][1,4]diazepin-2(3H)-one (neurounina-1) that increases both NCX1 and NCX2 activity in a concentration-dependent manner (Molinaro et al. 2013), and 5-(2-chlorophenyl)-7-nitro-1-(pyrrolidin-1-ylmethyl)-1H-benzo[e][1,4]diazepin-2(3H)-one 2,2,2-trifluoroacetate (CN-PYB2), that selectively stimulates NCX1 activity in a concentration-dependent manner (Natale et al. 2020). More important, since NCX activity is involved in stroke pathophysiology, neurounina-1 has been reported as neuroprotectant agent in in vitro and in vivo model of adult and neonatal brain ischemia (Molinaro et al. 2013; Cerullo et al. 2018).

In addition to the conventional pharmacological strategies, new techniques were used to selectively inhibit each NCX gene product. These strategies consist in the antisense oligodeoxynucleotide, small interference RNA, and microRNA directed against mRNA encoding for NCX1, NCX2, or NCX3. On the contrary, when it is required to increase NCX expression and/or activity, it may be useful to use antimiRNA strategy to prevent NCX downregulation. For instance, miR-103-1 downregulates NCX1 in stroke; thus the antimiR-103-1 was proposed to reduce brain damage and neurological deficits in a preclinical model of stroke (Vinciguerra et al. 2014). This strategy, coupled with new nanotechnologies for drug delivery and release in CNS, might offer an additional opportunity to develop new effective therapies for stroke.

Glossary

CBD1 and CBD2 Calcium binding domain 1 and 2 of the f loop

f loop Intracellular domain between transmembrane segments 5 and 6 of the sodium calcium exchanger

Forward or Ca^{2+} efflux mode Mode of operation of NCX extruding calcium and intruding sodium ions

Na^+/H^+ Exchangers

Rebecca Flessner and John Orlowski
Department of Physiology, Faculty of Medicine and Health Sciences, McGill University, Montreal, QC, Canada

Synonyms

Sodium/proton exchanger; Sodium/proton antiporter; Alkali cation/proton exchanger; Alkali cation/proton antiporter; Solute carrier 9 family

Definition

Sodium (Na^+)/proton (H^+) exchangers or antiporters (NHE or NHA) are a structurally diverse group of integral membrane proteins that mediate the counterion movement of Na^+ in exchange for H^+ across biological membranes of virtually all living organisms. Certain NHEs/NHAs also

transport other alkali metals or monovalent cations such as lithium (Li^+), potassium (K^+), and ammonium (NH_4^+). As such, this class of transporters is more aptly referred to as alkali or monovalent cation/proton exchangers or antiporters. Mammals encode 13 distinct *NHE/NHA* genes (classified as the solute carrier 9 (*SLC9*) family by the Human Genome Organization, HUGO), several of which undergo alternative splicing of their precursor mRNAs that has the potential to expand their functional diversity. These transporters are expressed in cell- and subcellular-specific patterns and exhibit unique substrate specificities, drug sensitivities, and regulatory properties. They are instrumental in regulating not only cellular and systemic pH, electrolyte and fluid volume homeostasis, but also in supporting other vital biological processes that range from organellar biogenesis, trafficking, and function to the control of cell differentiation, shape, adhesion, migration, proliferation, survival, and apoptosis. Given their involvement in such wide-ranging activities, it is not surprising that disruptions of their normal operations have been linked to various pathophysiologic conditions, including heart and brain ischemia/reperfusion injuries, diabetes, hypertension, congenital secretory diarrhea, infertility, tumor progression, and neurological disorders. Thus, there is considerable interest in developing therapeutic strategies to countermand these afflictions.

Basic Characteristics

The *SLC9* gene family consists of three subgroups: the *SLC9A* (encoding SLC9A1–9/NHE1–9), *SLC9B* (encoding SLC9B1–2/NHA1–2), and *SLC9C* (encoding SLC9C1–2/NHE10–11) subfamilies that share approximately 13–71% amino acid identity (Fig. 1a) (Brett et al. 2005; Casey et al. 2010; Pedersen and Counillon 2019). Several of the *SLC9* genes undergo alternative cis-splicing of their precursor mRNAs which in principal increases their protein diversity (Table 1), but evidence supporting unique functional properties for the different splice-variants is wanting. Much of our basic understanding of these transporters comes from studies of the SLC9A (NHE1–9) subfamily. NHE1 is present in most tissues whereas NHE2–5 are expressed in a tissue-specific manner (Table 2). Irrespective of their tissue distribution, all are primarily active at the plasma membrane where they preferentially exchange extracellular Na^+ (and to a lesser extent Li^+ and NH_4^+) for cytoplasmic H^+ (i.e., Na^+-selective NHEs) (Table 3). However, NHE3 and NHE5 are also present in intracellular vesicles that are thought to serve as reservoirs of functional transporters that can be rapidly mobilized to the plasma membrane (or conversely internalized from the cell surface) in response to various hormonal, metabolic, or physical stimuli. By contrast, NHE6–9 are widely expressed and reside predominately in organelles of the biosynthetic (i.e., Golgi cisternae, trans-Golgi Network, and post-Golgi vesicles) and endocytic (i.e., early/sorting, recycling, and late endosomes) pathways, though low levels can also be detected at the cell surface (Table 2). While their kinetic properties have not been extensively characterized, limited measurements indicate that endomembrane NHEs are capable of transporting not only Na^+ but also K^+, the main cytoplasmic monovalent cation, in exchange for H^+ (i.e., non-selective alkali cation NHEs). Structurally, members of the SLC9A/NHE and SLC9B/NHA subfamilies share a similar predicted membrane topology with 12 highly conserved transmembrane α-helices at their amino-termini responsible for ion translocation and less-conserved carboxy-termini that are involved in membrane-targeting and regulation of activity (Fig. 1b). By contrast, SLC9C1–2/NHE10–11 are projected to possess 14 transmembrane helices involved in ion exchange, plus an additional 4 transmembrane helices encoding a unique voltage-sensor, followed by a cyclic nucleotide binding domain located in the cytoplasm. However, all of the exchangers are presumed to assemble and function as homodimers. The NHEs/NHAs operate as electroneutral (e.g., $1Na^+:1H^+$) secondary active transporters that can reversibly exchange ions depending on their relative electrochemical concentration gradients. The plasma membrane Na^+-selective NHEs display classical Michaelis-Menten kinetics with respect to the extracellular Na^+ concentration (Fig. 1c). On the other hand, they exhibit positive cooperative binding of intracellular H^+ (i.e.,

Hill coefficient > 1). This feature allows the exchangers to have low activity at resting physiological pH (i.e., ~pH 7.2) but can activate quickly in response to slight increases in intracellular acidity (Fig. 1c).

The following section provides an overview of the tissue and subcellular distributions, functions, and pathophysiological disorders of SLC9 family members (summarized in Table 2). Additional details can be found in the following reviews (Orlowski and Grinstein 2011; Donowitz et al. 2013; Pedersen and Counillon 2019). Due to space constrains, it was not possible to cite much of the primary literature.

SLC9A Subfamily

***NHE1*:** NHE1 is responsible for maintaining cytoplasmic pH near neutral, thereby protecting cells against excessive acidification. NHE1 activity is also coupled functionally with Cl^-/HCO_3^- or anion exchangers to mediate the electroneutral absorption of NaCl, followed by the attendant uptake of water, into cells to restore cell volume following hyperosmotic-induced cell shrinkage. In addition to these housekeeping roles, NHE1 accumulates within certain microdomains of the plasma membrane in some cell types where it has been implicated in more specialized functions. For example, NHE1 accrues at the leading edge of migrating fibroblasts where it associates with the cytoskeletal-associated proteins ezrin, radixin, and moesin. This interaction influences cell shape and facilitates remodelling of the cortical actin cytoskeleton during adhesion and migration. In rat heart, NHE1 localizes at intercalated discs and transverse tubules of both atrial and ventricular myocytes where it is postulated to regulate the pH microenvironment of pH-sensitive proteins at the intercalated discs (e.g., connexin43) and cytoplasmic surface of sarcoplasmic reticulum cisternae (e.g., ryanodine receptors), thereby modulating impulse conduction and excitation-contraction coupling. In mouse hippocampus, NHE1 resides predominantly at presynaptic nerve terminals of both excitatory glutamatergic and inhibitory γ-aminobutyric acid (GABA)-ergic neurons, suggesting an important role in synaptic transmission.

Despite its involvement in numerous physiological processes, ablation of *Nhe1* expression by gene knockout (KO) in mice is not embryonic lethal, but the homozygous mutants suffer from postnatal growth retardation, ataxia, seizures, and significant mortality (~2/3 of pups die by 4 weeks of age). Mutations in *NHE1* have also been documented in humans and are associated with related neurological deficits, including ataxia and epilepsy (Lichtenstein-Knorr Syndrome). The underlying mechanisms are complex and not fully resolved. The neuronal hyperactivity leading to convulsive episodes in constitutive *Nhe1* KO mice was initially attributed, at least in part, to upregulation of voltage-sensitive Na^+ channels in excitatory pyramidal cells of the hippocampus and cortex. However, ensuing analyses using conditional *Nhe1* KO mice indicated that the enhanced network excitability arose predominantly from depressed GABA release from

Na^+/H^+ Exchangers, Table 2 Functional characteristics of the mammalian SLC9/NHE gene family

Gene	Tissue distribution & membrane location	Principal physiological functions	Relations to pathophysiology
SLC9A1/ NHE1	Ubiquitous Plasma membrane/ basolateral in epithelia	Na^+ (Li^+, NH_4^+) /H^+ Cytoplasmic pH regulation Cell volume regulation Fluid secretion Cell shape, adhesion, migration, & proliferation	Ischemia/reperfusion injuries Diabetes-associated vascular hypertrophy Ataxia, seizures, postnatal lethal Lichtenstein-Knorr syndrome Reduced parotid gland secretion
SLC9A2/ NHE2	Multiple tissues (stomach, colon > prostate, testis, kidney > others) Plasma membrane/ apical in epithelia.	Na^+ (Li^+) /H^+ Fluid secretion (Re)absorption of HCO_3^- in renal distal tubules Maintenance of intestine epithelial tight junctions	Gastric achlorhydria Elevated levels of renin in renal cortex Absorptive defects in kidney, colon, and pituitary Reduced parotid gland secretion Low fertility
SLC9A3/ NHE3	Kidney, intestines, other epithelial tissues, brainstem Apical membrane & subapical vesicles of epithelia	Na^+ (Li^+, NH_4^+) /H^+ Na^+ (direct), HCO_3^-, Ca^{2+} and H_2O (indirect) (re)absorption in kidney and intestines Early endosome acidification Regulation of brainstem control of breathing	Diarrhea Metabolic acidosis, hyperkalemia, urinary salt wasting, and hypotension Renal tubular proteinuria Decreased cortical bone mineral density and trabecular bone mass Sudden infant death syndrome?
SLC9A4/ NHE4	Stomach, kidney, Plasma membrane / basolateral in epithelia	Na^+ (NH_4^+) /H^+ Cytoplasmic pH regulation Fluid secretion NH_4^+ absorption by medullary thick ascending limb	Impaired gastric acid secretion Hyperchloremic metabolic acidosis Impaired urinary net acid excretion
SLC9A5/ NHE5	Multiple tissues (spleen > > testis > brain) Plasma membrane & intracellular vesicles	Na^+ (Li^+)/H^+ Cytoplasmic pH regulation Modulation of dendritic spine growth in response to neuronal activity	Elevated BDNF/TrkB signaling, learning, and memory
SLC9A6/ NHE6	Ubiquitous Plasma membrane & recycling endosomes Stereocilia of sensory hair cells	(Na^+, K^+)/H^+ Recycling endosomal and hair cell stereocilia pH regulation Maintenance of apical bile canalicular membranes in polarized hepatocytes	Christianson syndrome Autism spectrum disorder
SLC9A7/ NHE7	Ubiquitous *trans*-Golgi network & associated secretory vesicles	(Na^+, K^+)/H^+ Organellar pH regulation	Intellectual disability Overexpression enhances breast tumor growth and formation
SLC9A8/ NHE8	Ubiquitous Apical membranes in renal and intestinal epithelia Golgi cisternae & *trans*-Golgi network; late endosomes	(Na^+, K^+)/H^+ Renal and intestinal Na^+ absorption, Modulates late endosomal morphology and protein trafficking along the degradative pathway	Impaired mucin synthesis and HCO_3^- secretion in stomach and colon Reduced ocular surface function and degeneration of retinal pigmented epithelial and photoreceptor cells Male infertility
SLC9A9/ NHE9	Ubiquitous Plasma membrane & recycling endosomes Stereocilia of sensory hair cells	(Na^+, K^+)/H^+ Recycling endosomal and hair cell stereocilia pH regulation	Attention-deficit hyperactivity disorder Autism-spectrum disorder

Values obtained from References (Yu et al. 1993; Peti-Peterdi et al. 2000; Szabó et al. 2000; Chambrey et al. 2001; Nakamura et al. 2005; Xu et al. 2008; Pedersen and Counillon 2019). Range of values for certain substrates reflects analyses of NHEs from different mammalian species (rat, rabbit, and human) and assay conditions

parvalbumin-positive inhibitory interneurons rather than changes in the intrinsic excitatory properties of glutamatergic neurons (Bocker et al. 2019).

On the other hand, NHE1 over-activity contributes to ischemia-reperfusion injury in energy-demanding tissues such as heart and brain. Under hypoxic conditions, cells switch from aerobic to anaerobic metabolism of the limited stores of glucose and glycogen leading to intracellular acidification (due to lactate and H^+ buildup). While activation of NHE1 can rapidly restore intracellular pH, the concomitant increase in intracellular Na^+ cannot be expelled effectively by the Na^+/K^+-ATPase due to depleted ATP levels. Disruption of the transmembrane Na^+ and K^+ gradients triggers a cascade of events leading to a pathological rise in intracellular Ca^{2+} and activation of numerous signaling pathways that exacerbate and accelerate cardiovascular and cerebrovascular injury, a phenomenon known as excitotoxicity. A damaging role for NHE1 in these circumstances is supported by studies showing that specific NHE1 antagonists or genetic ablation alleviate injuries associated with cardiac and neural ischemia both in vitro and in vivo (Karmazyn 2013). Finally, elevated NHE1 activity is implicated in cancer and has been shown to promote tumorigenesis at multiple levels including cell proliferation, migration, invasion, and suppression of apoptosis. Inhibition

of NHE1 attenuates primary tumor growth and metastasis in animal studies, and thus may be an additional target in the design of potent combination chemotherapies (Stock and Pedersen 2017).

Aside from intracellular acidification and cell shrinkage, NHE1 activity can also be regulated by covalent modifications to its C-terminal tail. Phosphorylation by extracellular-regulated kinases 1 and 2 (Erk1/2), calmodulin kinase II (CaMKII), and p38 kinase are stimulatory and allow the exchanger to be active at more alkaline pH. Protein-protein interactions with calmodulin, carbonic anhydrase II, and calcineurin homologous proteins 1, 2, and 3 (CHP1–3) are also known to increase NHE1 activity. Finally, phosphoinositides located in the inner leaflet of the plasma membrane, particularly phosphatidylinositol 4,5-bisphosphate (PI(4,5)P_2 or PIP_2), are a key component in NHE1 function since a reduction of PIP_2 levels dramatically decreases NHE1 activity. As a result, NHE1 activity is indirectly dependent on ATP levels because PIP_2 levels are reduced in low-ATP states.

***NHE2*:** NHE2 is highly expressed on the apical membranes of epithelial cells in the gastrointestinal tract and kidneys, among other tissues. NHE2 is thought to contribute to cytoplasmic pH homeostasis as well as luminal Na^+ and indirectly bicarbonate absorption; however, *Nhe2* KO mice display no apparent intestinal or renal absorptive defects. This is likely due to compensatory increases in NHE3 activity, as the expression patterns of these two isoforms overlap considerably. NHE2 plays an important role in gastric parietal cell viability; loss of NHE2 in mice leads to parietal cell degeneration and decreased acid secretion in the stomach. Finally, NHE2 has a key function in repairing epithelial cell damage, as NHE2 KO mice display an impaired ability to repair the epithelial wall and restore tight junctions following damage to the stomach and intestines.

Like NHE1, basal NHE2 activity is dependent on binding CHP1 and is activated by stimuli that elevate protein kinase A (PKA) and protein kinase C (PKC). Interestingly, regulation of NHE2 is sometimes dependent on its location. For example, epidermal growth factor (EGF) increases NHE2 levels in the intestines but does not affect its expression in the kidneys. Similarly, extracellular acidosis stimulates an increase in NHE2 mRNA in the intestines but leads to a decrease in NHE2 mRNA in the kidneys.

***NHE3*:** Similar to NHE2, NHE3 is highly expressed in the apical membrane of intestinal and renal epithelial cells. In addition to its localization at the plasma membrane, NHE3 is present in subapical vesicles that can be trafficked rapidly to and from the cell surface membrane in response to different stimuli. NHE3 plays a major role in renal and intestinal Na^+ absorption, which is critical for water reabsorption and urine concentration. In addition, transport of H^+ ions into the renal lumen is one of the major pathways for bicarbonate reabsorption. *Nhe3* KO mice have diarrhea, increased urine output, decreased blood pressure, and mild acidosis. Thus, despite overlapping expression with NHE2 and NHE8, NHE3 is thought to be the major intestinal and renal NHE.

Loss-of-function mutations in NHE3 have been documented in patients with congenital sodium diarrhea (CSD), a rare condition characterized by severe, uncontrollable diarrhea with high fecal Na^+ loss from birth. Decreased NHE3 activity has also been observed in patients with inflammatory bowel disease (IBD) and may contribute to diarrhea in these individuals as well. In contrast, NHE3 overactivity may be a contributing factor to hypertension and thus could be a potential therapeutic target, although this link has only been documented in animal studies thus far.

NHE3 activity is responsive to both local and systemic stimuli. In the gut, NHE3 activity is adjusted in response to digestion, whereas renal NHE3 activity is regulated in response to total body volume and acid-base homeostasis. Hormonal stimulation of PKA, which phosphorylates the C-terminal tail of NHE3, inhibits its activity and modulates its subcellular location. Activation of PKC also downregulates NHE3 in a similar manner, but this seemingly occurs independently of direct phosphorylation by PKC. Conversely, phosphorylation by protein kinase CK2 or serum- and glucocorticoid-inducible kinase 1 (SGK1) stimulates NHE3 trafficking to the cell surface, therefore increasing its activity. This acute regulation of NHE3 activity also requires the binding of other ancillary proteins, such as CHP1, ezrin, and Na^+/H^+ exchanger regulatory factors 1 and 2

(NHERF1 and NHERF2). In addition to these acute regulatory mechanisms, NHE3 is regulated at the transcriptional and translational levels. Glucocorticoids, thyroxine, aldosterone, butyrate, and chronic metabolic acidosis lead to increased expression of NHE3, whereas chronic exposure to proinflammatory cytokines interferon-gamma (IFN-γ) and tumor necrosis factor alpha (TNF-α) lead to a reduction in NHE3 levels.

NHE4: NHE4 is expressed at high levels in the basolateral membranes of stomach parietal and chief cells as well as epithelial cells of the renal thick ascending limb and distal convoluted tubule. NHE4 is also present at lower levels in renal collecting ducts and proximal tubules. In stomach, NHE4 activity is coupled with the Cl^-/HCO_3^- exchanger 2 or anion exchanger 2 (AE2). Together, these two exchangers facilitate the electroneutral absorption of NaCl and, therefore, water absorption. *Nhe4* KO mice display reduced stomach acid secretion, a decreased number of parietal and mature chief cells, and an increased number of necrotic and apoptotic cells. Notably, this phenotype is similar to that of *Ae2* KO mice and suggests that the physiological role of NHE4 is to maintain cell volume and protect against apoptosis during acid secretion. In the kidney, NHE4 is important for ammonia excretion in the urine, where it is thought to catalyze Na^+/NH_4^+ exchange and serves as a principal means of renal acid secretion. *Nhe4* KO mice display reduced NH_4^+ reabsorption, metabolic acidosis, and a distinct inability to increase renal net acid secretion upon oral acid load. In rat and human colon crypt epithelia, NHE4 is activated in response to aldosterone, but not to cAMP or hyperosmolarity. Conversely, in rabbit gastric epithelium, cAMP and hyperosmolarity elevate NHE4 activity. Thus, the regulation of NHE4 is also cell-type dependent. At present, there are no known human diseases related to NHE4 dysfunction.

***NHE5*:** NHE5 transcripts are detected at low levels in most tissues but are highest in spleen $>>$ testis $>$ brain. However, most studies have examined its roles in brain where it localizes to discrete vesicles in neurons of the cerebral cortex, amygdala, hippocampus, and other regions. NHE5 has been shown to regulate pH of the postsynaptic compartment of hippocampal neurons which indirectly controls dendritic spine growth. Following synaptic activity, NHE5 is trafficked from recycling endosomes to the plasma membrane of dendritic spine heads. The increase in NHE5 activity leads to an acidification of the synaptic cleft, which inhibits N-methyl-D-aspartate (NMDA) receptors and attenuates dendritic spine growth. Conversely, NHE5 KO mice, while outwardly normal, display increased synaptic spine density in the brain and enhanced learning and memory that correlates with elevated brain-derived neurotrophic factor (BDNF)/tyrosine receptor kinase B (TrkB) signaling. In addition to its role at the plasma membrane, NHE5 contributes to the endosomal acidification and cell surface trafficking of the TrkA receptor, which in turn promotes neurite outgrowth in rat neuroendocrine PC12 cells treated with nerve growth factor (NGF). While mutations in NHE5 have not been linked to human disease, a study in rats showed an elevated level of NHE5 in C6 glioma cells is responsible for elevated MET and EGF tyrosine kinase receptor signaling and increased tumor growth, proliferation, and invasion.

NHE5, like NHE3, is acutely regulated by trafficking between the plasma membrane and recycling endosomes. Internalization of NHE5 relies on an interaction with β-arrestin2, which depends upon phosphorylation of an acidic serine/threonine di-isoleucine motif in its C-terminal tail by protein kinase CK2. Filamentous actin dynamics are also important for its internalization, as disruption of the actin cytoskeleton with cytochalasin D increased NHE5 abundance at the plasma membrane. On the other hand, trafficking of NHE5 from endosomes to the plasma membrane is enhanced by interactions with secretory carrier membrane protein 2 (SCAMP2) and AMP-activated protein kinase (AMPK), the latter activated upon metabolic stress. Finally, NHE5 transport activity is inhibited by PKA, PKC, and cell shrinkage.

***NHE6*:** NHE6 is widely expressed but is especially abundant throughout the central nervous system. This isoform regulates the pH homeostasis and membrane trafficking of early and recycling endosomes. Mutations in NHE6 are linked to Christianson Syndrome, an X-linked

neurodevelopmental disorder characterized by developmental delay, epileptic seizures, ataxia, hyperkinetic behavior, and degeneration of cortical, hippocampal, and especially cerebellar neurons. It is thought that these neurological deficits are largely due to disrupted endosomal trafficking, as loss of NHE6 in neurons causes over-acidification of early and recycling endosomes and enhanced degradation of their neurotrophic (e.g., TrkB receptor) and ionotropic (e.g., AMPA receptors) cargo in hippocampal neurons. Consequently, these neurons display reduced dendritic arborization, decreased density of mature dendritic spines and impaired neuronal circuit strength and synaptic plasticity. Decreased NHE6 activity has also been linked to Alzheimer's disease. The acidic endosomal pH associated with reduced NHE6 activity correlated with more efficient production and secretion of amyloid beta (Aβ) from endosomes which may contribute to the formation of Aβ plaques.

The mechanisms responsible for regulating NHE6 activity remain largely unknown. However, RACK1 is known to interact with the NHE6 C-terminal tail and appears to have a role in regulating NHE6 trafficking between endosomes and the plasma membrane. Loss of RACK1 leads to a decrease in cell surface levels of NHE6 accompanied by an increase in endosomal pH. Thus, RACK1 activity could play a role in regulating endosomal pH and trafficking by altering NHE6 localization.

***NHE7*:** NHE7 expression is ubiquitous but especially abundant in the brain, skeletal muscle, and various secretory tissues. It localizes mainly to the *trans*-Golgi network (TGN), although lower levels are also detected in the Golgi cisternae as well as post-Golgi vesicles that deliver cargo to the plasma membrane. A gain-of-function mutation in NHE7 has been identified in two unrelated families with X-linked intellectual disability (Khayat et al. 2019). These individuals display moderate to severe cognitive dysfunction, hypotonia, and muscle weakness. This correlated with excessive alkalinization of the TGN and aberrant glycosylation of exported proteins.

The distribution of NHE7 between the TGN and vesicles seems to rely on interactions with SCAMP1, SCAMP2, and SCAMP5. For example, expression of a dominant-negative SCAMP2 results in NHE7 redistribution to recycling endosomes. On the other hand, the factors that regulate NHE7 ion exchange activity are largely unknown. One study, however, has shown that calmodulin has a stimulatory effect on NHE7 activity.

NHE8: NHE8 is expressed in multiple tissues and is found in the *mid*- and *trans*-Golgi cisternae as well as late endosomes/multivesicular bodies. Similar to the other endomembrane NHEs, NHE8 is thought to play a role in regulating the pH of these compartments. NHE8 also seems to be important for endosomal trafficking, as NHE8 knockdown in HeLa cells disrupts protein trafficking and causes late endosomal and lysosomal clustering around the perinuclear region.

In addition to its intracellular localization, NHE8 is found on the apical membrane of epithelial cells in renal proximal tubules and gastrointestinal tract. Like NHE3, NHE8 is involved in Na^+ and bicarbonate reabsorption in the kidney. Notably, NHE3 and NHE8 appear to be developmentally regulated such that NHE8 is the primary brush border NHE in neonates and NHE3 is predominant in adults. Despite this, NHE8 KO mice display no renal deficits due to a compensatory upregulation of NHE3 surface expression and activity. NHE8 KO mice also show no indication of absorptive deficits in the intestines due to compensation by both NHE2 and NHE3. However, NHE8 appears to have a more critical role in mucosal protection of the stomach and intestines, as NHE8 KO mice display decreased mucosal pH and increased susceptibility to ulcers. Consistent with this, decreased NHE8 levels have been documented in the colons of ulcerative colitis patients (Li et al. 2016).

NHE8 activity can be acutely regulated by altering its trafficking to and from the plasma membrane. For example, acid loaded cells display increased NHE8 surface expression despite unchanged total cell protein levels. NHE8 activity is also upregulated at the transcriptional level by somatostatin, but downregulated by glucocorticoids, TNF-α, and EGF signaling.

NHE9: NHE9 is ubiquitously expressed and largely confined to a subpopulation of recycling endosomes that overlap partially with NHE6. Mutations in NHE9 have been linked to attention deficit hyperactivity disorder, autism spectrum disorder, and epilepsy. Autism-associated variants of NHE9 were found to disrupt trafficking of the glutamate aspartate transporter (GLAST) and glutamate uptake in astrocytes, thereby disrupting normal neuronal function. Abnormal elevation of NHE9 activity has also been linked to cancer progression, particularly glioblastomas, and correlated with enhanced EGF receptor signaling that promoted tumor growth, enhanced cell migration, and poor survival outcomes.

SLC9B Subfamily

***NHA1–2*:** NHA1 is expressed exclusively in the testes, where it is localized specifically to sperm flagella. While the properties of NHA1 transport are unknown, loss of NHA1 in mice causes a partial reduction in sperm motility and, consequently, reduced pregnancy rates in females. NHA2 is also found in sperm flagella and its knockdown results in a similar phenotype. Loss of NHA1 leads to a compensatory upregulation of NHA2 and vice versa, indicating these two proteins are functionally redundant in the testes. Double KO of NHA1 and NHA2 causes complete infertility in male mice.

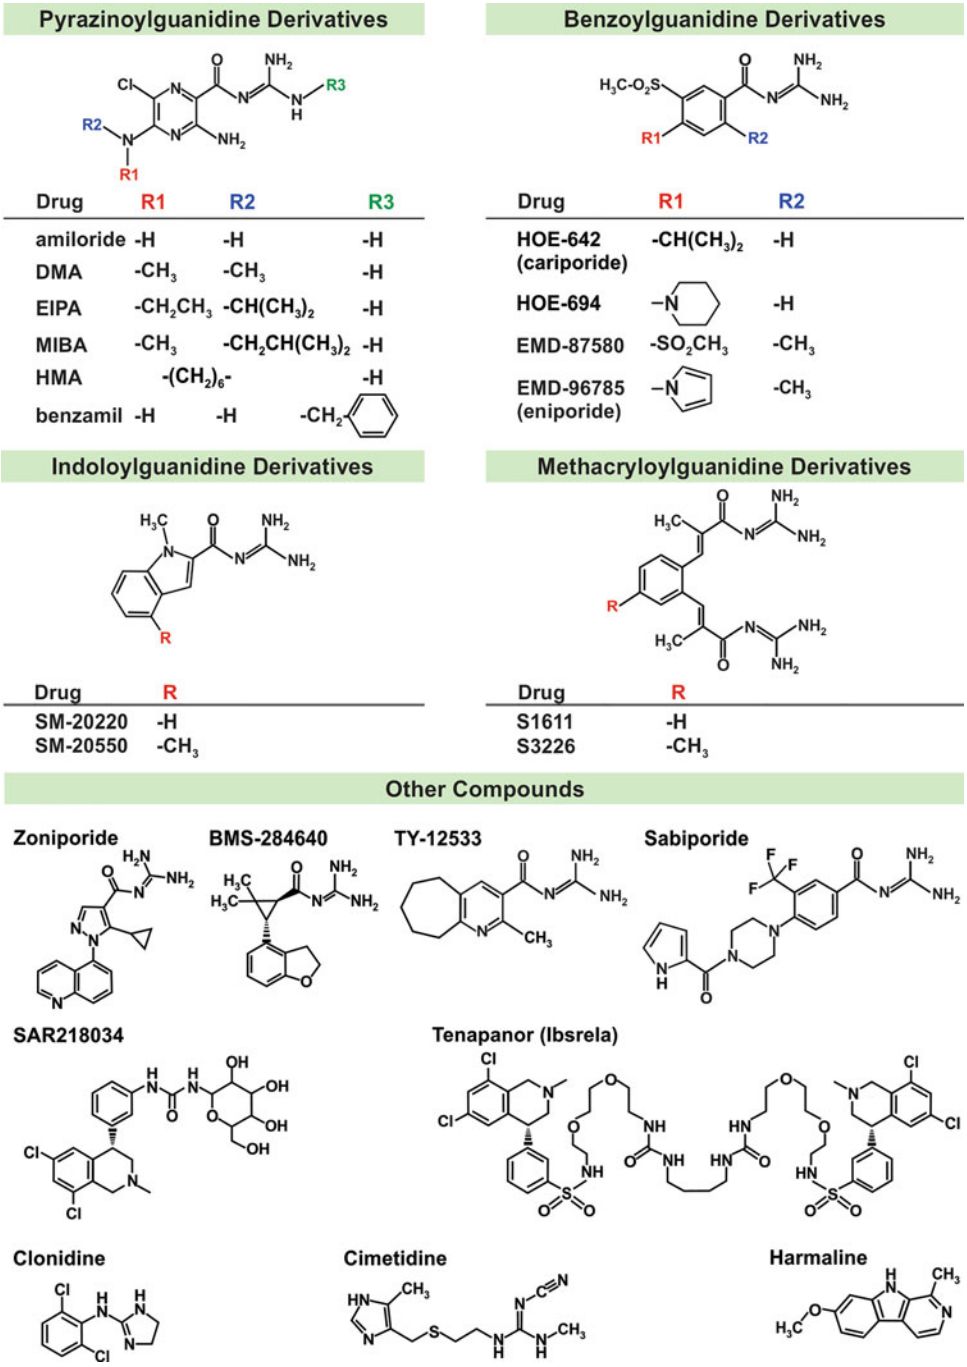
Unlike NHA1, NHA2 is ubiquitously expressed and appears to have specialized localizations and functions depending on the cell type. In β cells of the pancreas, NHA2 is localized to endosomes and has an important role in insulin secretion. NHA2-depleted mice have disrupted clathrin-mediated endocytosis, reduced secretagogue-induced insulin secretion, and abnormal glucose tolerance. Interestingly, however, loss of NHA2 does not affect endosomal pH in β-cells. NHA2 is also found at the plasma membrane of renal distal convoluted tubules where the fine-tuning of Na^+ reabsorption takes place to maintain systemic salt homeostasis. NHA2 has been postulated to be the Na^+/Li^+ countertransporter associated with essential hypertension.

