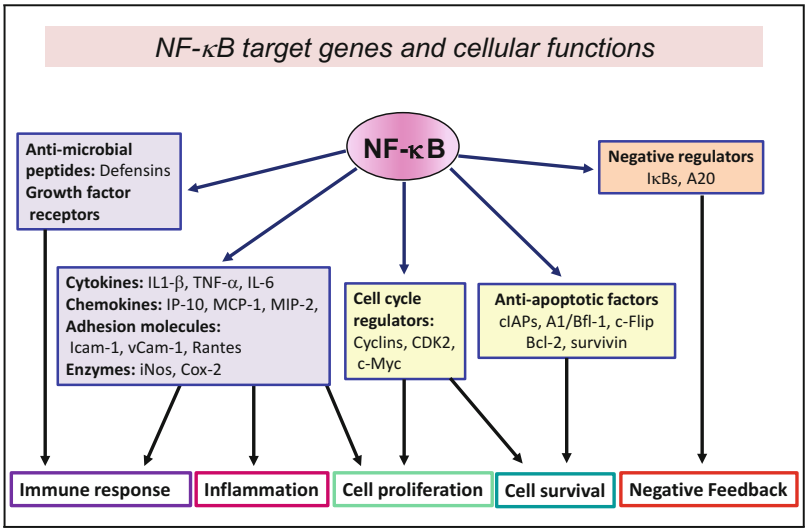
The innate immune response is initiated once the host detects the presence of foreign pathogens. This recognition step is performed by specialized cells of the innate immune system, the macrophages, and the dendritic cells. These cells express at their surface or intracellularly a number of pattern recognition receptors (**PRRs**), each of which has the ability to recognize specific pathogen-derived substances called pathogen-associated molecular patterns (**PAMPs**) characteristics of various classes of microbes including bacteria, viruses, and parasites. Activation of the classical NF-κB signaling pathway is essential to this acute phase of antimicrobial defense. Defective NF-κB activity in mice and humans is often associated with susceptibility to microbial infections. Indeed, activation of NF-κB dimers (mainly RelA/p50) induces transcription of genes encoding cytokines (► Cytokines), chemokines, adhesion molecules, and antimicrobial peptides (**defensins**), all of which are essential to build the innate immune response, clear the pathogen, and initiate the adaptive immune response (Figs. 3 and 4).

NF-κB is also crucial for the proper functioning of the adaptive immune system not only by acting on the immune cells themselves but also by participating in the development and organization



NF-κB, Molecular Target, Fig. 4 NF-κB cellular functions and target genes. NF-κB contributes to the induction of multiple target genes that can be divided into five major functional classes, which specify diverse cellular functions. NF-κB controls its own activity by inducing the expression of its regulators, the IκB proteins, and establishing a negative feedback regulatory loop. NF-κB induced multiple genes whose products are mediators of inflammation such as pro-inflammatory cytokines (TNFα, IL-1 and IL-6), adhesion molecules (VCAM-1, ICAM-1, E-selectin, RANTES), and the inflammatory enzymes, cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS). NF-κB has critical immunoregulatory functions both in the innate immune defense against pathogens and in the development, maintenance, and activation of the adaptive immunity. The anti-apoptotic function of NF-κB requires the activation of genes whose products are implicated in the inhibition of caspase activity such as the cellular inhibitors of apoptosis (cIAPs) and the cellular FLICE-inhibitory protein (cFLIP) or are negative regulators of the mitochondrial cell death program such as the Bcl-2 family protein members, Bfl-1/A1 and Bcl-X_L. NF-κB plays a role in cell proliferation and differentiation in particular by regulating the expression of the genes encoding the cell cycle regulator, cyclin D1, and the oncogene c-Myc (Yang et al. 2016)

of the secondary lymphoid organs (lymph nodes, spleen, and Peyer's patches), in which both B and T lymphocytes undergo maturation and activation. NF-κB proteins have an important role in lymphocyte development and homeostasis, primarily through regulation of the balance between cell proliferation and cell death (Fig. 3). The anti-apoptotic function of NF-κB is required during early development and expansion of B cells, which occurs in the bone marrow, and T cells, which takes place in the thymus. Different genetic approaches have uncovered the involvement of NF-κB proteins in T-cell activation and function. For instance, NF-κB is involved in the production of interleukin-18 (IL-18) and interferon-γ (INF-γ) (▶ Interferons), two cytokines required to develop the cellular or T-helper 1 (T_H1) immune response. Activation of both the canonical and noncanonical NF-κB pathways controls B-cell maturation and function such as immunoglobulin class switching and cytokine production. Analysis of the contribution of individual NF-κB family members to the development of secondary lymphoid organs led to the identification of NF-κB target genes specifically activated in different cell types (stromal, dendritic, and lymphoid) and implicated in the development and maintenance of the secondary lymphoid organs.

NF-κB, Inflammation and Inflammatory Diseases

Inflammation (▶ Inflammation) is a physiological protective mechanism by which the body defends itself against infection or tissue damage. This process is normally transient, well controlled, and responsible for tissue repair and regeneration. In certain circumstances however, the inflammatory response is chronically activated and leads to

the development of chronic inflammatory diseases (Liu et al. 2017).

NF-κB is one of the most important regulators of inflammatory responses. Pro-inflammatory stimuli such as those elicited by the cytokines TNFα and IL-1 are the most potent activators of NF-κB and trigger expression of pro-inflammatory genes encoding pro-inflammatory cytokines (TNFα, IL-1, and IL-6), chemokines, adhesion molecules, inflammatory enzymes (cyclooxygenase-2, COX-2 and inducible nitric oxide synthase, iNOS), and **matrix metalloproteinases** (MMPs) (▶ Matrix Metalloproteases) (Figs. 3 and 4). Massive production of pro-inflammatory mediators (TNFα and IL-1) amplifies the inflammatory response despite the activation of negative feedback mechanisms, for instance, the induced expression of the NF-κB inhibitors (IκBs) that is supposed to limit the duration of NF-κB activation. Recruitment of inflammatory cells such as macrophages and inflammatory T cells to the site of inflammation occurs quite rapidly after NF-κB activation. Cellular homeostasis is disturbed and tissue destruction occurs. High NF-κB activity is observed at the center of inflammation in several diseases affecting different tissues or organs including rheumatoid arthritis (▶ Inflammation and Rheumatoid Arthritis), systemic lupus erythematosus (SLE), atherosclerosis, inflammatory bowel diseases (IBDs), asthma, and psoriasis.

NF-κB is also implicated in the regulation of inflammasomes, in particular the NLRP3 inflammasome (Taniguchi and Karin 2018) (▶ Inflammasome). These multiprotein complexes assemble intracellularly upon infections or tissue damage and activate inflammatory caspases (Caspases) such as caspase-1. Activated caspase-1 cleaves pro-IL-1β and pro-IL-18 into their mature forms which are released and mediate inflammation. NF-κB induces the expression of pro-IL-1β and upregulates the amount of NLRP3, a pattern recognition receptor (PRR) which belongs to the NOD-like receptor (NLR) family and that sense pathogens or intracellular tissue damage. Excessive inflammasome activation is however prevented by autophagy, a key process that removes cellular waste. Autophagy is also controlled by NF-κB which appears as a key factor to regulate proper activation of inflammasomes and a well-controlled inflammatory response.

NF-κB, Cell Survival, Cell Proliferation, and Cancer

NF-κB controls the expression of genes that prevent programmed cell death (PCD) through apoptosis (Apoptosis) or necrosis. The classical pathway is responsible for inhibition of PCD triggered by activation of several receptors including type I and type II TNF receptors (TNF-RI and TNF-RII), Toll-like receptor 4 (TLR4), and T- and B-cell receptors, which are able to generate both survival and death signals once activated. NF-κB favors survival by inducing the expression of several anti-apoptotic genes (Fig. 4) whose products act at different steps along the receptor-mediated or the mitochondrial pro-apoptotic cascades. The first clear evidence that NF-κB is an effective inhibitor of apoptosis came from the analysis of RelA-deficient mice that die during embryonic development from a massive liver apoptosis. Defective NF-κB activation is unable to protect the hepatocytes from the toxic effects caused by the massive release of TNFα that occurs in the liver of a developing embryo. A similar phenotype is observed in mice defective in IKKβ and IKKγ, the two components of the IKK complex that are crucial for the activation of the anti-apoptotic program mediated through the classical NF-κB pathway. The alternative pathway also supports an anti-apoptotic program important for the survival of premature B cells and development of secondary lymphoid organs as described above (Zhang et al. 2017).

This protective effect of NF-κB against apoptosis has a dramatic side effect in cancer cells as it antagonizes the killing potential of most anti-cancer drugs that also activate NF-κB. In addition, aberrant NF-κB activity is observed in the large majority of human cancers and plays a central role in tumor development and progression to malignancy. Genetic mutations affecting the NF-κB or IκB subunits are relatively rare. Mutations leading to constitutive activation of NF-κB in certain malignant cells are found in signaling components that normally prevent excessive NF-κB

activation. However, the major cause of NF-κB activation relies on chronic inflammation in the tumor microenvironment (Taniguchi and Karin 2018; Didonato et al. 2012). Activated NF-κB in the tumor microenvironment is responsible for the massive production of pro-inflammatory cytokines that promote tumor cell growth. Therefore NF-κB is a major factor in the development of inflammation-associated cancers (▶ Cancer). Considering this central role of NF-κB in cancer, targeting NF-κB represents an attractive therapeutic approach in cancer therapy.

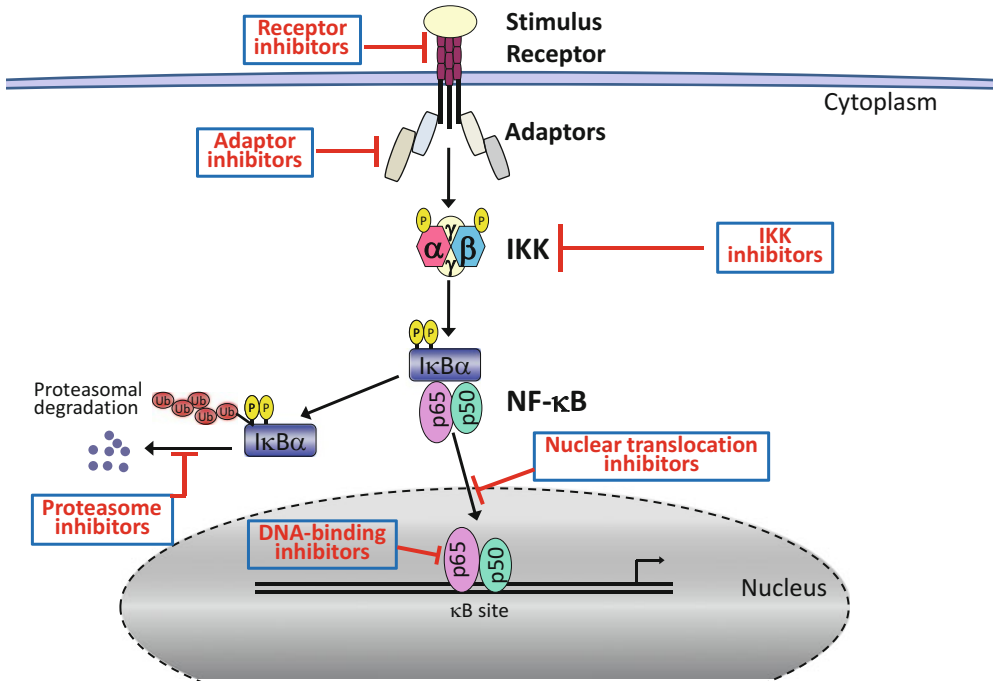
Drugs

There are several hundred reported NF-κB inhibitors (partially listed at www.nf-kb.org). These inhibitors include natural products, chemicals, metabolites, and synthetic compounds. A large majority of these products, in particular commonly used anti-inflammatory drugs such as corticosteroids and the nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, sulindac, ibuprofen, and sulfasalazine, have the ability to partially inhibit NF-κB activity in cell culture. However, the precise mechanism of action and the specific molecular target of most of these inhibitors remain unclear (Begalli et al. 2017; Durand and Baldwin 2017).

Several strategies targeting different steps of the signaling cascade can be used to inhibit NF-κB activation and function (Fig. 5). One general approach is to interfere with NF-κB nuclear activity by altering dimerization, nuclear translocation, binding to DNA, or interaction with the transcriptional machinery. This includes the use of decoy oligonucleotides that have κB sites and compete NF-κB dimers out of their target promoters or cell-permeable peptides able to block specifically the nuclear translocation of NF-κB.

A second approach to target NF-κB is to interfere with its activation by blocking the activation of the IKK complex or the degradation of IκBs (Didonato et al. 2012; Begalli et al. 2017; Durand and Baldwin 2017). Among the molecules tested are proteasome inhibitors, many of which inhibit IκB degradation and thereby NF-κB nuclear translocation. One proteasome inhibitor, bortezomib, is used for the treatment of solid and hematologic tumors. It is still unclear whether its therapeutic effect in cancer treatment is entirely or partially due to inhibition of NF-κB as the proteasome is involved in the degradation of many different polyubiquitinylated proteins and has no specificity for NF-κB signaling. A more promising approach to selectively inhibit NF-κB activation was to target IKKβ which drives NF-κB activation in response to a large number of stimuli and in many pathological conditions. The pharmacology industry came up with numerous small molecule inhibitors of IKKβ, some of which were evaluated in animal models for inflammatory diseases or cancer and in early-phase clinical trials. One such study revealed that pharmacological inhibition of IKKβ increases IL-1β secretion by myeloid cells leading to inflammasome activation and endotoxin-induced septic shock during bacterial infections (Taniguchi and Karin 2018; Didonato et al. 2012). Despite sustained effort of the pharmaceutical industry, no NF-κB or IKKβ inhibitor has been clinically approved. This is largely due to dramatic side effects and toxicity associated with systemic blockade of NF-κB or IKKβ function as NF-κB is central in maintaining normal immune responses and tissue homeostasis.

What path to follow next? Effective NF-κB drug development will have to embrace the complexity of the regulatory networks controlling NF-κB activation in a particular cell type, in response to a specific signal or in a disease context. Several new lines of research can be explored and can count on the undefective efforts of the basic research to understand and dissect the molecular events associated with NF-κB dynamic regulation. One approach is to target the signaling cascade upstream of NF-κB by designing small molecule inhibitors targeting rate-limiting protein-protein interactions downstream of receptor activation. One example would be to limit the formation of the mature TNFR1 complex by interfering with the interaction between Traf2 and TRADD, two key adaptors required for the recruitment of IKK to the activated TNFR1 complex. Recent information on crystal structures of interacting domains within Traf2 and TRADD



NF-κB, Molecular Target, Fig. 5 Inhibition of NF-κB signaling. Many therapeutic approaches are developed to inhibit NF-κB signaling. Anti-TNFα and anti-IL-1 drugs which block the signaling cascade at the level of the receptor are currently used in the treatment of inflammatory and autoimmune diseases. Selective IKK inhibitors targeting either the catalytic activity of IKK (ATP analogs) or the IKK complex formation or activation (allosteric IKK inhibitors and NEMO-binding domain peptide) preventing IκB phosphorylation have been characterized but none of these inhibitors is clinically approved. Proteasome inhibitors such as Bortezomib and lactacystin are not specific for NF-κB but are able to block the degradation of ubiquitinylated IκBs. Inhibition of NF-κB nuclear translocation using specific drugs or the IκBα super-repressor (nondegradable form of IκBα) is another way to inhibit NF-κB signaling. Glucocorticoids can interfere with the DNA-binding and transcriptional activity of NF-κB. Inhibitors targeting adaptor proteins may be of interest to specifically block IKK and NF-κB activation by a specific cytokine or receptor ligand

(Napetschnig and Wu 2013) make it realistic to design selective inhibitors that would block the TNFR1 pathway while leaving IKK-NF-κB activation intact in pathways that do not require Traf2 or TRADD. In the same line, precious information on IKK complex formation are provided by structural studies already available on IKKβ and IKKγ (Napetschnig and Wu 2013). In addition, IKK signaling is also regulated by ubiquitinylation/deubiquitinylation of IKKγ. This should be explored to design specific inhibitors that could modulate IKK activation in a specific pathway instead of blocking it completely. Another line of research is a system biology approach combined with transcriptomic analysis. Screening of small drug inhibitors targeting components of the NF-κB signaling networks can be performed in vivo by examining the gene expression profile associated with the disruption of a specific pathway. The Library of Integrated Network-Based Cellular Signatures (LINCS) Program launched by the National Institute of Health (NIH) (www.lincsproject.org) is creating a network-based understanding of biology by analyzing changes in gene expression and other cellular processes that occur when cells are exposed to diverse stimuli. This public database also contains the transcriptional profiles of genetic knockdowns of proteins involved in NF-κB signaling. In some case, effective inhibition could be similar to gene

knockdown. This transcriptional analysis might help in identifying bioactive compounds that disrupt a specific pathway within the complex NF-κB signaling network.

Glossary

Ankyrin Repeat The ankyrin repeat motif is one of the most common protein-protein interaction domains. Ankyrin repeats are modules of about 33 amino acids repeated in tandem. They are found in a large number of proteins with diverse cellular functions such as transcriptional regulators, signal transducers, cell-cycle regulators, and cytoskeletal proteins.

Defensins Defensins are a group of antimicrobial and cytotoxic peptides made by immune cells. There are seven defensins in humans, six alpha-defensins, and one beta-defensin, which are involved in the innate immune defense at the surface of epithelia from the respiratory tract, the intestinal tract, or the urinary tract.

IKK Complex The IκB kinase (IKK) complex is a high-molecular-weight (600–900 Kd) multisubunit complex present in the cytosol of most cell types. It contains two highly homologous catalytic subunits, IKKα (or IKK1) and IKKβ (or IKK2) that are serine/threonine protein kinases. They are structurally related and contain an amino-terminal kinase domain, a central leucine zipper region required for their dimerization and a carboxyl-terminal helix-loop-helix domain, which mediates protein interaction. The catalytic subunits interact through their carboxyl-terminal end with the third subunit, IKKγ (or NEMO for NF-κB essential modulator). IKKγ is the regulatory subunit of the IKK complex. It is structurally composed of protein-protein interaction motifs including two coiled-coiled domains, a leucine-zipper domain and a zinc-finger domain. IKKγ is essential for the structural organization and stability of the complex. IKKγ also has a regulatory function as it connects the IKK complex to potential upstream activators.

Matrix Metalloproteinases Matrix metalloproteinases (MMPs) also called metalloproteases, zinc endopeptidases, or matrixins are the largest and most diverse of the four groups of proteases. They are zinc-dependent, calcium-activated proteases synthesized as inactive precursors (or zymogens), which are proteolytically cleaved to generate the active enzyme. All matrixins contain an N-terminal peptide and a zinc-binding catalytic active site. The N-terminal peptide, which is cleaved during the activation step, contains a conserved motif, the cysteine switch whose cysteine residue chelates the zinc of the active site, rendering the enzyme inactive. MMPs degrade components of the extracellular matrix such as collagen and participate in several cellular processes including tissue remodeling, wound healing, angiogenesis, and tumor invasion.

PAMPs Pathogen-associated molecular patterns (PAMPs) are microbial components derived from pathogens such as bacteria, viruses, fungi, and parasites. PAMPs are specifically recognized by the Toll-like receptors (TLRs), which are expressed by cells of the innate immune defense such as dendritic cells and macrophages. PAMPs comprise for very diverse components including lipopolysaccharide (LPS) from Gram-negative bacteria, lipoproteins and lipopeptides, flagellin, and bacterial and viral unmethylated CpG DNA or double-stranded RNA (dsRNA) produced by most replicating viruses.

Phosphorylation Phosphorylation is the reversible process of introducing a phosphate group onto a protein. Phosphorylation occurs on the hydroxyamino acids serine and threonine or on tyrosine residues targeted by Ser/Thr kinases and tyrosine kinases, respectively. Dephosphorylation is catalyzed by phosphatases. Phosphorylation is a key mechanism for rapid posttranslational modulation of protein function. It is widely exploited in cellular processes to control various aspects of cell signaling, cell proliferation, cell differentiation, cell

survival, cell metabolism, cell motility, and gene transcription.

PRRs Pattern recognition receptors (PRRs) are receptors expressed by cells from the innate immune system acting as sensors to rapidly detect invading pathogens. PRRs recognize conserved pathogen-associated molecular patterns (PAMPs) and distinguish foreign organisms such as bacteria, viruses, fungi, or parasites, from cells of the host. PRRs are divided into three families. The most studied family is the Toll-like receptors (TLRs). TLRs are membrane proteins anchored in the plasma membrane or at the surface of endosomes. TLRs are characterized by a common ligand-binding domain, which is composed of leucine-rich repeats (LRRs). Their recognition of either extracellular pathogens or PAMPs present in endosomes activates the innate and adaptive immune responses through signaling cascades controlling selective activation of NF-κB and other inducible transcription factors. The other two families of PRRs, the NOD-like receptors (NLRs) and the RIG-like helicases (RLHs) are soluble receptors present in the cytosol and act as sensors to detect a variety of viral and bacterial products. NOD1 and NOD2 (two NLRs) detect bacterial peptidoglycan, while the retinoic acid-inducible gene-1 (RIG-1) and the melanoma differentiation-associated gene-5 (MDA-5) are RNA helicases that sense viral double-stranded RNA (dsRNA).

Rel Homology Domain The Rel homology domain (RHD) is an evolutionarily conserved domain found in some eukaryotic transcription factors, including NF-κB, the nuclear factors of activated T cells (NFATs), and the Drosophila proteins Dif and Relish. Some of these transcription factors form multiprotein DNA-bound complexes. Phosphorylation of the RHD appears to play a role in the regulation of the activity of some of these transcription factors and modulation of expression of their target genes. Structurally, the RHD is composed of two immunoglobulin-like-beta-barrel subdomains that grip the DNA in the major groove. The amino-terminal portion of the RHD contains a recognition loop that directly interacts with DNA bases. The carboxyl-terminal portion of the NF-κB RHD contains the site for interaction with the IκBs.

Definition

The nicotinic receptor (nAChR) comprises a family of receptor subtypes that respond to the neurotransmitter acetylcholine (ACh) and the tobacco alkaloid nicotine (Zoli et al. 2018).

nAChR are found in:

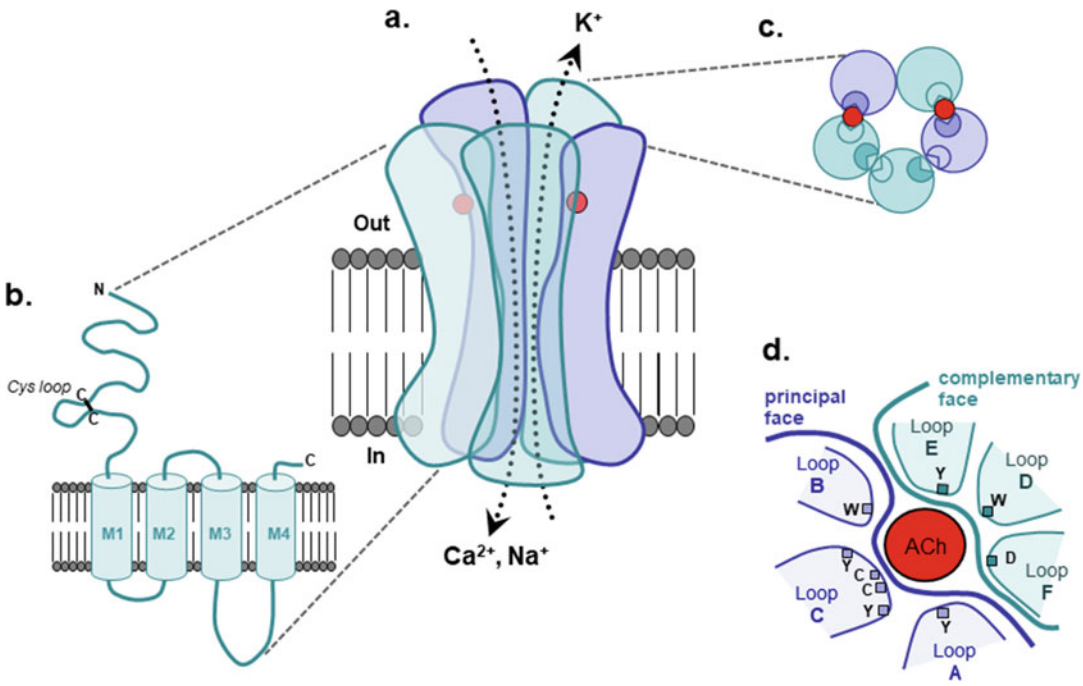
1. Skeletal muscle (*muscle nAChR*, comprised of α1-, β1-, γ- or ε-, and δ-subunits. The γ-subunit is expressed during development and is replaced by ε in nAChR in mature neuromuscular junctions). Also present in electrogenic tissues of electric fish, notably rays and eels of the genera *Torpedo* and *Electrophorus*
2. Sympathetic, parasympathetic, and sensory neurons of the peripheral nervous system (PNS), (*ganglionic nAChR*, typically comprised of combinations of α3-,α5-,β2-, and β4-subunits, also homomeric α7-nAChR composed of α7-subunits only). Also present in chromaffin cells and cell lines of PNS or chromaffin origin (notably SH-SY5Y and PC12 cells). Sensory (dorsal root ganglion) neurons may also express α9- and α10-subunits.
3. CNS neurons (in mammals: heteromeric nAChR comprised of α/β-combinations from α2-, α3-, α4-, α5-, α6-, β2-, β3-, and β4-subunits or homomeric α7-nAChR; also nAChR containing α7 in combination with β2-subunits). α4β2∗-nAChR (where ∗ indicates the possible inclusion of additional subunits in the pentamer) and α7-nAChR are the most prevalent subtypes in the mammalian brain. Avian species express an additional subunit, α8, that is most closely related to the α7-subunit and can form α7α8 heteromeric nAChR.
4. Non-neuronal cells, including astrocytes; endothelial cells of the vascular system; epithelial cells of the skin, lungs, and gastrointestinal tract; immune cells; macrophages; and muscle cells (express various populations of neuronal nAChR subunits; also expressed in some disease states, e.g., cancer cells and activated microglia). Mechanosensory hair cells are exceptional in expressing α9- and α10-subunits only.
5. Invertebrate nervous systems (e.g., insects) and muscle (e.g., nematodes) (an evolutionarily distinct portfolio of α- and β-like subunits constitute various *invertebrate nAChR*)

All subtypes of vertebrate nAChR except muscle nAChR are collectively referred to as *neuronal nAChR*.

The muscle nAChR is the prototype of the cys-loop family of ligand-gated ion channels (LGIC) that also includes $GABA_A$, $GABA_C$, glycine, $5HT_3$ receptors, and invertebrate glutamate-, histamine-, ACh-, and 5HT-gated chloride channels. These receptors are more distantly related to prokaryotic LGICs that lack the cys-loop (Nemecz et al. 2016).

Basic Characteristics

The nAChR is comprised of five subunits, each of which spans the lipid bilayer to create a water-filled pore or channel (Fig. 1a). Each subunit consists of four transmembrane segments; the second transmembrane segment (M2) lines the ion channel (Fig. 1b). Agonist binding leads to channel opening and the passage of cations. The extracellular N-terminal domain of every subunit contains a "cys-loop" that is the signature sequence of the



Nicotinic Receptors, Fig. 1 nAChR structure. (**a**) Schematic representation of a heteromeric nAChR. Five subunits span the lipid bilayer to create a water-filled central channel that is permeable to cations when opened in response to agonist binding. Binding of agonist molecules (represented by red spheres) to two orthosteric binding sites is required for channel opening. (**b**) Structure of a single subunit. Each subunit has a large extracellular domain containing the "cys-loop" and traverses the membrane four times; the second transmembrane domain M2 lines the ion channel. There is a variable intracellular loop between transmembrane spans M3 and M4 that contains putative phosphorylation sites; this region is likely to be important for regulation and trafficking of nAChR and interacts with chaperone, cytoskeletal, and scaffolding proteins. (**c**) Top view of the nAChR. Five subunits surround the central pore. The two orthosteric binding sites with ACh bound (red spheres) are found at subunit interfaces. Unorthodox and noncanonical binding sites involving the fifth subunit are also indicated. (**d**) The orthosteric (agonist) binding site. Agonist (red sphere) binds to a site at the interface between two subunits. The principal (α) subunit contributes amino acids in three loops (A, B, C) to bind the agonist, supported by additional hydrophobic residues in three loops (D, E, F) from the complementary face of the adjacent subunit (γ, ε, or δ in muscle nAChR, α or β in neuronal nAChR) (Changeux 2018). Amino acids are indicated by their single-letter codes

LGIC family: 2 cysteine residues, separated by 13 amino acids, form a disulfide bond to create a loop (Fig. 1b).

The *orthosteric binding site* for agonists, including ACh and nicotine, occurs at the interface between two adjacent subunits (Fig. 1c), in the extracellular part of the receptor created by the N-terminal domains of its subunits (Figs. 1a and 2). The principal face of the binding site is found on α-subunits that possess a pair of adjacent (vicinal) cysteine residues and a number of key hydrophobic residues organized in three loop structures (A, B, C) that coordinate the agonist (Fig. 1d). All α-subunits except for α5 and α10 can contribute to the orthosteric binding site. The adjacent subunit (γ, ε, or δ in muscle nAChR; β in neuronal heteromeric nAChR; α in homomeric α7-nAChR; or α10 in α9/α10-nAChR) contributes the complementary face of the orthosteric binding site, providing three conserved loops (D, E, F) containing predominantly hydrophobic residues (Fig. 1d). In muscle nAChR and αβ-heteromeric neuronal nAChR, there are two orthosteric binding sites, and both sites must be occupied by agonist for effective opening of the ion channel. Homomeric α7-

nAChR present five orthosteric binding sites (Bouzat et al. 2018).