SLC9C Subfamily

NHE10–11: NHE10 was originally referred to as the sperm NHE (sNHE) because it is expressed almost exclusively in the flagella of spermatozoa, a pattern similar to NHA1. Loss of NHE10 renders sperm immotile and causes complete infertility; a phenotype that could be rescued by alkalinizing agents, such as ammonium chloride, or cAMP analogues. Subsequent studies revealed that NHE10 forms a complex with an atypical soluble adenylyl cyclase (sAC/Adcy10) that is directly stimulated by bicarbonate. Activation of sAC activity produces cAMP that then binds to the cyclic nucleotide binding domain of NHE10 and allows it to activate at more depolarized membrane potentials. The resulting sustained NHE10 activity alkalizes the sperm and activates CatSper channels that facilitate Ca^{2+} influx. In turn, the elevated intracellular Ca^{2+} activates signaling pathways that enhance sperm motility. While mutations in *NHE10/SLC9C1* have not been linked to male infertility in humans, the exchanger could be a potential target for contraception. NHE11 is also predominantly expressed in testes, but virtually nothing is known about its function.

Drugs

A wide variety of drugs have been developed to inhibit NHE activity, particularly NHE1 and NHE3, in an effort to treat pathophysiologic conditions where these transporters are over-activated, such as cardiovascular and cerebral ischemic disease and hypertension (Fig. 2 and Table 4). The first drug identified as an NHE inhibitor was the potassium-sparing diuretic, amiloride [3,5-diamino-6-chloro-*N*-(diaminomethylidene)pyrazine-2-carboxamide], which consists of a guanidinium group connected to a pyrazine ring. Amiloride acts as a competitive inhibitor of Na^+ and consequently the potency of this drug is reduced by high Na^+ concentrations. However, amiloride is not a specific NHE inhibitor as it also inhibits epithelial Na^+ channels as well as Na^+/Ca^{2+} exchangers. To create inhibitors with higher potency and specificity for the NHEs,



Na^+/H^+ Exchangers, Fig. 2 Chemical structures of SLC9/NHE inhibitors

additional hydrophobic groups were added to create derivatives such as 5-(*N*-dimethyl)amiloride (DMA), 5-(*N*-ethyl isopropyl)amiloride (EIPA), MIBA, 5-(N-methyl-N-isobutyl)amiloride, 5-(N,N-hexamethylene)amiloride (HMA) and benzamil. Other modifications to amiloride resulted in a

Range of values for certain drugs reflects analyses of NHEs from different mammalian species (rat, rabbit and human) and assay conditions. N.A., no affinity. Values obtained from References (Counillon et al. 1993; Maidorn et al. 1993; Yu et al. 1993; Schwark et al. 1998; Kuribayashi et al. 1999; Peti-Peterdi et al. 2000; Szabó et al. 2000; Chambrey et al. 2001; Masereel et al. 2003; Touret et al. 2003; Nakamura et al. 2005; Xu et al. 2008; Linz et al. 2012; Spencer et al. 2014; Pedersen and Counillon 2019)

group of benzoylguanidine compounds which contain a phenyl group rather than a pyrazine ring. These include cariporide (HOE-642), HOE-694, eniporide (EMD-96785), EMD-87580 and sabiporide. Similar to the pyrazinoylguanidine derivatives, these drugs are specific NHE inhibitors and do not exert effects on Na^+ channels or Na^+/Ca^{2+} exchangers. Of the NHE isoforms, NHE1 is the most sensitive to amiloride and its derivatives, although other isoforms are also inhibited at higher concentrations (Table 4). NHE3 and NHE4 have markedly reduced affinities for these drugs. Importantly, NHE inhibitors with structures dissimilar to amiloride have also been developed. For example, zoniporide, SM-20220, SM-20550, and BMS-284640 contain bicyclic moieties and are highly selective NHE1 inhibitors. Drugs such as clonidine, cimetidine, and harmaline, which are used for other therapeutic applications, are also weak NHE inhibitors.

Significant interest has been placed on the study of NHE1 inhibition in the hopes of treating cardiac and cerebral ischemia-reperfusion injuries (reviewed in (Avkiran and Marber 2002)). Animal studies have demonstrated that NHE1 inhibition limits tissue damage during ischemia, such as reducing infarct size. However, there has been limited success in clinical trials thus far. A large-

scale phase II clinical trial concluded that eniporide administration during myocardial infarction had no effect on infarct size or clinical outcomes. However, another large-scale trial showed that cariporide had cardioprotective benefits, but only in patients undergoing coronary artery bypass graft surgery when the drug was administered prior to ischemia. Thus, NHE1 inhibitors may be useful for treating ischemia-reperfusion injury in the select cases where it can be administered in advance.

Pharmacological inhibition of NHE1 may also be beneficial for cancer treatment (reviewed in (Stock and Pedersen 2017)). NHE1 is thought to be upregulated in cancer cells, where its ion exchange activity maintains low intracellular H^+ concentrations while creating a highly acidic external tumor microenvironment. Thus, inhibiting NHE1 has the potential to cause intracellular acidosis and trigger apoptosis in cancer cells. NHE1 inhibitors have had considerable success in reducing cancer growth in cell studies; for example, HMA significantly reduced pH and induced apoptosis in human leukemic cells. Animal studies have also demonstrated a reduction in tumor growth, proliferation, and metastasis in response to amiloride treatment. Additional studies evaluating NHE1-specific inhibitors in animal models are needed to further evaluate the efficacy of NHE1 inhibition in cancer therapies.

In addition to NHE1 inhibitors, drugs that specifically inhibit NHE3 have been developed and include S3226, SAR218034, and Tenapanor. Tenapanor inhibits NHE3 activity in the intestines, which reduces the absorption of Na^+ and water from the gut and has received approval in the United States of America to treat patients with constipation-predominant irritable bowel syndrome (Markham 2019). By the same mechanism, Tenapanor may also be useful in treating hypertension. Finally, animal models indicate that S3226 may be beneficial in preventing acute renal failure following ischemia to the kidneys (Hropot et al. 2001), although this has not yet been tested in clinical trials.

Na^+/K^+-ATPase

G. Scheiner-Bobis
Institute of Veterinary Physiology and Biochemistry, Justus Liebig University Giessen, Giessen, Germany

Synonyms

Na $^+$/K $^+$-ATPase: Na $^+$/K $^+$ exchanging ATPase; Sodium pump; Sodium- and potassium-activated adenosine 5′-triphosphatase (EC 7.2.2.13)

Definition

The Na^+/K^+-ATPase is an integral protein of the plasma membrane of animal cells. By utilizing the energy from ATP hydrolysis, it transports 3 Na^+ ions from the cytosol to the extracellular space in exchange for 2 K^+ ions that are taken up from the extracellular medium.

Whereas Na^+ ions are moved against their electrochemical gradient, K^+ ions are taken up against their chemical gradient but following their electrical gradient.

This uneven transport of positive charge – 3 out versus 2 in – is coupled to various elementary functions of the cell: (i) it is the main contributor for the formation and maintenance of the membrane potential of the cell; (ii) it participates in the osmotic regulation of the cell volume; (iii) it provides the basis for neuronal communication in higher organisms; and (iv) it generates the driving force for all Na^+ gradient-coupled secondary active transport systems in all animal cells.

Basic Characteristics

The Subunit Composition of Na^+/K^+-ATPase

The Na^+/K^+-ATPase belongs to the P-type ATPases, a family of more than 50 enzymes that also includes the Ca^{2+}-ATPase of the sarcoplasmic reticulum or the gastric H^+/K^+-ATPase.

P-type ATPases have in common that during ion transport a phospho-intermediate is formed by transfer of the γ-phosphate group of ATP to an aspartic acid found at the beginning of the highly conserved sequence DKTGS/T (Scheiner-Bobis 2002).

The Na^+/K^+-ATPase is an oligomeric protein that consists of α and β subunits. Four different isoforms of the α subunit (α1, α2, α3, and α4) have been identified with relative molecular masses varying between 100 and 113 kDa. They cross the membrane ten times, forming transmembrane domains M1 to M10, and both amino and carboxy termini are localized on the cytosolic side (Scheiner-Bobis 2002). The three β subunit isoforms (β1, β2, and β3) are highly glycosylated proteins of about 60 kDa, with the mass of the protein moiety ranging from 36 to 38 kDa. The β subunit crosses the membrane only once, and the amino terminus is localized on the intracellular side of the membrane. In addition to the α and β subunits, which are absolutely required for catalytic activity, a third cytosolic peptide of 7–11 kDa from the family of FXYD proteins, originally referred to as the γ subunit, appears in some tissues to be involved in regulating the activity of Na^+/K^+-ATPase by influencing its interactions with ATP, ouabain, and Na^+ or K^+ ions. The quaternary structure Na^+/K^+-ATPase with all three subunits has been recently resolved (Morth et al. 2007, 2011).

Na^+/K^+-ATPase Acts as a Sodium-Potassium Pump

Although the ion-transporting process of the sodium pump can be summarized by the equation

$$\mathrm{ATP} + \mathrm{H_2O} + 3\mathrm{Na^+(in)} + 2\mathrm{K^+(out)} \rightarrow \mathrm{ADP} + \mathrm{Pi} + 3\mathrm{Na^+(out)} + 2\mathrm{K^+(in)},$$

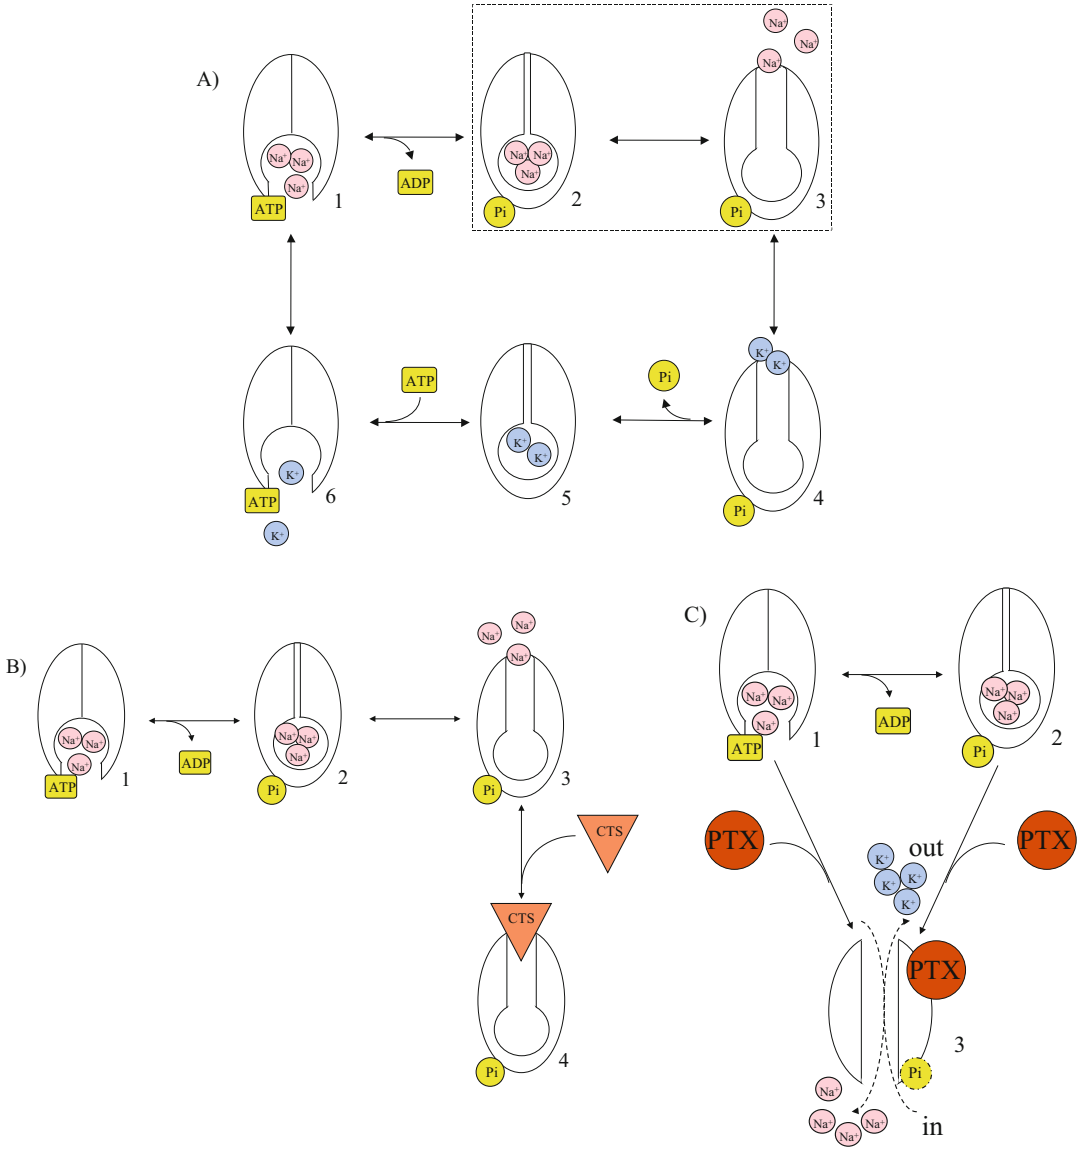
in reality the mechanism of ion translocation is sequential and far more complex than this equation implies. In order to ensure vectorial transport of the Na^+ or K^+ ions and the generation of an ion gradient, the ion-conducting structure of the sodium pump opens at any time of the ion-transporting process only towards one of the two surfaces of the membrane. This is associated with strong conformational changes in the enzyme protein structure, referred to as E_1 and E_2.

Thus, the catalytic cycle of the Na^+/K^+-ATPase can be described by juxtaposition of distinct reaction sequences that are associated with these two different conformational states (Scheiner-Bobis 2002). In the first step of the catalytic cycle, the enzyme in the E_1 conformation binds Na^+ and ATP with very high affinity (K_D values of 0.19–0.26 mM and 0.1–0.2 μM, respectively) (Fig. 1a, Step 1). After autophosphorylation by ATP at the aspartic acid within the sequence DKTGS/T, the enzyme occludes the 3 Na^+ ions (E_1-P($3Na^+$); Fig. 1a, Step 2) and releases them into the extracellular space after attaining the E_2-P $3Na^+$ conformation, characterized by low affinity for Na^+ ($K_{0.5}$ = 14 mM) (Fig. 1a, Step 3). The following E_2-P conformation binds 2 K^+ ions with high affinity (K_D approx. 0.1 mM; Fig. 1a, Step 4). The binding of K^+ to the enzyme induces a spontaneous dephosphorylation of the E_2-P conformation and leads to the occlusion of 2 K^+ ions ($E_2(2K^+)$; Fig. 1a, Step 5). Intracellular ATP accelerates the release of K^+ from the $E_2(2K^+)$ conformation (Fig. 1a, Step 6) and thereby also the return of the $E_2(2K^+)$ conformation to the E_1ATPNa conformation. The affinity of the $E_2(2K^+)$ conformation for ATP, with a $K_{0.5}$ value of about 0.45 mM, is very low.

Drugs

The Na^+/K^+-ATPase Is the Molecular Target for Cardiotonic Steroids (CTS) and Palytoxin

A vast number of toxins that specifically interact with the Na^+/K^+-ATPase and inhibit its catalytic activity have been isolated from various plants and animals (Fig. 2). Most of these substances are steroids, all characterized by the typical sterane backbone that is also found in steroid hormones. The sterane basic structure is made of three six-membered rings (A, B, and C) and a single five-membered ring (D) that form A/B, B/C, and C/D contacts. There are, however, several basic differences in the structures of the



Na^+/K^+-ATPase, Fig. 1 (**a**) The reaction cycle of Na^+/K^+-ATPase**.** In the E1 conformation the enzyme binds Na^+ and ATP with high affinity (Step 1) and becomes phosphorylated at a conserved aspartate residue by the γ-phosphate of ATP. That leads to the occlusion of 3 Na^+ ions within the transmembrane domains of the α-subunit (Step 2) followed by their release to the extracellular space (Step 3). This new conformational state, termed E_2-P, with low affinity for Na^+ binds K^+ with high affinity (Step 4) and occludes this cation after dephosphorylation of the aspartic acid (Step 5). Binding of ATP with low affinity to the $E_2(2\ K^+)$ conformational state leads to K^+ release into the cytosol (Step 6). The dashed box highlights the electrogenic steps of the catalytic cycle. (**b**) Binding of CTS to the sodium pump. CTS bind preferentially after Na + release to the E_2-P conformation of the enzyme and inhibit ATP hydrolysis and ion transport. (**c**) Binding of palytoxin to Na^+/K^+-ATPase. Palytoxin (PTX) binds either to the E1 or to the E1-P conformational state of the enzyme and arrests the natural ion-conducting structure of the α-subunit in a permanently open state (step 3). This rather unique conformation of a pump ion-conducting structure, that normally opens at any time towards one of the two surfaces of the plasma membrane, resembles the situation of ion channels, that, upon stimulation, retain their ion-conducting structure open towards both sides of the membrane. As a consequence of the ion channel–like conformation of the palytoxin/sodium pump complex, Na^+ and K^+cations flow down their concentration gradients (Na + into the cell, K+ out of the cell). The dotted line around the phosphate indicates that phosphorylation is not absolutely required

classical steroid hormones and the sodium pump inhibitors. Whereas in the classical steroid hormones the orientation of the A/B, B/C, and C/D contacts is trans-trans-trans, in steroidal inhibitors of the sodium pump the orientation is cis-trans-cis. In addition, the sodium pump steroidal inhibitors carry either a five-membered and single unsaturated (cardenolides) or six-membered and double unsaturated (bufadienolides) lactone ring at position C-17 (D-ring) (Fig. 2). At C-3 (ring A) both groups can carry one or several sugar molecules (glycosides). The most common sugars that are bound to natural cardiac glycosides are glucose, galactose, mannose, rhamnose, and digitalose. The sugar moiety itself has no activity but its addition to the steroid backbone affects the pharmacodynamics and kinetic profile of the particular glycoside. The type of sugar attached influences the potency of the compounds as it affects their absorption. The same applies for the lactone moiety of the CTS.

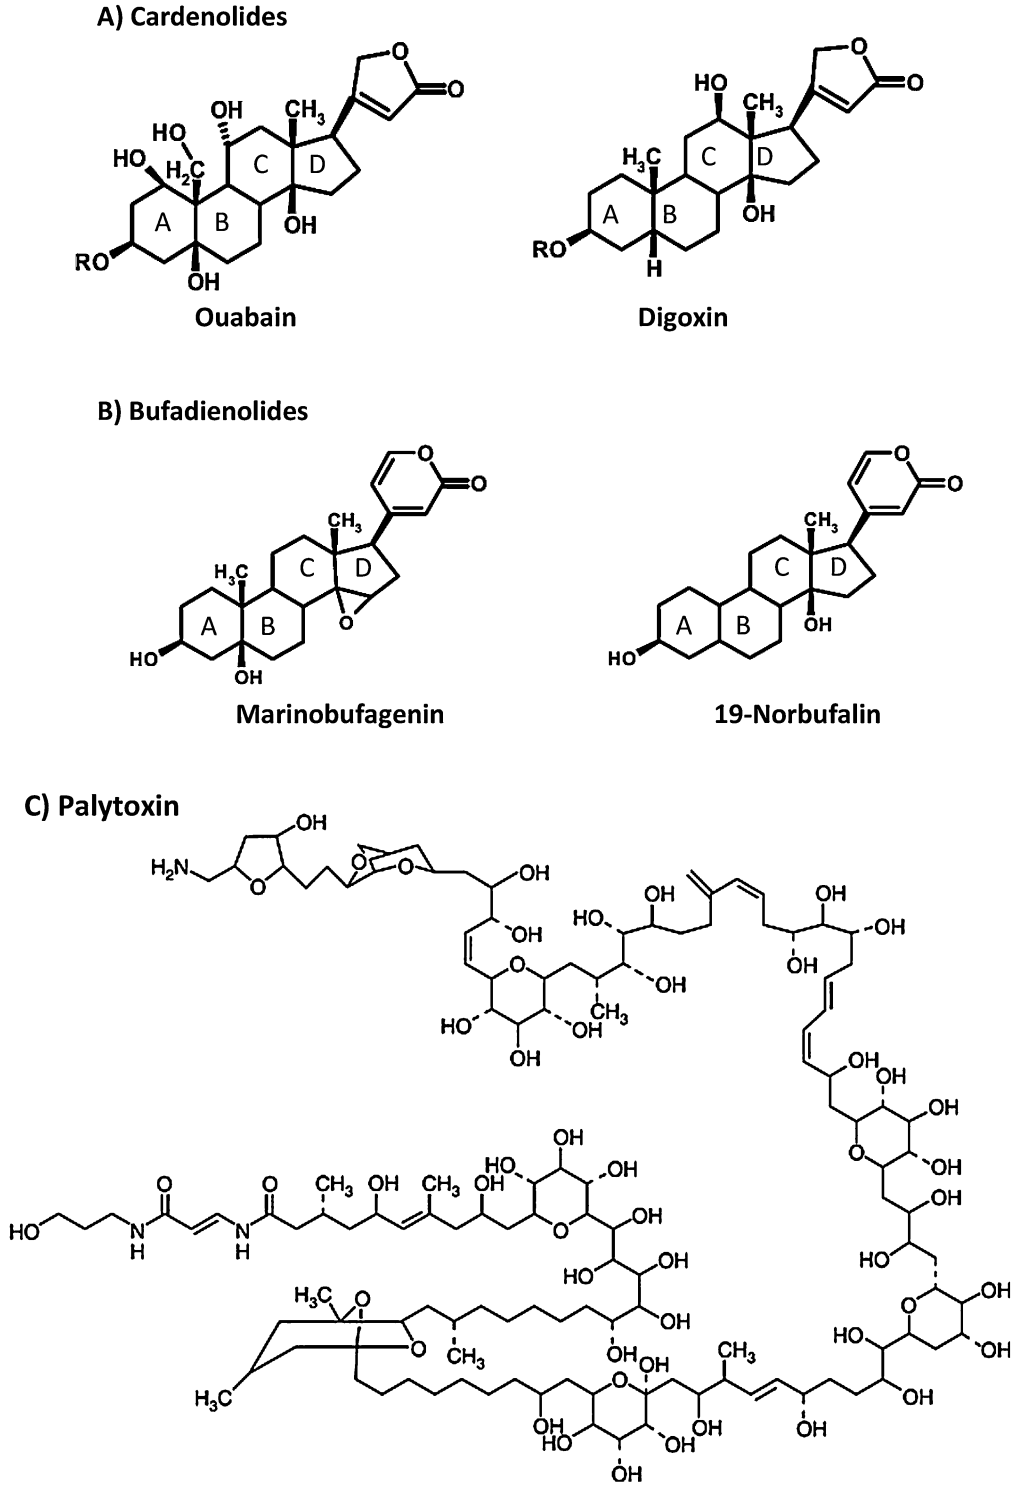
Plant-derived cardenolides or animal-derived bufadienolides are highly specific and strong inhibitors of the sodium pump. As a result of sodium pump inhibition, $[Na^+]i$ on the cytosolic side increases. In the myocardium, where the Na^+/Ca^{2+} exchanger (NCX) is present at high density, the cytosolic elevation of $[Na^+]i$ due to sodium pump inhibition forces the NCX into reverse mode. As a result, instead of extruding Ca^{2+} from the cytosol to the extracellular space, the reverse operational mode of NCX triggers $[Ca^{2+}]i$ elevation and a positive inotropic response in cardiac muscle cells. This mechanism that links sodium pump inhibition to cardiac Ca^{2+} elevation and inotropic response of the heart muscle constitutes the basis for the clinical use of several natural or synthetic cardenolides or bufadienolides in the treatment of chronic heart failure (NYHA II and IV), tachycardia, and dilatative cardiomyopathy. Because of their beneficial effects on the heart, cardenolides or bufadienolides are referred to as cardiotonic (=heart stimulating) steroids (CTS).

The Na^+/K^+-ATPase is the only enzyme known to interact with CTS, which reversibly bind to the extracellular side of the Na^+/K^+-ATPase at the E_2-P conformational state [E_2-P* ouabain] and inhibit ATP hydrolysis and ion transport (Fig. 1b, step 4).

Besides CTS, the highly toxic palytoxin (LD_{50} for rodents is 10–250 ng/kg), produced by corals of the genus *Palythoa*, is also a highly specific inhibitor of Na^+/K^+-ATPase (Fig. 2) (Scheiner-Bobis 2002). Unlike the CTS, however, which stop ATP hydrolysis and ion flow, palytoxin, by binding to either the E1 or the E_1-P conformation (Fig. 1c, steps 1 or 2, respectively), converts the sodium pump into an ion channel with a conductance of approximately 10 pS by arresting its natural ion-conducting structure in a permanently open conformation that allows K^+ to flow down its concentration gradient out of the cell and Na^+ into the cell (Fig. 1c, step 3). Thus, the reason for the high toxicity of palytoxin might be associated with the collapse of the membrane potential, and the ensuing loss of basic cell functions. In addition, depolarization is a key event that affects numerous secondary systems. Thus, the concentration of Ca^{2+} becomes elevated in several organs through the opening of Ca^{2+} channels and leads to the production of inositol trisphosphate, the activation of phospholipase A_2 and metabolism of arachidonic acid, and numerous other physiological responses that all stem from the increased Na^+ influx and the ensuing increase in the concentration of cytosolic Ca^{2+} that accompany the initial K^+ outflow. The strong tumor-promoter activity of palytoxin might be associated with these events (Wattenberg 2006).

Na^+/K^+-ATPase Acts as Signal Transducer for Cardiac Glycosides

The most popular assumption for the action of cardiac glycosides is that an inhibition or partial inhibition may induce inotropy of the heart by raising intracellular cytosolic Ca^{2+}($[Ca^{2+}]_i$) via a coupling of Na^+/K^+-ATPase with the Na^+/Ca^{2+} exchanger (NCX; Fig. 3). This Na^+ lag hypothesis has been recently modified: It is assumed that an inhibition of the sodium pump by cardiac glycosides may lead to a local increase of Na^+ in a tiny reactive space between the plasmalemma and the endoplasmic/sarco-plasmic reticulum (ER/SR) in smooth muscle cells and astrocytes, which has been named *plasmERosome* (Fig. 3) (Blaustein



Na^+/K^+-ATPase, Fig. 2 (continued)

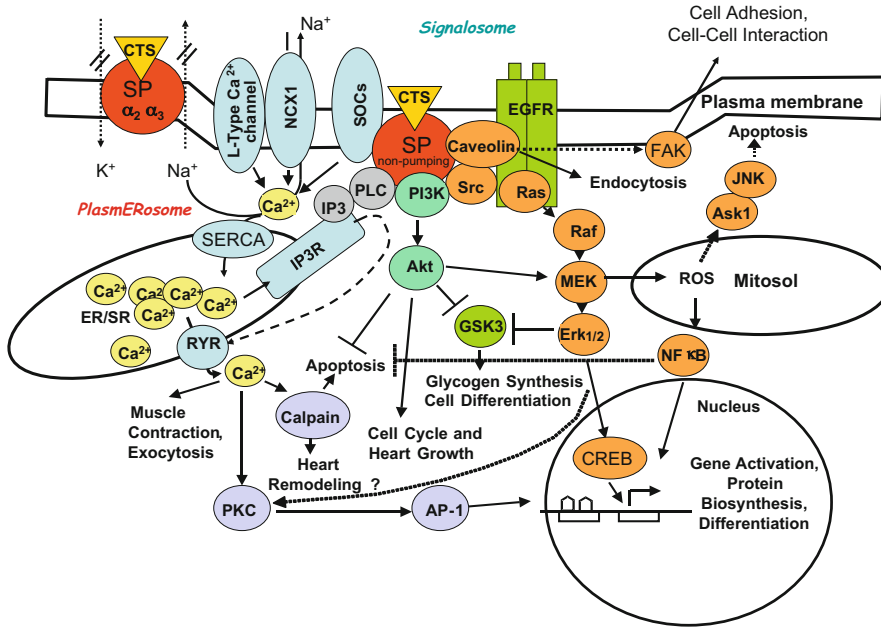
et al. 2000). This may explain why a partial inhibition of the sodium pump isoforms α_2 and α_3 located here result in a small, transient increase in the sub-plasmalemmal Na^+ concentration, which activates NCX1 and leads to a small local rise of Ca^{2+}. This, in turn, stimulates the release of more Ca^{2+} from the ER/SR to the cytoplasm. In arterial smooth muscle cells, this pathway is postulated to lead to arteriolar contraction and might be one of the reasons for essential hypertension.

Nevertheless, numerous recent investigations prove that interaction of CTS with the Na^+/K^+-ATPase located in caveolae at the plasma membrane leads to a series of events that trigger various intracellular signaling cascades. The same results are also obtained when CTS interact with nonpumping sodium pump mutants (Liang et al. 2006), indicating that a local $[Na^+]$ elevation followed by a $[Ca^{2+}]$ rise is not necessarily required for the induction of the signaling process. In this model, named *signalosome*, CTS-induced signaling events might differ depending upon the cell type and the nature of the CTS used. Figure 3 summarizes a series of signaling cascades proposed to explain the results from numerous investigations in various tissues. Thus, binding of CTS leads to a direct interaction of the amino-terminal end of the catalytic α subunit of Na^+/K^+-ATPase with the inositol trisphosphate (IP_3) receptor protein of the ER/SR and/or with phospholipase C (which raises IP3 levels) leads subsequently to a rise of $[Ca^{2+}]_i$. This promotes positive inotropy of the heart, arterial smooth muscle contraction, exocytosis, and leads to remodeling of the heart. Additionally, such effects may be induced by direct interaction of Na^+/K^+-ATPase within the plasma membrane with L-type Ca^{2+} channels. Elevated $[Ca^{2+}]_i$ leads to an activation of protein kinase C (PKC), which activates cardiac genes via transcription factor AP-1. This may lead to cardiac hyperplasia. Besides these possibilities, CTS may activate via the Na^+/K^+-ATPase-Src-caveolin-epidermal growth factor complex the Ras-Raf-MEK-ERK1/2 pathway. CTS-induced activation of the Ras-Raf-MEK-ERK1/2 pathway may also activate the formation of reactive oxygen species (ROS) in mitochondria that stimulate nuclear factor κB (NFκB). In kidney tubule and heart cells, activation of genes by this route leads to differentiation of the tissue. In epithelial cells this same signaling cascade involving Src-Ras-Raf-MEK-ERK1/2 stimulates transcription factors CREB and ATF-1 and promotes expression of tight junction proteins such as claudins and formation of blood-tissue barriers. In tumor cells, cardiac glycosides activate apoptosis via Ask1 and JNK, leading thereby to cell death, whereas in heart and kidney cells stimulation of ROS formation leads to the activation of NFκB and inhibition of apoptosis. The amino terminal end of the α subunit of Na^+/K^+-ATPase also interacts with phosphatidylinositol 3-kinase (PI3K). CTS binding to Na^+/K^+-ATPase may thus activate protein kinase B (Akt), which induces hypertrophy of the tissue and blocks apoptosis simultaneously. Akt also inactivates glycogen synthase kinase (GSK-3 α/β), which stimulates glycogen synthesis and is a master switch in regulating cell fate, specificity, and tumorigenesis. Binding of CTS to the Na^+/K^+-ATPase-Src-caveolin-epidermal growth factor complex stimulates the focal adhesion kinase (FAK), which alters cell adhesion and cell–cell interactions but also induces the endocytosis of Na^+/K^+-ATPase. This may then lead to the degradation of CTS. It is unclear whether the sodium pump is able to be recycled.