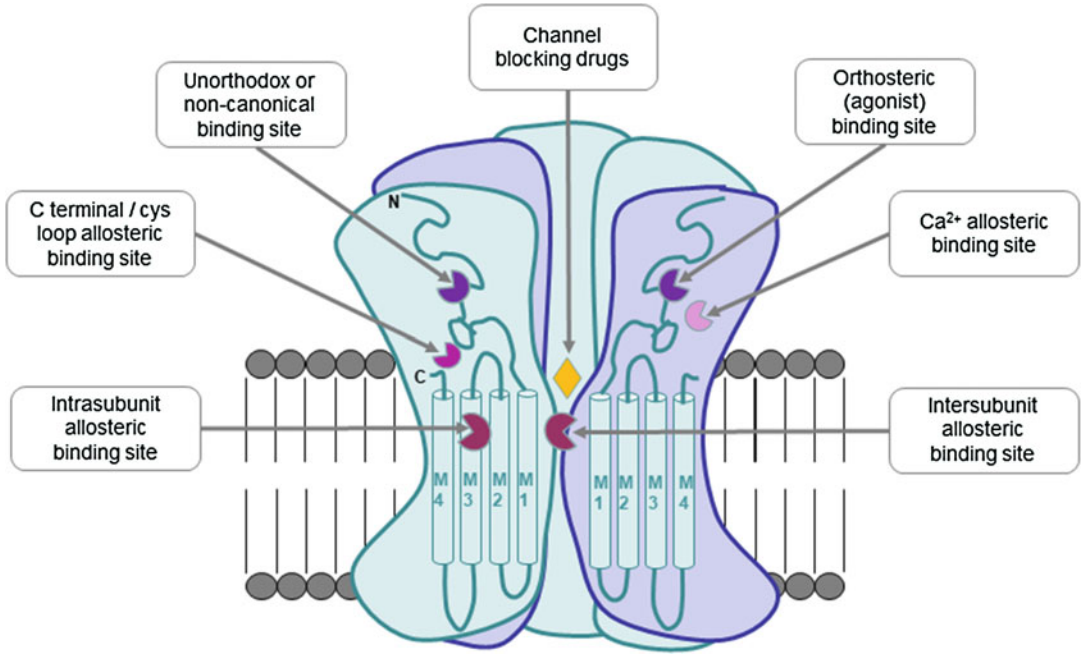
Heteromeric neuronal nAChR containing three α-subunits (e.g., $\alpha4_3\beta2_2$) have an additional *"unorthodox" agonist binding site* for ACh at the α/α-interface (Fig. 1c): agonist binding to such sites is not sufficient to cause the ion channel to open but can modify nAChR function dictated by the orthosteric sites (Wang and Lindstrom 2018).

nAChR function: in the resting (closed) state, the ion channel is occluded by a "hydrophobic girdle" that constitutes a barrier to ion permeation. Agonist binding to the orthosteric sites promotes a conformational change that results in a rotational movement of the M2 helices lining the pore, widening the pore by ~3 Å (Nemecz et al. 2016). This results in an influx of Na^+ and Ca^{2+} (the relative permeability of these two cations depends on nAChR subtype) and an efflux of K^+ under normal physiological conditions. Despite the presence of agonist, the nAChR channel closes within seconds to minutes, to enter a desensitized state. In this condition, the nAChR is refractory to activation. Multiple desensitized states have been proposed to exist (Nemecz et al. 2016). The rates of desensitization and recovery are nAChR subtype dependent and are also influenced by agonist concentration.

At the muscle end plate, nAChR activation produces depolarization that triggers muscle contraction. In sympathetic ganglia, postsynaptic nAChR mediate synaptic transmission, resulting in the depolarization of postganglionic neurons and the increased likelihood of generating an action potential. In the vertebrate CNS, it is uncommon for nAChR to have a postsynaptic role in mediating synaptic transmission. nAChR are more typically found at presynaptic and extrasynaptic locations on brain neurons where they exert a modulatory influence on synaptic activity and brain function (Zoli et al. 2018). This is achieved by alteration in excitability and/or increases in intracellular Ca^{2+}. Thus presynaptic nAChR promote the release of various neurotransmitters in different brain regions; extrasynaptic somatodendritic nAChR can influence local excitability and cell signaling and may produce long-term changes by altering gene expression. For example, α7-homomeric nAChR have exceptionally high relative permeability to Ca^{2+} (comparable to that of the NMDA receptor). Their association with glutamate synapses supports a contribution to long-term potentiation (LTP), through presynaptic facilitation of glutamate release and extrasynaptic enhancement of excitability. Postsynaptic α7-nAChR can activate Ca^{2+}-dependent cell signaling pathways, leading to activation of ERK, CREB, and immediate early genes such as cFos.

Allosteric modulation: in addition to the orthosteric and unorthodox binding sites, nAChR present multiple *allosteric binding sites* (Changeux 2018; Wang and Lindstrom 2018) (Fig. 2). Ligands targeting these sites typically have no intrinsic activity but may positively or negatively modulate agonist-induced responses. The various allosteric sites are well placed to modulate the conversion of agonist binding into channel opening. Most attention has focused on positive allosteric modulators (PAMs).

1. *Extracellular noncanonical binding sites*: analogous to the orthosteric and unorthodox binding sites but lacking the ability to bind ACh (primarily because they lack key amino acids in the principal binding face). For example, an $\alpha4_2\beta2_3$-nAChR presents β/α- and β/β-binding sites: although insensitive to ACh, other ligands (e.g., the anticholinesterase inhibitor galantamine) may bind to these noncanonical sites and hence influence receptor function (Wang and Lindstrom 2018). The β/β-noncanonical binding site is analogous to the benzodiazepine site of $GABA_A$ receptors.
2. *Extracellular Ca^{2+} binding site*: located at subunit interfaces, below the orthosteric sites, and closer to the membrane (Changeux 2018).
3. *Intrasubunit transmembrane sites*: for example, PNU-120596 binds to the intrasubunit vestibule located between the transmembrane spans of a single α7-subunit; occupancy of four such binding sites per pentamer is



Nicotinic Receptors, Fig. 2 nAChR binding sites for ACh and drugs. Schematic representation of binding sites on the nAChR for ACh and other agonists, allosteric modulators, and channel-blocking drugs. Only one site per category is indicated, but multiple sites may exist on the pentameric protein

reported to be necessary for positive modulation by PNU-120596 (Bouzat et al. 2018).

4. *Inter-subunit transmembrane sites*: for example, the large macrocyclic lactone ivermectin binds between the M3 and M1 transmembrane domains of adjacent subunits, toward the extracellular face of the membrane, and in close apposition with the M2 domain that lines the ion channel. Hence it is able to stabilize the open state of the ion channel (Changeux 2018).
5. *Sites at or near the extracellular C-terminus*: for example, 17β-estradiol binds to the C-terminus of the α4-subunit, facilitating interaction with the cys-loop to enhance channel opening (Wang and Lindstrom 2018).

Irrespective of where they bind, PAMs have been classified as *Type I* (increase agonist peak responses without altering timecourse (desensitization)), *Type II* (increase agonist peak responses and prolong responses by decreasing or reversing desensitization), or *Type III* (have weak intrinsic agonist activity as well as potentiating agonist responses) (Wang and Lindstrom 2018).

Drugs

Nature has created a diverse array of plant and animal toxins that act at mammalian muscle and neuronal nAChR or invertebrate nAChR, because the critical physiological functions of nAChR make them prime targets for defensive or predatory strategies. More recently, the perceived validity of neuronal nAChR as therapeutic targets has prompted the generation of new synthetic agonists and allosteric modulators. Examples are listed in Table 1.

Agonists activate nAChR by binding to the orthosteric agonist-binding sites (Fig. 1). Agonist can remain bound (often with higher affinity) when the nAChR enters the desensitized state.

Competitive antagonists interact with the nAChR at, or close to, the agonist-binding sites, stabilizing the receptor in a conformation with the channel closed and preventing agonists from accessing their binding site. Inhibition by reversible competitive antagonists is surmountable with increasing agonist concentration, shifting the concentration response relationship to the right.

Nicotinic Receptors, Table 1 Some drugs that act at nAChR

	Drug	Source	Specificity
Agonists	ACh	Endogenous agonist	nAChR and muscarinic receptors
	(±)-Anatoxin-a	*Anabaena flos-aquae* (blue-green algae)	Potent, nonselective
	Carbamylcholine	Synthetic carbamate analogue of ACh	Muscarinic > nicotinic
	Choline	Endogenous precursor and breakdown product of ACh	α7-nAChR selective
	(−)-Cytisine	*Fabaceae* genera	Potent partial agonist at α4β2-heteromeric neuronal nAChR Weak full agonist at α7-nAChR
	Dimethylphenylpiperazinium (DMPP)	Synthetic	Classical ganglionic agonist
	(±)-Epibatidine	*Epipedobates tricolor* (South American frog)	Very potent, nonselective
	Imidacloprid	Synthetic chloro-nicotinyl insecticide	Insect CNS nAChR
	5-Iodo-A-85380	Synthetic	β2-containing nAChR > others
	Levamisole	Synthetic imidazothiazole	Nematode muscle nAChR
	Lobeline	*Lobelia inflata*	A nonclassical agonist, also has non-specific actions
	(−)Nicotine	*Nicotiana tabacum*	Definitive agonist for nAChR (but an antagonist at α9-containing nAChR)
	Sazetidine A	Synthetic	α4β2-selective, stoichiometry dependent: $\alpha4_2\beta2_3 \gg \alpha4_3\beta2_2$
	Trans-metanicotine (TC-2403)	Synthetic	β2-containing > others
	Varenicline	Synthetic	Potent partial agonist at α4β2-heteromeric neuronal nAChR Weak full agonist at α7-nAChR
Competitive antagonists	α-Bungarotoxin	*Bungarus multicinctus* (banded krait)	Muscle and α7-, α8-, α9-, and α10-nAChR; some invertebrate nAChR
	α-Conotoxin	*Conus* sp.	Various/subtype-specific
	Decamethonium	Synthetic	Muscle > ganglionic
	Dihydro-beta-erythroidine (DHβE)	*Erythrina* sp.	β2 > β4
	D-Tubocurarine	*Strychnos toxifera; Chondrodendron tomentosum*	Nonselective
	Methyllycaconitine (MLA)	*Delphinium brownii*	Selective for α7-, α8-, α9-, and α10-nAChR, some invertebrate nAChR; weaker inhibition of α6 > α4 > muscle nAChR

(continued)

Nicotinic Receptors, Table 1 (continued)

	Drug	Source	Specificity
Noncompetitive antagonists	Chlorisondamine	Synthetic	Ganglionic (long-lasting blockade of CNS nAChR)
	Hexamethonium	Synthetic	Ganglionic (does not cross the blood-brain barrier)
	Histrionicotoxin	*Dendrobates histrionicus*	Nonselective
	Mecamylamine	Synthetic	Ganglionic: (terminology from historical clinical use; relatively non-selective for all neuronal heteromeric nAChR; crosses the blood brain barrier)
Positive allosteric modulators	LY2087101	Synthetic	Type I/intramembrane site $\alpha7 > \alpha4\beta2$-nAChR
	PNU-120596	Synthetic	Type II/intramembrane site α7-nAChR selective
	Galantamine	*Galanthus caucasicus*	Type III/noncanonical binding site
Negative allosteric modulators	Anesthetics (e.g., halothane, ketamine)	Synthetic	Transmembrane sites on α4β2-nAChR selectivity unclear

Noncompetitive antagonists do not compete for binding to the agonist-binding sites, but interact with distinct sites that modify nAChR function. Their inhibition is not surmountable with increasing agonist concentration. Some noncompetitive antagonists are "channel blockers" that act by either blocking the entrance to the nAChR channel or entering the lumen of the channel (Fig. 2). The action of such drugs can be "state-dependent," requiring prior activation of the nAChR to allow access to the channel. Many compounds that have other primary targets can also act as noncompetitive antagonists of nAChR, typically by blocking the ion channel. Examples include antagonists of voltage-operated Ca^{2+} channels, NMDA channel blockers, antidepressants, steroids, and β-amyloid peptide.

Positive allosteric modulators (PAMs) potentiate responses to nicotinic agonists by acting at a site distinct from the agonist-binding site (Fig. 2). Nonselective and subtype-selective PAMs have been characterized.

Negative allosteric modulators (NAMs) potentially act at the same sites as PAMs but have the opposite effect and diminish agonist responses (Zoli et al. 2018). Fewer examples have been reported, but both volatile and intravenous general anesthetics fall into this category. Drugs that act by occluding the nAChR pore (channel blockers) are not NAMs. However, drugs can display multiple actions that may differ in their concentration dependence.

Therapeutic or Agrochemical Applications

Historically ganglionic nAChR have been targets for treating hypertension. Muscle nAChR are inhibited by muscle relaxants such as atracurium besilate during surgery. The discovery of a large family of nAChR subtypes in the CNS, coupled with observations that nicotine has antinociceptive, neuroprotective, and procognitive effects, has made neuronal nAChR potential targets for treating a wide range of disorders. These include Alzheimer's and Parkinson's diseases, schizophrenia, attention-deficit hyperactivity disorder (ADHD), and pain. nAChR in peripheral cells are of interest in treating inflammation in different scenarios including ulcerative colitis and wound healing. Nicotine, cytisine (Tabex), and varenicline (Chantix, Champix) are in use for smoking cessation.

Imidacloprid is a widely used neonicotinoid insecticide that kills pests and other insects by targeting their central nAChR. Levamisole is used to kill nematodes by acting on nAChR in the worm's muscles.

Nitric Oxide

Andreas Friebe
Physiologisches Institut, Universität Würzburg, Würzburg, Germany

Synonyms

Nitrogen monoxide; Nitrogen(II) oxide

Definition

Nitric oxide (NO) is a colorless gas. It occurs in the atmosphere as a by-product of fossil fuel combustion. NO is also produced in mammalian and nonmammalian cells as well as in plants by enzymes called NO synthases (NOS). Being a radical, its half-life is in the range of seconds. Nevertheless, NO acts as an endogenous signaling molecule based on its ability to cross cell membranes. By activation of its receptor, NO-sensitive guanylyl cyclase, as well as by covalent reaction, e.g., with oxygen species or amino acid residues, NO is able to convey physiological and pathophysiological functions.