Endogenous Cardiac Glycosides Act as Hormones

Cardenolides and bufadienolides are generally considered to be of plant origin. Bufadienolides,

Na^+/K^+-ATPase, Fig. 2 Specific inhibitors of Na^+/K^+-ATPase: (**a**) Cardenolides are characterized by a five-membered lactone at position C17 of the steroid moiety. (**b**) Bufadienolides carry a six-membered lactone at C17. (**c**) Palytoxin ($C_{129}H_{223}N_3O_{54}$) produced by corals of the genus *Palythoa*. (R in ouabain is rhamnose; R in digoxin: 3 digitoxoses)



Na+/K+-ATPase, Fig. 3 Mechanisms of action of cardiac glycosides via the sodium pump in the plasmERosome and in the signalosome. The Na^+ lag hypothesis assumes the existence of a sub-plasmalemmal space called the plasmERosome. A cardioactive steroid (CST)–dependent transient local rise of $[Na^+]_i$ in this compartment caused by stimulation of store-operated channels (SOC) or by CTS-dependent inhibition of α_2 and α_3 sodium pump subunits may subsequently lead to a local rise of $[Ca^{2+}]_i$. This signal is amplified by filling up the sarco/endoplasmic reticulum (SR/ER) via the sarcoplasmic Ca^{2+}-ATPase (SERCA) to a higher extent with Ca^{2+}. Any agonist-stimulated Ca^{2+} release leads to an amplified Ca^{2+} release via the inositol tris-phosphate receptor (IP_3R) that stimulates the opening of the ryanodine Ca^{2+} channel (RYR), thus resulting in a higher degree of vasoconstriction. In a noninhibited Na^+/K^+-ATPase, Ca^{2+}in the PlasmERosome will be extruded by the Na^+/Ca^{2+}exchanger (NCX1) and the plasmalemmal Ca^{2+}-ATPase. When Na^+/K^+-ATPase acts as a signalosome in caveolae, endogenous and exogenous CTS induce various signal transducing pathways, even with a nonpumping enzyme. The abbreviations used are: AP-1 (activator protein 1), Ask-1 (apoptosis signal-regulating kinase 1), CREB (cAMP response element–binding protein), ERK 1/2 (extracellular signal–regulated kinases 1 and 2), FAK (focal adhesion kinase), GSK3 (glycogen synthase kinase 3), IP_3 (inositol (1,4,5) trisphosphate) IP_3R (IP_3 receptor), JNK (c-Jun N-terminal kinase), MEK (mitogen activated ERK-activating kinase, a MAP kinase), MKK (MAP kinase kinase), NCX1 (Na^+/Ca^{2+}exchanger), NF-κB (nuclear factor κB), PI3K (phosphatidylinositol 3-kinase), PKC (protein kinase C), PLC (phospholipase C), Raf (Raf, a MAP kinase kinase kinase), Ras (a MAP kinase kinase), ROS (reactive oxygen species), SOC (store-operated Ca^{2+} channel), Src (sarcoma kinase), SP (sodium pump)

however, have also been found in the skin of *Bufo sp*. and have been considered for a long time to be the only CTS synthesized in animals. Numerous, more recent investigations have shown, however, that CTS are not only produced in various animals but also that they act as hormones that can trigger specific cell responses at nanomolar concentrations (Wattenberg 2006).

Several cardiac glycosides have meanwhile been isolated and identified in mammals (Schoner and Scheiner-Bobis 2007a, b, 2008). The cardenolide ouabain was isolated from human blood and bovine adrenal glands and hypothalamus. Digoxin was isolated from urine of humans not being treated with this drug. The bufadienolides marinobufagenin, telocinobufagin, and 19-norbufalin were isolated from human fluids and tissues. There is a high probability that the zona fasciculata cells of the adrenal cortex, and possibly also the hypothalamus, are able to synthesize cardenolides. An adrenal tumor secreting ouabain and producing hypertension has been described. Na^+-dependent release of ouabain, angiotensin II, endothelin, and

catecholamines from cells of the midbrain may stimulate the release of endogenous ouabain from adrenal glands. An increase of sympathetic tone in stress and physical exercise leads to a rapid rise of endogenous ouabain and to a rapid fall after discontinuation. A constant and small rise of ouabain plasma concentrations (in the nanomolar concentration range, either from endogenous or exogenous sources) leads to arterial hypertension and remodeling of the heart and the arterial wall. Fifty percent of Caucasians with uncomplicated arterial essential hypertension and low plasma renin activity have been shown to exhibit elevated concentrations of endogenous ouabain. Possibly, endogenous digoxin, whose biosynthesis has also been demonstrated to take place in the adrenal gland, counteracts the secretion of endogenous ouabain from midbrain cells and lowers the sympathetic tone. This suppressive effect of digoxin could represent a very important mechanism for the therapeutic action of exogenously applied digoxin as well. There is good evidence that the secretion of the bufadienolide marinobufagenin from adrenal glands is activated via angiotensin II and catecholamines from the adrenal glands when the Na^+ concentration increases in midbrain and hypothalamus. Marinobufagenin and telocinobufagin are also elevated in essential hypertension. Contrary to the case with other cardenolides, marinobufagenin shows a natriuretic action on kidney tubular cells containing mainly the α_1 isoform of Na^+/K^+-ATPase (Fedorova et al. 2001).

Rostafuroxin, A Cardenolide Derivative with Antihypertensive Action

If 50% of Europeans with essential hypertension are affected by this disease because of an elevated secretion of endogenous ouabain, then there might be a chance to block its interaction at the cardiac glycoside binding site of Na^+/K^+-ATPase and thus lower blood pressure. Initial studies involving the cardenolide analogue rostafuroxin (PST 2238; Fig. 4) demonstrated that very low concentrations of this compound can overcome ouabain-induced hypertension in experimental animals (Ferrari et al. 2006). These first promising results from animal experiments could not be confirmed in five double-blind, crossover phase-II studies involving 410 hypertonic (140–169 mmHg) patients; a blood pressure–reducing effect was not found at any of the tested concentrations of the drug (Staessen et al. 2011). This rather disappointing outcome should not, however, preclude any further investigations in the same direction.

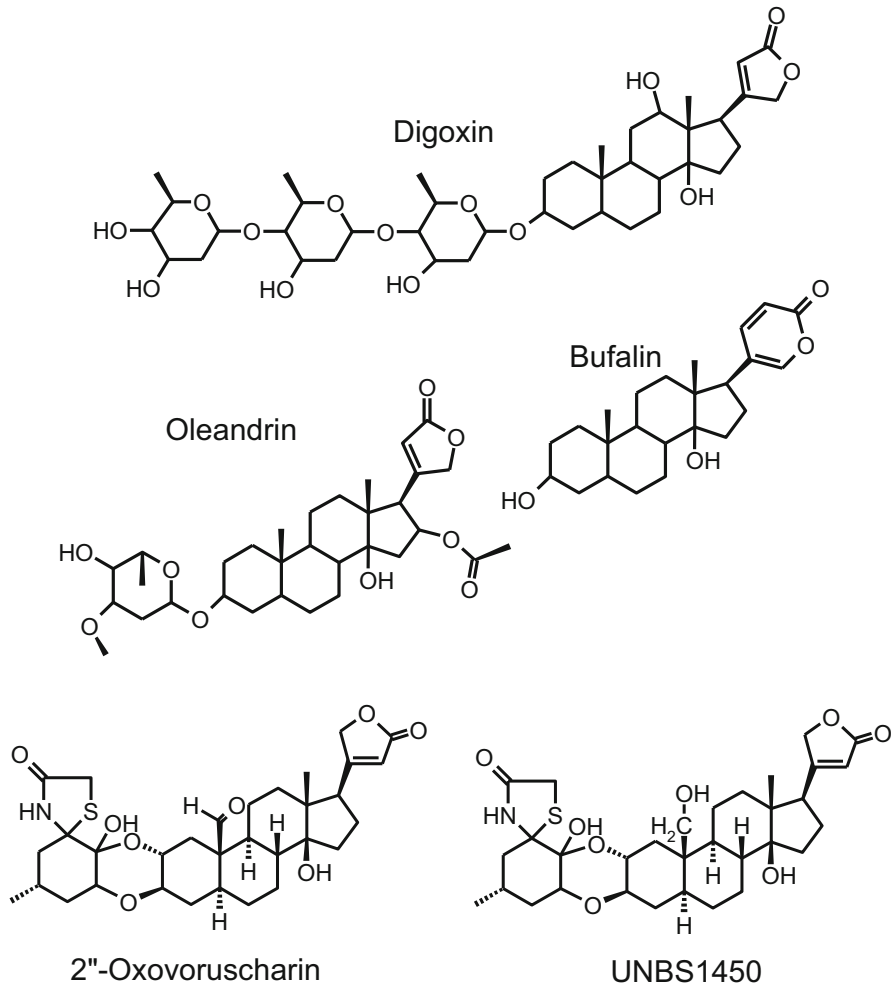
Na^+/K^+-ATPase, Fig. 4 Ouabain antagonist

Natural and Synthetic Cardenolides and Bufadienolides as Anti-Cancer Agents

There is increasing evidence that proliferation of cancer cells is affected by cardiac glycosides and that the extent of this effect depends on the nature of the steroid derivative and on the cancer cell line being used for in vitro testing (Prassas and Diamandis 2008; Menger et al. 2013; Slingerland et al. 2013). Thus, digitalis or ouabain have been shown to induce apoptosis in human breast cancer or neuroblastoma cells, respectively, whereas bufalin and the class of the more hydrophobic cardenolides like digoxin, oleandrin, and the 2″–oxovoruscharin and its derivative UNSB1450 (Fig. 5) have been shown in vitro and in vivo to have anti-cancer activity primarily in leukemia, lymphoma, melanoma, and ovarial and prostate cancer cells (Prassas and Diamandis 2008; Menger et al. 2013; Slingerland et al. 2013). Thus far, three cardiac glycosides have entered phase I clinical trials to determine their potency as anti-cancer agents. Two of them, Anvirzel™



Na^+/K^+-ATPase, Fig. 5 Cardiac glycosides and their derivatives with anti-cancer action

(extract from *Nerium oleander* containing the CTS oleandrin and oleandigenin) and PBI-02504 (more concentrated extract from *Nerium oleander*) had positive effects on a rather small percentage of treated patients. Thus, 7 out of 45 patients treated with PBI-02504 achieved stable disease conditions for more than 4 months (Hong et al. 2014).

The activity of the compound UNSB1450 has been tested in 57 human cancer models and it was always more potent than usual reference compounds such as irinotecan, mitoxantrone, oxaliplatin, paclitaxel, or temozolomide (Slingerland et al. 2013). UNSB1450 binds with high affinity to all α subunit isoforms of Na^+/K^+-ATPase. It affects the actin cytoskeleton and can therefore be considered not only antiproliferative but also anti-migratory (Slingerland et al. 2013). With the above background, UNSB1450 entered phase I clinical trials in Belgium. Unfortunately, however, the phase I study was interrupted in 2011 for financial reasons before reaching conclusions about the maximum tolerated dose.

Although at the current stage none of the CTS and derivatives tested have been certified as an anti-cancer remedy, the various phase I clinical studies are encouraging and should lead to continued investigation in this direction.

Definition

NADPH (nicotinamide adenine dinucleotide phosphate) oxidase (EC 1.6.3.1) is an enzyme that produces superoxide anions by transferring electrons from reduced NADPH (the electron donor) to oxygen (O_2). In the reaction, each NADPH molecule donates two electrons, which reduce two oxygen molecules, respectively, yielding two superoxide anions. NADPH oxidase is not a single protein but a multi-subunit protein complex (Babior 2004). While the term NADPH oxidase generally refers to such a protein complex, sometimes it is also ambiguously used to describe the catalytic subunit of the enzyme (aka the NOX subunit). The NADPH oxidase family contains different isoforms of the catalytic subunit, which may differ in the enzyme composition, subcellular localization, expression patterns, and/or biochemical properties. Some isoforms of NADPH oxidase produce hydrogen peroxide instead of superoxide.

Basic Characteristics

Prototype NADPH Oxidase

The prototype of NADPH oxidase was originally discovered in professional phagocytes (i.e., white blood cells or leukocytes that can ingest invading microorganisms), including neutrophils, eosinophils, monocytes, and macrophages. The basic composition of NADPH oxidase in phagocytes includes two membrane-bound subunits gp91phox (currently classified as NOX2) and p22phox; three cytosolic subunits p67phox, p47phox, and p40phox; as well as a small GTPase Rac1 or Rac2. Within the NOX2 protein, there is one molecule of FAD (flavin adenine dinucleotide) bound to the cytosolic C-terminus, as well as two heme groups located in the membrane-associated portion of the protein. FAD and likely the heme groups comprise the electron transfer mechanism that is essential for carrying out the redox reaction. In its inactivated state, the cytosolic subunits and Rac locate in the cytosol. Upon activation, these subunits translocate to the membrane and bind with NOX2 and p22phox. It is thought that activation of NADPH oxidase is caused by the migration of the cytosolic components to the cell membrane so that the complete oxidase can be assembled (Babior 2004).

Isoforms

In mammalian cells, the NADPH oxidase family contains seven isoforms of the NOX subunit, namely, NOX1 to NOX5 and DUOX1 and DUOX 2. It is thought that a specific NOX subunit determines the final enzymatic complex composition, modes of activation, and the products of the enzymatic reaction (Bedard and Krause 2007; Altenhofer et al. 2015).

NOX1: NOX1 is also known as NOH-1, MOX1, or GP91-2. NOX1 is predominantly expressed in colon epithelial cells and vascular smooth muscle cells. Activation of NOX1 requires the membrane-bound stabilizing subunit p22phox, two cytosolic subunits NOXO1 (in lieu of p47phox) and NOXA1 (in lieu of p67phox), and the small G protein Rac. NOX1 generates superoxide (Bedard and Krause 2007; Altenhofer et al. 2015).

NOX2: NOX2 is also known as gp91phox or CYBB. NOX2 is the prototype of NADPH oxidase. NOX2 is highly expressed in phagocytic leukocytes such as neutrophils and macrophages. NOX2 is also widely expressed in other types of cells at varying levels. Optimal activation of NOX2 requires the membrane-bound stabilizing subunit p22phox; three cytosolic subunits p67phox, p47phox, and p40phox; as well as

Rac. NOX2 generates superoxide (Bedard and Krause 2007; Altenhofer et al. 2015).

NOX3: NOX3 is also known as GP91-3. NOX3 is mainly expressed in the inner ear. NOX3 is also found to be expressed in various fetus organs (including the kidney, liver, lung, and spleen). Activation of NOX3 requires membrane-bound p22phox, cytosolic NOXO1, and probably NOXA1, but not Rac. NOX3 generates superoxide (Bedard and Krause 2007; Altenhofer et al. 2015).

NOX4: NOX4 is also known as RENOX, KOX-1, or KOX. NOX4 appears to be ubiquitously expressed in the body, as well as in various tumor cells. The activity of NOX4 requires membrane-bound p22phox, but does not require any cytosolic subunits. The activity of NOX4 appears to be largely influenced by its level of expression. The intracellular localization of NOX4 appears to be variable. In addition to the conventional plasma membrane compartment, NOX4 (probably a splice variant of NOX4 called NOX4D) has also been detected in the nucleus, mitochondria, and endoplasmic reticulum. NOX4 primarily generates hydrogen peroxide (Bedard and Krause 2007; Altenhofer et al. 2015).

NOX5: Like NOX3, NOX5 is also mainly expressed in fetus tissues. NOX5 activation is driven by intracellular calcium, which binds to the EF hand domains located in the N-terminal region of NOX5. The calcium sensitivity of NOX5 can be enhanced by calmodulin. The activity of NOX5 requires neither any cytosolic subunits nor the membrane-bound stabilizing subunit. NOX5 is also expressed in the testis and lymphoid tissues. NOX5 generates superoxide (Bedard and Krause 2007; Altenhofer et al. 2015).

DUOX1 and DUOX2: DUOX1 and DUOX2 are also, respectively, known as Thox1, LNOX1, or NOXEF1, and Thox2, LNOX2, or NOXEF2. DUOX1 and DUOX2 are mainly expressed in the thyroid gland. The membrane-bound stabilizing subunits for DUOX1 and DUOX2 are DUOXA1 and DUOXA2, respectively, instead of p22phox. Activation of DUOX1 and DUOX2 does not require cytosolic subunits, but is stimulated by calcium. Both DUOX1 and DUOX2 generate hydrogen peroxide (Bedard and Krause 2007; Altenhofer et al. 2015).

Biological Functions

The basic function of NADPH oxidase is to produce superoxide and hydrogen peroxide, two members of a group of oxygen-containing substances called reactive oxygen species (ROS). In the body, superoxide or hydrogen peroxide can be further converted to other ROS molecules, such as hypochlorous acid, singlet oxygen, hydroxyl radical, and peroxynitrite, via spontaneous or enzyme-catalyzed processes. In activated phagocytes, NOX2 functions to kill invading microorganisms and parasites by generating a large quantity of ROS. In human beings, a deficiency in NADPH oxidase function in phagocytes causes chronic granulomatous disease, which is characterized by severe infections that are extremely difficult to treat. About 60% of cases of chronic granulomatous disease are caused by mutations of the NOX2 gene; other cases can be caused by genetic mutations of p22phox, p67phox, or p47phox. Other confirmed functions of individual NADPH oxidase isoforms include the following:

1. In the inner ear, NOX3 plays a key role in the generation of otoconia, small calcium carbonate crystals found in the vestibular apparatus, which are utilized to perceive linear acceleration and gravity. Mice deficient in NOX3 are unable to form otoconia and therefore suffer from a disturbed equilibrium exhibiting a so-called “head-tilt” phenotype.
2. DUOX1/2 expressed in the thyroid is involved in the biosynthesis of thyroid hormones, which requires hydrogen peroxide (Babior 2004; Bedard and Krause 2007).

In addition to these specialized functions of NADPH oxidase in specific organs, evidence suggests that NADPH oxidases may have other more generalized functions in a spectrum of cells. Theoretically, all NADPH oxidases may change the redox balance inside cells by producing ROS, thereby influencing functions of certain proteins that are redox-sensitive. Many of these redox-sensitive proteins are involved in intracellular signal transduction. By modulating such cell signaling pathways, it is argued that NADPH oxidases may regulate a variety of biologic or pathophysiologic processes, including cell proliferation,

differentiation, survival, apoptosis, tumorigenesis, angiogenesis, fibrosis, inflammation, and tissue regeneration/wound healing. Under different conditions, a role of NADPH oxidases can be either beneficial or detrimental. On the other hand, evidence also suggests that aberrant expression or activation of NADPH oxidases may increase oxidative stress. Hence it is thought that NADPH oxidases may be involved in the pathogenesis of various oxidative stress-related diseases, such as cardiovascular disease, kidney disease, liver disease, lung disease, neurodegenerative disease, cancer, inflammatory disease, and aging. More specifically, current experimental data have pointed to a role of NOX1 in atherosclerosis, diabetic retinopathy, and liver fibrosis and a role of NOX4 in stroke, diabetic nephropathy, and osteoporosis (Bedard and Krause 2007; Altenhofer et al. 2015).

Drugs

Based on the rationale that oxidative stress may participate in the pathogenesis of different diseases, and the fact that NADPH oxidases are the only known enzymes solely dedicated to generate ROS, NADPH oxidase inhibitors are believed to be a promising therapeutic option for diseases associated with oxidative stress. Developing isoform-specific NADPH oxidase inhibitors seems to be a bottleneck in research; so far all of the reported NADPH oxidase inhibitors are not strictly isoform selective. Therapeutic efficacies and potential side effects of these novel NADPH oxidase inhibitors still remain to be established by long-term animal studies and clinical trials (Altenhofer et al. 2015; Drummond et al. 2011).

GKT136901 and GKT137831: These compounds are pyrazolopyridine derivatives. They inhibit NOX1, NOX4, and NOX5, with IC_{50} (concentrations with 50% inhibition of activity) values in a sub-μM range. They are approximately tenfold less effective against NOX2 oxidase. They show minimal off-target effects against more than 100 protein targets tested, including endothelial nitric oxide synthase (eNOS) and xanthine oxidase. These compounds have a high oral bioavailability and favorable pharmacokinetic and safety profiles in vivo. In animal studies, GKT136901 or GKT137831 showed beneficial effects against atherosclerosis, ischemic retinopathy, hepatic fibrosis, tumor angiogenesis, diabetic nephropathy, and osteoporosis (Altenhofer et al. 2015; Drummond et al. 2011).

ML171: ML171 (also known as 2-acetylphenothiazine) is a specific NOX1 oxidase inhibitor with an IC_{50} value of <300 nM for NOX1 and is >tenfold less effective for NOX2/3/4 and xanthine oxidase. ML171 appears to target the NOX1 catalytic subunit but not its cytosolic regulators (NOXO1, NOXA1, or Rac). ML171 shows some inhibitory effects toward serotonin and adrenergic receptors with low potencies. This compound is predicted to have favorable pharmacokinetics and safety profiles for in vivo applications (Altenhofer et al. 2015; Drummond et al. 2011).

VAS2870 and VAS3947: VAS2870 and VAS3947 are triazolopyrimidines, which inhibit NOX2 with IC_{50} values being 0.77 and 2.0 μM, respectively. VAS3947 also inhibits NOX1 and NOX4 with similar potencies (IC_{50} ~10 μM). VAS2870 is also reported to have inhibitory effects on NOX4 and NOX5 (IC_{50} values unknown), but has no inhibition on xanthine oxidase or eNOS. The mechanism(s) of NADPH oxidase inhibition by these compounds are not clear. In animal studies, VAS2870 shows beneficial effects on experimental stroke (reduced brain infarct volume and improved neurological outcome) (Altenhofer et al. 2015; Drummond et al. 2011).

S17834: S17834 is a polyphenol reported to have NADPH oxidase-inhibiting properties. It does not inhibit xanthine oxidase or eNOS. NOX isoform selectivity of S17834 is unknown. An off-target effect of S17834 is the activation of adenosine monophosphate-activated protein kinase (AMPK), which may mask the benefits produced by NADPH oxidase inhibition. In chronic animal studies, in vivo administration of this compound suppressed the development of atherosclerosis (Altenhofer et al. 2015; Drummond et al. 2011).

DPI, Apocynin, AEBSF, and Plumbagin: DPI (diphenylene iodonium), apocynin, AEBSF [4-(2-aminoethyl)benzenesulfonyl fluoride], and

plumbagin are historically used as pharmacological tools to inhibit NADPH oxidase in the laboratory. These inhibitors lack NOX isoform selectivity and are associated with significant off-target effects and/or low potencies. Hence these compounds are not suitable for further drug development (Altenhofer et al. 2015; Drummond et al. 2011).

Neprilysin and the Natriuretic Peptides

Neprilysin (NEP), also known as neutral endopeptidase, CD10, enkephalinase, common acute lymphoblastic leukemia antigen, and endopeptidase 24.11, is a well-known enzyme that was described in the early 1970s and fully characterized at the turn of the century (Bayes-Genis et al. 2016a). NEP is ubiquitous, mainly is expressed in the kidneys, but also present in the lungs, endothelial cells, vascular smooth-muscle cells, cardiac myocytes, fibroblasts, neutrophils, adipocytes, testes, and brain, with the highest concentrations in the proximal tubules of nephrons. NEP is also promiscuous in function, with >50 putative peptide substrates with varying levels of in vitro and/or in vivo evidence of functional relevance (Erdös and Skidgel 1989).

In the cardiovascular system, NEP cleaves numerous vasoactive peptides, some of them with mainly vasodilating effects including natriuretic peptides, adrenomedullin, and bradykinin, and other with mainly vasoconstrictor effects: angiotensin I and II, and endothelin-1 among others. Nevertheless, the relative affinity of neprilysin is variable among substrates, with highest affinity for atrial natriuretic peptide (ANP), C-type natriuretic peptide (CNP), and angiotensin I and II, and lowest affinity for brain natriuretic peptide (BNP), endothelin-1, and bradykinin (Mangiafico et al. 2013). The natriuretic peptides ANP and BNP are of predominantly cardiac origin, whereas CNP is largely sourced from endothelial cells throughout the systemic vasculature. Bioactive NPs act via G protein-coupled transmembrane receptors activating cyclic guanosine monophosphate (cGMP) as a

second messenger (Potter 2011). ANP and BNP act via the NPR-A receptor to exert natriuretic, diuretic, hemoconcentrating, and vasodilating effects in association with suppression of the renin-angiotensin-aldosterone and sympathetic nervous systems, and trophic effects that oppose cardiac hypertrophy and fibrosis. CNP, operating via the NPR-B receptor, is not natriuretic but is central to vasomotion, opposes vascular cell hyperplasia, and has a unique role in long bone development. All three NPs are cleared via the NPR-C receptor in concert with proteolysis (Potter 2011; Charles et al. 1996).

Neprilysin is responsible for the initial proteolytic cleavage of ANP and CNP; it also plays a role in processing BNP but does not cleave the amino-terminal prohormone fragments (Lafferty et al. 1989; Kenny et al. 1993; Stephenson and Kenny 1987; Yandle et al. 1989). Much of the impact of inhibiting neprilysin in preclinical and clinical settings has been presumed to be due to enhancement of NP bioactivity. The ranking of avidity of the enzyme for the NPs is CNP > ANP > BNP. In health, proteolytic cleavage and removal by the "clearance" NP receptor NPR-C play equal roles in metabolism of the NPs, but in high-NP states such as HF, it seems likely that neprilysin plays an increasingly important role (Potter 2011).

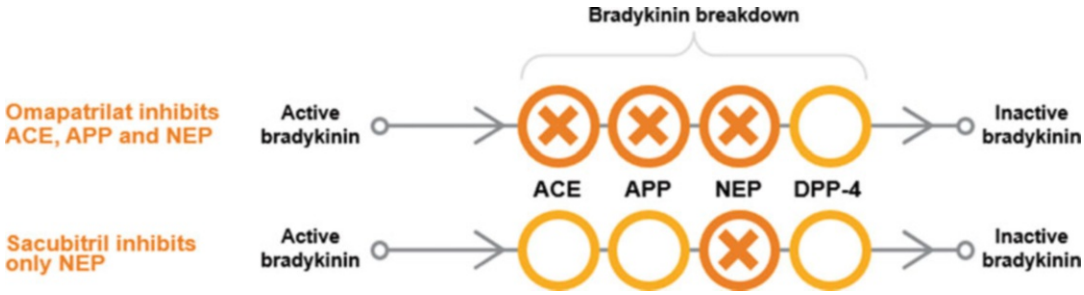
Neprilysin Inhibitors

For decades, neprilysin has been an important biotarget, in which academia and industry have actively researched in conjunction for inhibitors (NEPI) useful in clinical practice. More recently, neprilysin has also been proposed as a putative biomarker given the detection of circulating soluble neprilysin (sNEP) (Bayes-Genis et al. 2015a, b). The present review will focus mainly in the road to development of NEPIs, and less on sNEP. At present, data on sNEP are scarce, and there are several open issues regarding pre-analytical and analytical methods that deserve further insight before sNEP may be considered a valid and robust biomarker in precision medicine and prognostication.

The development of multiple neprilysin inhibitors has enabled clarification of the role of the enzyme in regulating levels of NPs and other substrates. While during the 1980s and 1990s, it seemed that all efforts to treat HF were only focused on the modulation of the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system, in parallel, several therapeutic failures happened in an attempt to find a formulation (fine tuning) to inhibit neprilysin. Such failures were both caused by the way to inhibit neprilysin (NEPI monotherapy), as well as due to inappropriate route of administration and dosage.

Thiorphan was the first synthetic NEPI and was followed by many other agents, suitable for both oral and parenteral administration. In healthy humans and during hypertension and HF, NEPIs alone induced elevations in endogenous plasma concentrations of ANP and BNP in association with increased circulating and urine cGMP and at least brief beneficial hemodynamic responses. Nevertheless, the hypotensive effects of NEPI alone were modest and transient, and in severe HF NEPI had no significant effect (Cavero et al. 1990). Other NEPIs had similar fate. Candoxatril was shown to have favorable hemodynamic effects compared with placebo in patients with chronic HF (Lang et al. 1991), and ecadotril led to numerically more deaths, as well as no evidence of clinical efficacy compared with placebo in patients with HF (Cleland and Swedberg 1998). Consequently, the development of both candoxatril and ecadotril for HF was discontinued.

Evidence of concurrent activation of the RAAS, together with augmentation of NP bioactivity by NEPI monotherapy, inspired development and testing of agents that combine NEPI and ACE-inhibiting activity: the so-called vasopeptidase inhibitors. Several vasopeptidase inhibitors have been developed, including omapatrilat, fasidotril, sampatrilat, and mixanpril (Nathisuwan and Talbert 2002). In the IMPRESS trial of 573 patients with NYHA class II–III HF, omapatrilat decreased rates of a composite endpoint (death, hospitalization, or discontinuation of treatment for worsening HF) to 6% compared to 10 % on lisinopril ($p = 0.035$) (Rouleau et al. 2000). However, in the phase III trial Omapatrilat



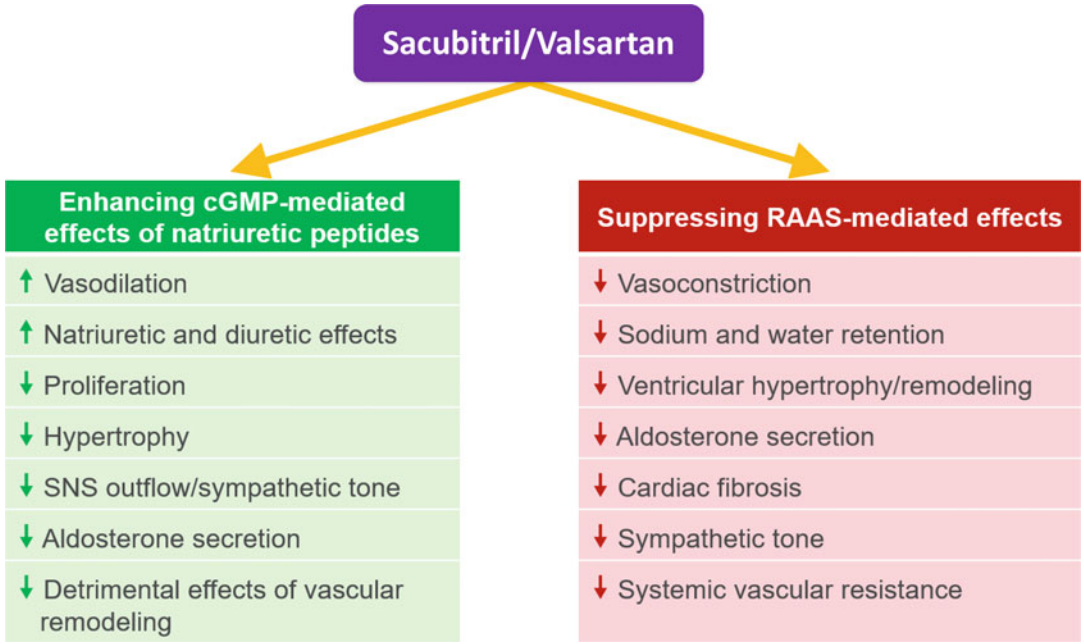
Neprilysin Inhibitors, Fig. 1 Impact on bradykinin breakdown by omapatrilat and sacubitril/valsartan. Sacubitril/valsartan does not excessively increase bradykinin. (ACE = angiotensin-converting enzyme; APP = aminopeptidase P; AT_1 = angiotensin II type 1; DPP-4 = dipeptidyl peptidase-4; NEP = neprilysin)

Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) of 4400 patients, omapatrilat was not superior to enalapril with respect to the primary endpoint of death from any cause or admission for HF (Packer et al. 2002). These indications of benefit from vasopeptidase inhibition were overshadowed by an excess of severe angioedema, which led to cessation of vasopeptidase development. The increased incidence of angioedema (24 patients [0.8%] vs. 14 patients [0.5%] for omapatrilat and enalapril, respectively) is believed to have been caused by excess bradykinin produced by the combined vasopeptidase inhibitor effects of inhibiting not only ACE and neprilysin but also aminopeptidase P (Fig. 1). In the OVERTURE Trial, omapatrilat was given once daily (to reflect its use in patients with hypertension), even though its pharmacologic advantages over enalapril in patients with HF were not maintained throughout the 24-h dosing interval (Rouleau et al. 2000). These issues could be avoided by the combination of NEPI with an ARB blocker into one compound, instead of ACEI, and to prescribe them twice daily (Fig. 2).

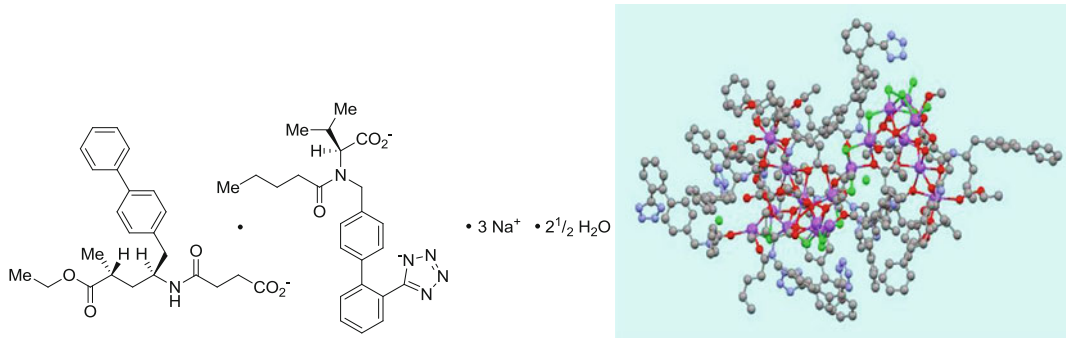
ARNIs in HFrEF and HFpEF

The combination of NEPI and ARB, also known as angiotensin receptor neprilysin inhibitor (ARNI) (Fig. 3), has been evaluated in large clinical trials with both reduced and preserved ejection fraction. Table 1 summarizes the impact of NEPI, ACEI, vasopeptidase inhibitors, and ARNI on vasoactive peptides and physiological effects (Bayes-Genis et al. 2016b).

The PARADIGM-HF trial was the largest (n = 8442) and most geographically diverse (1043 clinical centers) trial in HF performed to date (McMurray et al. 2014). This was an intention-to-treat study evaluating the clinical benefit of the ARNI sacubitril/valsartan against enalapril in patients with LVEF<40% (protocol subsequently amended to LVEF <35%). Patients were required to have BNP levels of ≥150 pg/mL or ≥100 pg/mL with hospitalization secondary to HF in the preceding 12 months (or NT-proBNP ≥600 pg/m or ≥400 pg/mL), in addition to taking stable beta-blockers and ACEI/ARB doses that were equivalent to enalapril 10 mg daily in the 4 weeks prior to screening. Subjects were randomized in a double-blinded manner to receive sacubitril/valsartan 200 mg twice daily (n = 4187) or enalapril 10 mg twice daily (n = 4212) in combination with conventional systolic HF therapy including beta-blockers (93% of patients), diuretics (80%), MRAs (56%), and digoxin (30%), in addition to implantable cardioverter defibrillators (ICD) (15%) or cardiac resynchronization therapy (CRT) (7%). The trial was early terminated due to overwhelming reductions in death from cardiovascular causes and the primary endpoint (CV death or first hospitalization for worsening HF). After a mean treatment duration of 27 months, treatment with sacubitril/valsartan was associated with significant reductions in the primary endpoint, as



Neprilysin Inhibitors, Fig. 2 Simultaneous inhibition of NEP and suppression of the RAAS with sacubitril/valsartan has complementary effects. (cGMP = cyclic guanosine monophosphate; NEP = neprilysin; NP = natriuretic peptide; RAAS = renin-angiotensin-aldosterone system; SNS = sympathetic nervous system)



Neprilysin Inhibitors, Fig. 3 Sacubitril/valsartan 2D scheme and 3D structure. Sacubitril/valsartan is a crystalline salt complex comprising sacubitril and valsartan in their anionic forms, sodium cations and water molecules

there were 914 events in the sacubitril/valsartan group and 1117 in the enalapril group (21.8 vs. 26.5%, respectively, HR 0.80; $p < 0.001$). The incidence of both components of the composite endpoint were significantly reduced with sacubitril/valsartan as CV death occurred in 13.3 vs. 16.5% of enalapril patients (HR 0.80, $p < 0.001$), and first hospitalization from worsened HF occurring in 12.8 and 15.6% of patients, respectively (HR 0.79, $p < 0.001$). All-cause mortality rates were significantly reduced (17.0 vs. 19.8%, HR 0.84, $p < 0.001$) and the average reduction in the KCCQ clinical score reflects significantly fewer symptoms or physical limitations secondary to HF in the sacubitril/valsartan group. There was no difference in the incidence of new-onset AF or worsened renal function.

N

Due to the unethical nature of withholding an ACE inhibitor or ARB in patients with HFrEF, sacubitril/valsartan could not be compared directly with placebo (McMurray et al. 2015). Therefore, the investigators made indirect comparisons, using putative placebos. They quantified the effect of sacubitril/valsartan on a number of key cardiovascular outcomes and on all-cause mortality. Compared in this way, sacubitril/valsartan was shown to have striking effects on all outcomes examined, with the relative risk reduction for cardiovascular mortality ~32–34% (for cardiovascular morbidity and mortality, it was 39–43%). There were even larger effects on heart failure hospitalization, with relative risk reductions of 46–49% (McMurray et al. 2015).

Additional analysis from PARADIGM-HF indicates that fewer sacubitril/valsartan-treated patients required intensification of medical treatment for heart failure (520 vs. 604; HR 0.84; $p = 0.003$) or an emergency department visit for worsening heart failure (HR 0.66; $p = 0.001$) (Packer et al. 2015). The patients in the sacubitril/valsartan group had 23% fewer hospitalizations for worsening heart failure (851 vs. 1079; $p < 0.001$) and were less likely to require intensive care (768 vs. 879; 18% rate reduction, $p = 0.005$), to receive intravenous positive inotropic agents (31% risk reduction, $p < 0.001$), and to have implantation of a heart failure device or cardiac transplantation (22% risk reduction, $p = 0.07$). These advantages were apparent even though the enalapril group had a meaningfully higher mortality rate throughout the trial, leading to the preferential exclusion of high-risk enalapril-treated patients with progressing symptoms, and the enalapril group had greater intensification of background therapy, which would have been expected to ameliorate deleterious changes in clinical status. Importantly, sacubitril/valsartan

also significantly reduced sudden cardiac death relative enalapril (HR 0.80, $p = 0.008$) (Desai et al. 2015).

The age-strata analysis showed that the rate of death and heart failure hospitalization increased with age, yet this gradient was not as pronounced in PARADIGM-HF as in prior trials. The benefit of sacubitril/valsartan over enalapril was similar across age categories and intolerance of sacubitril/valsartan leading to treatment withdrawal was uncommon, even in elderly individuals. Of note, a larger number of patients with a broader range of ages were included in PARADIGM-HF than in any previous trial in HFrEF ($\geq$75 years ($n = 1563$); $\geq$80 years ($n = 587$)) (Jhund et al. 2015).

The biomarker sub-study revealed that, as expected, neprilysin inhibition with sacubitril/valsartan increased levels of both urinary cyclic GMP and plasma BNP (Packer et al. 2015). In contrast, in comparison with enalapril, patients receiving sacubitril/valsartan had consistently lower levels of NTproBNP (reflecting reduced cardiac wall stress) and troponin (reflecting reduced cardiac injury) throughout the trial. The contrasting effects of sacubitril/valsartan on the two types of natriuretic peptides represent an important finding, because the levels of the two peptides characteristically parallel each other during the course of heart failure (Packer et al. 2015). However, because BNP (but not NT-proBNP) is a substrate for neprilysin, levels of BNP reflect the action of the drug, whereas levels of NTproBNP will reflect the cardioprotective effect of the drug.

Strengths of PARADIGM-HF include its randomized, prospective, active-treatment controlled design, and clinically relevant endpoints. The trial was adequately powered to detect differences in hospitalization and mortality, two endpoints that clinicians focus therapy on preventing in HF patients. Despite a higher incidence of hypotension in the sacubitril/valsartan arm, discontinuation of therapy was significantly less common overall in the sacubitril/valsartan group (17.8 vs. 19.8%, $p = 0.02$). Additionally, fewer patients taking sacubitril/valsartan required a discontinuation of therapy due to renal failure (0.7 vs. 1.4%, $p = 0.002$) or adverse events (10.7 vs. 12.3%, $p = 0.03$). Angioedema occurred in 19 patients receiving sacubitril/valsartan and 10 patients on enalapril, not reaching statistical significance. None of the reported angioedema included airways compromise.

The next frontier was HFpEF. Approximately, 50% of HF patients have HFpEF. Therapies for HFpEF are directed toward symptom management and cardiovascular risk factors due to the lack of clinical trials that demonstrate therapeutic benefits with agents commonly utilized in HFrEF. The safety and efficacy of sacubitril/valsartan among HFpEF patients showed promising results in a phase 2 trial (Solomon et al. 2012). The PARAMOUNT trial was a randomized, double-blind, parallel-group, active controlled trial (Solomon et al. 2012). Patients were eligible if they were aged $\geq$40 years with an LVEF of at least 45% and a documented history of HF with associated signs or symptoms (dyspnea on exertion, orthopnea, paroxysmal dyspnea, and peripheral edema). Additional requirements included a NT-proBNP level greater than 400 pg/mL. Patients were randomized to sacubitril/valsartan 50 mg twice daily or valsartan 40 mg twice daily. Both arms were titrated to their final doses of 200 mg twice daily or 160 mg twice daily, respectively, over 2–4 weeks. The primary endpoint was a change from baseline in NT-proBNP at 12 weeks. Baseline characteristics were similar between groups. Most patients were elderly, female, overweight, and classified as NYHA class II. The change in NT-proBNP was seen at week 4 in the sacubitril/valsartan group compared to the valsartan group, although not reaching significance ($p = 0.063$). However, at 12 weeks, NT-proBNP was significantly reduced in the sacubitril/valsartan group compared to valsartan ($p = 0.005$). The findings from PARAMOUNT suggested that sacubitril/valsartan could have favorable effects in patients with HFpEF.

PARAGON-HF was designed to test the hypothesis that sacubitril/valsartan would improve outcomes in HFpEF (Solomon et al. 2019). A total of 4,822 patients were randomly assigned to sacubitril/valsartan or valsartan. The comparator was valsartan because most HFpEF

patients already take a renin-angiotensin system inhibitor. Patients were required to have signs and symptoms of HF, LVEF of 45% or greater, evidence of natriuretic peptide elevation, and structural heart disease. The median follow-up was 34 months. The primary endpoint was a composite of total (first and recurrent) heart failure hospitalizations and cardiovascular death. The rate ratio for the primary endpoint was 0.87 (95% confidence interval [CI] 0.75–1.01; $p = 0.059$). This reduction was just short of statistical significance and was driven by a decline in heart failure hospitalization with no effect on cardiovascular death or all-cause mortality.

Several sensitivity analyses, including assessment of investigator-reported outcomes, favored sacubitril/valsartan. Several secondary endpoints, such as quality of life, change in New York Heart Association (NYHA) class, and percentage of patients with worsening renal function, favored sacubitril/valsartan. Sacubitril/valsartan was associated with more hypotension, but less hyperkalemia and less renal dysfunction compared with valsartan, findings similar to those seen in the PARADIGM-HF trial.

Importantly, there was heterogeneity in the population with respect to treatment response. In particular, there was greater benefit in patients with ejection fraction below the median of 57%, with a 22% reduction (rate ratio 0.78; 95% CI 0.64–0.95) and in women, with a 28% reduction (rate ratio 0.73; 95% CI 0.59–0.90) in the primary endpoint (Solomon et al. 2019).

In conclusion, neprilysin is back to the center stage after an eventful career spanning almost half century. The impact of neprilysin blockade and natriuretic peptide rise observed with the new ARNIs has revolutionized the way we treat heart failure and impacted our knowledge on neprilysin-regulated neurohormones pathophysiology. Current findings indicate that the benefit of sacubitril/valsartan observed in PARADIGM-HF in HFrEF could extend to HF patients with ejection fraction below the normal range, including those designated HFmrEF, as suggested by a sub-analysis of PARAGON-HF, but not in truly HFpEF patients.

Neurodegeneration

Alvin V. Terry Jr
Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta University, Augusta, Georgia

Synonyms

Neuronal cell death; Neuronal cell deterioration

Definition

Neurodegeneration refers to the processes whereby neuronal cells progressively deteriorate,

loose their structure and/or function, and eventually die.

Since the body's ability to replace lost neurons (i.e., such as via neurogenesis) is quite limited when compared to many non-neuronal cells, degenerative processes affecting neurons can be particularly devastating.

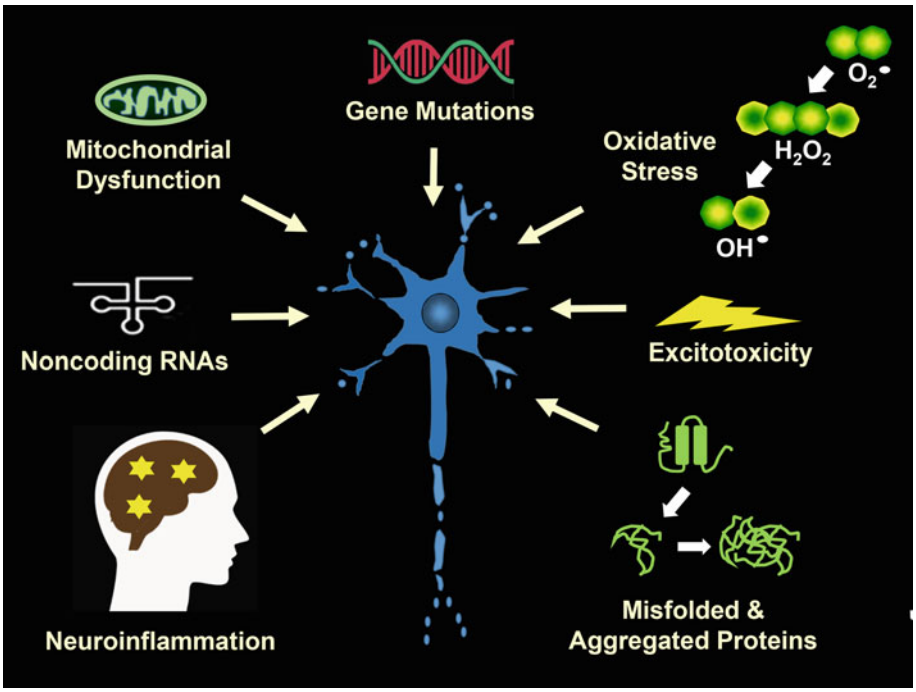
Basic Mechanisms

The basic mechanisms underlying the neuronal cell degeneration and death observed in the neurologic disorders as diverse as Alzheimer's disease and stroke have not been fully elucidated. However, a number of distinct biological factors and processes clearly contribute to neurodegeneration including gene mutations and noncoding RNAs, increased oxidative stress and free radical damage, impaired mitochondrial function, excitotoxicity, immunologic and inflammatory mechanisms, misfolded and aggregated proteins, impaired trophic factor support, and altered cell signaling (see illustration in Fig. 1). In the process of neuronal degeneration, cells eventually die as a result of apoptosis, necrosis, or a combination of these processes (Martin 2001).

Table 1 provides an overview of the major differences between necrosis and apoptosis.

Necrosis

Necrosis occurs as a pathological response to cell injury most commonly resulting from trauma, ischemia, hypoxia, neurotoxins, or infection. Necrosis typically occurs when a cell is too severely damaged for the orderly energy-dependent process of apoptosis (see below) to occur. Following one or more of the insults listed above, neuronal degeneration or death occurs in groups of contiguous cells in a localized region, and the initiation of inflammatory processes can be clearly observed in tissue sections (Schwartz and Osborne 1995). The processes of necrosis are summarized in Table 1 on the left and illustrated at the top of Fig. 2.



Neurodegeneration, Fig. 1 Illustration of some of the major biological processes and factors that can lead to neurodegeneration

N

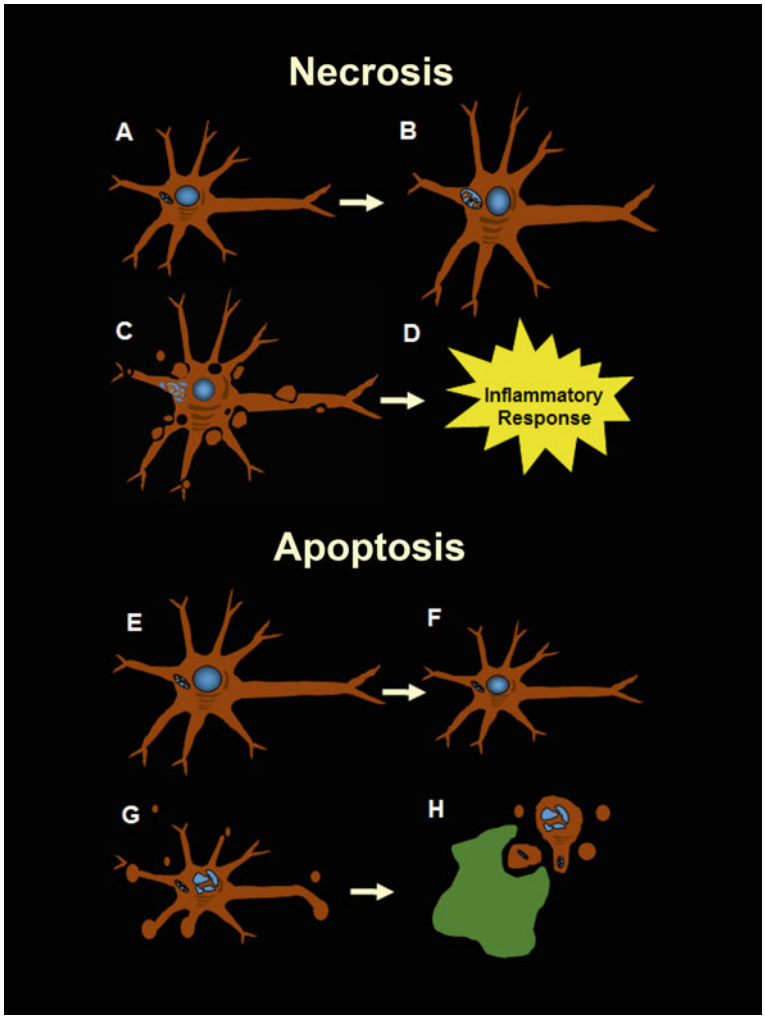
Neurodegeneration, Table 1 Comparison of necrosis and apoptosis

Necrosis	Apoptosis
Cellular swelling	Cellular shrinkage
	Nuclear and cellular pyknosis
Little or no chromatin condensation	Chromatin condensation
Rupture of organelles and plasma membrane	Organelles and plasma membrane not usually ruptured
Release of cytoplasmic contents and inflammation	Release of cytoplasmic contents and inflammation not usually present
Random DNA degradation	DNA fragmentation
Caspases not involved	Activation of caspases
	Cytoplasmic blebbing
	Formation of apoptotic bodies which are engulfed and cleared by phagocytes

Apoptosis

The term apoptosis is derived from an ancient Greek word meaning "dropping off" like leaves falling from trees in the autumn season. In modern cell biology, the term is used to describe the orderly form of programmed cell death that occurs in multicellular organisms. Neuronal apoptosis is triggered by a number of factors including lipid peroxidation (and membrane damage) induced by reactive oxygen species, genetic mutation, or DNA damage (or degradation) resulting from radiation or other destructive agents. A loss of trophic factor support, as well as some of the same factors that induce necrosis (see above), can also initiate apoptotic processes. Cell death by apoptosis also occurs extensively during the development of the mammalian nervous system and is required for the formation of appropriate connections between neurons and their targets. The processes involved in apoptosis generally differ from necrosis (see Table 1) in several important details, most notably, that neuronal death with apoptosis usually involves individual cells that are phagocytized before they can release their cytoplasmic contents and induce an inflammatory response in adjacent tissues. In addition, in the process of apoptosis, phagocytes are able to recognize dying or degenerating cells by their expression of death-related cell surface epitopes. Furthermore, mitochondria are preserved until the late stages of apoptosis, whereas they typically swell and disintegrate early in necrosis. The major cellular changes observed in neuronal apoptosis are summarized in Table 1 on the right and illustrated at the bottom of Fig. 2.

As noted above, neuronal apoptosis serves a number of important roles in normal brain development and is a key mechanism by which defective or damaged neurons are removed from the brain. However, in a number of brain disorders including Alzheimer's disease (AD), dementia with Lewy bodies (DLB), and Parkinson's disease (PD), inappropriate apoptosis may occur leading to accelerated neuronal loss and progressive disease symptoms. Conversely, in neural tumor cells, such as neuroblastoma and medulloblastoma cells, apoptotic pathways may be disabled, and the cells become resistant to chemotherapeutic drugs that kill cancer cells by inducing apoptosis. Neuroblastoma and medulloblastoma are important pediatric solid tumors that arise in the sympathetic neuron lineage and cerebellum, respectively. Apoptosis may be accelerated or retarded by a variety of hormones, metabolic by-products, electrolytes, and other endogenous substances. As examples, altered serum levels of thyroid hormone or ammonia, altered plasma or extracellular levels of excitatory amino acids such as glutamate and aspartate, imbalances of calcium and other electrolytes, and lactic acidosis are all known to initiate or modify apoptotic processes. Apoptosis is also influenced by synaptic communication in both the central and peripheral nervous systems. For example, in transsynaptic degeneration, neurons deteriorate and often undergo apoptosis if they fail to be innervated (from the afferent side) due to the loss of presynaptic neurons. This process has been observed in the lateral genicular body after optic nerve lesions and in the inferior olivary nucleus after destruction of the central tegmental tract. Efferent, motor neurons degenerate if they fail to match with target muscle fibers or their muscle targets are lost, such as after amputation of a limb.



Neurodegeneration, Fig. 2 *Top*: Illustration of the major cellular changes observed in neuronal necrosis. A normal neuronal cell (**a**) when exposed to an insult (e.g., trauma, ischemia, hypoxia, neurotoxins, infection, etc.) initially swells (**b**), mitochondria and other organelles swell and rupture, the plasma membrane lyses (**c**), and spillage of the cellular contents into the extracellular space follows. A general inflammatory response (**d**) is then triggered and macrophages attack and phagocytize the cellular debris. *Bottom*: Illustration of the major cellular changes observed in neuronal apoptosis. A normal neuronal cell (**e**) when exposed to specific triggers (e.g., lipid peroxidation, genetic mutation, DNA damage, excitotoxic injury, etc.) initially shrinks (**f**), chromatin becomes pyknotic and condenses and then migrates to the nuclear membrane, DNA fragmentation and degradation occurs, and several organelles (e.g., Golgi apparatus, endoplasmic reticulum) disappear. Afterward, blebbing of the plasma membrane occurs (**g**), and the cell then fragments into small apoptotic bodies that are subsequently phagocytosed and digested (**h**) without triggering inflammation

Regulation of Apoptosis

Apoptosis is regulated by a complex molecular cascade that controls the activation of a family of cysteine proteases known as caspase proteins (caspases-1–14). Caspases are responsible for breaking down vital structural and functional proteins, leading to the characteristic cytomorphology associated with apoptosis. While multiple molecular pathways (e.g., mitochondrial, death receptor, endoplasmic reticulum pathways) have been identified that lead to the activation of caspases, the mitochondrial

(intrinsic) pathway is most associated with neuronal apoptosis. The mitochondrial pathway regulates caspase activity by controlling mitochondrial release of cytochrome c by pro- and anti-apoptotic members of the Bcl-2 family of proteins. These proteins interact through dimerization in the mitochondrial membrane. The ratio of pro-apoptotic (e.g., Bax, Bad) to anti-apoptotic (e.g., Bcl-2, Bcl-XL) protein levels is a key determinant in regulating cytochrome c release and subsequent caspase activation. For example, high Bax/Bcl-2 and Bax/Bcl-XL ratios promote cytochrome c release, while low Bax/Bcl-2 and Bax/Bcl-XL ratios inhibit cytochrome c release. Downstream of mitochondria, cytochrome c forms a complex with caspase-9 and Apaf-1 to form the apoptosome. This complex cleaves procaspase-3 to form activated caspase-3 which can initiate cellular disassembly. While caspase-3 is known as a downstream effector caspase, its activity can still be inhibited by members of the inhibitor-of-apoptosis (IAP) protein family (e.g., XIAP); XIAP is itself potentially inhibited by Smac/Diablo, a mitochondrial protein (Michel et al. 1999).

As discussed above, apoptotic activity can be triggered by a broad array of stimuli including oxidative stress (e.g., ischemia, hypoxia), pro-inflammatory cytokines, excitotoxicity, neurotrophin withdrawal, mitochondrial dysfunction, and abnormal intracellular calcium concentrations. A number of these stimuli can alter Bcl-2 family protein expression via potent regulatory genes such as p53 and par-4 in order to promote cytochrome c release and induce caspase-3 activation. Increased neuronal apoptosis has been demonstrated in classic neurodegenerative disorders including AD. Interestingly, these disorders are also characterized by alterations in apoptotic regulatory proteins including several Bcl-2 family proteins and caspases. For example, Bcl-2 and caspase-3 are increased in the cortex of postmortem AD brains. These increases are thought to be due to a compensatory upregulation in response to the neurodegenerative process. In contrast, lower Bcl-2 levels have been reported in the frontal cortex of patients with autism, a classic neurodevelopmental disorder. Accumulating data suggest important roles for apoptotic pathways in the pathophysiology of a spectrum of neuropathological disorders (Michel et al. 1999).

Apoptosis-Necrosis Cell Death Continuum

There is now a substantial body of evidence of an apoptosis-necrosis cell death continuum. In this continuum, neuronal death can result from varying contributions of coexisting apoptotic and necrotic mechanisms. Moreover, the long-standing paradigm in the field of cell biology that specifically divided cell death processes into those that are regulated (apoptosis) and those that are accidental and unregulated (necrosis) has been overturned by the discovery that tumor necrosis factor (TNF) can induce regulated cell death with apoptotic or necrotic features depending on the specific context. Recently discovered forms of regulated (non-apoptotic) cell death include necroptosis, ferroptosis, parthanatos, cyclophilin D-(CypD)-dependent necrosis, neutrophil extracellular trap (NET)-associated cell death (termed NETosis), pyroptosis, and autophagic cell death (autophagy) (Fricker et al. 2018). The most studied (non-apoptotic) forms of cell death with specific relevance to neurodegeneration to date include necroptosis and autophagy. These processes are discussed briefly below. The other forms of cell death noted above have been reviewed elsewhere (Brinkmann et al. 2013: Green et al. 2014; Galluzzi et al. 2014; Lupfer et al. 2015; Fricker et al. 2018).

Necroptosis

Necroptosis is a programmed form of necrosis that may have evolved as an inflammatory defense mechanism against pathogens and to eliminate infected cells (Mocarski et al. 2015). Necroptosis is dependent on the kinase activity of receptor-interacting kinase 1 (RIP1), kinase activity of RIP3, and expression of the mixed lineage kinase domain-like (MLKL) (Galluzzi et al. 2014). The process is initiated by the binding of the TNF family of cytokines such as TNFα, Fas/CD95, and TRAIL (TNF-related

apoptosis-inducing ligand) to membrane receptors to activate intracellular RIP family kinases. Necroptosis is gaining attention as a mediator of neuroinflammation and neurodegeneration, and it has been linked to a variety of inflammatory conditions such as multiple sclerosis, amyotrophic lateral sclerosis (ALS), stroke, ischemia-reperfusion injury, myocardial infarction, arteriosclerosis, and Crohn's disease. It is currently unknown, however, whether necroptosis is a driving force in these diseases or a secondary consequence of some other pathologic process (Fricker et al. 2018).

Autophagy

Autophagy is a catabolic (lysosome-dependent) process used by cells to eliminate misfolded proteins, protein aggregates, and damaged organelles. The process is also used to recycle important cellular constituents such as amino acids, lipids, nutrients, and metabolites. Autophagy is a normal, orderly biological process that is accelerated by a variety of cellular stressors, such as nutrient starvation, DNA damage, growth factor withdrawal, organelle damage, and the accumulation of abnormal proteins. Because neurons are postmitotic, they are dependent on high basal levels of autophagy compared to non-neuronal cells since misfolded proteins and damaged organelles cannot be diluted through cell division. Moreover, the axons and dendrites of neurons have long and extended cytoplasms that present additional challenges for preventing dysfunctional organelles and cellular waste from accumulating over time. While autophagic processes in young neurons are efficient, aged neurons are vulnerable to slowdowns in the proteolytic clearance of autolysosomal substrates. Such slowdowns can result in the accumulation of ubiquitinated protein aggregates which lead to impairments in neuronal function and degeneration. The importance of autophagy in the pathophysiology and treatment of age-related neurodegenerative illnesses such as AD and PD is becoming increasingly recognized (Son et al. 2012; Nixon 2013; Fujikake et al. 2018).

Important Mediators of Neurodegeneration

Oxidative Stress

A variety of metabolic pathways generate highly reactive by-products known as free radicals including hydrogen peroxide, superoxide anions, and hydroxyl radicals. These substances can be used by various cells as part of the immune response to serve useful functions such as to combat infectious organisms and neoplastic cells and to execute cells programmed for death during the normal course of development. In abnormal circumstances such as associated with traumatic and ischemic injury or neurodegenerative diseases such as AD and PD, free radicals may be excessively produced, aberrantly controlled, or inadequately scavenged. In such cases, free radicals cause injury as a result of membrane lipid peroxidation, DNA damage, iron accumulation, and protein nitrosylation. Excess free radicals are normally scavenged and inactivated by several endogenous substances such as vitamin E (-α-tocopherol), which can quench lipid peroxidation, superoxide dismutase which scavenges superoxide radicals, and glutathione peroxidase which removes hydrogen peroxide and lipid peroxides. Therefore, alterations or deficits in any of these endogenous substances can contribute to and/or initiate neurodegeneration.