Although having been present in the earth's atmosphere for millions of years, nitric oxide was first identified by Joseph Priestly in 1772. Its physiological role became obvious only about 50 years ago. In 1982, Furchgott and Zawadzki (Furchgott and Zawadzki 1980) discovered that stimulation of endothelial cells with acetylcholine led to the release of a vasorelaxing factor, termed "endothelium-derived relaxing factor" (EDRF). In the subsequent years, EDRF was identified as NO by several independent research groups. Based on its presumed chemical instability and its radical character, a biological role of NO was first dismissed; however, subsequent work led to the identification of NO-producing enzymes (NO synthases, NOS) and the description of an NO receptor, namely, NO-sensitive guanylyl cyclase (NO-GC). Following the establishment of NO as physiological mediator along with its up- and downstream effectors, research focused on this novel pathway and led to the development of various enzymes involved in NO signaling. NO, initially identified in the vascular system, was found to regulate many different organs and tissues, including central and peripheral nervous system, but also to modulate various responses such as angiogenesis, apoptosis, immune response, or cell proliferation (Moncada et al. 1991). On the basis of their initial groundbreaking discoveries, Robert F. Furchgott, Louis Ignarro, and Ferid Murad were awarded the Nobel Prize in 1998.

Basic Mechanisms

Enzymatic NO Synthesis

Three isoforms of the NO synthase (NOS; EC 1.14. 13.39) are known (Förstermann and Sessa 2012), which were originally named after the

tissues in which they were first identified: neuronal NOS (nNOS; NOS type 1), inducible NOS (iNOS; NOS type 2; identified first in macrophages), and endothelial NOS (eNOS; NOS type 3). It was soon realized that NOS activity requires Ca^{2+}. nNOS and eNOS are both constitutively expressed enzymes that are regulated by intracellular Ca^{2+}/calmodulin. In contrast, iNOS is not constitutively expressed but rather induced by immunological stimuli; this isoform is independent of cytosolic Ca^{2+} as it constantly binds the Ca^{2+}/calmodulin complex.

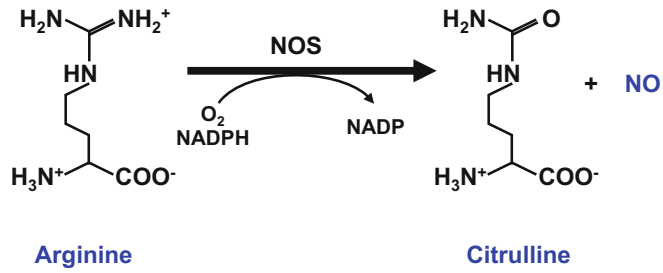
NO production results from a complicated redox reaction with arginine being transformed to citrulline in the presence of oxygen (Figs. 1 and 2). Necessary cofactors for all three isoforms include tetrahydrobiopterin (BH4), heme, NADPH, flavin adenine dinucleotide (FAD), and flavin mononucleotide (FMN).

NO synthesis results from the biochemical conversion of arginine to citrulline. All NOS isoforms require BH4, heme NADPH, FAD, and FMN as cofactors. Arginine analogs such as N^G-monomethyl-l-arginine, N^G-nitro-l-arginine, and asymmetric dimethylarginine act as inhibitors of NOS.

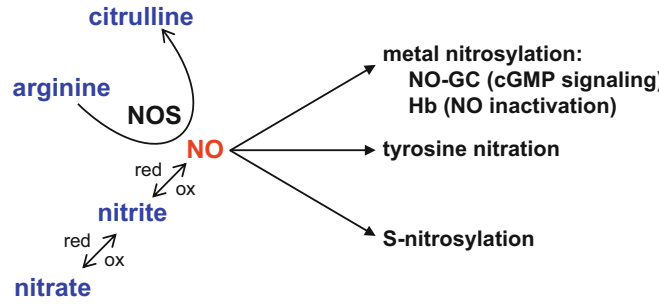
Nonenzymatic NO production

Nitric oxide may also be produced in an NOS-independent way under physiological conditions. Nonenzymatic NO generation was first shown to occur in the human stomach under acidic conditions. This pathway involves circulating nitrate which is reduced to nitrite by oral bacteria followed by further reduction under acidic conditions to form NO or other nitric oxide species (Fig. 2). Later, this nitrate-nitrite-NO pathway was shown to occur throughout the body in order to regulate blood flow, intercellular signaling, and responses to hypoxia. It is believed that the serial reduction of nitrate/nitrite serves as a backup system under hypoxic/ischemic or acidic conditions which impede oxygen-dependent NOS activity.

NO is produced either enzymatically by NOS or nonenzymatically after reduction of nitrate and nitrite. Possible reactions of NO include S-nitrosylation, tyrosine nitration, or metal nitrosylation. Nitrosylation of Fe-containing heme proteins such as NO-sensitive guanylyl cyclase (NO-GC) and hemoglobin (Hb) is thought to represent the physiological signaling and inactivation pathways, respectively.



Nitric Oxide,
Fig. 1 Catalytic reaction of NO synthases



Nitric Oxide,
Fig. 2 Generation and reactions of NO

NO Donors

Several compounds have been known for a long time to release NO or an NO-like species. Most of them belong to the group of organic nitrates and nitrites. For over 100 years, glyceroltrinitrate (GTN) has been exploited in the therapy of coronary heart disease. GTN releases NO after biotransformation, e.g., by mitochondrial aldehyde dehydrogenase (ALDH-2). Thereby, GTN effectively lowers the preload in patients. Other therapeutically used NO donors which do not need biotransformation but release NO spontaneously are molsidomine and sodium nitroprusside. Besides, a plethora of NO-releasing substances, e.g., NONOates, which exhibit varying release kinetics and stoichiometries have been introduced for research purposes.

NO Inactivation

Despite ample information on the mechanism of NO synthesis, much less information is available on how NO is inactivated and degraded. Binding to the heme moiety of hemoglobin yielding nitrate and methemoglobin is probably the most important physiological way of NO inactivation. Thereby, the dense capillarization of most tissues limits the range of NO diffusion and thus its half-life. Another important way to inactivate NO is the diffusion-limited reaction with superoxide ions under formation of peroxynitrite (Pacher et al. 2007). Being a very powerful and toxic oxidant, peroxynitrite may have pathophysiological importance based on its reaction with protein thiols, iron/sulfur centers, or zinc fingers. As superoxide concentrations are limited by the action of superoxide dismutase, the inactivation of NO to peroxynitrite will be favored under conditions that allow the formation of high concentrations of each compound.

Further chemical ways of NO inactivation include the oxidation to nitrite/nitrate which are excreted with the urine. The direct reaction between NO and oxygen, however, appears to be of minor importance due to the low concentrations of the reactants in vivo. This reaction may, however, be favored under conditions in which the concentrations of NO and oxygen are enriched such as in hydrophobic cell membranes.

NO Receptor

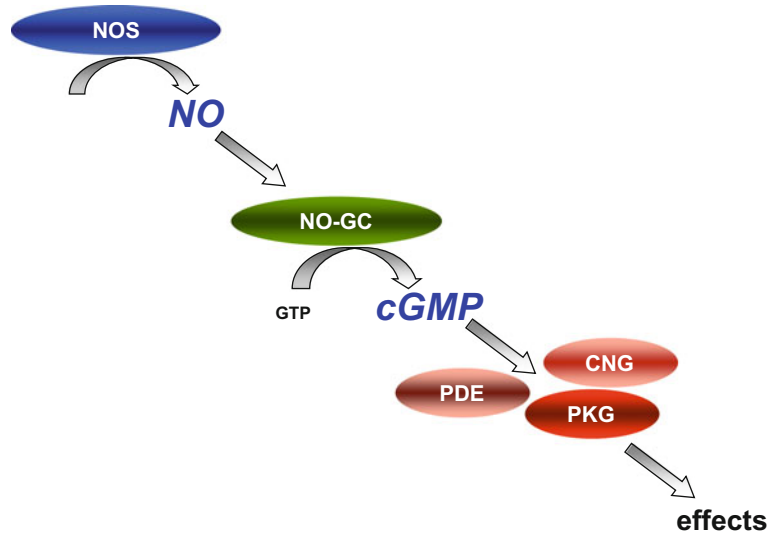
The commonly accepted receptor mediating the physiological effects of NO is NO-sensitive guanylyl cyclase (NO-GC; Fig. 3). Binding of NO to the enzyme's prosthetic heme group leads to a conformational change of the dimeric enzyme which dramatically increases its catalytic activity. As a consequence, the substrate guanosine triphosphate (GTP) undergoes a cyclization reaction resulting in the synthesis of cyclic guanosine monophosphate (cGMP). cGMP acts as intracellular second messenger by activating target enzymes such as cGMP-dependent protein kinase G (PKG) and cGMP-regulated ion channels (CNG). In addition, cGMP modulates the activity of several phosphodiesterases (PDE). Depending on the subtype of PDE, cGMP may either increase or decrease cAMP or cGMP levels. The resulting crosstalk is of paramount importance in various cell types such as cardiomyocytes, smooth muscle cells, or platelets.

NO from either of the three NOS activates NO-GC by binding to its prosthetic heme to increase the production of cGMP. cGMP acts on three different effector molecules: whereas cGMP-dependent protein kinase G (PKG) and cGMP-regulated ion channels (cyclic nucleotide-gated channels, CNG) are activated by cGMP to increase phosphorylation and ion permeability, respectively, cGMP either activates or inhibits PDE depending on the enzyme subtype. This may result in increased or decreased levels of either cGMP or cAMP in a given cell.

Physiological Effects of NO

Endothelial NO

Although NO synthesis in endothelial cells can be induced by various substances such as acetylcholine, substance P, bradykinin, or histamine, the main stimulus for NO production is vascular shear stress. Thereby, NO and the subsequent cGMP cascade exerts an important role in



Nitric Oxide, Fig. 3 NO/cGMP signaling cascade

maintaining basal blood flow. Shear-induced NO release results in vasodilatation, thus leading to decreased vascular resistance and reduction of blood pressure. Long-term effects of endothelial NO include the inhibition of smooth muscle proliferation which helps to prevent atherosclerosis. Whereas these effects are mediated by NO diffusion to the medial layer of the blood vessel, NO also diffuses in luminal direction, and physiological NO effects are also mediated by NO-GC-expressing blood cells. NO thus induces the inhibition of platelet aggregation and adhesion as well as inhibition of leukocyte adhesion and transmigration.

Neuronal NO

NO can be released from neurons of the central (CNS) and peripheral nervous system as well as the enteric nervous system (ENS).

In the CNS, NO acts mainly as neuromodulator: NO has been shown to modulate synaptic signaling, thus influencing learning and memory processes. Here, long-term regulation of synaptic transmission rather than acute neurotransmission is mediated by nNOS. Retrograde communication across synaptic junctions is thought to involve NO-GC as target, thus involving cGMP and downstream targets. In several animal models, NOS inhibitors have shown to impair learning and to induce amnesia. Similarly, blockade of nNOS can lead to hypertension indicating the involvement of nNOS-derived NO in the regulation of blood pressure. Furthermore, neuronal NO/cGMP is involved in the regulation of sleep, circadian clock, as well as pain processing.

The peripheral nervous system also contains nitrergic nerves that express nNOS. These nerves innervate vascular smooth muscle, and nNOS-derived NO is thus thought to participate in the regulation of vascular tone. In addition, penile erection is initiated by activation of nitrergic nerves leading to corpus cavernosum smooth muscle relaxation.

The importance of NO in the ENS is still not fully elucidated. In the ENS, the major inhibitory non-adrenergic, non-cholinergic (NANC) neurotransmitter is NO; accordingly, these neurons are called “nitrergic.” However, other transmitters are often co-released from nitrergic nerves including vasoactive intestinal peptide (VIP) or ATP.

In both the gastrointestinal (GI) and urogenital tract, NO from nitrergic nerves targets NO-GC. In contrast to vascular tissue in which NO-GC in SMC is the primary target of eNOS-derived NO, gastrointestinal smooth muscle contains at least

three NO-GC-expressing cell types, i.e., SMC, interstitial cells of Cajal, and fibroblast-like cells. As all three of them lie in close proximity to nitrergic varicosities, the inhibitory neurotransmission of NO is likely to influence smooth muscle tone of the GI tract through a concerted action on all three cell types. Besides the transport of chyme, nNOS-derived NO regulates the smooth muscle tone in ureter and bile ducts; as a consequence, NO is thought to modulate the passage of bile and urine.

Inflammatory NO

Inducible NOS is normally not present in tissues. Inflammatory stimuli such as lipopolysaccharides or cytokines are known to induce the expression of iNOS mainly in macrophages but also in other cells. In contrast to the constitutive forms of NOS (eNOS, nNOS), iNOS produces high concentrations of NO. As a major component of the immune response, NO exerts toxic effects on bacteria, parasites, and viruses. NO's mechanism of toxicity includes the inhibition of iron−/sulfur-containing enzymes and the induction of DNA damage in parasitic microorganisms but also in tumor cells. However, as a consequence of the high NO concentrations achieved in the immune response, the reaction with superoxide is favored which may also lead to detrimental effects within the host.

Pathophysiological Effects of NO

As stated above, the main toxic mechanism of NO is the superoxide-dependent formation of peroxynitrite. As this reaction is favored at high concentrations of the reactants, iNOS-derived NO is most likely to exert toxicity on the invading organism but also on healthy cells of the host organism. NO derived from eNOS and nNOS is less likely to cause pathophysiological effects based on the fact that lower NO concentrations are produced for signaling purposes and that cGMP is not involved in NO toxicity. However, excess stimulation of eNOS and nNOS was shown to contribute to neurodegenerative pathologies as well as cardiovascular diseases especially in patients with neuronal or cardiovascular risk factors.

Mechanistically, peroxynitrite promotes oxidation and tyrosine nitration reactions which will affect a plethora of biomolecules. In addition, nitrosylation of thiols and metals are also known to affect protein and nonprotein structures. Thus, these NO-dependent reactions may cause excitotoxicity, neuronal apoptosis, cytochrome oxidase inhibition, and energy depletion due to inhibition of mitochondrial respiration. As a consequence, excessive NO is involved in many different diseases: Harmful NO metabolites are involved in neurodegeneration seen, e.g., in stroke, multiple sclerosis, Alzheimer's, and Parkinson's disease. In the cardiovascular system, nitrosylation and nitration reactions participate in the development of atherosclerosis, myocardial infarction, or ischemia/reperfusion injury. Further diseases connected with excessive NO production include rheumatoid arthritis, inflammatory bowel disease, diabetes mellitus, and certain forms of cancer. In septic shock, massive expression of iNOS in the vascular wall may result in extreme fall of vascular resistance, hypotension, and vascular damage.