Excitotoxic Amino Acids

Excitotoxic amino acids play a deleterious role in a number of neurologic diseases and are known to contribute to neurodegeneration. These substances are released in response to a wide variety of insults to the CNS and include glutamate, aspartate, and several oxidation products of cysteine and homocysteine. For example, in stroke, excitatory amino acids are released in the penumbra of ischemic lesions and further released when perfusion is restored and thus are believed to contribute significantly to reperfusion injury. These compounds are also released following traumatic brain injury, during prolonged seizures, and are thought to contribute to the neurotoxicity associated with the amyloid plaques observed in

AD. Overactivation of N-methyl-D-aspartate (NMDA) receptors (a subtype of glutamate receptor) by glutamate leads to alterations in a number of signal systems and ion channels activating apoptosis.

Mitochondrial Dysfunction, Energy Failure, and Ion Dysregulation

Mitochondria play critical roles in cellular respiration, metabolism, energy production, as well as intracellular signaling, free radical production, and apoptosis. Accordingly, they play important roles in both neuronal survival and death. Since neurons have high-energy requirements, they are especially vulnerable to injury and death from dysfunctional mitochondria (Golpich et al. 2017). Neuronal degeneration as a consequence of energy failure within mitochondria can be precipitated by ischemia, as well as several acquired and genetic disorders of metabolism. For example, mitochondrial energy disruption and neurodegeneration occur in Wernicke's encephalopathy, an acquired metabolic disorder resulting from ethanol abuse and/or thiamine deficiency. Similar neuropathology can be observed in Leigh's syndrome, an inherited neurometabolic disorder in which point mutations in mitochondrial DNA are evident. Friedrich's ataxia, the most common inherited ataxia, is an autosomal recessive disease in which protein aggregates appear to disrupt mitochondrial iron metabolism, leading to abnormal free radical formation and altered energy metabolism. In the cases highlighted above, specific irreversible processes lead to a decrease in high-energy phosphates (e.g., ATP, creatine phosphate), possibly leading further to elevated acyl-CoA levels that inhibit multiple metabolic processes. Local electrolyte (ion) imbalances and/or ion channel dysfunction are also thought to contribute significantly to neurodegenerative processes. Ion changes are commonly among the early events in apoptosis, and in fact, alterations in calcium homeostasis are among the best-documented factors in neurodegeneration. Direct evidence of the importance of ion channels in neurodegeneration comes from genetic disorders that affect specific ion channels (i.e., channelopathies). Channelopathies may underlie certain forms of migraine, episodic ataxias, and epilepsy. Indirect evidence that ion dysregulation plays an important role in some forms of neurodegeneration comes from preclinical studies (i.e., stroke models in animals) in which calcium and sodium channel blockers reduce infarct size.

Neuroinflammation

There is extensive evidence that inflammatory processes contribute to the pathology of multiple neurodegenerative illnesses. The term "neuroinflammation" is used to broadly represent the inflammatory processes occurring in the CNS involving both the innate and adaptive immune systems (Gelders et al. 2018). Microglia are the principal innate immune cells in the brain, although astrocytes, macrophages, natural killer cells, mast cells, oligodendrocytes, and neurons all contribute to innate immune responses. Microglia play a major role in homeostatic processes in the brain including synaptic pruning; clearing of apoptotic cells, misfolded proteins, and waste products; and providing trophic support for neurons. They represent the first line of defense in the brain and react to pathogens and tissue damage by releasing oxygen free radicals and secreting a variety of substances known to stimulate local inflammation such as inflammatory cytokines, complement and coagulation proteins, as well as binding proteins. As an example, inflammatory factors found in degenerating sites in Alzheimer's disease brains include activated microglia, the cytokines interleukin IL-1 and IL-6, an early component of the complement cascade, Clq, as well as acute-phase reactants such as C-reactive protein. A significant role of the adaptive immune system in neurodegenerative disorders is exemplified by alterations in subsets of T- and B-cells and increases in autoantibody levels in the blood, cerebrospinal fluid, and brain tissues. The positive (anti-inflammatory) or negative (pro-inflammatory) role of these subsets of T- and B-cells appears to be dependent on the levels of specific cytokines and chemokines. The aging process (a major contributor to many neurodegenerative illnesses) is associated with negative effects on both innate and adaptive immune responses. In the setting of unhealthy

aging, microglia display prolonged activation to insults where pro-inflammatory cytokines (e.g., IL-6, TNF, IL-1b) are elevated, and the microglia also exhibit reduced motility, impaired phagocytosis, and impairments in their ability to provide trophic support to neurons (Stephenson et al. 2018).

Neurotrophin Support and Altered Cell Signaling

A continuous supply of a variety of polypeptide molecules known as neurotrophic factors (or neurotrophins) is essential to the nervous systems of all vertebrates throughout development as well as in adult life (Huang and Reichardt 2001). These important molecules interact with specific receptors and initiate a variety of cellular signaling systems. During the period of target innervation, limiting amounts of neurotrophic factors regulate neuronal numbers by allowing survival of only some of the innervating neurons, the remaining being eliminated by apoptosis. Increasing evidence indicates that several neurotrophic factors also influence the proliferation, survival, and differentiation of precursors of a number of neuronal lineages. In the adult, neurons continue to be dependent on trophic factor support, which may be provided by the target or by the neurons themselves. Altered trophic factor support and cell signaling as a result of excess free radicals or peroxynitrites has been implicated in the neurodegenerative processes associated with several neurologic diseases. Furthermore, the ability of neurotrophins to promote survival of peripheral and central neurons during development and after neuronal damage has stimulated the interest in these molecules as potential therapeutic agents for the treatment of nerve injuries and neurodegenerative diseases. Examples of therapeutically relevant neurotrophins (from a neurodegenerative disease standpoint) are nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) (see further discussion below).

Misfolded and Aggregated Proteins

Mammalian cells typically contain thousands of different proteins that must fold into specific three-dimensional structures to acquire functional activity. The biologically active conformation (i.e., the native state) of these proteins, while thermodynamically favorable, is often only marginally stable under physiological conditions. Metastable proteins can adopt a multitude of conformational states including misfolded conformations that are prone to forming toxic aggregates, including soluble oligomers and fibrillar amyloid deposits, which are linked with neurodegeneration in AD and PD, and many other pathologies. To maintain homeostasis, all cells contain an extensive network of molecular chaperones to regulate protein synthesis, folding, and degradation. In the context of neurodegenerative disease, these molecular chaperones can become dysfunctional (Hartl 2017).

Gene Mutations, Noncoding RNAs, and Exosomes

While most of the common neurodegenerative disorders are sporadic with unknown etiology, it is now widely believed that the susceptibility to one or more of these illnesses probably involves a combination of genetic and environmental risk factors. Many of these illnesses (e.g., AD, PD, amyotrophic lateral sclerosis – ALS) have familial forms that have been particularly useful for genetic analyses where specific mutations have revealed the importance of protein and enzyme abnormalities to the illness pathology. Examples include the amyloid precursor protein and presenilin genes in AD, α-synuclein and Parkin in PD, and superoxide dismutase in ALS. Next-generation sequencing has resulted in a rapidly evolving literature over the last several years for both the identification of candidate genes and the development of diagnostic markers for neurodegenerative diseases. Gene-expression studies have implicated biological pathways such as inflammation, protein homeostasis, and RNA splicing as critical to the development and progression of multiple neurodegenerative disorders. Another rapidly evolving area of (genetics-related) research focuses on the "epigenetic" contributions of noncoding RNAs (ncRNAs) to the pathophysiology of

neurodegenerative diseases. Noncoding RNAs (ncRNAs) are functional RNA molecules that are transcribed from DNA but not translated into proteins. Typically, ncRNAs function to regulate gene expression at the transcriptional and posttranscriptional level. They play a major role in heterochromatin formation, histone modification, DNA methylation targeting, and gene silencing. ncRNAs are now known to play critical roles in brain evolution, development, homeostasis, stress responses, and plasticity (Salta and De Strooper (2017)). Among the ncRNAs, the most widely studied group with relevance to neurodegeneration are the microRNAs (miRNAs) which are now known to play dynamic roles in neurodevelopment, neuroplasticity, and stress responses (Sharma and Lu 2018). Recent research has demonstrated that miRNAs are often transported in body fluids within exosomes, small cell-derived vesicles that function in intercellular communication processes. Once released into the extracellular fluid, exosomes fuse with other cells and transfer their cargo to the acceptor cell. Exosomes can thus transport miRNAs that can have positive or negative effects on neural plasticity. Exosomes are also involved in the spread of "toxic" proteins in neurodegenerative disorders which are mutated or "misfolded" proteins and serve as template for the formation of oligomers.

Pharmacological Intervention

There are multiple mechanisms known to underlie neurodegeneration that at least theoretically could be targeted for pharmaceutical intervention. Currently however, there is no clinically available therapeutic agent that can reliably protect the brain from progressive neurodegenerative processes for sustained periods. Due to the extensive amount of preclinical research that has been conducted in recent years, there is a basis for optimism, however. It appears likely that some of these approaches may result in clinically effective therapeutic modalities in the near future. A short (representative) overview of some of the investigational approaches to combat neurodegeneration is provided below.

Inhibitors of Oxidative Stress

There are both epidemiologic evidence and prospective data from in vitro studies and animal experiments that support the premise that lipophilic antioxidants such as vitamin E, coenzyme Q10 (CoQ10), vitamin A, carotenoids, docosahexaenoic (DHA), and eicosapentaenoic acids (EPA) may have a therapeutic role in neurodegenerative illnesses. Several of these compounds have been evaluated in prospective clinical trials, however, to date; the data have provided negative, conflicting, or equivocal results with some studies showing slightly positive effects and others showing little or no effect. A number of issues require further attention in this area such as the identification of optimal doses of the various antioxidant compounds as well as the evaluation of selected combinations of these agents. These issues are important since specific compounds are known to scavenge or inactivate specific oxidative agents, and thus a single compound would not intuitively be expected to combat free radicals originating from several sources.

Modulators of Glutamate Transmission

The prototypic glutamate NMDA antagonist dizocilpine (MK-801) has been shown to reduce the detrimental effects of excess glutamate (as well as other insults to neurons) in vitro as well as in a variety of animal models, thus supporting this general pharmacological approach in human neurodegenerative illnesses. Unfortunately, dizocilpine is too toxic for use in humans. Several glutamate antagonists have been (or are in the process of being) evaluated both preclinically and clinically as neuroprotective agents. Memantine (another NMDA antagonist) is available adjunctively (to be administered with acetylcholinesterase inhibitors) for the treatment of moderate to severe AD. Riluzole (a drug which inhibits glutamate release) is available clinically for the treatment of ALS and is somewhat effective in slowing progression. Riluzole has also been shown to reduce infarct size in stroke and

brain injury after trauma in animal models, and accordingly human studies are anticipated in the near future. Currently there is considerable interest in developing compounds that modulate metabotropic glutamate receptors (mGluRs). A variety of mGluRs agonists and antagonists as well as positive and negative allosteric modulators are in varied stages of development and testing (Ribeiro et al. 2017). Other agents that modulate glutamate receptors such as AMPA antagonists and compounds that interact allosterically at the polyamine and glycine receptor sites are also being evaluated.

Targeting Mitochondrial Dysfunction

It is clear that mitochondrial dysfunction is present in multiple neurodegenerative diseases; however, it is not always clear if the dysfunction is a causal factor in the illness or a result of some other pathologic process. The types of mitochondrial dysfunction that have been characterized in neurodegenerative illnesses include oxidative damage, altered mitochondrial dynamics and quality control, impaired ATP synthesis, NAD+ depletion, disrupted calcium homeostasis, and the production of abnormal protein or peptide aggregates. Thus, mitochondria are thought to contain multiple targets that are potentially druggable. In animal models, mitochondria-targeted antioxidants such as MitoQ and mitochondria-targeted peptides such as elamipretide have been found effective as have treatments designed to enhance mitochondrial biogenesis by increasing the activity of transcription factors such as PGC1α and NRF2 or of AMPK. In addition, replenishing NAD+ pools with molecules such as NMN67 or improving mitochondrial dynamics (e.g., mitochondrial division inhibitor-1, mdivi-1) has also shown benefit in animal models. Unfortunately, the approaches evaluated to date (e.g., NRF2, MitoQ) showed no effect in clinical trials (Murphy and Hartley 2018).

Neuroinflammation

Currently, reducing neuroinflammation in neurodegenerative diseases is one of the most active areas of focus in drug discovery research. Inflammatory processes associated with neurodegenerative disease suggest a number of therapeutic targets, including inhibitors of complement activation or cytokines, free radical scavengers, and inhibitors of microglial activation. In retrospective studies, the use of nonsteroidal anti-inflammatory drugs (NSAIDs) has been associated with a reduced incidence or slowed progression of AD, indicating a potential for therapeutic use of this class of agent. However, to date, no NSAIDs have been found to be effective in prospective clinical trials in neurodegenerative diseases. Other areas of current focus include the modulation of eicosanoid signaling, agonists of peroxisome proliferator-activated receptor-γ (PPARγ) (a nuclear hormone receptor that acts as a transcription factor in the regulation of inflammatory gene expression), and human plasma-derived products such as immune globulins. Other compounds in various stages of testing include minocycline, an antibiotic that crosses the blood-brain barrier and exhibits anti-inflammatory and neuroprotective effects, and cannabinoid receptor ligands (e.g., CB2 agonists) that have anti-inflammatory activity. Novel epigenetic approaches (e.g., histone deacetylase 2 (HDAC2) inhibitors) for modulating the activation states of microglia and astrocytes are also currently under investigation (Fu et al. 2019).

Inhibitors of Apoptosis, Necroptosis, and Growth Factor-Like Molecules

As indicated earlier, apoptosis is inhibited by certain proteins, such as Bcl-2 and Bcl-x. In contrast, Bax and the tumor suppressor protein, p53, have been shown to enhance the onset of apoptosis. Accordingly, drugs which have the ability to enhance the expression of Bcl-2 and Bcl-x or to inhibit the expression of Bax and p53 could theoretically have the potential to reduce neurodegeneration. Drugs that inhibit apoptosis-inducing enzymes including caspases may also have a role. The expression of Bcl-2 and other proteins in this family is also modulated by trophic factors such as NGF and basic fibroblast growth factor (FGF), endogenous neurotrophins

which have been shown to block cell death and preserve the phenotype of various cells in the nervous system. Unfortunately, NGF, FGF, as well as most other peptide molecules fail to adequately penetrate the brain from peripheral administration and are thus considerably limited from a therapeutic standpoint. Recent interest has thus focused on low molecular weight growth factor-like molecules, molecules that increase the release of growth factors in the brain (or increase their receptors), or various downstream signaling molecules. There is also increasing evidence that inhibition of necroptosis using inhibitors of RIP1, RIP3, or MLKL can confer neuroprotective effect in neurodegenerative disorders (Zhang et al. 2017).

Autophagy Inducers

Defective autophagy has been reported in multiple neurodegenerative diseases; thus the induction of autophagy for enhancing the clearance of misfolded proteins is considered a potential treatment strategy. The therapeutic potential of this therapeutic strategy has been demonstrated in a variety in vitro systems and in vivo transgenic models of neurodegenerative diseases. Examples include mTOR inhibitors like rapamycin or its analogs that stimulate autophagy as well as mTOR-independent autophagy inducers such as lithium, carbamazepine, rilmenidine, and trehalose (Panda et al. 2019).

Other Investigational Approaches

A myriad of additional pharmaceutical approaches to neurodegenerative diseases at varying stages of development includes new calcium channel antagonists, compounds that stimulate the expression of antioxidant enzymes such as superoxide dismutase, small molecules that can serve as chemical chaperones to stabilize unfolded monomer conformations and/or to destabilize misfolded oligomers, as well as metal chelators that can sequester metal ions to block protein aggregation. Finally, it may turn out that the most effective strategy to combating devastating neurodegenerative diseases will be a combination therapy (or multi-target) approach such that taken to treat cancer, hypertension, infectious disease, etc. (Trippier et al. 2013).

Definition

Metabotropic tachykinin or neurokinin receptors (NK-1R, NK-2R, and NK-3R encoded, respectively, by tachykinin (*TACR*)*1*, *TACR2*, and *TACR3* genes) belong to the G-protein-coupled receptor family. After the binding of peptides belonging to the tachykinin family of peptides (substance P, hemokinin-1, neurokinin A, neurokinin B, eledoisin, ranakinin, neuropeptide K, kassinin), tachykinin receptors mediate many physiological and pathophysiological actions.

Basic Mechanisms

Neurokinin receptors (NK-1R, NK-2R, and NK-3R) belong to the G-protein-coupled receptor family (also known as 7TM receptors, serpentine receptors, or seven-transmembrane domain receptors). The binding of tachykinins to these

receptors promotes a change in the Gα subunit coupled to the NK receptor. Seven-transmembrane-helix receptors show the same structural unit (Graefe and Mohiuddin 2020): three extracellular and three intracellular loops flanked by seven intermembrane domains, an amino-terminal extracellular domain which is responsible for the receptor specificity, and a carboxy-terminal cytoplasmic domain involved in the desensitization of the receptor (in this mechanism, the phosphorylation of both threonine and serine residues of the C-terminus plays an important role). Once tachykinins bind to the NK receptor, the binding to protein Gα is mediated by the third cytoplasmic loop of the receptor; subsequently, a change in the Gα subunit occurs allowing the exchange of GTP for GDP, and hence the signaling cascade is induced. Five subtypes of this subunit (Gαs, Gαi, $G\alpha q_{11}$, $G\alpha_{12/13}$, Gαo), associated with several signaling pathways, have been described. Tachykinins (substance P (SP), hemokinin-1, neurokinin A (NKA), neurokinin B (NKB)), after binding to NK receptors (the conserved carboxy-terminal domain of tachykinins, Phe-X-Gly-Leu-Met-NH_2, interacts with them), control several signaling pathways by activating the second messenger adenylate cyclase which promotes the synthesis of cyclic adenosine monophosphate cytoplasmic and the activation of protein kinase A (these mechanisms are mediated by the Gαs subunit); by stimulating the release of [^{3}H]-arachidonic acid which inhibits various types of adenylate cyclase and by means of the mitogen-activated protein kinases (MAPKs) which increases the phosphorylation of extracellular signal-regulated kinases (mediated by the Gαi subunit); by stimulating the synthesis of inositol (1,4,5) trisphosphate (which promotes the release of Ca^{2+} from the endoplasmic reticulum) and diacylglycerol (which activates protein kinase C) (mediated by the $G\alpha q_{11}$ subunit); by regulating changes in cytoskeletal rearrangement (depending on the activation of the Rho/Rock signaling pathway that modulates the myosin regulatory light chain protein) when cells are preparing to migrate (mediated by the $G\alpha_{12/13}$ subunit); or by activating the Wnt-β- catenin signaling pathway (mediated by the Gαo subunit) (Muñoz and Coveñas 2018).

SP, via the NK-1R, regulates many cell signaling pathways controlling cell function (e.g., promotes the synthesis of DNA and the activation of phospholipases A_2/C), exerts an antiapoptotic action (activating the basal kinase activity of Akt (protein kinase B) via phosphatidylinositol-3 kinase), favors the synthesis of pro-inflammatory cytokines (e.g., interleukins 1, 6, and 12, tumor necrosis factor (TNFα)), and activates pro-inflammatory transcription factors (e.g., nuclear factor kappa B (NF-κB); an NF-κB binding site has been located in the promoter of the *TACR1* gene, a promoter which also contains binding sites for other transcription factors (e.g., AP1, Sp1, Oct2) that control inflammatory genes) (Muñoz and Coveñas 2019). SP, via the NK-1R, is involved in cell proliferation (activating the MAPK cascade (including p38MAPK and ERK1/2) that induces the activation of the AP-1 transcription factor, a heterodimer of c-jun and c-fos), cell migration (promotes changes in cellular shape (e.g. blebbing) in which the Rho/Rock system is involved), angiogenesis (the NK-1R expressed in endothelial cells mediates its proliferation), glycogen breakdown (to obtain glucose for cell metabolism) and inflammation (Muñoz and Coveñas 2019). SP, via the NK-1R, also induces c-myc mRNA/protein synthesis (involved in the progression through S to the G2/M phase of the cell cycle) and the formation of the epidermal growth factor receptor complex which contains the adapter proteins Grb2 and SHC. SP regulates the expression of the hypoxia-inducible factor and increases the expression of vascular endothelial growth factor C and, by enhancing the activation of several signaling pathways (Akt, JNK, ERK1/2), increases the expression of degradative matrix metalloproteinases. SP regulates the NK-1R/Hairy and Enhancer of Split 1, a transcriptional inhibitor of the Notch signaling pathway, induces the mammalian target of rapamycin signaling axis, and activates p70 S6 kinase and the eukaryotic initiation factor 4E-binding protein 1.

The activation of the NK-2R (coupled to the $G\alpha q_{11}$ protein) activates the RhoA-Rho kinase

pathway and the release of adenosine triphosphate which is mediated by protein kinase C, Ca^{++}/calmodulin signals, and multidrug resistance protein transporters. The ablation of the *TACR2* promotes gastric emptying disturbances and upregulates the expression of vasoactive intestinal polypeptide and nitric oxide synthase; NF-κB and Creb signalings are involved in these changes. An association between the age-related decline of rostral cholinergic basal forebrain volume and a NK-3R single-nucleotide polymorphism has also been reported as it is known that puberty onset time is associated with the single-nucleotide polymorphism A63P located in the *TAC3* gene.

Tachykinin receptors are widely distributed by the peripheral/central nervous systems; they are also found in immune (e.g., macrophages, dendritic cells, monocytes, lymphocytes) and endothelial cells, smooth muscle, skin, thyroid gland, spleen, thymus, lymph nodes, lung, genitourinary/gastrointestinal tracts, and cancer cells (in which the NK-1R is overexpressed) (Muñoz and Coveñas 2018). Thus, the NK-1R is involved in immunoregulatory and vasodilatory (endothelial cells express the receptor) mechanisms mediated by SP. The distribution of the NK-2R is less widespread than that found for the NK-3R (this is mainly expressed in brain limbic areas). Tachykinins (mainly SP and NKA) are widely distributed by the peripheral and central nervous systems, are present in body fluids (breast milk, blood, cerebrospinal fluid), and are located in non-nerve cells (endothelial cells, fibroblasts, smooth muscle, platelets, Leydig cells, immune cells (eosinophils, macrophages, monocytes, lymphocytes)) and cancer cells (Muñoz and Coveñas 2019). The distribution for both SP and NKA is more widespread than that observed for NKB. The *TAC1* gene (in chromosome 7) encodes SP (it can be processed originating SP biological active fragments (SP_{1-4}, SP_{1-7}), neuropeptide K and NKA, and the *TAC3* gene, NKB. SP carboxy- and amino-terminal sequences are cleaved by proteolytic enzymes: carboxy-terminal fragments (e.g., SP_{6-11}) show a high affinity for the NK-3R, whereas amino-terminal fragments (e.g., SP_{1-4}, SP_{1-7}) bind to NK-1R and NK-2R (Duarte et al. 2016). SP is hydrolyzed by angiotensin-converting hormone (plasma) and p-endopeptidase (extracellular fluid) and has a lower half-life in tissues (seconds/minutes) than in plasma (hours). Tachykinins bind to all three NK receptors (a lack of specificity due to the conformational flexibility of the tachykinergic peptides occurs) showing different degrees of affinity for them: SP shows the highest affinity for the NK-1R, and for this reason it has also been named SP receptor; hemokinin-1 (present in non-neural tissues) also shows a high affinity for the NK-1R; NKA has a high affinity for the NK-2R and NKB for the NK-3R (Muñoz and Coveñas 2019). Chemical modifications can change affinity; thus the substitution to NKB with MePhe and Asp improves receptor binding and provides a NK-3R selective analog. The NK-1R has different active conformations, each of which shows a different affinity for distinct antagonists or agonists. This receptor has seven hydrophobic alpha-helical transmembrane domains. The intracellular C-terminus and the extracellular N-terminus of the NK-1R, respectively, contain potential phosphorylation and glycosylation sites: NK-1R signaling is regulated by phosphorylation/glycosylation mechanisms. SP, via the NK-1R, promotes the phosphorylation, desensitization (a low concentration of SP favors the return of the NK-1R to the cell membrane; a high concentration induces the ubiquitination/degradation of the receptor), and internalization (clathrin-dependent mechanism) of the NK-1R. Two isoforms, with different signaling capabilities (e.g., in cancer cells), of the NK-1R are known: the full-length and the truncated (the oncogenic isoform of the NK-1R that mediates tumor cell malignancy) forms (Muñoz and Coveñas 2018). In cancer cells, the full-length form is downregulated, whereas the truncated form is upregulated. The expression of the NK-1R was increased when SP activated the NF-κB. SP binds to the extracellular loops of the NK-1R, but non-peptide NK-1R antagonists bind in a pocket relatively deep between the III–VI transmembrane segments of the receptor. Gln165 (IV), His197 (V), His265 (VI), and Tyr287 (VII) residues play an important role in the binding of non-peptide NK-1R antagonists to the NK-1R, whereas other residues (Ser169,

Glu193, Lys194, Phe264, Phe267, Pro271, Tyr272) also contribute to this binding. Moreover, it is known that transmembrane domains 5 and 6 are involved in NK-3R ligand binding and trafficking, whereas the third intracellular loop in NK-3R signaling. The activation of the NK-3R affects gene expression (genes involved in synaptic plasticity, cell growth, and cell signaling) and chromatin structure (relaxation) by means of histone acetylation.

To date, the SP/NK-1R system is the most tachykinergic studied system, and the involvement of the tachykinin/NK receptor system in many physiological and pathophysiological mechanisms is known. The broad physiological actions exerted by tachykinins are explained by the binding capacity of tachykinins to all three NK receptors. Table 1 shows some examples of this involvement, not only for SP but also for NKA and NKB. The data shown in Table 1 suggest that NK receptor antagonists could be potentially used for the treatment of many human pathologies.

Drugs

Peptides are mainly released under a pathological situation or after a strong cell activation, and it seems that NK receptor antagonists exert a therapeutic effect acting on deranged tachykinergic systems in which a high amount of peptides is released. Although tachykinins, via NK receptors, are involved in the molecular bases of many physiological/patophysiological mechanisms, only five NK receptor antagonists (all of which are non-peptide NK-1R antagonists) have currently been approved for use in humans for the treatment of acute/delayed chemotherapy-induced nausea/vomiting and for postoperative nausea/vomiting: aprepitant (Emend, L-754,030, MK-869; oral administration; Cinvanti, aprepitant injectable solution), fosaprepitant dimeglumine (Ivemend, a water-soluble prodrug of aprepitant which is converted to aprepitant by ubiquitous phosphatases; intravenous administration), rolapitant (Varubi, oral administration), netupitant (oral administration) and fosnetupitant (a prodrug form of netupitant which is converted by phosphatases to its active form; intravenous administration) (Fig. 1). In preclinical studies, the effective action of NK receptor antagonists has been demonstrated, but in general, the action has unfortunately been ineffective in clinical trials. This can be explained by the low dose of the drug administered, the inappropriate selection of patients/end points, and/or the lack of knowledge on the molecular interaction between NK receptors and their antagonists. It is pivotal to know in depth the structure-function relationship of tachykinins-NK receptors for a rational design of new drugs. To date, no NK-2R or NK-3R antagonist (Figs. 2, 3) has been approved to be administered in humans; although they all were safe, this was mostly due to a lack of efficacy. NK-2R or NK-3R antagonists have been tested in clinical trials for the treatment of depression, diarrhea, schizophrenia, gastrointestinal disorders, asthma, panic disorder, and major depressive disorder. NK-1R antagonists exert (in a dose-dependent manner: the greater the concentration, the greater the therapeutic effect; the greater the number of NK-1Rs, the greater the concentration of the NK-1R antagonist) antiemetic, anxiolytic, analgesic, anti-inflammatory, anticonvulsant, antipruritic, apoptotic, antitumor, antidepressant, antiangiogenic, antimetastatic, and antiviral effects. The therapeutic effect exerted by NK receptor antagonists depended on the number of NK receptors expressed and on the degree of affinity of NK receptor antagonists for NK receptors.

In many pathologies, the SP/NK receptor system is upregulated (Table 1). In inflammatory processes the NK-1R and SP are upregulated; in chronic stress, acute pancreatitis, asthma, and HIV-positive patients, the NK-1R expression was also upregulated; in the latter patients, the SP level was also increased in blood, and it is known that SP, via the NK-1R, increases HIV replication in immune cells. In the skin, SP induces the degranulation of mast cells increasing capillary permeability and edema formation. In mastocytosis (abnormal growth/accumulation of mast cells), an increase in the plasma level of SP and in the number of NK-1R-positive cells has been observed. Moreover, changes in the levels of both the NK-1R and SP have been observed in

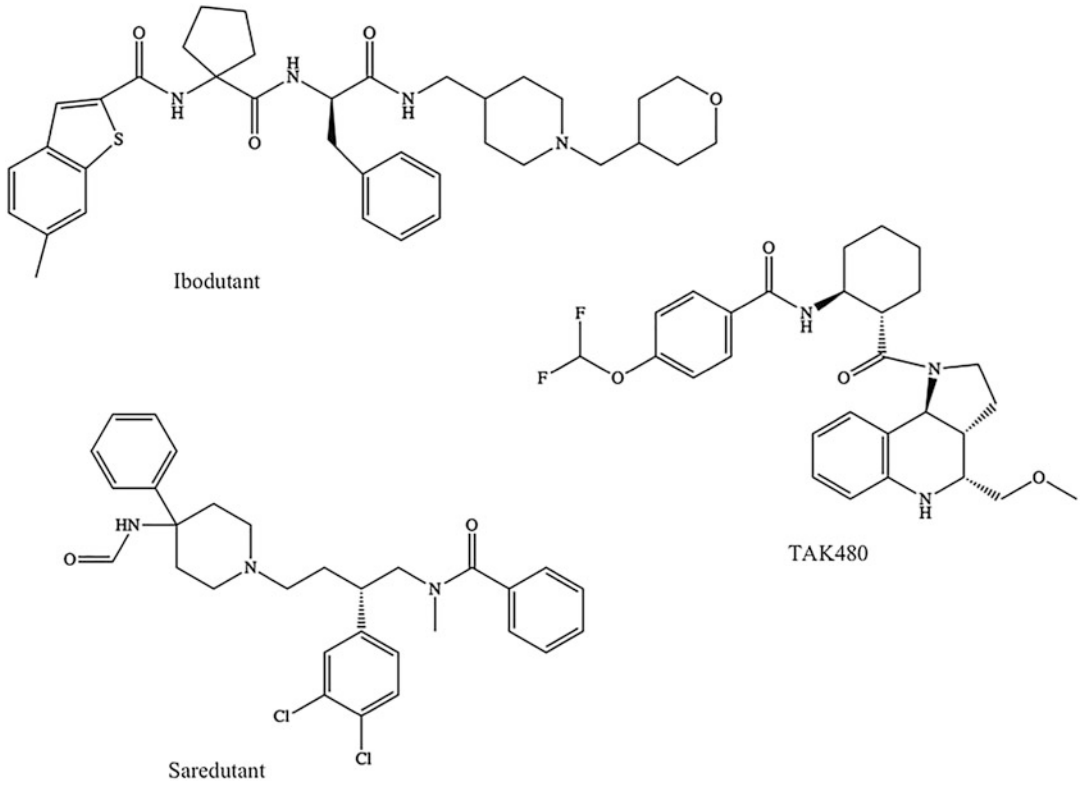
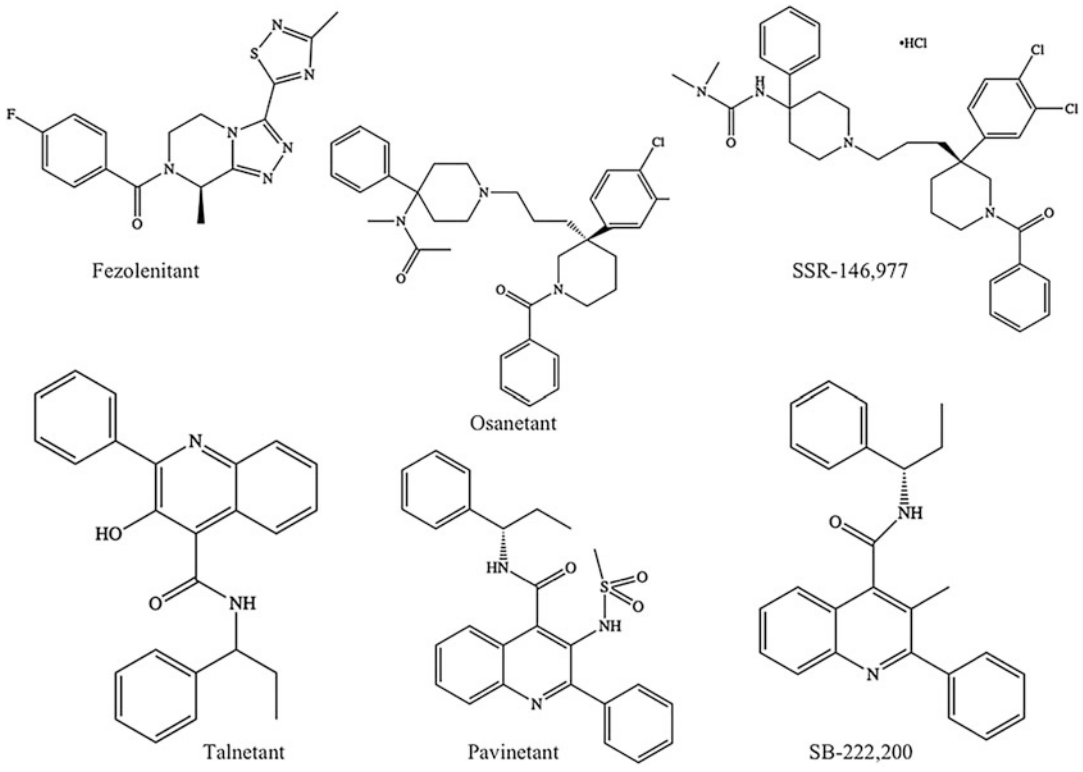
bipolar disorder and schizophrenia. In the latter disease, fibromyalgia, major depression (antidepressant drugs decrease SP synthesis), and in people attempting suicide, the level of SP was increased. In Crohn's disease and ulcerative colitis, SP (in the inflamed mucosa) and the NK-1R (in arterioles and lymphatic tissue) were upregulated. SP is involved in rheumatoid arthritis: the joint with severe arthritis is densely innervated by SP-containing fibers, and an increase in the level of SP in the synovial fluid/serum has been reported; synovial endothelial cells express the NK-1R. In pseudomembranous colitis and asthma, an overexpression of the NK-1R has been observed, whereas a high level of SP has been found in the nasal secretion of coughing subjects, and it is known that SP is involved in the proliferation, migration, invasion, and metastasis of cancer cells in which the NK-1R is overexpressed. In acute cystitis, the SP/NK-1R system is upregulated, and when bacteria infect the urinary bladder and promote pain and dysuria, the SP/NK-1R system which mediates pain is activated. The upregulation of the SP/NK-1R system in the abovementioned pathologies suggests that the NK-1R is a therapeutic target and that the use of NK-1R antagonists is a potential therapeutic strategy for the treatment of these pathologies.

NK-1R antagonists are divided into non-peptide (compounds with different chemical compositions) (Fig. 1) and peptide (also known as SP analogue antagonists; in the SP molecule, L-amino acids are replaced by D-amino acids) antagonists. The latter are not brain-penetrant, can exert a toxic effect, show poor potency, and are degraded rapidly by peptidases (its use is limited in clinical practice), whereas non-peptide NK-1R antagonists show, in general, opposite



Neurokinin/Tachykinin Receptors, Fig. 2 Chemical structures of NK-2R antagonists: ibodutant (MEN-15,596), TAK-480 and saredutant (SR-48,968)

characteristics. The latter antagonists are safe and well tolerated, even at high dose (1,140 mg/day for 45 days), and serious side effects have not been reported; instead, they were mild or moderate: headaches, somnolence, fatigue, irritability, tinnitus, dizziness, and pharyngitis. NK-1R antagonists are moderate inhibitors of the CYP3A4 metabolic pathway and, for certain drugs, a dose reduction is required. These antagonists reduce the intensity of the itch (patients with pruritus showed an increase in the serum level of SP; the release of this peptide from C fibers promotes a neurogenic inflammation). Proximal airways and larynx are innervated by C vagal afferent fibers containing SP which enhance cough via the NK-1R, and, in fact, antagonists of this receptor are antitussive drugs. Doxorubicin (an anthracycline antineoplastic drug) increases fibrosis in the cardiac tissue and apoptosis in cardiomyocytes, promoting a cardiomyopathy. NK-1R antagonists attenuate cardiac fibrosis by preventing cardiomyocyte apoptosis, decrease cardiotoxicity, and increase cancer cell sensitivity to doxorubicin. NK-1R antagonists decrease edema formation and blood-brain barrier dysfunction, reduce liver inflammation, and promote the synthesis of cytokines (e.g., IL-6, IL-10) that exert a hepatoprotective effect. In seizure, the level of SP is augmented, and NK-1R antagonists increase the anticonvulsant efficacy of sodium channel blockers. NK-1R antagonists improve obesity, decrease alcohol intake, prevent the induction of the vomiting pathways mediated by the nucleus tractus solitarius and area postrema, and, in patients with irritable bowel syndrome, reduce anxiety and pain. In cancer, the SP/NK-1R system is involved in cancer progression, migration, invasion, and metastasis: the receptor is overexpressed in tumor cells and SP promotes the proliferation of these cells. A higher expression of the NK-1R is



Neurokinin/Tachykinin Receptors, Fig. 3 Chemical structures of NK-3R antagonists: fezolinetant, osanetant (SR-142,801), pavinetant (AZD-4,901), SB-222,200, SSR-146,977, and talnetant (SB-223,412)

related to a higher invasion/metastatic potential, larger tumor size, and poorer survival. This means that the NK-1R can be used as a biomarker for cancer leading to earlier diagnosis and treatment. Like the NK-1R, in cancer patients, an increase in the plasma level of SP has been reported, and this observation can also be used as a predictive factor for tumor development and/or a high risk of developing cancer. The NK-1R is involved in the viability of tumor cells, and hence this receptor is a new target for the treatment of tumors with NK-1R antagonists (e.g., aprepitant) (Fig. 1). Aprepitant is a broad-spectrum anticancer drug (e.g., retinoblastoma, osteosarcoma, glioma, neuroblastoma, carcinoma). NK-1R antagonist and fosaprepitant also exert an antitumor action (Fig. 1). Aprepitant is mainly metabolized in human liver by cytochrome P450, family 3, subfamily A (CYP3A4); it shows half-life ranges from 9 to 13 h and binds to plasma proteins. Aprepitant promotes apoptosis in cancer cells by increasing mitochondrial reactive oxygen species (a Ca^{2+} flux from the endoplasmic reticulum into mitochondria occurs); activates the caspase-3-dependent apoptotic pathway, via suppression of antiapoptotic target genes of NF-κB; increases apoptotic markers (propidium iodide/annexin-V) and the level of pro-apoptotic proteins (cleaved caspase-3 and 9, Bam, Bim, PARP) and mRNA expression of pro-apoptotic targets (p21, p73, Bax, Bid, Bad); decreases antiapoptotic proteins (Bcl-xL, Bcl-2); downregulates the expression of lymphoid enhancer-binding factor 1, cyclin B1, cyclin D1 CDK4, and CDC25A; blocks c-myc expression (the molecule by which p73 regulates NF-κB activity); alters cell cycle and DNA replication rates; and induces a cell increase in the G_0/G_1 phase and a decrease of cells in the S phase. Aprepitant also decreases the cardiotoxicity induced by doxorubicin and increases tumor cell sensitivity to this drug.

Table 1 shows the involvement of the NKA/NK-2R system in physiological and pathophysiological mechanisms. In uterine leiomyomata, the upregulation of the TACR2 mRNA has been described. The inhibition of the NK-2R is a therapeutic strategy for the treatment of irritable bowel syndrome (Szymaszkiewicz et al. 2019), and, in the acute inflammation of the intestine, NK-2R antagonists promote recovery from colitis, prevent inflammation, and counteract changes in enteric glial gene expression. Ibodutant (MEN-15,596) (Fig. 2), a NK-2R antagonist, improves stool pattern, abdominal pain, and overall symptoms in patients suffering from irritable bowel syndrome with diarrhea. In an experimental model of visceral hypersensitivity, the same antagonist blocked abdominal nociception. Ibodutant reduced NK-2R internalization in colon smooth muscle cells (this could exert a beneficial effect in gut diseases showing hypermotility, since NK-2R mediates spasmogenic activity on enteric smooth muscle cells) and also blocked bronchoconstriction. The NK-2R plays an important role in the neuro-immuno cross talk causing airway inflammation, including severe asthma. In this disease, the NK-2R is upregulated, and this upregulation is attenuated by bone marrow-derived mesenchymal stem cells which induce the synthesis of anti-inflammatory substances. The blockade of the NK-2R (located on the vagal endings) inhibited respiratory changes (e.g., respiratory rate increase) induced by NKA. In allergic rhinitis, mast cells overexpress the NK-2R; by targeting these receptors, the allergic airway inflammation occurring in this disease can be prevented. NK-2R also mediates the activation of dendritic cells which induce the type 1 immune response, and hence NK-2R antagonists could be used for the treatment of chronic inflammation produced by excessive type 1-dominant immunity. In the bladder, NK-2R antagonists attenuated increase bladder compliance, intravesical pressure, and bladder-afferent firing, whereas in recurrent major depressive disorder, monocytes upregulated the expression of the NK-2R and NKA favored TNFα release and the activation of NF-κB (the latter was blocked by NK-2R antagonists). In psoriasis, NK-2R-immunoreactive nerves and non-neuronal inflammatory cells (expressing NKA and NK-2R) were increased compared to healthy controls, and the number of cells expressing the NK-2R was related to pruritus intensity. The NK-2R antagonist, saredutant (SR-48,968) (Fig. 2), blocked gastric motility, and another NK-2R antagonist (TAK-480) (Fig. 2) accelerated defecation, blocked smooth muscle contraction, and improved visceral hypersensitivity. Saredutant counteracted stress-related conditions by normalizing the activity of the hypothalamic-pituitary-adrenal axis and by increasing the hippocampal expression of the brain-derived neurotrophic factor. Saredutant also exerts antidepressant and anxiolytic (without impairing cognition) effects and inhibits the release of growth hormone/growth hormone-releasing hormone and the contraction of vein smooth muscle cells mediated by NKA.

Table 1 shows the involvement of the NKB/NK-3R system in physiological and pathophysiological mechanisms. In uterine leiomyomata, the expression of NKB and NK-3R is upregulated. NKB has been involved in reproductive mechanisms and in gynecological disorders since favors the release of follicle-stimulating and luteinizing hormones. The NK-3R antagonist, ESN-364, blocks the hypothalamic-pituitary-gonadal axis and regulates gonadotropin secretion (e.g., luteinizing hormone). NK-3R antagonists (e.g., talnetant (SB-223,412)) inhibited the release of testosterone, luteinizing hormone, and follicle-stimulating hormone, and another NK-3R antagonist, pavinetant (AZD-4,901) (Fig. 3), decreased the release of luteinizing hormone in patients with polycystic ovary syndrome (characterized by a high release of this hormone). Using NK-3R antagonists, the rodent litter size was decreased. NKB signaling is increased in menopausal women in whom NK-3R antagonists (pavinetant) have been tested against menopausal hot flushes with promising results (effective and safe) (Anderson et al. 2019). In schizophrenia, NK-3R antagonists (e.g., talnetant, osanetant) (Fig. 3) improved positive symptoms. The NKB/NK-3R has also been involved in fear consolidation, since when a genetic silencing of the *TAC2*-expressing neurons occurred, an impaired

fear consolidation appeared, whereas osanetant (SR-142,801, a NK-3R antagonist) inhibited fear memory consolidation. An increase in NKB level was observed before social isolation stress symptoms appeared. Osanetant exerts an anxiogenic effect, and, after a stressing stimulus, the NK-3R is internalized and translocated into the nucleus. In the nucleus of smooth muscle cells, the presence of NKB has also been observed. SB-222,200 (Fig. 3), a selective NK-3R antagonist, respectively, counteracted the decrease and increase of surface and cytoplasmic NK-3R densities induced by a dopamine D1/D2 receptor agonist (apomorphine), but not the increase in nuclear NK-3R density induced by the same agonist. SB-222,200 also blocked the development of oral squamous cell carcinoma in cases of bone destruction, although NK-3R agonist analogues showed antitumor/antimigration effects and NKB antiangiogenic actions.

In humans, NK receptor antagonists are safe and well tolerated; they are available as potential therapeutic agents, but unfortunately this potential is currently minimized. The antitumor and antipruritic action of NK-1R antagonists (in combination with radiotherapy/cytostatic drugs or alone) must be studied in depth (e.g., an adequate dose of NK-1R antagonists for the treatment of a specific pathology must be established) as much pivotal data demonstrate that the SP/NK-1R system is involved in both pathologies and hence they are currently the most promising future lines of research. The potential therapeutic dose of the NK-1R antagonist administered must be established according to a determined pathology (cancer, pruritus) by its pharmacokinetic characteristics (e.g., elimination/excretion, absorption, distribution by different tissues and plasma). A lower dose will not reach the necessary threshold to promote a therapeutic effect, and this might be related to the number of NK receptors that must be blocked by the NK receptor antagonist. In this sense, it has been suggested that to obtain a therapeutic antitumor action, aprepitant (>20 mg/kg/day) must be administered daily and for a long period of time depending on the response to treatment. NK receptors are promising targets in many diseases, and NK receptor antagonists could be used for numerous therapeutic interventions.

NPY

Definition

Neuropeptide Y (NPY) is a 36 amino acid polypeptide with tyrosine residues at both ends of the molecule. It is characterized structurally by a "PP-fold" consisting of an extended polyproline helix and an α-helix connected by a β-turn. Based on structural and evolutionary criteria, NPY is closely related to **peptide YY** (PYY) and **pancreatic polypeptide** (PP).

Basic Characteristics

NPY is primarily (but not exclusively) synthesized and released by neurons, which in the peripheral nervous system are predominantly sympathetic neurons. In most cases, NPY acts as a co-transmitter that is preferentially released upon high-frequency nerve stimulation. NPY can be metabolized by the enzyme ***dipeptidylpeptidase 4*** (also known as ***CD26***) (Elmansi et al. 2019) to generate the biologically active fragment $\boldsymbol{NPY_{3–36}}$.

NPY has been highly conserved during evolution and has many effects in the central and peripheral nervous system. In the central and peripheral nervous system, NPY auto- and heteroreceptors (mostly Y_2 subtype) mediate prejunctional inhibition of **neurotransmitter release**. Central effects include a potent stimulation of food intake, anxiolytic effects (Reichmann and Holzer 2016), anti-seizure activity, and various forms of neuroendocrine modulation (Kalra and Crowley 1992). Based on these effects, it has been proposed to play a role in addiction (Thorsell and Mathé 2017), **learning** and **memory** (Gøtzsche and Woldbye 2016), **anxiety** and post-traumatic stress disorder (Reichmann and Holzer 2016), and obesity and **appetite control** (Loh et al. 2015), the latter probably reflecting a central and peripheral effect.

In the peripheral nervous system, NPY was primarily identified as a potent vasoconstrictor that has direct effects on blood vessels and also potentiates **vasoconstriction** by other agents (mostly via Y_1 receptors) (Franco-Cereceda and Liska 1998). Despite reductions of renal blood flow, NPY enhances diuresis and natriuresis in the kidney (Bischoff and Michel 1998). NPY can inhibit pancreatic insulin release and inhibit **lipolysis** in adipocytes (Loh et al. 2015). It also can regulate gut motility and gastrointestinal and renal epithelial secretion. In some cell types, e.g., in vascular smooth muscle cells, NPY appears to enhance cell growth. Peripheral effects of NPY have been proposed to be relevant in cardiovascular diseases including **atherosclerosis**, congestive **heart failure** and arrhythmia (Tan et al. 2018), inflammatory bowel disease (El-Salhy and Hausken 2016), **osteoporosis** (Horsnell and Baldock 2016), and some forms of **cancer**, particularly those of childhood (Tilan and Kitlinska 2016).

NPY, PYY, and PP act upon the same family of receptors, which are classified together as **NPY receptors**. Based on IUPHAR recommendations, the NPY receptors are designated by a capital Y, and the various receptors within the family are designated by subscript numbers (Michel et al. 1998). Five mammalian subtypes of NPY receptors have been cloned and are designated Y_1, Y_2,

Y_4, Y_5, and y_6. The Y_4 receptor preferentially binds PP, whereas NPY (and PYY) are much less potent at the Y_4 receptor than at the other subtypes; hence, this PP-preferring subtype will not be discussed here. The y_6 receptor is found in mice and rabbits, represents a nonfunctional pseudo-gene in humans and primates, and is absent from the rat genome (Khor et al. 2016).

Sequence comparisons show that receptors Y_1, Y_4, and y_6 are more closely related to each other than to the receptors Y_2 and Y_5 (Michel et al. 1998). This is apparent not only from sequence identity but also from other features, such as cysteines believed to form disulfide bonds and the size of the third cytoplasmic loop, which is large in Y_5. The receptors Y_2 and Y_5 are equally distantly related to one another as to the $Y_1/Y_4/y_6$ group. In fact the $Y_1/Y_4/y_6$ group, the Y_2, and the Y_5 receptor are more distantly related to one another than any other G-protein-coupled receptors that bind the same endogenous ligand, despite the fact that Y_1, Y_2, and Y_5 each bind two distinct endogenous ligands, namely, NPY and PYY. However, based on pharmacological recognition profiles, the receptors Y_1 and Y_5 are more similar to one another than to the receptor Y_4 (see below).

- Y_1 receptors have been cloned from humans, rats, mice, and from non-mammals such as *Xenopus laevis*. The genomic organization of the Y_1 subtype gene has been determined in humans and mice, and the human gene has been located on chromosome 4q(31.3–32). Three splice variants in the 5′ region of the human Y_1 receptor yield multiple promoters with tissue-specific expression patterns (Cerda-Reverter and Larhammar 2000). Two splice variants of the murine Y_1 receptor have been described. While both variants bind NPY, the form with a shortened seventh transmembrane-spanning region and a lacking C-terminal tail does not appear to couple to signal transduction as efficiently as the full-length form. Messenger RNA for the Y_1 receptor has been detected in a variety of human, rat, and murine tissues including the brain, heart, kidney, and gastrointestinal tract.
- Y_2 receptors were originally cloned from human SMS-KAN cells. Later cloning studies in rats demonstrated that the cloned Y_2 receptor is also the molecular correlate of a previously proposed PYY-preferring receptor in the gastrointestinal tract. Messenger RNA for the Y_2 receptor has been detected in various parts of the CNS, whereas only low levels of Y_2 mRNA were found in human peripheral tissues.
- Y_5 receptors were cloned from humans and rats. Interestingly, the corresponding gene resides on human chromosome 4q in the same location as the human Y_1 receptor gene, but in opposite orientation (Cerda-Reverter and Larhammar 2000). Messenger RNA for Y_5 receptors was detected by Northern blotting and in situ hybridization in several rat brain areas, including those believed to be important for the regulation of food intake, as well as in testis.

All known NPY receptors belong to the large superfamily of G-protein-coupled, heptahelical receptors. They appear to use similar signal transduction pathways, and no clear and consistent alignment of a specific receptor type with a distinct transduction pathway has been identified. In almost every cell type studied (with the possible exception of some prejunctional receptors), NPY receptors act via pertussis toxin-sensitive G-proteins, i.e., members of the G_i and G_o family. The typical signaling responses of NPY receptors are similar to those of other G_i/G_o-coupled receptors. Thus, inhibition of adenylyl cyclase is found in almost every tissue and cell type investigated and also with all cloned NPY receptor subtypes upon heterologous expression. Additional signaling responses that are restricted to certain cell types include inhibition of Ca^{2+} channels, e.g., in neurons, and activation and inhibition of K^+ channels, e.g., in cardiomyocytes and vascular smooth muscle cells. Based on experiments with Ca^{2+} entry blockers, it has been postulated that NPY stimulates Ca^{2+} channels in the vasculature. In some cell types, members of the NPY family can mobilize Ca^{2+} from intracellular stores. While this appears to involve inositol phosphates in some

cells, inositol phosphate-independent Ca^{2+} mobilization has been postulated in other cell types. A sensitivity of certain responses to NPY to the cyclooxygenase inhibitor, indomethacin, indicates possible activation of a phospholipase A_2 by NPY receptors, but this has yet to be demonstrated definitively. Activation of a phospholipase D or of a tyrosine kinase, which can occur with some G_i/G_o-coupled receptors, has also not clearly been demonstrated. Thus, in general, Y receptors demonstrate a preferential coupling to pertussis toxin-sensitive G-proteins, i.e., the G_i and G_o family, which is followed by the responses typically under the control of these G-proteins (Michel et al. 1998).

Drugs

NPY receptors and NPY-induced responses were originally classified based on agonist orders of potency, but the advent of several subtype-selective antagonists has at least partly superseded the use of agonists for classification purposes. In some cases, however, particularly in vivo, agonists may still be required for receptor characterization. This is based on the use of NPY, PYY, [Pro^{34}]-substituted analogues (which may or may not contain an additional [Leu^{31}] substitution), and on C-terminal fragments of NPY and PYY (including the endogenous $NPY_{3–36}$ and $PYY_{3–36}$).

Y_1 receptors are characterized by an agonist order of potency of NPY $\geq$ PYY $\geq$ [Pro^{34}]-substituted analogue >PP > C-terminal fragment. Some C-terminal fragments that contain exchanged residues may act as partial or full agonists at Y_1 receptors (Hofmann et al. 2018) and in some cell lines even as antagonists; whether such partial antagonism also occurs with intact tissues or in vivo remains to be determined. Y_1-selective antagonists include BIBO 3304 ((R)-N-[[4-(aminocarbonylaminomethyl)-penyl]methyl]-N2-(diphenylacetyl)-argininamide trifluoroacetate, K_i or K_B 0.2–1 nM) and BIBP 3226 ((R)-N^2-diphenylacetyl)-N-[(4-hydroxyphenyl)methyl]-arginine amide, K_i or K_B 1–10 nM), with BIBP 3435 ((S)-N^2-(diphenylacetyl)-N-[(4-hydroxyphenyl)methyl]-argininamide) being a much less active stereoisomer which can be used as an inactive control for the latter one. Other Y_1 receptor antagonists include SR 120819A ((R,R)-1-(2-[2–2-naphthylsulphamoyl-3-phenyl-propionamido]-3-[4[N-(4-[dimethylaminomethyl]-*cis*-cyclohexylmethyl)amidinophenyl]propionyl)-pyrrolidine) or the polypeptide GR 231118 (also known as 1229U91 or GW1229, homodimeric Ile-Glu-Pro-Dpr-Tyr-Arg-Leu-Arg-Tyr-$CONH_2$), but the latter has also been reported to be an agonist at Y_4 receptors in some cases.

The Y_1 receptor has been crystallized with the two high-affinity antagonists UR-MK299 ((R)-N(α)-diphenylacetyl-N(ω)-[2-([2,3-(3)H]propionylamino)ethyl]aminocarbonyl-(4-hydroxybenzyl) arginin-amide) and BMS-193885 (dimethyl 4-[3-[3-[4-(3-methoxyphenyl)piperidin-1-yl]propylcarbamoylamino]phenyl]-2,6-dimethyl-1,4-dihyd ropyridine-3,5-dicarboxylate;(2S)-2-hydroxypr opanoic acid), and the structure has been solved with high resolution. By NMR analysis, mutagenesis and homology modeling full-length NPY was docked into the structure providing a first vision on ligand interaction on a molecular level (Yang et al. 2018).

Y_2 receptors are characterized by an order of potency of NPY ≈ PYY $\geq$ C-terminal fragment >> [Pro^{34}]-substituted analogue > PP. BIIE 0246 ((S)-N^2-[[1-[2-[4-[(R,S)-5,11-dihydro-6(6 h)-oxodibenz[b,e]azepin-11-yl]-1-piperazinyl]-2-oxoethyl] cyclopentyl]acetyl]-N-[2-[1,2-di-hydro-3,5-(4H)-dioxo-1,2-diphenyl-3H-1,2,4-triazol-4-yl]ethyl]-argininamide) is a Y_2-selective antagonist with an affinity of 3 nM. More recently, JNJ-31020028 (*N*-[4-[4-[2-(diethylamino)-2-oxo-1-phenylethyl] piperazin-1-yl]-3-fluorophenyl]-2-pyridin-3-ylbenzamide) was discovered that has been set up as tool to further understand Y_2 receptors in vivo (Aydin et al. 2011).

Structural characterization of the receptor by NMR and homology modeling clearly demonstrated the relevance of the C-terminus for the binding mode of NPY (Kaiser et al. 2015). Furthermore, Y_2 receptor-selective peptides with high metabolic stability are currently studied in

clinical trials to treat obesity (Østergaard et al. 2018).

Y_5 receptors are characterized by an order of potency of NPY $\geq$ PYY $\approx$ [Pro^{34}]-substituted analogue $\approx$ $NPY_{2–36} \approx PYY_{3–36} >> NPY_{13–36}$; rat PP had very low potency at the rat and human Y_5 receptor, while human and bovine PP had affinities similar to those of NPY and PYY. Y_5-selective antagonists include CGP 71683A (*trans*-naphthalene-1-sulfonic acid 4-[4-amino-quinazolin-2-ylamino) methyl]-cyclohexylmethylamide hydrochloride) with an affinity of 1 nM. Furthermore, Y_5 receptor-selective agonists are based on aminoisobutyric acid at position 32 (Cabrele et al. 2001).

As additional tools, transgenic mice overexpressing NPY and knockout mice lacking NPY, Y_1 receptors or Y_5 receptors have been published.

Definition

Produced *de novo* in the central nervous system, neurosteroids are steroids that affect neuronal function, without having any hormonal activity (Baulieu and Robel 1990). They exert their action either through genomic pathways, by interacting with a nuclear receptor leading to regulation of transcription, or through non-genomic pathways, that include interaction with plasma membrane or cytoplasmic receptors (Schverer et al. 2018).

The common point of neurosteroids is that they can modulate neuroplasticity, thus leading to behavioral consequences that will be developed below.

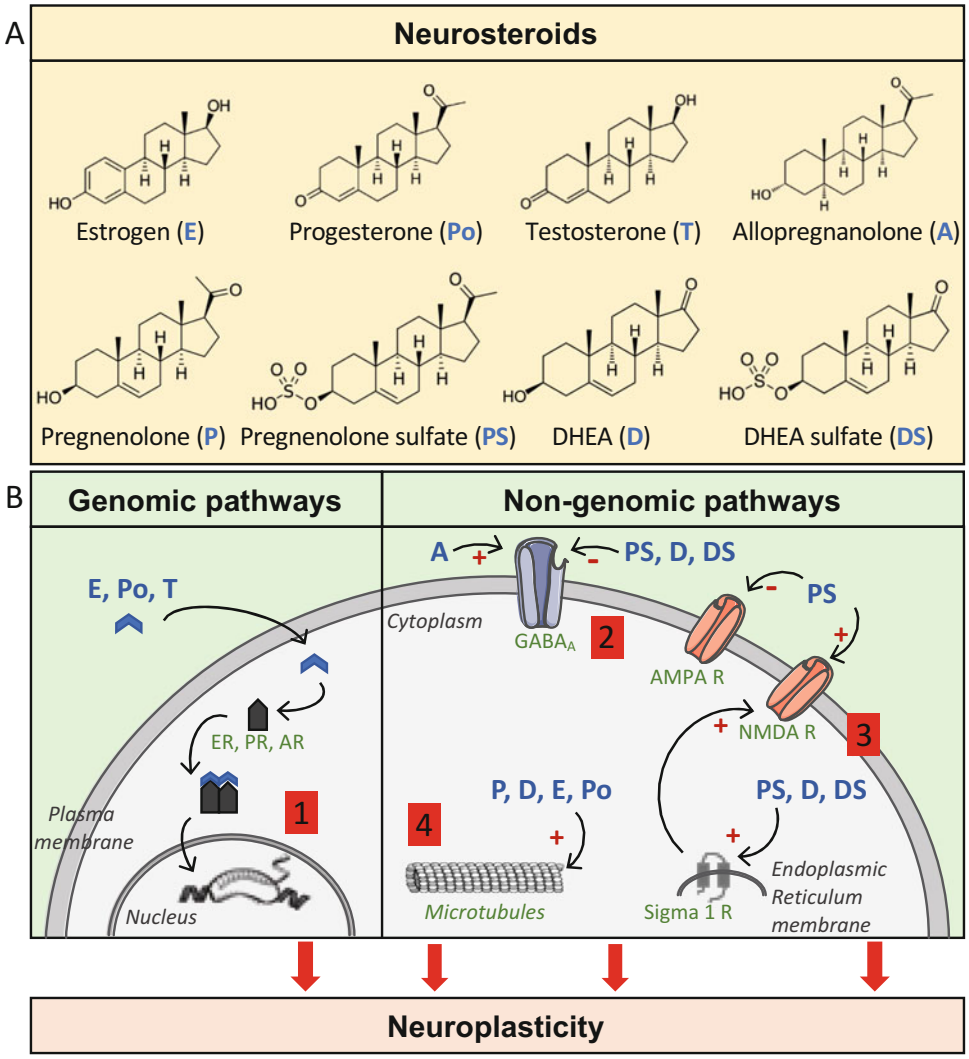
Basic Characteristics

Biosynthesis

Early studies have reported that some steroids were present in the brain even when the steroidogenic glands adrenals and gonads were ablated. Unlike peripheral steroids, neurosteroids are devoid of any hormonal activity, meaning that they are not secreted and transported via systemic circulation. Rather, they are produced in the central nervous system in both neurons and glial cells, thanks to the same enzymatic system found in peripheral steroidogenic cells. The biosynthesis of neurosteroids is thus similar to that of steroids, starting in the mitochondria by the conversion of cholesterol into pregnenolone. This is the result of an enzymatic complex composed of the mitochondrial enzyme cholesterol side-chain cleavage, ferredoxin and ferredoxin reductase (Do Rego et al. 2009). Pregnenolone is then transformed into metabolites in the smooth endoplasmic reticulum and the cytoplasm through pathways that have been well characterized. The resulting metabolites are progestrogens, estrogens, androgens, mineralocorticoids, and glucocorticoids (Do Rego et al. 2009). The most common metabolites of pregnenolone characterized as neurosteroids are progesterone, estradiol, testosterone, pregnenolone sulfate, dehydroepiandrosterone, dehydroepiandrosterone sulfate, and allopregnanolone (Fig. 1a). They all can affect brain activity, either through genomic or through non-genomic pathways.