Pathophysiological effects also arise from reduced NO bioavailability. Endothelial dysfunction is commonly associated with a decrease in NO levels which may be explained either by reduced endothelial NO production or by increased inactivation of endothelial NO by reactive oxygen species. Endothelial dysfunction participates in serious cardiovascular and metabolic diseases such as hypertension, angina pectoris, myocardial infarction, stroke, renal failure, glaucoma, and diabetes mellitus.

Pharmacological Relevance

Since reduced NO production and excess NO release are linked to various diseases, reducing as well as increasing NO effects may be therapeutically reasonable. Options to increase NO levels are direct application of proper NO (as NO gas), substances that release NO (NO donors), or an

NO-like compound. In order to increase NO-induced effects, stimulation of downstream pathways (NO-GC stimulators or PDE inhibitors) is conceivable. In case of excess NO, several different NOS inhibitors are available.

Genuine NO can be applied as inhalative treatment. Inhaled NO has been used to treat pulmonary hypertension in newborns, postoperative pulmonary hypertensive crises, and acute hypoxemic respiratory failure in patients with underlying pulmonary hypertension. NO donors are a heterogeneous group with most therapeutically used substances being organic nitrates. Glyceroltrinitrate (GTN) has been used for over 100 years in the treatment of acute attacks of coronary heart disease. While the oxidative state of the NO released from nitrates is not entirely clear, other compounds such as sodium nitroprusside release radical NO. In addition, nitroxyl donors (HNO; e.g., Angeli's salt, CXL 1020) have been/are being developed in order to treat acute decompensated heart failure.

Riociguat was the first approved drug belonging to the group of NO-GC stimulators. These compounds do not release NO by themselves, but increase cGMP signaling by sensitizing NO-GC toward endogenously produced NO (Sandner et al. 2019). Riociguat can be used in patients with pulmonary hypertension, whereas other stimulators resembling riociguat structurally are aimed to treat patients with heart failure, diabetic nephropathy, achalasia, or sickle cell disease.

Inhibition of cGMP-degrading phosphodiesterases (PDE) is probably the best-known option to increase NO-induced cGMP-mediated effects. Prototypical substances are the PDE5 inhibitors sildenafil, vardenafil, and tadalafil. PDE5 inhibition in the corpus cavernosum blocks the degradation of cGMP which results from activation of nitrergic nerves followed by stimulation of NO-GC.

Excessive NO production by either NOS may be counteracted with isoform-specific NOS inhibitors. In the case of nNOS, suitable inhibitors could prevent excitotoxicity and neurodegeneration, whereas under septic conditions, iNOS-specific inhibitors might reduce cardiovascular symptoms. Arginine analogs (e.g., N^G-monomethyl-l-arginine, N^G-nitro-l-arginine, and asymmetric dimethylarginine) are potential candidates; however, due to moderate potency and poor selectivity, they are not a therapeutic option. Other iNOS inhibitors, e.g., 1400 W, failed in clinical trials because of inherent toxicity.

Non-selective Cation Channels

Veit Flockerzi and Andreas Beck
Institut für Experimentelle und Klinische Pharmakologie und Toxikologie, Universität des Saarlandes, Homburg, Germany

Synonyms

Non-specific cation channels; NSCCs

Definition

Non-selective cation channels are macromolecular pores in the cell membrane that form an aqueous pathway enabling cations such as Na^+, K^+, or Ca^{2+} to flow rapidly, as determined by their electrochemical driving force, at roughly equal rates ($>10^7$ cations per channel pore and per second).

Basic Characteristics

In general, ion channels are multi-protein complexes residing in cellular membranes and allowing ions, mainly Na^+, K^+, Ca^{2+}, and Cl^-, to flow rapidly as determined by their electrochemical driving force in a thermodynamically downhill direction. The channel proteins are dynamic structures; they form channels that can exist in at least two conformational states, open and closed. In the closed state the channel can be inactive and/or is reluctant to be activated. Fast shifts in the submillisecond range between these states can be regulated by the membrane potential (voltage-gated ion channels), by ligands (ligand-gated ion channels) or agonists. In many cases these shifts can be modulated on a longer timescale (milliseconds to minutes) by hormones, neurotransmitters, drugs, and toxins.

The open channel has in most cases a selective permeability, allowing a restricted class of ions to flow, for example, Na^+, K^+, Ca^{2+}, or Cl^-, and, accordingly, these channels are called Na^+ channels, K^+ channels, Ca^{2+} channels, and Cl^- channels. In contrast, cation-permeable channels with little selectivity reject all anions but discriminate little among small cations. Different types of channels have different pore size dimensions, and ion discrimination is accomplished by a selectivity filter formed by channel-specific amino acid residues with characteristic arrangements of ion-binding sites in the pore region. Structural and dynamic differences were identified between selective and non-selective ion channels. Interactions of different ions within the channel significantly shape the landscape of free energy inside the pore, and it is suggested that structural plasticity within the selectivity filter and the selection of certain conformations by different ions are key molecular determinants in non-selective channels for a highly efficient permeation of different ions (Shi et al. 2018).

The first in-depth characterized non-selective cation channel was the nicotinic acetylcholine receptor (nAChR, see Nicotinic Receptors), which is a ligand-gated ion channel (see below) that does not select well among cations ($P_{Ca}/P_{monovalent\ cations}$ 4-7); the channel is even permeable to choline, glycine ethyl ester, and tris buffer cations. A number of other plasma membrane cation channels including certain ionotropic glutamate receptors, ionotropic purinergic (ATP) receptors (P2X receptors), cyclic nucleotide-gated channels (CNG channels), and the mechanosensitive Piezo channels are also called non-selective; they favor the flow of Ca^{2+} over monovalent cations with relative permeabilities of <1.5 (glutamate receptors of the AMPA/Kainate-type), <5 (glutamate receptors of the NMDA-type,

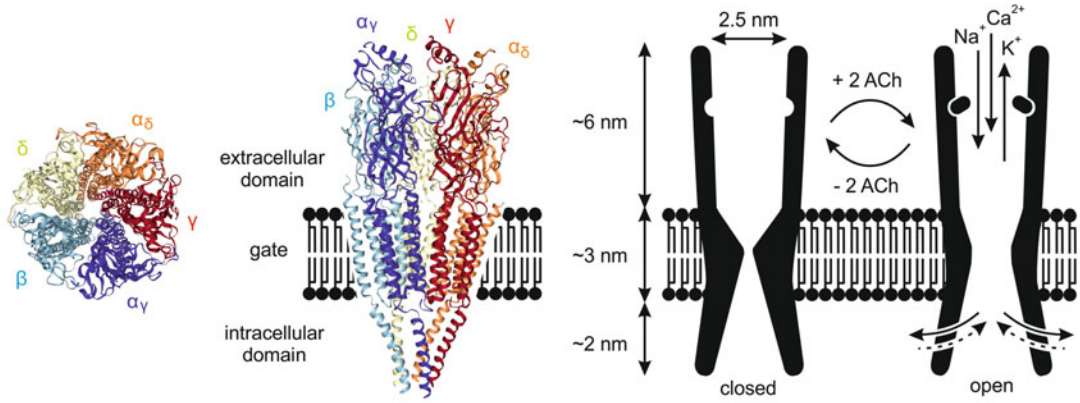
Piezo1/2), <12 (P2X receptors), and <90 (CNG channels) (Pankratov and Lalo 2014). Others, like hyperpolarization-activated and cyclic nucleotide-gated channels (HCN channels), conduct both K^+ and Na^+, but are impermeable to divalent cations, and the acid-sensing ion channel (ASIC) is mainly permeable to Na^+ with only minor permeability to Ca^{2+}. Another group of ion channels, which belong to the superfamily of transient receptor potential (TRP) channels (Nilius and Flockerzi 2014), have also been implicated to represent non-selective cation channels. Their permeability ratio for Ca^{2+} and monovalent cations varies widely with some TRP channels being highly selective for Ca^{2+} (TRPV5/6 $P_{Ca}/P_{Na} > 100$) and others being virtually Ca^{2+}-impermeable (TRPM4/5). Finally, besides Piezo, a subset of other channels activated by stretch have been implicated to be non-selective cation channels (Hille 2001). These channels appear to be ubiquitously expressed, but their structures are still unknown.

Non-selective cation channels are found in excitable and non-excitable cells. Driven by the electrochemical gradient, i.e., negative membrane potential and high extracellular levels of Na^+ and Ca^{2+} as compared to the cytoplasm, opening of non-selective cation channels in general leads to significant flux of Na^+ and Ca^{2+} into the cell. Subsequently, the resulting membrane depolarization and cytosolic Ca^{2+} increase triggers various cell-specific responses and functions. While the ligand-gated acetylcholine, glutamate, and ATP receptor channels directly transduce intercellular signals, CNG and some TRP channels indirectly deliver G protein- and/or receptor tyrosine kinase-mediated signaling as they are activated by intracellular second messenger molecules (cAMP, cGMP, Ca^{2+}, DAG). Other TRP channels, ASIC, and Piezo channels are involved in sensing chemical and physical conditions of the extracellular environment, and the activity of HCN channels contributes to the generation of rhythmic activity in heart and brain cells.

Due to recent methodological advances, within the last two decades detailed membrane structures of several non-selective cation channels, i.e., members of the ionotropic acetylcholine, glutamate, and ATP receptors as well as CNG, HCN, Piezo, ASIC, and TRP channels, have been identified by crystallographic analysis and/or cryo-electron microscopy. Like other ion channels, non-selective cation channels are composed of a certain number of subunits that are assembled in a predetermined arrangement and stoichiometry around a central, cation-selective pathway. The subunit compositions of the ion channels define their biophysical properties.

The structure of non-selective cation channels is extremely diverse: nACh receptor channels consist of five subunits (pentamer) with four transmembrane domains each; P2X receptor channels and ASICs are composed of three subunits with two transmembrane domains each; CNG, HCN, and TRP channels form tetramers with six transmembrane domains per subunit; ionotropic glutamate receptor channels are formed by four subunits with four transmembrane domains each; Piezo channels appear as trimers, predicted to encompass at least 26 transmembrane domains (Saotome et al. 2018) per subunit. Transmembrane segments are mainly formed by 19–21 amino acid residues that are folded into a α-helix. The α-helix is a rod-like structure, the tightly coiled polypeptide main chain of which forms the inner part of the rod, and the side chains extend outward in a helical array. Each residue is related to the next one by a rise of 0.15 nm along the helix axis and a rotation of 100°, which gives 3.6 amino acid residues per turn of helix. Accordingly, one turn of the helix is 0.54 nm, which is equal to 0.15 times the number of residues per turn. The hydrocarbon core of cellular membranes is typically 3 nm wide, which accordingly can be traversed by a α helix consisting of 19–21 residues.

For example, the pentameric nAChR, found in the membrane of vertebrate skeletal muscle at the synapse between nerve and muscle, also called the neuromuscular junction (muscle type nAChR), is cylindrical with a mean diameter of about 6.5 nm (Fig. 1). All five rod-shaped subunits ($\alpha_\gamma\gamma\alpha_\delta\delta\beta$) span the membrane. The receptor protrudes by <6 nm on the synaptic side of the membrane and by <2 nm on the cytosolic side. The pore of the channel is along its symmetry axis and includes an extracellular entrance domain, a



Non-selective Cation Channels, Fig. 1 The nicotinic acetylcholine receptor (nAChR) is localized within the cell membrane; above the cell membrane is the synaptic cleft, below the cytoplasm. Structure of the nAChR from top (left) and side view (middle; PDB 2BG9). The different colors code for the five subunits α_δ, α_γ, β, δ, and γ. Drawing (right) of the closed (left) and open (right) nAChR showing acetylcholine (ACh) binding to the α subunits and cation movement. Dimensions of the receptor were taken from reference (Corringer et al. 2000)

transmembrane domain and a cytosolic entrance domain. The diameter of the extracellular entrance domain is <2.5 nm, and it becomes narrower at the transmembrane domain. The pore is lined by five α-helices, one from each subunit, and adjacent extended loop regions (Corringer et al. 2000). If two ACh molecules bind to the receptor sites at the extracellular surface of the receptor, far from each other and from the pore, this pathway opens, allowing permeation of Na^+ (crystal radius 0.095 nm), K^+ (crystal radius 0.133 nm), and Ca^{2+} (crystal radius 0.099 nm), and initiates depolarization.

Monovalent or divalent cations, but not anions, readily flow through the open form of the nAChR channel. What makes the channel cation selective? The amino acid sequences of the pore-forming helices and the adjacent loop components contain three rings of negatively charged residues. One of them is located within the transmembrane region of the pore, and the other two flank the cytosolic entrance to the pore. Apparently, the upper part of the channel, namely, the α-helical components, acts as a water pore, whereas the lower loop components contribute to the selectivity filter of the channel (Corringer et al. 2000). Anions, such as Cl^-, cannot enter the pore because they are repelled by the negatively charged rings. Studies on the permeability of a series of organic cations differing in size, such as alkylammonium ions, triaminoguanidinium, histidine, and choline, indicate that the narrowest part of the open pore has the dimension of less than 0.65 × 0.65 nm square.

At the level of a single channel, addition of ACh is followed by transient openings of the channel. The current *i* flowing through an open nAChR channel is 4 pA at a membrane potential *V* of −100 mV. Since one ampere (A) represents the flow of 6.24×10^{18} charges per second, 2.5×10^7 Na^+ ions per second flow through an open channel. The conductance *g* of a plasma membrane channel is the measure of the ease of flow of current between the extracellular space and the cytosol or vice versa and is equal to *i/(V-Er)*, where *Er* is the reversal potential at which there is no ionic net flux; *g* is expressed in units of siemens (the reciprocal of an ohm), *i* in amperes, and *V* in volts. *Er* equals 0 mV for non-selective cation channels; thus, a current of 4 pA at a potential of 100 mV corresponds to a conductance of 40 pS. Non-selective cation channels reveal single-channel conductances of 10–170 pS with about 10 pS for HCN channels, 15–30 pS for P2X receptors and Piezo channels, 20–40 pS for NMDA receptors and CNG channels, 25–50 pS for nACh receptors, and 10–170 pS for TRP channels.

Drugs

While certain compounds activate specific non-selective cation channels (e.g., acetylcholine activates nACh receptors, ATP activates P2X receptors, capsaicin activates TRPV1, menthol activates TRPM8, etc.), most non-selective cation channels, mainly TRP channels, are commonly inhibited by trivalent cations such as Gd^{3+} and La^{3+}, 2-aminoethoxydiphenyl borate (2-APB), the imidazole derivative SKF 96365, and the polycation ruthenium red. The nonsteroidal anti-rheumatic drugs flufenamic and niflumic acid also inhibit some TRP channels. However, few TRPs are activated by 2-APB or flufenamic acid. Drugs to specifically target single members of the TRP channel family are still rare. The tarantula spider toxin GsMTx4 specifically inhibits mechanosensitive Piezo channels. Acid-sensing ion channels belong to the group of degenerin/epithelial Na^+ channels (DEG/ENaC) and are sensitive to amiloride, P2X receptors are inhibited by suramin and PPADS (pyridoxalphosphate-6-azophenyl-2′,4′-disulfonic acid), and HCN channels are blocked by the verapamil derivative ivabradine (Nilius and Flockerzi 2014). The ionotropic glutamate receptors of the NMDA type are specifically inhibited by AP5 (R-2-amino-5-phosphonopentanoate) and certain anesthetics such as ketamine.

Proteases; Proteinases; Proteolytic enzymes

Definition

Proteolytic enzymes catalyze the breaking of the carbon-nitrogen bonds between amino acids that are found in peptides and proteins. Most proteolytic enzymes are hydrolases, and hydrolysis of a peptide bond is a form of an acid-base reaction, in which a hydrogen ion (proton) is transferred. The terms “protease,” “proteinase,” and “proteolytic enzyme” are synonymous but strictly speaking can only be applied to peptidases that hydrolase bonds in proteins. Because there are many

peptidases that act only on peptides, the term "peptidase" is recommended. Peptidases are included in subclass 3.4 of enzyme nomenclature (Barrett et al. 2004; Puente et al. 2003). There is a group of enzymes that break peptide bonds by a different mechanism: an asparagine residue is induced to cyclize to form a succinimide, which breaks the peptide bond and releases a peptide. These kinds of enzymes are known as asparagine peptide lyases (Rawlings et al. 2011).

Basic Characteristics

Active Site Residues

Peptidases are found in all forms of life. There are about 1252 peptidases in humans, plus an additional 349 proteins that are homologous to peptidases, but either have no or different catalytic activity. This represents 3% of all the genes in the human genome.

Hydrolysis of a peptide bond is an example of a nucleophilic attack. The nucleophile in the reaction is either an activated water molecule or part of the side chain of an amino acid, and peptidases are described as having either a water nucleophile or a protein nucleophile. Peptidases with a water nucleophile either utilize one or two metal ions as ligands for the water molecule, in which case the peptidase generally acts at neutral pH, or the water is bound by two aspartic acid residues, in which case the peptidase usually has an acidic pH optimum. For peptidases with a protein nucleophile, the nucleophile is either the hydroxyl group from a serine or threonine residue or the thiol group from cysteine. Thus there are five major catalytic types: aspartic, metallo-, serine, threonine, and cysteine peptidases. A sixth type, glutamic peptidases, is known, but the only known examples are from fungi and viruses. There are still several peptidases for which the catalytic type is as yet undetermined.

A metallopeptidase binds a divalent metal ion tetrahedrally, with three ligands being amino acid residues and the fourth the water molecule that becomes the nucleophile in the reaction. The amino acid ligand residues are conserved. Most commonly, a zinc ion is bound, but peptidases that bind cobalt, manganese, nickel, and copper also exist. Metal ligands are most often histidine residues but can also be aspartic and glutamic acids and more unusually asparagine, glutamine, or lysine. When a peptidase binds two metal ions, five residues are involved, one of which ligates both ions. The metal ion is described as co-catalytic. Besides metal ligands, other residues are often essential for catalytic activity. The peptidases that are involved in the turnover of extracellular matrices, known as matrixins or matrix metallopeptidases (MMPs), are examples of metallopeptidases containing the motif HEXXH. In this motif, the two histidines are metal ligands while the glutamic acid is an active site residue. Glutamate carboxypeptidase binds two zinc ions via two histidines, an aspartic acid and two glutamic acids, and in addition has two active site residues, an aspartic and a glutamic acid. Aspartic peptidases bind and activate water via two aspartic acid residues.

Peptidases with a protein nucleophile often have an active site containing two or three residues. A second residue, most often a histidine (though lysine and arginine can substitute), is required to interact with the nucleophile and become a proton acceptor or general base in the catalytic reaction. If a catalytic triad exists, which is often the case when a histidine residue is the general base, then an aspartic or glutamic acid, asparagine, or glutamine is thought to orientate the imidazolium ring of the histidine side chain. In the cysteine peptidase cathepsin B, the order of the catalytic residues is Cys, His, Asn. In the serine peptidase chymotrypsin, the order is His, Asp, Ser.

For many serine and cysteine peptidases, catalysis first involves formation of a complex known as an acyl intermediate. An essential residue is required to stabilize this intermediate by helping to form the oxyanion hole. In cathepsin B, a glutamine performs this role and sometimes a catalytic tetrad (Gln, Cys, His, Asn) is referred too. In chymotrypsin, a glycine is essential for stabilizing the oxyanion hole.

Threonine peptidases (and some cysteine and serine peptidases) have only one active site residue, which is the N-terminus of the mature protein. Such a peptidase is known as an N-terminal

nucleophile hydrolase or Ntn-hydrolase. The amino group of the N-terminal residue performs the role of the general base. The catalytic subunits of the proteasome are examples of Ntn-hydrolases.

The order and nature of the active site residues and metal ligands is conserved between homologous peptidases. All the peptidases in a family will have the same catalytic type, with only two exceptions where the nucleophile can be either a serine, threonine, or cysteine.

Classification and Nomenclature

Peptidases have been classified by the *MEROPS* system since 1993 (Rawlings and Barrett 1993), which has been available via the *MEROPS* database and website (http://www.ebi.ac.uk/merops) since 1996 (Rawlings et al. 2018). The classification is based on sequence and structural similarities. Because peptidases are often multidomain proteins, only the domain directly involved in catalysis, and which bears the active site residues, is used in comparisons. This domain is known as the peptidase unit. Peptidases with statistically significant peptidase unit sequence similarities are included in the same family. To date, 262 families of peptidase have been detected (plus an additional 10 families of asparagine peptide lyases). Examples from 86 of these families are known in humans. A family is named from a letter representing the catalytic type ("A" for aspartic, "G" for glutamic, "M" for metallo, "C" for cysteine, "S" for serine, "T" for threonine, "P" for mixed catalytic type, "N" for asparagine peptide lyase, and "U" for unknown catalytic type) plus a number. Examples of family names are shown in Table 1. There are 76 families of metallopeptidases (33 in human), 16 of aspartic peptidases (4 of which are found in human), 96 of cysteine peptidases (30 in human), 56 of serine peptidases (22 in human), 6 of threonine peptidases (3 in human), 3 of glutamic peptidases (none in human), 2 of mixed catalytic type (1 in human), and 9 families for which the catalytic type is unknown (none in human). It should be noted that within a family, not all of the members will be peptidases. Usually non-peptidase homologues are a minority and can be easily detected because not all of the active site residues are conserved.

All peptidases within a family will have a similar tertiary structure, and it is not uncommon for peptidases in one family to have a similar structure to peptidases in another family, even though there is no significant sequence similarity. Families of peptidases with similar structures and the same order of active site residues are included in the same clan. A clan name consists of two letters, the first representing the catalytic type as before and the second assigned sequentially. A clan may contain peptidases of more than one catalytic type. So far this has only been seen for peptidases with protein nucleophiles, and these clans are named with an initial "P." Only five such clans are known. Clan PA includes peptidases with a chymotrypsin-like fold, which besides serine peptidases such as chymotrypsin also includes some cysteine peptidases from viruses. Clan PB contains the Ntn-hydrolases, which can be threonine, cysteine, or serine in type. Clan PC includes the cysteine peptidase gamma-glutamyl hydrolase and the serine peptidase alpha-aspartyl dipeptidase. Clan PD contains the self-processing proteins, including the cysteine peptidase hedgehog, and three families of intein-containing asparagine peptide lyases. Clan PE contains ornithine acetyltransferase precursor, which is a self-processing threonine peptidase and DmpA aminopeptidase, a serine peptidase. There are 56 clans of peptidases, or in other words there are 56 independent origins of peptidases.

Peptidases that are thought to be species variants of the same protein and have similar properties are included in the same *MEROPS* identifier. The identifier consists of the three-character family name (padded with zeroes if necessary), a dot, and a unique three digit number. Examples of *MEROPS* identifiers are shown in Table 1. Two special kinds of identifier are used for non-peptidase homologues in the *MEROPS* database for proteins and pseudogenes. For proteins, the three digit number begins with a nine, and for pseudogenes the first digit is replaced by a "P." There are 4,354 different *MEROPS* identifiers.

With the onset of genomic biology, there are now many sequences derived from genome