Regulation of Neuroplasticity Through Genomic Pathways

As detailed below, neurosteroids are molecules that can modulate brain activity, acting on neuroplasticity processes. Neuroplasticity allow the brain and the organism to adapt to changing environment, via learning and memory processes. It involves the remodeling of brain structure and function in response to internal and external stimuli, occurring in specific brain areas, throughout the lifespan in both healthy and pathological conditions. Functional plasticity can be observed when repetitive electrical activity induces a long-term potentiation or depression of synaptic efficacy in brain regions. Structural plasticity refers to the complexity of the neuronal arborization (i.e., number and length of ramifications), and the dynamic of dendritic spines, which are small protrusions that serve as postsynaptic biochemical compartments receiving excitatory inputs. Neuroplasticity is a phenomenon regulated by a



Neurosteroids, Fig. 1 (**a**) Chemical structure of neurosteroids and their abbreviations. (**b**) Mechanism of action of neurosteroids. 1. In genomic pathways, the neurosteroids estrogen, progesterone, and testosterone enter in the cytoplasm of the cells, bind to their specific receptor that undergo dimerization and enter in the nucleus. The complex activates the transcription of genes involved in neuroplasticity. 2. Allopregnanolone is a positive allosteric modulator of the GABAA receptor, whereas pregnenolone sulfate, dehydroepiandrosterone, and dehydroepiandrosterone sulfate inhibits it. 3. Pregnenolone sulfate inhibits the AMPA receptor and potentiates the activity of the NMDA receptor. Pregnenolone sulfate, dehydroepiandrosterone, and dehydroepiandrosterone sulfate activate the sigma 1 receptor that in turn potentiates the activity of the NMDA receptor. 4. Pregnenolone, dehydroepiandrosterone, estrogen, and progesterone promote the activity of the microtubules. All these actions influence neuroplasticity. (Abbreviations. *ER* estrogen receptor, *PR* progesterone receptor, *AR* androgen receptor, *GABA$_A$* stands for the GABA$_A$ receptor, *AMPA R* AMPA receptor, *NMDA R* NMDA receptor, *Sigma 1 R* sigma 1 receptor)

plethora of actors, including a large variety of proteins involved in intracellular signaling pathways, and both the excitatory and inhibitory neurotransmissions, respectively, mediated by the neurotransmitters glutamate and γ-aminobutyric acid (GABA).

The genomic pathways of neurosteroids involve nuclear receptors (Fig. 1b). They are

well characterized for estrogen, progesterone, and testosterone that specifically bind to estrogen, progesterone, and androgen receptors, respectively. These receptors are anchored in the cytoplasm by chaperone proteins, and the binding of the ligand releases this anchoring, allowing dimerization of the receptor (Sever and Glass 2013). This leads to the unmasking of the nuclear localization sequence, followed by the migration of the complex in the nucleus, the association with transcriptional coactivators, and the recognition of specific DNA sequences (Sever and Glass 2013). The consequence of the genomic pathways of neurosteroids is the activation of gene transcription, leading to a series of effects, such as a trophic effect on neurons and glia, the modulation of neurotransmission, and the synthesis of proteins that promote neuroplasticity (Arnal et al. 2017) (Fig. 1b).

Regulation of Neuroplasticity Through Non-genomic Pathways

Some neurosteroids have no nuclear receptor identified. Instead, they exert their activity through non-genomic pathways, by modulating plasma membrane or cytoplasmic targets (Schverer et al. 2018). At plasma membrane, neurosteroids modulate the activity of the GABA type A ($GABA_A$) receptors, as well as the glutamate receptors N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA). In the cytoplasm, neurosteroids interact with sigma 1 receptors and microtubule cytoskeleton (Schverer et al. 2018).

In 1941, Selye demonstrated the anesthetic properties of steroid hormones. It was the first evidence that these molecules could alter brain function (Selye 1941). It is now well established that this effect is due to allopregnanolone, a metabolite of progesterone (Bitran et al. 1995). This neurosteroid acts on the $GABA_A$ receptors that are mainly involved in the inhibitory neurotransmission in the brain. Two sites for allopregnanolone were identified on this receptor: a direct activation site and a potentiation site, where allopregnanolone can enhance the activity of GABA (Fig. 1b). In addition, since allopregnanolone is inactive on NMDA and AMPA receptors of glutamate (Mellon 2007), this neurosteroid is therefore characterized as an inhibitory neurosteroid. Further studies have demonstrated that other neurosteroids such as pregnenolone sulfate, dehydroepiandrosterone, and dehydroepiandrosterone sulfate were able to, in contrast, inhibit the activity of $GABA_A$ receptors, hence leading to a decrease in the inhibitory neurotransmission (Fig. 1b).

On the other hand, the excitatory glutamatergic neurotransmission, supported by NMDA and AMPA receptors, was also shown to be under the influence of neurosteroids. AMPA receptors are involved in the initiation of the glutamatergic response and NMDA receptors are responsible for its maintaining (Shi et al. 1999). Pregnenolone sulfate can act directly on these receptors at sites that have not been identified yet. This neurosteroid was shown to inhibit the activity of AMPA receptors, and to have a dual effect on NMDA receptors, depending on the subunit composition. Indeed, NMDA receptors can be composed of either NR2A, NR2B, NR2C, or NR2D subunits. Pregnenolone sulfate can potentiate the activity of NR2A- and NR2B- subunits while having the opposite effect on NR2C- and NR2D-containing receptors. In brain regions having a high level of plasticity, such as the hippocampus and the prefrontal cortex, NR2A and NR2B subunits are the most present compared to the other two, and this explains why pregnenolone sulfate is often described as an "excitatory" neurosteroid (Fig. 1b). In addition, pregnenolone sulfate, dehydroepiandrosterone, and its sulfate conjugate can also activate sigma 1 receptors. They are endoplasmic reticulum resident chaperone proteins located in the cytoplasm of neurons and glial cells. Their activation results in the potentiation of NMDA receptor activity (Fig. 1b). Overall, due to the consequence of their action on their targets, pregnenolone sulfate, dehydroepiandrosterone, and dehydroepiandrosterone sulfate are considered as excitatory neurosteroids, whereas allopregnanolone is described as an inhibitory neurosteroid.

While these sulfated neurosteroids and allopregnanolone can modulate neurotransmission,

pregnenolone, dehydroepiandrosterone, progesterone, and estrogen were shown to interact with the microtubule cytoskeleton (Fig. 1b). Pregnenolone and dehydroepiandrosterone bind to the microtubule-associated protein 2 (MAP 2) (Schverer et al. 2018). MAP 2 is strongly involved in the regulation of microtubule dynamics by enhancing tubulin assembly and promoting microtubule stability (Gordon-Weeks and Fournier 2014). In addition, pregnenolone can bind to the cytoplasmic linker protein of 170 kDa (CLIP-170), which is also a microtubule-associated protein (Gordon-Weeks and Fournier 2014). Acting through this pathway, pregnenolone was shown to promote microtubule polymerization, leading to neurite outgrowth in vitro (Schverer et al. 2018). It has also been reported that estrogen and progesterone were both able to alter microtubule function, although no target has been identified yet (Camacho-Arroyo et al. 2011). Since the cytoskeleton is a critical actor of neuroplasticity (Gordon-Weeks and Fournier 2014), these data are the direct evidence that these neurosteroids can modulate structural plasticity (Fig. 1b).

Behavioral Consequences

An increasing body of evidence have suggested the positive activity of neurosteroids on neuroplasticity through modulation of their nuclear, cytoplasmic, and plasma membrane targets. Studies conducted in adult healthy humans and rodents showed that administration of some neurosteroids could alter the behavior.

Anxiolytic and Sedative Properties

Neurosteroids are long known for their anxiolytic and sedative properties. Indeed, administration of progesterone produced sedative and anxiolytic effects in men and women (Söderpalm et al. 2004). Allopregnanolone, a metabolite of progesterone, was shown to be the active compound responsible for such effects (Bitran et al. 1995). This neurosteroid was identified to be a positive allosteric modulator of the $GABA_A$ receptor, leading to the reinforcement of the inhibitory neurotransmission in the brain. This mechanism of action could explain the behavioral effects associated to allopregnanolone.

Effects on Memory

The biological substrate for memory processes is neuroplasticity, and as seen before, neuroplasticity involves gene expression regulation, and the excitatory and the inhibitory neurotransmissions involving glutamate and GABA receptors, respectively. It is now well established that neurosteroids can modulate memory processes, and their effects are summarized in Table 1. Numerous studies have demonstrated a potent effect of estrogens on memory processes (Hojo et al. 2008). This could rely on the genomic action of estrogen on the estrogen receptor, since it leads to improved neuroplasticity in the rodent hippocampus (Hojo et al. 2008). Progesterone effects were also investigated in rodents and humans, and a growing body of evidences reported that this neurosteroid has a negative impact on memory processes (Barros et al. 2015). The mechanism of action of progesterone is still under investigation, but it seems that it could interfere with long-term potentiation mechanisms, which are critical for memory function (Barros et al. 2015). Regarding testosterone, although it was shown to improve memory in rodents (Wagner et al. 2018), it did not improve age-related memory impairments in men (Resnick et al. 2017), suggesting that this neurosteroid does not have a beneficial role in memory processes. Pregnenolone and dehydroepiandrosterone were both shown to improve memory in rodents, probably through their action on cytoskeleton leading to neuroplasticity enhancement (Schverer et al. 2018). Their sulfated conjugates have also shown a positive impact on memory in rodents, since they can increase the excitatory neurotransmission mediated by NMDA and AMPA receptors (Schverer et al. 2018). In addition allopregnanolone, via its action on $GABA_A$ receptors, is also able to reverse memory alterations in a rodent model (Schverer et al. 2018). Overall, it seems that most of the neurosteroids could act as memory enhancers.

Neurosteroids, Table 1 Neurosteroid effects on memory processes

Neurosteroid	Effect on memory	Target	Reference
Estrogen	Enhancement (in rodents)	Estrogen receptor	Hojo et al. (2008)
Progesterone	Alteration (in rodents and humans)	Unknown	Barros et al. (2015)
Testosterone	Enhancement in rodents	Unknown	Resnick et al. (2017)
	No effect in humans		Wagner et al. (2018)
Pregnenolone	Enhancement (in rodents)	Cytoskeleton modulation	Schverer et al. (2018)
Dehydroepiandrosterone	Enhancement (in rodents)	Cytoskeleton modulation	Schverer et al. (2018)
Pregnenolone sulfate	Enhancement (in rodents)	NMDA receptor, sigma 1 receptor	Schverer et al. (2018)
Dehydroepiandrosterone sulfate	Enhancement (in rodents)	NMDA receptor, sigma 1 receptor	Schverer et al. (2018)
Allopregnanolone	Enhancement (in rodents)	$GABA_A$ receptor	Schverer et al. (2018)

Potential Use in Therapeutic

Neurosteroids have shown potential therapeutic activity in diverse pathological conditions and summarized in Table 2, and this could be directly due to the action on their targets leading to neuroplasticity modulation.

Central Nervous System Injuries

Injuries to the central nervous system include retinal degeneration, stroke, spinal cord and traumatic brain injury. They are all characterized by axon damage, leading to an environment that is not in favor of regeneration, explaining the limited capacity of self-repair in the central nervous system. Axonal regeneration is therefore a challenging field of research. In this context, neurosteroids have demonstrated regenerative properties. This is the case of progesterone, which showed a protective effect on traumatic brain injury in several models, through various mechanisms (Wei and Xiao 2013). Indeed, progesterone promotes axonal regeneration by having anti-inflammatory and neurotrophic properties, but is also by being protective against excitotoxicity, apoptosis, and lipid peroxidation (Wei and Xiao 2013). A synthetic derivative of pregnenolone also showed a protective effect in three animal models of spinal cord injury (Duchossoy et al. 2011). Indeed, it improved the recovery of locomotor function, and this correlated with preservation of MAP 2 at the injury site and of dendritic arborization of motoneurons caudally to the injury site (Duchossoy et al. 2011). Therefore, both progesterone and pregnenolone seems to have a positive

impact on axonal regeneration in preclinical studies, although these promising results still need to be confirmed in humans.

Epilepsy

Epilepsy is a spectrum of neurological disorders, with a common point being an altered brain activity, causing unpredictable seizures or periods of unusual behavior or sensations. One strategy to decrease the seizure strength and frequency is to use molecules that decrease the intensity of neurotransmission. This is the reason why the allopregnanolone derivative ganaxolone was tested, because of its ability to increase the inhibitory neurotransmission through a potentiation of $GABA_A$ receptor activity. Ganaxolone showed anti-seizure properties in neonates (Yawno et al. 2017), pediatric, and adolescent patients with refractory epilepsy (Pieribone et al. 2007) and in adults with uncontrolled partial-onset seizures (Sperling et al. 2017).

Stress-Related Disorders

Stress-related disorders are chronic diseases such as anxiety, depression, posttraumatic stress disorder, which can occur after a chronic or intense stress exposure. Chronic stress is known to disrupt neuroplasticity, causing a plethora of symptoms including altered mood and cognitive deficits, such as alterations in memory or attention processes. Since neurosteroids are positive modulators of neuroplasticity, they were tested in patients with stress-related disorders. Testosterone and pregnenolone were found to be efficient to reduce depressive symptoms in humans (Brown et al. 2014; Walther et al. 2019). This was corroborated in preclinical studies using a pregnenolone derivative that cannot be metabolized, showing that this antidepressant activity could actually be due to pregnenolone and not to its metabolites (Schverer et al. 2018). The synthetic derivatives of allopregnanolone ganaxolone, brenanolone, and SAGE-217 were also tested in patients with stress-related disorders. Indeed, ganaxolone was given to patients with posttraumatic disorder. In this study, ganaxolone did not show any improvement of symptoms, which could be due to the dose that was not high enough to reach the brain and exert its beneficial effects on neuroplasticity (Rasmusson et al. 2017). Brexanolone, another allopregnanolone derivative, has recently been approved by the US Food and Drug Administration for the treatment of postpartum depression (Zorumski et al. 2019). This was based on several clinical studies showing that this molecule induces a reduction of the depressive symptoms in women (Meltzer-Brody et al. 2018). Finally, SAGE-217 was successfully tested in patients with major depression (Gunduz-Bruce et al. 2019). Altogether, these studies clearly show the potential of using the neurosteroid allopregnanolone to reduce depressive symptoms in humans.

Conclusion

Neurosteroids are steroids synthesized de novo in the central nervous system. Due to their mechanism of action involving diverse targets located in the plasma membrane or in the cytoplasm, they are able to modulate neuroplasticity. Therefore, neurosteroids could be innovative strategies for some pathological conditions in which both neuroplasticity and cognitive processes are altered.

Neurotrophins

Definition

Neurotrophic factors are peptides or protein molecules that support cell survival and cell death in neural and nonneural tissues. In this way, these molecules affect the development, maintenance, and plasticity of the nervous system during the development and in the adulthood (Sampaio et al. 2017).

Herein, the neurotrophic factors are grouped in families, such as the neurotrophin (NT) family, the glial cell-line-derived neurotrophic factor (GDNF) family ligands (GFLs), the neurokine family, fibroblast growth factor (FGF) family, and transforming growth factor-β (TGF-β) family. Moreover, the novel neurotrophic factors, cerebral dopamine neurotrophic factor (CDNF) and mesencephalic astrocyte-derived neurotrophic factor (MANF), are also explained in this text. Table 1 summarizes their main components and receptors involved in their mechanism of action and function.

Mechanism of Action

NT Family

The nerve growth factor (NGF), a neurotrophic factor essential for peripheral nervous system, was the first discovered member of the n eurotrophin family. Currently, NTs are a family of growth factors that comprises four structurally related neurotrophins: NGF, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4, also known as NT-4/5). Indeed, neurotrophins regulate the neuronal survival, proliferation, differentiation, neuritis growth, synaptic function, and synaptic plasticity (Saragovi et al. 2019).

Neurotrophins are initially synthesized as precursors named pro-neurotrophins that undergo maturation by enzymatic cleavage. The pro-neurotrophins and mature neurotrophins act in opposite ways by binding to different receptors (Sampaio et al. 2017). Pro-neurotrophins interact only with p75 neurotrophin receptor ($p75^{NTR}$), which triggers apoptosis through activation of Rac and Jun N-terminal kinase (JNK) during development and pathological situations (Di Liberto et al. 2019).

Mature neurotrophins can bind both to $p75^{NTR}$ and tropomyosin receptor kinase (Trk) receptors. There are three different Trk receptors described for mammals – TrkA, TrkB, and TrkC. NGF preferentially binds to TrkA, BDNF, and NT4 to TrkB and NT3 to TrkC (Sampaio et al. 2017). Trk receptors modulate synaptic strength and plasticity by regulating the expression and activity of ion channels and neurotransmitter receptors. Moreover, Trk receptors activation recruits intracellular signaling pathways, such as PI3K, AKT, Ras, and Erk signaling (Di Liberto et al. 2019).

GFL Family

GFL family is represented by GDNF, neurturin (NRTN), artemin (ARTN), and persephin (PSPN). GFLs are synthesized, secreted, and activated by a variety of tissues. This family began with the GDNF discovered as a potent neurotrophic factor for dopamine neurons survival. Due to preclinical evidence of its neuroprotective effects, GDNF is

Neurotrophic Factors, Table 1 Summary of neurotrophic factors' families and their main components, receptors, and functions

Family	Neurotrophic factors	Receptors	Functions
NT	NGF BDNF NT-3 NT-4, NT-4/5	$p75^{NTR}$ TrkA TrkB TrkC	Neuronal survival, proliferation, differentiation, neuritis growth, synaptic function, and synaptic plasticity
GFLs	GDNF NRTN ARTN PSPN	GFRα 1 to 4/RET complex	GDNF mediates the dopamine neuron survival and shows protective effects for sympathetic, parasympathetic, sensory, and motor neurons
Neurokine	IL-6, IL-11, IL-27, IL-31 CNTF CT-1 CLCF1 LIF OSM NPN	Neurokine receptors formed by α- and β-receptor subunits	Inflammatory process and immune homeostasis. Neurokines also act on the embryonic development, behavior, metabolism, hematopoiesis, tissue integrity, and aging
FGF	FHF subgroup: FGF11, 12, 13, and 14 Mitogenic FGF subgroup: FGF1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 16, 17, 18, 20, and 22 Endocrine FGF subgroup: FGF19 (mouse FGF15), 21, and 23	Mitogenic FGF subgroup: FGFR-1 to 4 Endocrine FGF subgroup: KL or KLB/FGFR complex	Mitogenic FGF subgroup: cellular proliferation and population growth Endocrine FGF subgroup: metabolic homeostasis
TGF	TGF-α and TGF-β	EGFR	Acting on the fibroblasts, regulating their cellular proliferation and differentiation
MANF and CDNF	MANF CDNF	Not identified	MANF: maintenance of endoplasmic reticulum homeostasis and UPR pathways CDNF: dopaminergic neurons survival

one of the most largely investigated neurorestorative approach for Parkinson's disease (Sampaio et al. 2017). Additionally, GDNF was later described as a protective agent in the periphery, for sympathetic, parasympathetic, sensory, and motor neurons.

GFLs signal selectively by binding to each one of the four members of GDNF family receptor α (GFRα1 to 4). Additionally, glycosylphosphatidylinositol (GPI) is necessary to anchor the GFRα to plasma membrane. In its turn, GFL-GFRα complex has high affinity by the receptor tyrosine kinase RET, inducing survival and regeneration of neurons through the PI3K/Akt, Ras/Erk, Src, and PLCg signaling pathways (Saragovi et al. 2019).

Neurokine Family

Also known as neuropoietic cytokine family, neurokine family consists of interleukin (IL)-6, IL-11, IL-27, IL-31, ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), cardiotrophin-like cytokine factor 1 (CLCF1), leukemia inhibitory factor (LIF), oncostatin M (OSM), and neuropoietin (NPN). Although these secreted proteins have a crucial role in the inflammatory process and immune homeostasis, they also mediate the embryonic development, behavior, metabolism, hematopoiesis, tissue integrity, and aging (Jones and Jenkins 2018).

CNTF was originally isolated due to its ability to sustain ciliary neurons in culture; however, it is now also known to play roles in glial differentiation. CNTF supports the survival and differentiation of sensory, sympathetic, and motor neurons. Its trophic effects also act on the oligodendrocytes and mesenchymal cells, including adipocytes, osteoblast, and muscle cells. CNTF is expressed by glial cells of the spinal cord, astrocytes,

Schwann cells, and skeletal muscles and released in response to injury (Pasquin et al. 2015).

Neurokine receptors display similar multisubunit structure and share overlapping polypeptide components. In general, neurokines have a low affinity or α-receptor subunits that require gp130 (an additional transmembrane component) for functional responsiveness. In the presence of ligand, the monomeric subunits associate to form the functional receptor complexes (Nathanson 2012). In addition, membership of neurokine family shows pleiotropic properties due to interaction with the shared signal-transducing receptor β-subunit. The bonded neurokine-β-receptor subunit activates several intracellular signaling pathways; among them Janus tyrosine kinase signal transducer and activator of transcription (Jak/STAT) pathway are highlighted (Jones and Jenkins 2018).

FGF Family

FGF family has a common ancestor, FGF13-like, that expands into multiple members. During the evolution, FGF13-like ancestor molecule bifurcated into FGF-homologous factor (FHF) subgroup (FGF11, 12, 13, and 14) and FGF4-like molecule. In your turn, FGF4-like is the precursor for two major functional subgroups: mitogenic and endocrine FGFs. Additionally, FGFs signal through four transmembrane receptor tyrosine kinases known as FGFR-1 to FGFR-4 with multiple splicing variants (Li 2019).

Mitogenic FGF subgroup includes FGF2, 5, 8, 9, and 10 and promotes cellular proliferation and population growth. This subgroup is involved in the development of ectodermic, mesodermic, and endodermic cells. As a result, mitogenic FGFs influence several systems (Li 2019). Of note, FGF2 has a key role in the central nervous system, promoting neurogenesis, survival, migration, differentiation, neuroregeneration, and synaptic plasticity, mainly during the development. Regarding the action mechanism, mitogenic FGFs binding to FGFRs activate three major pathways: PI3K/AKT, Ras/MAPK, and PLC/PKC (Di Liberto et al. 2019).

Otherwise, endocrine FGF subgroup comprises the FGF19 (mouse FGF15), 21, and 23 and regulates the metabolic homeostasis, affecting bile acids, glucose, lipid, and minerals metabolism, without direct proliferative activity. However, their functions seem to be important for cell survival. Lastly, endocrine FGFs act via a binary complex composed by transmembrane nonkinase accessory coreceptor, the α-Klotho (KL) or β-KL (KLB), and FGFRs (Li 2019).

TGF Family

TGFs were discovered as secreted products from cancer cells functionally related to epidermal growth factor (EGF). Subsequently, these growth factors have been found in normal cells. TGFs can transform fibroblasts, regulating their cellular proliferation and differentiation. TGFs divide themselves into TGF-α and TGF-β in accord with the ability to bind to EGF receptors (EGFR) (Moses et al. 2016).

In this sense, TGF-α binds to EGF receptors. This ligand can be found as a soluble protein or anchored to the plasma membrane as a biologically active precursor (Rayego-Mateos et al. 2018). Oppositely, TGF-β requires the EGF presence for phenotypic transformation, but it does not bind to EGF receptors (Moses et al. 2016). TGF-β is a growing family of secreted, dimeric growth factors and cytokines. Their functions include induction/specification of distinct cells and tissue phenotypes, homeostasis in the adult and development during the embryonic phase.

MANF and CDNF Family

MANF and CDNF are a novel neurotrophic factor family, homologous between themselves, functionally different from the classical secreted neurotrophic factors (Lindahl et al. 2017). They are mostly retained intracellularly and localized in the endoplasmic reticulum under normal conditions, being secreted from neurons only after calcium depletion (Poyhonen et al. 2019).

Although both MANF and CDNF display neurotrophic action, there are no transmembrane receptors identified for them. Evidence demonstrate that MANF is linked to the maintenance of endoplasmic reticulum homeostasis and unfolded

protein response (UPR) pathways (Lindahl et al. 2014). MANF mRNA is detected in astrocytes, microglia, and – in lower levels – in neurons from human and rodents. On the other hand, CDNF expression has not been investigated in detail. Currently, it is known that CDNF is a growth factor with a high specificity and activity to promote dopaminergic neuron survival (Lindahl et al. 2017).

Clinical Use

Alterations in the neurotrophic factor levels/expression and their signaling are involved in the development and/or progression of neurodegenerative and psychiatric disorders. Although neurotrophic factors play essential roles in the central and peripheral nervous system of vertebrates throughout development as well as in adult life, the therapeutic potential of these molecules is still inconsistent.

The therapeutic promise of neurotrophic factors for neurodegenerative disorders has been researched in the last decades. Even though these proteins show promising results in the preclinical tests, they failed in the clinical trial due to their pharmacokinetic properties. Moreover, serious side effects were observed after administration of different neurotrophic factors. Nevertheless, the new drug delivery approaches, such as gene therapy vectors, attempt to optimize the clinical benefit in reducing the side effects observed in patients. Consequently, the safety and efficacy of neurotrophic factors as a therapeutic strategy for neurodegenerative and psychiatric disorders still need to be elucidated.

NFAT Family of Transcription Factors

Fernando Macian
Department of Pathology, Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

NFAT; NFAT5; NFATc1; NFATc2; NFATc3; NFATc4

Definition

The NFAT family of transcription factors includes five different members: NFATc1 (also known as NFAT2 or NFATc), NFATc2 (NFAT1 or NFATp), NFATc3 (NFAT4 or NFATx), NFATc4 (NFAT3), and NFAT5 (TonEBP or OREBP). The gene encoding for the first NFAT protein was cloned more than 20 years ago and termed NFATp, as it was shown to be "preexistent" in the cytosol of resting T cells but to translocate into the nucleus and interact with the transcription factors Fos and Jun in activated T cells, where it bound in a trimeric complex to specific sites in the *Il2* gene promoter to induce the expression of interleukin (IL-)2 (Jain et al. 1993). NFAT proteins were shown to be regulated by calcineurin-mediated dephosphorylation in response to T cell receptor (TCR)-induced calcium signaling, which identified them as targets of the immunosuppressive effects of the calcineurin inhibitor cyclosporin A (Clipstone and Crabtree 1992; Jain et al. 1993). Initial studies focused on characterizing the functions of NFAT proteins in T cells; however, it soon became evident that members of this ubiquitously expressed family of transcription factors played essential roles in the regulation of programs of development and differentiation in a wide array of different cell types and tissues.

Basic Characteristics

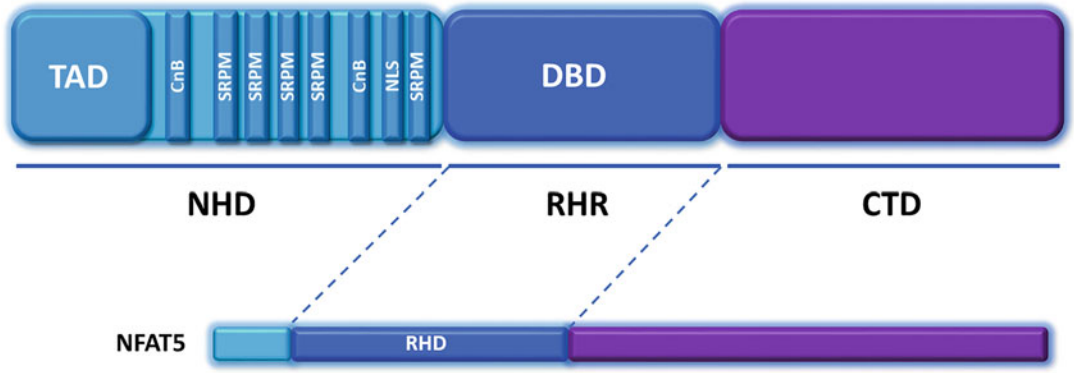
Structure of NFAT Proteins

All NFAT proteins share a conserved DNA-binding domain, which has structural homology with the Rel domain found in members of the NF-κB family of transcription factors. This domain is not only responsible for site-specific DNA binding, but it also mediates interactions with transcriptional partners, including Fos and Jun (Chen et al. 1998). With the exception of NFAT5, NFAT proteins also have an N-terminal regulatory domain, known as the NFAT homology domain (NHD), that contains the main transactivation domain as well as several regulatory regions. These include interaction sites for calcineurin and for NFAT kinases, which regulate NFAT activation through phosphorylation of multiple serine-containing motifs also present in the NHD (Fig. 1) (Hogan et al. 2003; Okamura et al. 2000). As all other NFAT family members, NFAT5 also has a Rel domain that contains the conserved DNA-binding region and a dimerization domain, but it lacks an NHD (Lopez-Rodriguez et al. 2001). The C-terminal regions of NFAT proteins are not conserved and may contain sites that allow interactions with other proteins.

Regulation of NFAT Activation

NFATc1, NFATc2, NFATc3, and NFATc4 are regulated by the calcium/calmodulin-activated phosphatase calcineurin (Macian 2005). NFAT5, which was also identified as the tonicity-responsive enhancer-binding protein (TonEBP), regulates the expression of osmoprotective genes in response to osmotic stress, though it can also modulate gene expression under isosmotic conditions in response to inflammatory stimuli (Aramburu and López-Rodríguez 2019).

NFAT activation is mainly controlled by its subcellular localization. The net result of the rate of nuclear import and export of NFAT proteins, which responds to their phosphorylation status,

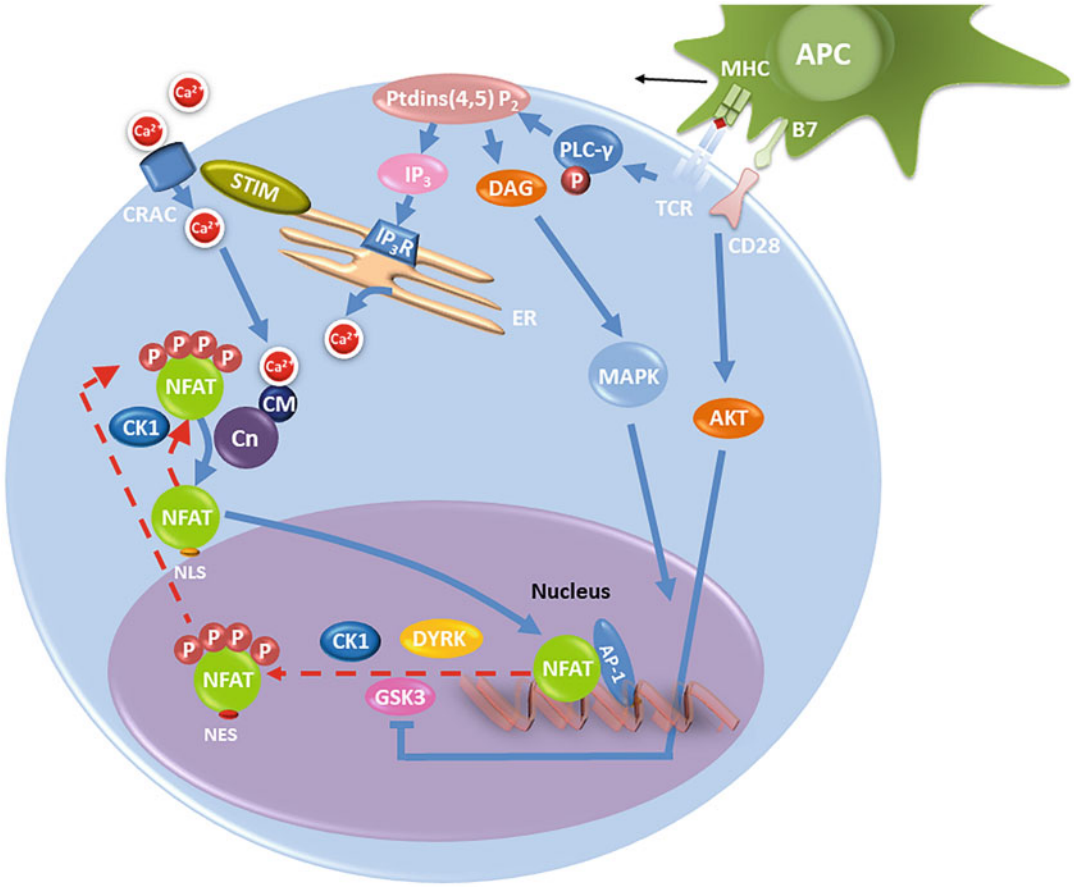


NFAT Family of Transcription Factors, Fig. 1 ***Structure of NFAT proteins.*** NFATc1, c2, c3, and c4 have a regulatory domain (NHD, NFAT-homology domain), which comprises a transactivation domain (TAD), several serine-rich phosphorylation motifs for NFAT kinases (SRPM), calcineurin-binding sites (CnB), and one or more nuclear localization signals (NLS). A conserved DNA-binding domain (DBD or Rel-homology region, RHR) follows the NHD and also contains residues required to interact with Fos and Jun proteins. NFAT5 shares the conserved Rel-homology (RHD) DNA-binding domain but differs in the rest of its structure from the other NFAT family members. The C-terminal domain (CTD) is not conserved among NFAT proteins

determines the overall level of NFAT that is present in the nucleus and, therefore, able to regulate gene expression. Other mechanisms have also been described, though, that may contribute to fine-tune the regulation of the transcriptional activity of NFAT.