Cancer, oral		Cathepsin S (C01.034)
Cancer, oropharyngeal	v	Ubiquitin-specific peptidase 46 (C19.052)
Cancer, ovarian		Caspase-9 (C14.010); ubiquitin-specific peptidase 11 (C19.014); ubiquitin-specific peptidase 15 (C19.022); ubiquitin-specific endopeptidase 39 [misleading] (C19.972); membrane-type matrix metallopeptidase-1 (M10.014); methionyl aminopeptidase 2 (M24.002); StcE peptidase (M66.001); testisin (S01.011); kallikrein-related peptidase 5 (S01.017); kallikrein-related peptidase 6 (S01.236); kallikrein-related peptidase 8 (S01.244); kallikrein-related peptidase 4 (S01.251); kallikrein-related peptidase 7 (S01.300)
Cancer, ovarian, epithelial		Matrix metallopeptidase-3 (M10.005)
Cancer, pancreatic		Ubiquitin-specific peptidase 5 (C19.001); ubiquitin-specific peptidase 49 (C19.073); ubiquitin-specific endopeptidase 39 [misleading] (C19.972); desumoylating isopeptidase 2 (C97.002); kallikrein-related peptidase 7 (S01.300)
Cancer, pancreatic neuroendocrine tumor		Ubiquitinyl hydrolase-L1 (C12.001)
Cancer, prostate		Calpain-1 (C02.001); calpain-2 (C02.002); ubiquitinyl hydrolase-L5 (C12.005); caspase-3 (C14.003); ubiquitin-specific peptidase 14 (C19.015); ubiquitin-specific peptidase 9X (C19.017); ubiquitin-specific peptidase 25 (C19.041); USP17-like peptidase (C19.078); matrix metallopeptidase-9 (M10.004); matrix metallopeptidase-3 (M10.005); membrane-type matrix metallopeptidase-3 (M10.016); methionyl aminopeptidase 2 (M24.002); glutamate carboxypeptidase II (M28.010); STAM-binding protein-like 1 (M67.003); kallikrein-related peptidase 14 (S01.029); transmembrane peptidase, serine 4 (S01.034); kallikrein-related peptidase 15 (S01.081); kallikrein-related peptidase 3 (S01.162); hepsin (S01.224); urokinase-type plasminogen activator (S01.231); epitheliasin (S01.247); kallikrein-related peptidase 4 (S01.251); matriptase (S01.302); PCSK6 peptidase (S08.075)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Cancer, skin multiple self-healing palmoplantar carcinoma	g	Family S79 unassigned peptidases (S79.UPW)
Cancer, skin, uveal melanoma	g	Ubiquitinyl hydrolase-BAP1 (C12.004)
Cancer, thyroid, non-medullary, 5	g	Factor VII-activating peptidase (S01.033)
Candidiasis	f	Canditropsin (A01.037)
Cardiac disease		Chymase (*Homo sapiens*-type) (S01.140)
Cardiomyopathy, dilated 1U	g	Presenilin 1 (A22.001)
Cardiomyopathy, dilated 1V	g	Presenilin 2 (A22.002)
Cardiorenal disease		Neprilysin (M13.001)
Cardiovascular disease		Membrane-type matrix metallopeptidase-1 (M10.014); tryptase alpha (S01.143); subtilisin NAT (S08.044); dipeptidyl-peptidase IV (eukaryote) (S09.003); serine carboxypeptidase A (S10.002)
Caspase-8 deficiency	g	Caspase-8 (C14.009)
Cataract		Calpain-2 (C02.002)
Cavitary optic disc anomalies	g	Matrix metallopeptidase-19 (M10.021)
cerebral arteriopathy, autosomal recessive, with subcortical infarcts and leukoencephalopathy	g	HtrA1 peptidase (*Homo sapiens*-type) (S01.277)
Cerebral arteriopathy, autosomal dominant, with subcortical infarcts and leukoencephalopathy, 2	g	HtrA1 peptidase (*Homo sapiens*-type) (S01.277)
Cerebral small vessel disease	g	HtrA1 peptidase (*Homo sapiens*-type) (S01.277)
Ceroid lipofuscinosis, neuronal, 2	g	Tripeptidyl-peptidase I (S53.003)
Chagas disease	p	Cruzipain (C01.075); aminopeptidase AMZ1 (M54.003); oligopeptidase B (S09.010)
Charcot-Marie-Tooth disease 2T	g	Neprilysin (M13.001)
Childhood-onset neurodegenerative disorder	g	Cathepsin D (A01.009)
Cholestasis		Aminopeptidase N (M01.001)
Cholesteryl ester storage disease	g	PLN02872 protein (*Homo sapiens*-type) (S33.017)
Chronic obstructive pulmonary disease		Matrix metallopeptidase-12 (M10.009); elastase-2 (S01.131); cathepsin G (S01.133); myeloblastin (S01.134)
CODAS syndrome	g	PIM1 peptidase (S16.002)
Colorectal neoplastic disease		Presenilin 1 (A22.001)
Combined oxidative phosphorylation deficiency 31	g	Mitochondrial intermediate peptidase (M03.006)
Complement component 2 deficiency	g	Complement component C2a (S01.194)
Complement component C1s deficiency	g	Complement component activated C1s (S01.193)
Complement factor B deficiency	g	Complement factor Bb (S01.196)
Complement factor D deficiency	g	Complement factor D (S01.191)
Complement factor I deficiency	g	Complement factor I (S01.199)
Cone-rod dystrophy 9	g	ADAM9 peptidase (M12.209)
Congenital bilateral aplasia of the vas Deferens, X-linked	g	Gpr64 (*Mus musculus*)-type protein (P02.007)
Coronary heart disease		PCSK9 peptidase (S08.039)
Coronary heart disease 6	g	Matrix metallopeptidase-3 (M10.005)
Corticobasal syndrome	g	Presenilin 1 (A22.001)
Cushing disease	g	Ubiquitin-specific peptidase 8 (C19.011)
Cyclic hematopoiesis	g	Elastase-2 (S01.131)
Cylindromatosis, familial	g	CylD peptidase (C67.001)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Cystic fibrosis		Cathepsin S (C01.034); elastase-2 (S01.131)
Deafness, autosomal recessive, 8	g	Transmembrane peptidase, serine 3 (S01.079)
Demyelinating disease		ADAM10 peptidase (M12.210)
Dermatitis, atopic		Kallikrein-related peptidase 7 (S01.300)
DiGeorge syndrome	g	HtrA2 peptidase (S01.278)
Diabetes mellitus, non-insulin-dependent, 1	g	Calpain-10 (C02.018)
Diabetes, type 2		BACE2 g.p. (*Homo sapiens*) (A01.041); neprilysin (M13.001); dipeptidyl-peptidase IV (eukaryote) (S09.003)
Diabetic ulcer		Granzyme B (*Homo sapiens*-type) (S01.010)
Diffuse panbronchiolitis	b	Pseudolysin (M04.005)
Dysplasia, acrocapitofemoral	g	Indian hedgehog protein (C46.003)
Dysplasia, Beukes familial hip	g	UfSP2 peptidase (C78.002)
Dysplasia, mandibuloacral with type B lipodystrophy	g	Farnesylated protein-converting enzyme 1 (M48.003)
Dysplasia, metaphyseal, Spahr-type	g	Matrix metallopeptidase-13 (M10.013)
Dysplasia, spondyloepimetaphyseal, Di Rocco-type	g	UfSP2 peptidase (C78.002)
Dysplasia, spondyloepimetaphyseal, Missouri-type	g	Matrix metallopeptidase-13 (M10.013)
Early-onset mitochondrial syndrome	g	HtrA2 peptidase (S01.278)
East Coast fever	p	Papain homolog (*Theileria*-type) (C01.079)
Ehlers-Danlos syndrome, dermatosparaxis-type	g	Procollagen I N-peptidase (M12.301)
Ehlers-Danlos syndrome, periodontal type, 1	g	Complement component activated C1r (S01.192)
Ehlers-Danlos syndrome, periodontal-type, 2	g	Complement component activated C1s (S01.193)
Emphysema		Cathepsin K (C01.036); matrix metallopeptidase-12 (M10.009); elastase-2 (S01.131)
Encephalitis/encephalopathy, mild, with reversible myelin vacuolization	g	Myelin regulatory factor (S74.003)
Endophthalmitis	b	Lysostaphin (M23.004)
Endotoxic shock		Caspase-1 (C14.001)
Enterocolitis	b	DegP peptidase (S01.273)
Enterokinase deficiency	g	Enteropeptidase (S01.156)
Epilepsy		Kallikrein-related peptidase 8 (S01.244)
Epileptic encephalopathy, early infantile, 36	g	ALG13 g.p. (*Homo sapiens*) (C85.005)
Epileptogenesis		Matrix metallopeptidase-9 (M10.004)
Factor II deficiency	g	Thrombin (S01.217)
Factor VII deficiency	g	Coagulation factor VIIa (S01.215)
Factor X deficiency	g	Coagulation factor Xa (S01.216)
Factor XI deficiency	g	Coagulation factor XIa (S01.213)
Factor XII deficiency	g	Coagulation factor XIIa (S01.211)
Familial hypercholanemia	g	Acyl-coenzyme A amino acid N-acyltransferase 2 (S09.A50)
Familial juvenile hyperuricemic Nephropathy 2	g	Renin (A01.007)
Farber lipogranulomatosis	g	Acid ceramidase precursor (C89.001)
Fibrosis		Procollagen C-peptidase (M12.005); fibroblast activation protein alpha subunit (S09.007)
Frontotemporal dementia	g	Presenilin 1 (A22.001)
Galactosialidosis	g	Serine carboxypeptidase A (S10.002)
Gastric ulcer		Pepsin A (A01.001); gastricsin (A01.003)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Gastroenteritis	b	DegP peptidase (S01.273); EspP peptidase (*Escherichia coli*) (S06.002); Tsh peptidase (S06.003); Sat peptidase (S06.004); Pic peptidase (S06.005)
Giardiasis	p	Giardain (C01.094)
Glioma		Matrix metallopeptidase-9 (M10.004)
Glutathionuria	g	Gamma-glutamyltransferase 1 (mammalian-type) (T03.006)
Graft-versus-host disease		Granzyme B (*Homo sapiens*-type) (S01.010)
Haim-Munk syndrome	g	Dipeptidyl-peptidase I (C01.070)
Hairy leukoplakia	v	Epstein-Barr virus-type assemblin (S21.003)
Heart failure		Corin (S01.019)
Hemolytic uremic syndrome atypical 3	g	Complement factor I (S01.199)
Hemolytic uremic syndrome atypical 4	g	Complement factor Bb (S01.196)
Hemophagocytic lymphohistiocytosis	v	Epstein-Barr virus-type assemblin (S21.003)
Hemophilia B	g	Coagulation factor IXa (S01.214)
Hennekam lymphangiectasia-lymphedema syndrome 3	g	ADAMTS3 peptidase (M12.220)
Herniated intervertebral disk		Chymopapain (C01.002)
Herniated intervertebral disk		Collagenase G/A (*Clostridium histolyticum*) (M09.002)
Herpes	v	Ubiquitin-specific peptidase 7 (C19.016); assemblin (S21.001)
Heterotaxy, visceral, 7, autosomal	g	Matrix metallopeptidase-21 (M10.026)
Hirschsprung disease, cardiac defects, and autonomic dysfunction	g	Endothelin-converting enzyme 1 (M13.002)
Holoprosencephaly 3	g	Sonic hedgehog protein (C46.002)
Huntington's disease		Cathepsin E (A01.010)
Hypercholesterolemia, autosomal dominant, 3	g	PCSK9 peptidase (S08.039)
Hyperenzymemia		Bikunin (LI02.001)
Hypertension		Renin (A01.007); aminopeptidase A (M01.003); angiotensin-converting enzyme (XM02.001); neprilysin (M13.001); endothelin-converting enzyme 1 (M13.002); corin (S01.019)
Hypertrophic scarring		Granzyme B (*Homo sapiens*-type) (S01.010)
Hypophosphatemic rickets, X-linked dominant	g	PHEX peptidase (M13.091)
Hypoplasia or aplasia of tibia with polydactyly	g	Sonic hedgehog protein (C46.002)
Ichthyosis, congenital, autosomal recessive 11	g	Matriptase (S01.302)
Ichthyosis, congenital, autosomal recessive 12	g	Caspase-14 (C14.018)
IFAP syndrome with or without BRESHECK syndrome	g	Site 2 peptidase (M50.001)
Immunodeficiency 12	g	Paracaspase (C14.026)
Immunodeficiency 24	g	ctps g.p. (*Brachydanio rerio*) (C26.A36)
Infectious mononucleosis	v	Epstein-Barr virus-type assemblin (S21.003)
Inflammation		Leukotriene A4 hydrolase (M01.004); fibroblast activation protein alpha subunit (S09.007)
Inflammatory bowel disease		Leukotriene A4 hydrolase (M01.004)
Inflammatory skin and bowel disease, neonatal, 1	g	ADAM17 peptidase (M12.217)
Influenza	v	Granzyme B (*Homo sapiens*-type) (S01.010)
Intellectual disability syndrome	g	OTUD6B peptidase (*Homo sapiens*) (C85.009)
Intervertebral disc disease	g	Matrix metallopeptidase-9 (M10.004)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Intimal hyperplasia		Chymase (*Homo sapiens*-type) (S01.140)
Intracerebral hemorrhage	g	Angiotensin-converting enzyme (XM02.001)
IPEX-like syndrome	g	Paracaspase (C14.026)
Iron-refractory iron deficiency anemia	g	Matriptase-2 (S01.308)
Ischemia, cardiac		Cathepsin D (A01.009); PIM1 peptidase (S16.002)
Ischemia, cerebral		Matrix metallopeptidase-12 (M10.009); 20 S constitutive proteasome peptidase complex (eukaryote) (XT01.001)
Ischemia, myocardial		SENP3 peptidase (C48.003); lumbrokinase (S01.243)
Ischemic heart disease		Dipeptidyl-peptidase IV (eukaryote) (S09.003)
Keratitis	b	Arginyl peptidase (S01.281)
Keratolytic winter erythema	g	Cathepsin B (C01.060)
Keratosis follicularis spinulosa decalvans X-linked	g	Site 2 peptidase (M50.001)
Kidney disease		Angiotensin-converting enzyme-2 (M02.006)
KSHV inflammatory cytokine syndrome	v	Herpesvirus 8-type assemblin (S21.006)
Late-infantile Batten disease	g	Tripeptidyl-peptidase I (S53.003)
Laurin-Sandrow syndrome	g	Sonic hedgehog protein (C46.002)
Leishmaniasis	p	CPA peptidase (C01.076); leishmanolysin (M08.001)
Leishmaniasis, cutaneous	p	Granzyme B (*Homo sapiens*-type) (S01.010)
Lethal congenital contracture syndrome 9	g	GPR126 vascular inducible G protein-coupled receptor (P02.017)
Lethal tight skin contracture syndrome	g	Farnesylated protein-converting enzyme 1 (M48.003)
Leukemia		Matrix metallopeptidase-7 (M10.008)
Leukemia, acute myeloid		Transmembrane peptidase, serine 11F (S01.321)
Leukemia, adult T-cell	v	Retropepsin (human T-cell leukemia virus) (A02.012)
Leukemia, chronic lymphocytic		SENP2 peptidase (C48.007); 20 S constitutive proteasome peptidase complex (eukaryote) (XT01.001)
Lewy body disease		Endothelin-converting enzyme 1 (M13.002); endothelin-converting enzyme 2 (M13.003)
Liver cirrhosis	g	Matrix metallopeptidase-2 (M10.003); matrix metallopeptidase-9 (M10.004)
Lymphoma, Burkitt	v	Epstein-Barr virus-type assemblin (S21.003)
Lymphoma, familial non-Hodgkin	g	Caspase-10 (C14.011)
Lymphoma, Hodgkin's	v	Epstein-Barr virus-type assemblin (S21.003)
Lymphoma, primary effusion	v	Herpesvirus 8-type assemblin (S21.006)
Machado-Joseph disease		Calpain-1 (C02.001); ataxin-3 (C86.001)
Macular degeneration, age-related, 7	g	HtrA1 peptidase (*Homo sapiens*-type) (S01.277)
Macular degeneration, age-related, 13	g	Complement factor I (S01.199)
Macular degeneration, age-related, 14	g	Complement component C2a (S01.194); complement factor Bb (S01.196)
Malaria	p	Plasmepsin-1 (A01.022); plasmepsin-2 (A01.023); plasmepsin-5 (*Plasmodium* sp.) (A01.075); falcipain-2 (C01.046); falcipain-1 (C01.077)
MASP2 deficiency	g	Mannan-binding lectin-associated serine peptidase 2 (S01.229)
Medullary cystic kidney disease 1	g	MUC1 self-cleaving mucin (S71.001)
Meningitis	b	IgA1-specific serine peptidase (*Neisseria*-type) (S06.001)
Meningitis, aseptic	v	Coxsackievirus-type picornain 3C (C03.011)
Meningitis, neonatal	b	C5a peptidase (S08.020)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Meningitis, pneumococcal		Caspase-3 (C14.003)
Mental retardation, autosomal recessive 1	g	Neurotrypsin (S01.237)
Mental retardation, X-linked 99	g	Ubiquitin-specific peptidase 9X (C19.017)
Mesothelioma		Dipeptidyl-peptidase IV (eukaryote) (S09.003)
Mesothelioma, malignant	g	Ubiquitinyl hydrolase-BAP1 (C12.004)
Microcephaly-capillary malformation syndrome	g	STAMBP isopeptidase (M67.006)
Microcornea, myopic chorioretinal atrophy, and telecanthus	g	ADAMTS18 peptidase (M12.028)
Microphthalmia, isolated, with coloboma, 5	g	Sonic hedgehog protein (C46.002)
Microvascular complications of diabetes 3	g	Angiotensin-converting enzyme (XM02.001)
Multicentric osteolysis, nodulosis, and arthropathy	g	Matrix metallopeptidase-2 (M10.003)
Multiple familial trichoepithelioma 1	g	CylD peptidase (C67.001)
Multiple mitochondrial dysfunctions syndrome 6	g	Mitochondrial processing peptidase beta-subunit (M16.003)
Multiple myeloma		20 S constitutive proteasome peptidase complex (eukaryote) (XT01.001)
Multiple sclerosis		Matrix metallopeptidase-12 (M10.009); myelin basic protein autolytic or peptidase activity (S9G.105)
Muscular dystrophy, limb-girdle, autosomal dominant 4	g	Calpain-3 (C02.004)
Muscular dystrophy, limb-girdle, autosomal recessive 1	g	Calpain-3 (C02.004)
Muscular dystrophy-dystroglycanopathy Congenital with brain and eye anomalies A9	g	Dystroglycan (S72.001)
Muscular dystrophy-dystroglycanopathy limb-girdle C9	g	Dystroglycan (S72.001)
Musculoskeletal syndrome		Matrix metallopeptidase-13 (M10.013)
Myasthenia gravis		Cathepsin V (C01.009)
Myocardial infarction		Corin (S01.019); 20 S constitutive proteasome peptidase complex (eukaryote) (XT01.001)
Myocarditis	v	Cardiovirus picornain 3C (C03.009)
Myopathy, myofibrillar, 7	g	Kyphoscoliosis peptidase (C110.001)
Necrotizing enterocolitis	b	Aeruginolysin (M10.056)
Nelson's syndrome	g	Ubiquitin-specific peptidase 8 (C19.011)
Neonatal sepsis	b	C5a peptidase (S08.020)
Nephronophthisis-like nephropathy 1	g	Aminopeptidase P3 (M24.026)
Netherton syndrome	g	Kallikrein-related peptidase 5 (S01.017); kallikrein-related peptidase 6 (S01.236)
Netherton/Omenn-like syndrome	g	Paracaspase (C14.026)
Neutropenia, severe congenital 1, autosomal dominant	g	Elastase-2 (S01.131)
Nonalcoholic fatty liver disease		Ubiquitin-specific peptidase 4 (C19.010)
Obesity		Cathepsin B (C01.060)
Obstructive sleep apnea/hypopnea syndrome with ischemic stroke	g	Calpain-10 (C02.018)
Olmsted syndrome, X-linked	g	Site 2 peptidase (M50.001)
Optic atrophy 11	g	YME1L1 g.p. (*Homo sapiens*) and similar (M41.026)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Osteoarthritis		Stem bromelain (C01.005); matrix metallopeptidase-13 (M10.013); membrane-type matrix metallopeptidase-1 (M10.014); ADAM17 peptidase (M12.217); ADAMTS4 peptidase (M12.221); ADAMTS5 peptidase (M12.225)
Osteogenesis imperfecta 13	g	Procollagen C-peptidase (M12.005)
Osteogenesis imperfecta 19	g	Site 2 peptidase (M50.001)
Osteoporosis		Cathepsin K (C01.036)
Pancreatitis, acute		Cathepsin B (C01.060); trypsin-2 type A (S01.258)
Pancreatitis, hereditary	g	Cationic trypsin (*Homo sapiens*-type) (S01.127); chymotrypsin C (S01.157)
Papillon-Lefevre syndrome	g	Dipeptidyl-peptidase I (C01.070)
Parkinson's disease		Cathepsin E (A01.010); presenilin 1 (A22.001); ubiquitin-specific peptidase 30 (C19.060); HtrA2 peptidase (S01.278)
Parkinson's disease 5	g	Ubiquitinyl hydrolase-L1 (C12.001)
Parkinson's disease 7	g	DJ-1 putative peptidase (C56.002)
Parkinson's disease 13	g	HtrA2 peptidase (S01.278)
Partial gonadal dysgenesis with minifascicular neuropathy 46,XY	g	Desert hedgehog protein (C46.004)
Pathological tissue damage		Matrix metallopeptidase-1 (M10.001); matrix metallopeptidase-8 (M10.002); matrix metallopeptidase-2 (M10.003); matrix metallopeptidase-9 (M10.004); matrix metallopeptidase-3 (M10.005); matrix metallopeptidase-7 (M10.008); matrix metallopeptidase-12 (M10.009)
Periodontitis	b	Gingipain K (C25.002)
Periodontitis, aggressive, 1	g	Dipeptidyl-peptidase I (C01.070)
Peripheral artery disease		Dipeptidyl-peptidase IV (eukaryote) (S09.003)
Perrault syndrome 3	g	Peptidase Clp (type 3) (S14.003)
Pharyngitis	b	DegP peptidase (S01.273)
Pharyngoconjunctival fever	v	Adenain (C05.001)
Pick disease of the brain	g	Presenilin 1 (A22.001)
Plasminogen deficiency	g	Plasmin (S01.233)
Pneumococcal pneumonia	b	Arginyl peptidase (S01.281)
Pneumonia	b	Aeruginolysin (M10.056)
Pneumonia, neonatal	b	C5a peptidase (S08.020)
Polycystic kidney disease 1 with or without polycystic liver disease	g	Polycystin-1 (P02.036)
Polymicrogyria, bilateral frontoparietal	g	GPR56 (*Homo sapiens*)-type protein (P02.008)
Polymicrogyria, bilateral perisylvian, autosomal recessive	g	GPR56 (*Homo sapiens*)-type protein (P02.008)
Polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract	g	Mername-AA196 putative peptidase (S09.054)
Preaxial polydactyly 2	g	Sonic hedgehog protein (C46.002)
Preeclampsia/eclampsia 5	g	Corin (S01.019)
Pregnancy loss, recurrent, 2	g	Thrombin (S01.217)
Premature aging	g	Spartan peptidase (M100.001)
Progressive supranuclear palsy		Cathepsin S (C01.034)
Prolidase deficiency	g	Xaa-Pro dipeptidase (eukaryote-type) (M24.007)
Proprotein convertase 1 deficiency	g	PCSK1 peptidase (S08.072)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Proteasome-associated autoinflammatory syndrome 1	g	Proteasome subunit beta5i (T01.015)
Proteasome-associated autoinflammatory syndrome 3	g	Proteasome subunit beta1i (T01.013); proteasome subunit beta 4 (T01.987)
Pseudo-TORCH syndrome 2	g	Ubiquitin-specific peptidase 18 (C19.030)
Psoriasis		Leukotriene A4 hydrolase (M01.004); endoplasmic reticulum aminopeptidase 1 (M01.018); ERAP2 aminopeptidase (M01.024); proteasome subunit beta1c (T01.010); proteasome subunit beta2c (T01.011); proteasome subunit beta5c (T01.012); proteasome subunit beta1i (T01.013); proteasome subunit beta2i (T01.014); proteasome subunit beta5i (T01.015)
Pycnodysostosis	g	Cathepsin K (C01.036)
Quebec platelet disorder	g	Urokinase-type plasminogen activator (S01.231)
Renal tubular dysgenesis	g	Renin (A01.007); angiotensin-converting enzyme peptidase (XM02.001)
Respiratory diseases	v	Coronavirus picornain 3C-like peptidase-1 (C30.001)
Restenosis		Matrix metallopeptidase-9 (M10.004)
Reticulate acropigmentation of Kitamura	g	ADAM10 peptidase (M12.210)
Retinitis pigmentosa 75	g	Cytosolic carboxypeptidase 5 (M14.025)
Ruijs-Aalfs syndrome	g	Spartan peptidase (M100.001)
Sarcoma, Ewing		Pappalysin-1 (M43.004)
Sarcoma, Kaposi's	v	Herpesvirus 8-type assemblin (S21.006)
Sarcoma, osteo		SENP2 peptidase (C48.007)
Schizophrenia		Human endogenous retrovirus K retropepsin (A02.011)
Sepsis	b	Dipeptidyl-peptidase I (C01.070); vibriolysin (M04.003); Aeruginolysin (M10.056); protein C (activated) (S01.218)
Severe fever with thrombocytopenia syndrome	v	Site 1 peptidase (S08.063)
Sjogren's syndrome		Kallikrein 13 (*Mus musculus*) (S01.173)
Solitary median maxillary central incisor	g	Sonic hedgehog protein (C46.002)
Soman poisoning		Xaa-Pro dipeptidase (eukaryote-type) (M24.007)
Spastic ataxia 5, autosomal recessive	g	Afg3-like protein 2 (M41.007)
Spastic paraplegia 7, autosomal recessive	g	Paraplegin (M41.006)
Spastic paraplegia 76, autosomal recessive	g	Calpain-1 (C02.001)
Spastic paraplegia 79, autosomal recessive	g	Ubiquitinyl hydrolase-L1 (C12.001)
Spermatogenic failure Y-linked 2	g	Ubiquitin-specific peptidase 9Y (C19.028)
Spinal muscular atrophy with progressive myoclonic epilepsy	g	Acid ceramidase precursor (C89.001)
Spinocerebellar ataxia 3	g	Ataxin-3 (C86.001)
Spinocerebellar ataxia 28	g	Afg3-like protein 2 (M41.007)
Spinocerebellar ataxia 43	g	Neprilysin (M13.001)
Spinocerebellar ataxia, autosomal recessive, 2	g	Mitochondrial processing peptidase non-peptidase alpha subunit (M16.971); mitochondrial processing peptidase subunit alpha unit 2 (M16.985)
Spinocerebellar ataxia, autosomal recessive, 7	g	Tripeptidyl-peptidase I (S53.003)
Spontaneous preterm delivery		Cystinyl aminopeptidase (M01.011)
Staphylococcal scalded skin syndrome	b	Exfoliatin A (S01.270)
Strabismus		Bontoxilysin (M27.002)
Streptococcal pharyngitis	b	Streptopain (C10.001)