Calcium and calcineurin: Engagement of calcium-coupled receptors induces the activation of the calcium/calmodulin-dependent phosphatase calcineurin, which binds NFAT proteins and directly dephosphorylates them, inducing their translocation into the nucleus. In T cells, where this complex regulation has been well characterized, recognition of antigen by the TCR induces activation of the phospholipase C γ, which hydrolyzes phosphatidylinositol 4,5-bisphosphate into inositol-1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 binds IP_3 receptors in the endoplasmic reticulum (ER), which causes calcium release from intracellular ER calcium stores. STIM proteins sense this release and interact with ORA1, an integral component of the calcium release-activated calcium (CRAC) channels in the plasma membrane, causing a further increase in the intracellular calcium levels (Feske et al. 2006; Feske et al. 2015; Zhang et al. 2005). In response to the increase in the intracellular calcium concentration, activated calcineurin binds to and dephosphorylates NFAT proteins, which are heavily phosphorylated and localized in the cytosol in resting cells (Fig. 2). At least 13 different phosphorylation sites located in serine-rich motifs and SPxx repeat motifs in the regulatory domain are dephosphorylated by calcineurin. This causes a conformational change in NFAT that exposes its nuclear localization signal, allowing NFAT import into the nucleus. There, it binds specific sites and cooperates with other transcription factors to activate the expression of distinct sets of genes (Hogan et al. 2003; Okamura et al. 2000).

NFAT kinases: Phosphorylation of NFAT proteins is required to promote nuclear export and to maintain cytosolic localization in resting cells. Several kinases have been reported to phosphorylate different serine-containing motifs. Casein kinase 1 (CK1) bids to the NHD and regulated NFAT nuclear export and cytosolic retention through phosphorylation of a serine-rich motif (Okamura et al. 2004). Glycogen synthase kinase 3 (GSK3) also phosphorylates serine-proline motives in NFATc2 and NFATc1, promoting NFAT nuclear export. These phosphorylation sites require previous priming by cyclic-AMP-dependent protein kinase-mediated phosphorylation of NFAT (Beals et al. 1997). The dual-specificity tyrosine-(Y)-phosphorylation-regulated kinases DYRK1A and DYRK2 also regulate



NFAT Family of Transcription Factors, Fig. 2 ***NFAT regulation by calcium/calcineurin and NFAT kinases in T cells.*** Pathways involved in the activation of NFAT by nuclear import and modulation of its transcriptional activity are represented with solid blue arrows, whereas the pathways involved in NFAT nuclear export or cytosolic retention are depicted with red dashed arrows. *AP-1* activator protein 1; *APC* antigen-presenting cell; Ca^{2+} calcium; *CK1* casein kinase 1; *CM* calmodulin; *Cn* calcineurin; *CRAC* calcium release-activated calcium channel; *CRM1* exportin 1; *DAG* diacylglycerol; *DYRK* dual-specificity tyrosine-(Y)-phosphorylation-regulated kinase; *ER* endoplasmic reticulum; *GSK3* glycogen synthase kinase 3; *IP3* inositol-1,4,5-triphosphate; *IP3R* inositol-1,4,5-triphosphate receptor; *MAPK* mitogen-activated protein kinases; *MHC* major histocompatibility complex; *NES* nuclear export signal; *NLS* nuclear localization signal; *P* phosphate; *PLC-γ* phospholipase C γ; *Ptdins(4,5)P2* phosphatidylinositol 4,5-bisphosphate; *STIM* stromal interaction molecule; *TCR* T cell receptor

NFAT nuclear export through phosphorylation of a serine/proline-rich motif that primes NFAT for subsequent phosphorylation by CK1 or GSK3 (Gwack et al. 2006). LRRK2 may also phosphorylate NFAT proteins to contribute to the regulation of NFAT activation (Liu et al. 2011). Interestingly, it has been shown that many of these kinases, including CK1 and GSK3, exist in a complex with the noncoding RNA repressor of NFAT (NRON) that inhibits nuclear import of NFAT by facilitating interactions of those kinases with NFAT (Sharma et al. 2011). Following a non-canonical calcineurin-independent IL-7-dependent pathway of activation, JAK3 has also been shown to phosphorylate NFATc1 in $CD4^{-}CD8^{-}$ thymocytes, to cause NFAT translocation into the nucleus in a calcineurin-independent manner (Patra et al. 2013).

Transcriptional regulation of NFAT: NFATc1/αA is an isoform of NFATc1 that is regulated at a transcriptional level by an autoregulatory loop controlled by an inducible promoter. This

promoter responds to constitutively expressed isoforms of NFATc1 and NFATc2 and other transcription factors that induce the expression and accumulation of the inducible NFATc1/αA isoform in activated cells (Serfling et al. 2006).

Posttranslational regulation: Several posttranslational mechanisms contribute to the regulation of NFAT activity. Sumoylation participates in NFAT nuclear retention and might also regulate NFAT transcriptional activity (Terui et al. 2004). Evidence also supports that poly(ADP-ribose) polymerase-1 (PARP-1) modifies NFATc1 and NFATc2, regulating nuclear export and transcriptional activity (Olabisi et al. 2008). Furthermore, NFATc2 can also be ubiquitinated by the E3 ubiquitin ligase HDM2 in breast cancer cells, leading to its degradation by the proteasome (Yoeli-Lerner et al. 2005).

Transcriptional Activity

NFAT proteins can cooperate with other transcription factors to form transcriptional complexes that activate or repress the expression of specific genes. Formation of those transcriptional complexes allows cells to integrate calcium signaling with other signaling pathways to regulate specific programs of gene expression. Initially identified as the nuclear component of the complex that directed the expression of IL-2 in activated T cells, activator protein 1 (AP-1) complexes are the best characterized NFAT partners. In response to the engagement of the TCR and co-stimulatory receptors, calcium signaling and the mitogen-activated protein kinase (MAPK) pathway converge in the activation of NFAT and the AP-1 proteins Fos and Jun (Jain et al. 1993). The DNA-binding domain of NFAT interacts with AP-1, forming a quaternary complex on DNA that induces the expression in T cells of many activation-induced genes, including numerous cytokines (Chen et al. 1998; Macian et al. 2001). The number of transcription factors that have been identified to cooperate with NFAT has grown with the years. In many cases, these interactions occur in specific cells of tissues and are responsible for the regulation of different programs of activation, differentiation, or development (Macian 2005; Wu et al. 2007). NFAT proteins are also able to form homodimers that bind to κB-like sites containing two tandem NFAT-binding sites separated by one or two bases (Jin et al. 2003). In addition, NFAT5 also forms homodimers that bind to DNA and regulate gene expression (Lopez-Rodriguez et al. 2001).

Functions

Adaptive immune system: Activation of effector cells is governed by the direct recognition of antigens by the B cell receptor (BCR) or peptides presented on major histocompatibility complex (MHC) molecules to cognate TCRs on T cells. NFAT functions have been extensively studied in T cells, although the participation of NFAT in the regulation of B cell responses has also been amply characterized. NFAT proteins are activated in B cells in response to BCR engagement and participate in the induction of programs of gene expression that regulate B cell activation and differentiation (Bhattacharyya et al. 2011; Venkataraman et al. 1994). In T cells, coordinated engagement of the TCR and co-stimulatory receptors (e.g., CD28) allows NFAT to cooperate with other transcription factors, such as Fos and Jun, to induce the expression of genes that are required to ensure effective T cell activation (Macian 2005; Muller and Rao 2010). However, in the absence of co-stimulation, TCR triggering still causes NFAT nuclear localization, which, without the opportunity to fully cooperate with Fos and Jun, forms homodimers that regulate the expression of genes that maintain T cells in a tolerant hyporesponsive state termed anergy (Macian et al. 2002; Baine et al. 2009). NFAT proteins also modulate immune tolerance through the modulation of regulatory T cell (Treg) function, a distinct population of T cells that express the transcription factor FoxP3 and have the capacity to suppress the activation of other effector immune cell populations. NFAT proteins not only regulate the expression of FoxP3 but also cooperate with this transcription factor to activate (*Ctla4*, *Cd25*, and *Gitr*) or repress (*Il2*) the expression of genes in Tregs and, therefore, control differentiation and function of these suppressor cells (Wu et al. 2006).

Interestingly, under conditions of chronic antigen stimulation, NFAT, in the absence of other transcriptional partners, controls the induction of exhaustion in T cells (Martinez et al. 2015).

T cell development is also regulated by NFAT. Immature thymocytes rearrange both the α- and β-chains of the TCR and mature from a double-negative ($CD4^-CD8^-$) thymocyte into a double-positive thymocyte that expresses both CD4 and CD8. NFATc1 has a crucial role in facilitating this process (Patra et al. 2013). Furthermore, genetic deletion of calcineurin activity in immature thymocytes leads to a positive selection block, whereas NFATc2 and NFATc3 regulate the thresholds of signal transduction that determine positive selection in the thymus (Gallo et al. 2007).

Mature CD4+ T helper cells can differentiate into different effector lineages, such as T_H1, T_H2, or T_H17 cells. These differentiation events have been shown to be regulated by NFAT that directs the expression of specific genes that help define the differentiation program of a particular T cell subtype. The ability of NFAT to direct distinct programs of differentiation relies on interactions with different transcriptional co-partners (Hermann-Kleiter and Baier 2010). As mentioned above, NFAT proteins also participate in the regulation of Treg function and have been implicated in the differentiation of follicular helper T cells (Martinez et al. 2016; Wu et al. 2006). NFAT proteins also participate in the orchestration of the $CD8^+$ T cell response, and NFATc1 controls programs of gene expression that confer cytotoxic function to these T cells (Klein-Hessling et al. 2017).

Innate immune system: NFAT proteins are expressed in many cells of the innate immune system and regulate their function, including eosinophils, neutrophils, mast cells, NK cells, dendritic cells, and macrophages. They serve a pivotal role in transforming molecular signals to expression of genes. Indeed, ligation of pattern recognition receptors (PRR) in myeloid cells can activate NFAT in response to the presence of pathogens (Fric et al. 2012). However, not only PRR but also other receptors can induce NFAT activation in cells of the innate immune system. For instance, ligation of the Fcε receptor in mast cells results in NFAT activation, which induces cytokine expression in those cells (Monticelli et al. 2004). Interestingly, not only calcineurin-regulated members of the NFAT family but also NFAT5 participates in the regulation of gene expression in response to pattern recognition receptors during the innate immune response (Buxadé et al. 2012).

Nonimmune tissues and organs: NFAT proteins are present in almost all tissues, although the expression of any individual NFAT protein can often be limited to specific cell types. For instance, whereas NFATc1, NFATc2, and NFATc3 are expressed in cells of the immune system, NFATc4 expression has not been reported in immune cells. An increasing number of studies have characterized the roles that different NFAT proteins play as regulators of development, differentiation, and function in many cell types and tissues (Wu et al. 2007). For instance, in *skeletal muscle,* the expression of specific NFAT proteins is developmentally regulated to control progression from immature precursors to mature myocytes and contribute to the specification of muscle fiber type (Calabria et al. 2009). NFAT also regulates *cartilage growth and bone remodeling*. The role that NFAT proteins play in osteoclast differentiation has been amply documented. In these cells, RANKL-mediated activation of NFATc1 directs the expression of a set of genes required for osteoclast differentiation (Takayanagi et al. 2002). Initial characterization of a mouse model that lacked NFATc1 unequivocally showed that NFATc1 played a key role in the formation of the heart's valves (de la Pompa et al. 1998). In the *adult heart*, NFAT proteins partner with members of the GATA and MEF2 families of transcription factors to control myocardial hypertrophy (Passier et al. 2000). NFATc3 and NFATc4 are expressed in perivascular mesenchymal cells and regulate the assembly of blood vessels during embryogenesis. Thus, mice that lack those two NFAT proteins present abnormal vascular development (Graef et al. 2001). Vascular endothelial growth factor (VEGF) is a major activator of NFAT proteins in *endothelial cells*, and

engagement of the VEGF receptor causes the expression of NFAT-dependent genes such as COX2 (Hernández et al. 2001). In the *nervous system*, NFAT regulates neuronal axon growth and is essential for neuronal development and the differentiation of Schwann cells (Graef et al. 2003; Kao et al. 2009). NFAT has also been shown to control beta cell growth in the *endocrine pancreas* and regulate insulin-signaling pathways and adipogenesis (Heit et al. 2006). NFATc1 has also been implicated in the maintenance of *stem cell* quiescence in the skin follicle by repressing the expression of the cell cycle kinase CDK4 (Horsley et al. 2008).

As mentioned above, NFAT proteins are central to the control of cell development and differentiation, in part by regulating proliferation and cell death. It is not surprising, therefore, that altered NFAT signaling occurs in *cancer cells* (Muller and Rao 2010). As expected, due to their pivotal role in lymphocyte development, dysregulated NFAT activity has been associated with several forms of B and T cell lymphoma and leukemia (Muller and Rao 2010). Furthermore, NFAT proteins regulate specific properties of different cancers. For instance, NFATc2 and NFAT5 positively modulate migration and invasion of breast cancer cells, while reports have shown that NFAT proteins promote tumor-associated angiogenesis and may directly activate the expression of oncogenes, such as *Myc* (Mancini and Toker 2009).

Drugs

Activation of NFAT is dependent on its dephosphorylation, and, therefore, the phosphatase calcineurin has been an important area of focus of research for NFAT inhibitor development. Pharmacological agents that inhibit calcineurin activity have been used to modulate NFAT activity and have become tremendously beneficial in the clinic since their introduction in the early 1980s. These drugs inhibit the activation of NFAT in immune cells, act as immunosuppressants, and are widely used for the treatment of autoimmune disease or the prevention of transplant rejection. Cyclosporine and FK506 are the most widely used and studied suppressors of NFAT activity. Both are calcineurin inhibitors whose mechanism of action is very similar. They bind separate intracellular peptidyl-prolyl isomerases (cyclophilin for cyclosporine; FKBP12 for FK506). These complexes then bind to distinct regions of calcineurin and inhibit its phosphatase activity. Nevertheless, the specificity of NFAT inhibition using calcineurin inhibitors is limited by the fact that NFAT is not their only target and they affect also other calcineurin targets in other tissues. This is a major mechanism that accounts for the significant toxic effects these drugs can have, including kidney dysfunction, hypertension, or neurotoxicity (Roy and Cyert 2020).

Due to the severe side effects that may occur after long-term administration of cyclosporine or FK506, finding new inhibitors with more specificity for NFAT has been pursued, which may result in drugs that could prevent most of the side effects of calcineurin inhibitors. Some studies have centered on targeting the interaction of NFAT and calcineurin. Calcineurin-binding sites on NFAT have been mapped to the N-terminal regulatory domain and include the amino acid sequence SPRIET. A closer analysis of this sequence among NFAT family members revealed the consensus-binding sequence PxIxIT, which laid the groundwork for the discovery using combinatorial libraries of the highly potent VIVIT peptide (Aramburu et al. 1998). This peptide has been successfully used in mouse models of graft rejection and tumor progression. The major benefit of the VIVIT peptide lies in its higher specificity for the inhibition of NFAT function; however, the PxIxIT sequence is also used by other calcineurin substrates (Roy and Cyert 2020). Other alternative approaches are also being explored including the design of compounds that may disrupt the ability of NFAT to bind DNA, enhance its nuclear export, or prevent interactions of NFAT and specific transcriptional partners (Lee et al. 2018; Mognol et al. 2019). The development of those new categories of drugs should lead to a higher degree of precision to specifically inhibit NFAT activity.

Definition

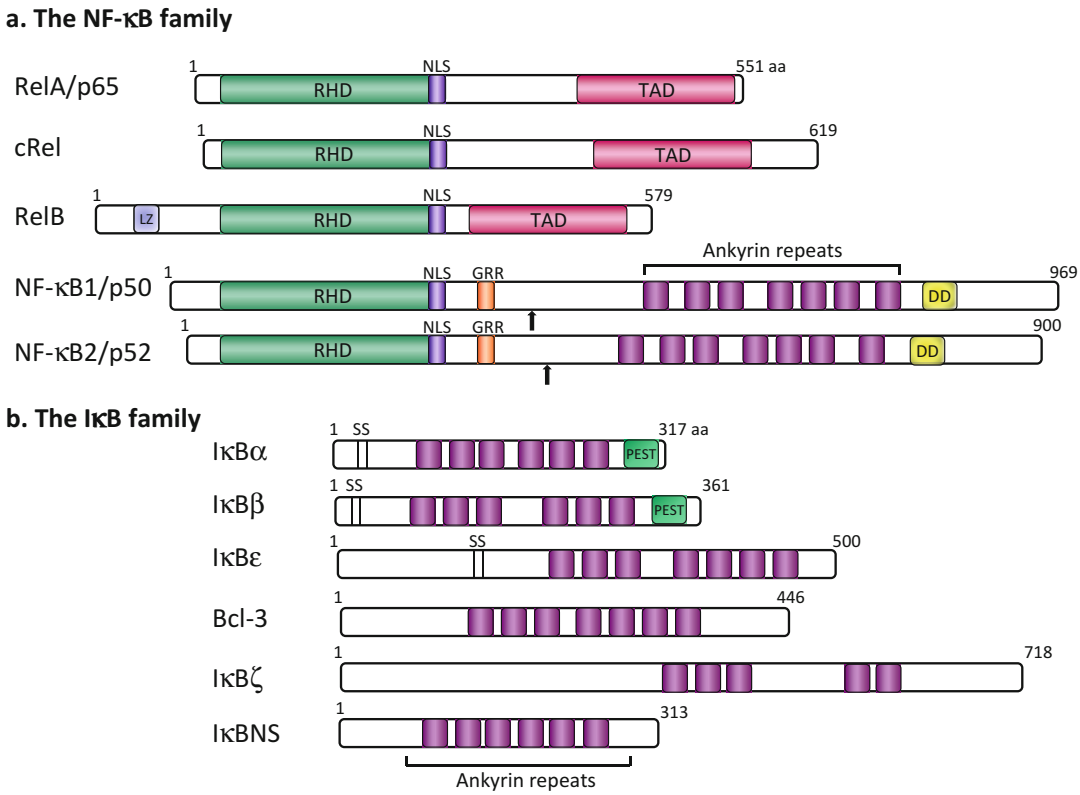
Nuclear factor kappa B (NF-κB) is the generic term for a family of dimeric eukaryotic transcription factors with a critical role in major cellular functions including the immune and inflammatory responses, cell proliferation and differentiation, and the control of cell survival. NF-κB is composed of members of the Rel family of DNA-binding proteins and includes the mammalian proteins RelA (or p65), RelB, cRel, p50, and p52 and the Drosophila proteins Dorsal, Dif, and Relish. These proteins form homo- or heterodimers that bind with different affinities to a consensus DNA sequence motif (called the κB site) consisting of the sequence 5'-GGGRNWYYCC-3' in which R is a purine, W is an adenosine or a thymine, Y is a pyrimidine, and N is any base.

Basic Characteristics

NF-κB Structure

NF-κB is a dimeric, ubiquitously expressed and evolutionary conserved transcription factor originally discovered as an inducible protein binding to a specific DNA sequence in the nuclei of activated B lymphocytes (Sen and Baltimore 1986). Over 30 years of research on NF-κB has revealed that NF-κB has a lot more functions in many biological systems (Zhang et al. 2017). In mammals, the NF-κB family consists of five members: RelA (p65), RelB, cRel, NF-κB1 (p105/p50), and NF-κB2 (p100/p52). Structurally, all five NF-κB proteins share a highly conserved 300 amino acid **Rel homology domain** (RHD) that encompasses a sequence-specific DNA-binding domain, a dimerization domain, and a nuclear translocation signal (NLS) (Fig. 1a). RelA, cRel, and RelB contain a transcription activation domain (TAD) and act as transcriptional activators. NF-κB1 and NF-κB2 are synthesized as large precursors, p105 and p100, that are posttranslationally processed to generate the mature forms, p50 and p52, which lack a TAD.

NF-κB proteins are principally regulated by subcellular localization, whereby the inactive cytoplasmic forms become transcriptionally active proteins upon translocation to the nucleus. In most resting cells, NF-κB is maintained inactive in the cytoplasm by binding to members of the "inhibitor of κB" (IκB) family (Fig. 1b) (Hayden and Ghosh 2008, 2012). The IκB proteins IκBα, IκBβ, IκBε IκBζ, IκBNS, and Bcl-3 contain 5–7 **ankyrin repeats**. These 33 amino

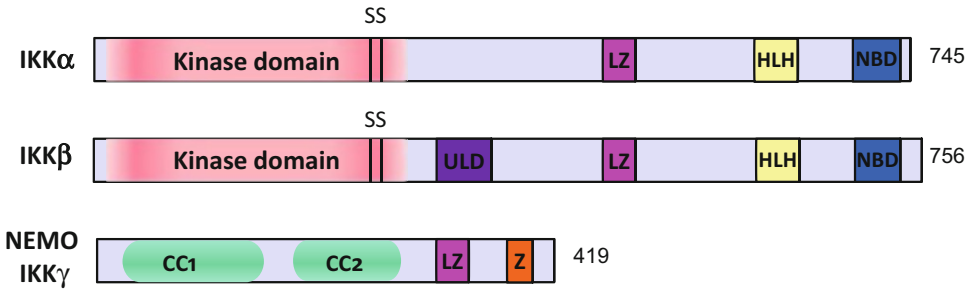


NF-κB, Molecular Target, Fig. 1 Schematic representation of the mammalian NF-κB proteins and their inhibitors, the IκB proteins. (**a**) NF-κB proteins share a highly conserved amino-terminal Rel homology domain (RHD), which includes a DNA-binding domain, a dimerization domain, and a nuclear localization signal (NLS). RelA (p65), cRel, and RelB contain in their carboxy-terminal part a nonhomologous transcriptional activation domain (TAD). RelB has an additional amino-terminal leucine zipper (LZ) motif. NF-κB1/p50 (or p105/p50) and NF-κB2/p52 (or p100/p52) contain a glycine-rich region (GRR), carboxy-terminal ankyrin repeats that are also present in IκB proteins, and a dead domain (DD). Proteolytic processing of NF-κB1/p50 and NF-κB2/p52 (cleavage sites indicated by arrows) generates their respective mature NF-κB proteins, p50 and p52. The number of amino acids (aa) is indicated for each protein. (**b**) The inhibitor of NF-κB (IκB) family includes Iκbα, IκBβ, IκBε, IκBζ, IκBNS, and Bcl-3. They are characterized by the presence of multiple ankyrin repeats that are essential for binding of IκBs to the RHD of NF-κB proteins. Iκbα, IκBβ, and IκBε, present in their amino-terminal region two critical serine residues (depicted SS) that once phosphorylated, target the IκBs for degradation. IκBα and IκBβ contain in their carboxy-terminal region a PEST domain rich in the amino acids proline, glutamic acid, serine, and threonine that acts as a targeting signal for protein degradation

acid helical structures are able to bind to the RHD of NF-κB and mask the NLS preventing NF-κB nuclear translocation. Ankyrin repeats are also found in the precursors NF-κB1 (p105) and NF-κB2 (p100), enabling them to function as IκBs and retain Rel proteins in the cytoplasm of unstimulated cells.

NF-κB Activation

There are two major signaling pathways leading to nuclear translocation and thereby activation of NF-κB proteins (Zhang et al. 2017; Hayden and Ghosh 2008, 2012). The most frequent, observed in all cell types, is the classical or canonical NF-κB activation pathway (Fig. 3). This pathway is rapidly activated by pro-inflammatory cytokines (► Cytokines) such as tumor necrosis factor-α (TNFα) (Tumor Necrosis Factor) and interleukin-1 (IL-1), as well as pathogen-associated molecular patterns (**PAMPs**). These effector molecules act through different receptors belonging to the tumor necrosis factor receptor (TNF-R) and



NF-κB, Molecular Target, Fig. 2 IKK complex. The IKK complex is composed of two kinases IKKα (or IKK1) and IKKβ (or IKK2) and a regulatory subunit NEMO (NF-κB essential modulator) or IKKγ. Both kinases contain a kinase domain sharing two conserved serine residues (depicted SS) necessary for the activation of the kinases through phosphorylation, a leucine zipper (LZ) motif allowing dimerization, an helix-loop-helix (HLH) region, and a Nemo-binding domain (NBD). IKKβ also contains an ubiquitin-like domain (ULD). NEMO contains two coiled-coiled domains (CC1 and CC2), a leucine zipper (LZ), and a zinc finger (ZF) at the carboxy-terminal region of the protein

Toll-like receptor (TLR)/interleukin-1 receptor (IL-1R) superfamilies (Toll-Like Receptors) and through assembly of large signaling complexes, activate a multiprotein complex, the IκB kinase (**IKK**) complex (Fig. 2). The most common form of this complex consists of two catalytically active protein kinases, IKKα (or IKK1) and IKKβ (or IKK2), forming heterodimers, which are associated with at least two molecules of the IKKγ regulatory subunit (also called NEMO). Though much has still to be learned about how IKK is activated, IKK is recruited to membrane bound multiproteins signaling complexes (called signalosomes) in which the linear ubiquitin assembly complex (LUBAC) (Iwai 2014) attaches a linear ubiquitin chain to IKKγ. This in turn leads to the activation of the catalytic IKK through autophosphorylation of two critical serines residues in their kinase domain.

The function of the activated IKK complex is to catalyze the rapid **phosphorylation** of the IκBs at two serine residues located in their amino-terminal regulatory domain (Fig. 1b) triggering their ubiquitin-mediated degradation by the 26S proteasome (▶ Ubiquitin/Proteasome Regulation). NF-κB dimers (predominantly RelA/p50 dimers) are released, they translocate to the nucleus where they bind to DNA, and activate gene transcription (▶ Transcriptional Regulation).

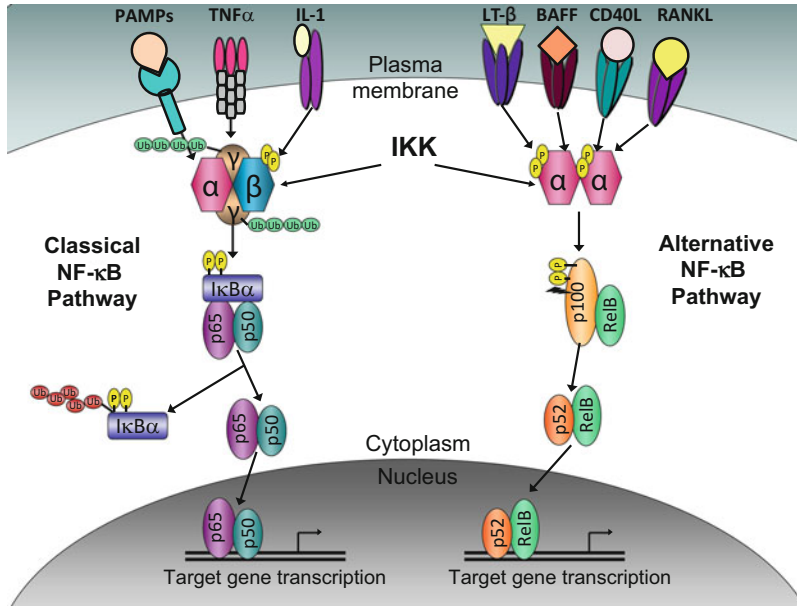
A second NF-κB activation pathway (Fig. 3), called the alternative or noncanonical pathway has a slower kinetics of activation. It responds to a subset of cytokines that bind to members of the TNF receptor superfamily. Cytokines such as lymphotoxin-β (LTβ), CD40 ligand (CD40L), the B-cell-activating factor BAFF (or Blys), and the receptor activator of NF-κB ligand (RANKL) (Fig. 3) turn on the alternative NF-κB pathway that strictly depends on the activation of IKKα homodimers, which phosphorylate NF-κB2 at two serine residues located at the carboxy-terminal end of the protein (Fig. 1b). Phosphorylation of NF-κB2 induces its ubiquitin-dependent processing to generate the mature p52 protein (amino-terminal portion of NF-κB2), while the carboxy-terminal part is degraded by the 26S proteasome. As NF-κB2 mainly associates with RelB, its processing leads to the formation of active p52/RelB heterodimers.

While the canonical NF-κB pathway is implicated in most cellular events associated with an immune response, the alternative pathway has more restrictive functions in the adaptive immunity such as the development of secondary lymphoid organs and the maturation and survival of B lymphocytes.

Cellular Functions

NF-κB and Immunity

NF-κB regulates both innate and adaptive immune responses (Immune Defense). Understanding the function of NF-κB in the



NF-κB, Molecular Target, Fig. 3 Classical and alternative NF-κB activation pathways. The classical (or canonical) NF-κB pathway is activated by a variety of stimuli including the pro-inflammatory cytokines, TNFα, and IL-1 and diverse pathogen-associated molecular patterns (PAMPs) that act through Toll-like receptors (TLRs). Binding of the ligand to its receptor induces assembly of large intracellular complexes to the receptor tail that ultimately recruit the classical IKK complex (composed of IKKα, IKKβ, and IKKγ). IKKγ undergoes nondegradative linear ubiquitination which induces IKK activation through autophosphorylation. Activated IKK phosphorylates the IκB proteins leading to their polyubiquitinylation and degradation. This leads to liberation and nuclear translocation of NF-κB dimers (mainly p65/p50) and coordinated expression of multiple inflammatory and innate immune genes. The alternative or noncanonical NF-κB pathway results in the nuclear translocation of p52/RelB dimers after phosphorylation-dependent processing of p100 (NF-κB2). It is strictly dependent on IKKα dimers that are activated by certain cytokines including lymphotoxin-β (LTβ), CD40 ligand (CD40L), and the B-cell-activating factor BAFF/Blys. Activation of the alternative pathway turns on a more limited gene expression program required for the activation and maintenance of the adaptive immunity

development, maintenance, and activation of cells from the immune system (including hematopoietic cells, macrophages, dendritic cells, B and T lymphocytes) has greatly benefited from the analysis of knockout mice in which individual NF-κB family members were defective (Zhang et al. 2017).