(continued)

Nonviral Peptidases, Table 1 (continued)

Disease	Type	Peptidases (MEROPS ID)
Stroke		Calpain-1 (C02.001); calpain-2 (C02.002); corin (S01.019)
Stroke, ischemic	g	Angiotensin-converting enzyme (XM02.001); thrombin (S01.217)
Systemic sclerosis		Matrix metallopeptidase-1 (M10.001)
Tetanus	b	Tentoxilysin (M27.001)
Theileriosis	p	Papain homolog (*Theileria*-type) (C01.079)
Thrombophilia due to protein C deficiency, autosomal dominant	g	Protein C (activated) (S01.218)
Thrombophilia due to protein C deficiency, autosomal recessive	g	Protein C (activated) (S01.218)
Thrombophilia due to thrombin defect	g	Thrombin (S01.217)
Thrombophilia, X-linked, due to factor IX defect	g	Coagulation factor IXa (S01.214)
Thrombosis		Atroxase (M12.147); coagulation factor Xa (S01.216); thrombin (S01.217); t-plasminogen activator (S01.232)
Thrombotic thrombocytopenic purpura congenital	g	ADAMTS13 peptidase (M12.241)
Tick-borne encephalitis	v	Flavivirin (S07.001)
Triphalangeal thumb-polysyndactyly syndrome	g	Sonic hedgehog protein (C46.002)
Tumor predisposition syndrome	g	Ubiquitinyl hydrolase-BAP1 (C12.004)
Tylosis with esophageal cancer	g	iRhom2 (S54.953)
Type 2A von Willebrand disease	g	ADAMTS13 peptidase (M12.241)
Ulcerative colitis		Matrix metallopeptidase-9 (M10.004)
Vaginal candidiasis	f	Candidapepsin SAP1 (A01.014); candidapepsin SAP2 (A01.060)
Vibratory urticaria	g	EGF-like module containing mucin-like hormone receptor-like 2 (P02.001)
Vitiligo-associated multiple autoimmune disease 1	g	Family S79 unassigned peptidases (S79.UPW)
Vitreoretinopathy, neovascular inflammatory	g	Calpain-5 (C02.011)
Wegener's granulomatosis	a	Myeloblastin (S01.134)
Weill-Marchesani syndrome 1	g	ADAMTS10 peptidase (M12.235)
Weill-Marchesani syndrome 4	g	ADAMTS17 peptidase (M12.027)
Winchester syndrome	g	Membrane-type matrix metallopeptidase-1 (M10.014)
Wolman disease	g	PLN02872 protein (*Homo sapiens*-type) (S33.017)

Viral diseases and genetic abnormalities involving only non-peptidase homologues are omitted. The following abbreviations are used: *a* autoimmune disease, *b* bacterial infection, *f* fungal infection, *g* genetic abnormality, *p* parasite infection, *v* viral infection. Links are provided to the relevant summary pages in the *MEROPS* database

sequencing projects that are too divergent to be considered species variants of known peptidases. Of the 1,137,158 sequences in the *MEROPS* database, only 274,396 (24%) have been assigned to an identifier.

It is recommended that a well-characterized peptidase should have a trivial name. Although not rigidly adhered to, there is a different suffix for each catalytic type: metallopeptidases names end with "lysin," aspartic peptidases with "pepsin," cysteine peptidase with "ain," and serine peptidases with "in."

Compound and Complex Peptidases

Most peptidases have only one peptidase unit; however, there are some exceptions. A compound

peptidase has more than one peptidase unit within a single protein molecule. An example is the somatic form of the angiotensin-converting enzyme, which has two peptidase units. The testicular form of this enzyme contains only the second peptidase unit and is transcribed from the same gene but at an alternative initiating methionine. Each peptidase unit has a *MEROPS* identifier, but additionally there is a special identifier for each compound peptidase, which is XM02.001 in the case of angiotensin-converting enzyme.

A complex peptidase consists of several proteins in a complex. The 20S proteasome is a complex of 28 subunits, arranged in 4 stacked rings each containing 7 different subunits. The first and fourth rings contain the same seven (alpha) subunits, as do the second and third (beta subunits). Each subunit is the product of an individual gene, and the subunits are homologous to each other. Only three of the beta subunits are catalytically active, each conferring a different specificity (trypsin-like, chymotrypsin-like, or peptidylglutamyl peptide hydrolyzing, now often known as caspase-like). The proteins form a cylinder with the six active sites on the inside, and the substrate protein is threaded through one end and degraded to peptides that exit at the opposite end. The 28S proteasome contains additional subunits which form a cap and attach to one end of the 20S proteasome. These extra subunits are important for unfolding the substrate protein. Again, there is not only a *MEROPS* identifier for each alpha and beta subunit, but also identifiers for the complexes. The 20S proteasome is XT01.001 and the 28S proteasome is XT01.002.

Precursors and Zymogens

Most peptidases are not synthesized as active enzyme but as precursors or zymogens. The zymogen is transported to the site where it is needed and then activated, usually by the removal of an N-terminal propeptide by proteolysis. For some members of family S1, especially members of the blood coagulation pathway, a propeptide is not released but cleavage is still required for activity. The propeptide remains attached to the peptidase by a disulfide bridge, becoming the heavy chain in a two-chain complex. Cleavage generates a new hydrophobic N-terminal residue, and a molecular rearrangement then activates the peptidase. For some members of peptidase family M10, the propeptide acts by providing a fourth ligand for the catalytic zinc ion, and only on release of the propeptide does the zinc interact with water and the peptidase become active. Because this fourth ligand is a cysteine, this method of activation is known as a cysteine switch.

Specificity and Substrate-Binding

The specificity of a peptidase describes where in a peptide or protein sequence cleavage will occur. Some peptidases will only cleave near the amino- and carboxy-termini of the substrate, and these are termed exopeptidases. A peptidase that does not require free termini and can cleave at any acceptable site within a peptide is termed an endopeptidase. Most endopeptidases are able to cleave proteins, but there are a few that can only cleave short peptides, and these are known as oligopeptidases. Neprilysin is an oligopeptidase that degrades peptide hormones such as substance P, thereby switching off the physiological signal. Some endopeptidases are isopeptidases, cleaving nonstandard peptide bonds. An example is isopeptidase T, which releases ubiquitin from ubiquitinated proteins by cleaving the isopeptide bond between the C-terminal Gly of ubiquitin and the amino group of a nonterminal lysine on the protein targeted for degradation.

There are several different types of exopeptidases: aminopeptidases, carboxypeptidases, dipeptidyl-peptidases, tripeptidyl-peptidases, peptidyl-dipeptidases, dipeptidases, and omega peptidases.

Generally, a family of peptidases contains either exopeptidases or endopeptidases, but there are exceptions. Family C1 contains not only endopeptidases such as cathepsin L but also the aminopeptidase bleomycin hydrolase. Some members of this family can act as exopeptidases as well as endopeptidases. For example, cathepsin B also acts as a peptidyl-dipeptidase, and cathepsin H also acts as an aminopeptidase. Family S9 includes prolyl oligopeptidase, dipeptidyl-

peptidase IV, and the omega peptidase acylaminoacyl-peptidase.

The specificity of an endopeptidase is more difficult to describe than that of an exopeptidase. A peptidase with limited specificity will only cleave after one type of amino acid. Examples are trypsin, which cleaves proteins at lysyl or arginyl bonds, and chymotrypsin, which cleaves after hydrophobic residues. Granzyme B and caspase-3, which are involved in apoptosis or programmed cell death, cleave only after aspartyl bonds. However, even this can be simplistic; recent evidence has shown that granzyme B from mouse does not cleave Bid, whereas in human cleavage of this protein initiates the apoptotic pathway. The lysosomal endopeptidase legumain cleaves asparaginyl bonds but under acidic conditions can cleave aspartyl bonds; experiments with processing of the tetanus toxin have shown that only a few asparaginyl bonds are cleaved. Whether this is because only a few bonds are available to the peptidase because of the structure of the substrate or because the specificity of the peptidase is more complicated is unclear. Peptidases that cleave a variety of peptide bonds are described as having broad specificity.

Cleavage occurs at the scissile bond. Residues in the substrate toward the N-terminus are numbered P1, P2, P3, etc., whereas residues toward the C-terminus are numbered P1′, P2′, P3′, etc. Cleavage occurs between P1 and P1′. For a peptidase with limited specificity, only the residue in P1 or P1′ is important for specificity. A peptidase with an extended substrate-binding site will have a preference for residues in other positions. For example, cathepsin L prefers substrates with phenylalanine in P2 and arginine in P1. However, this is a preference only, and cathepsin L cleaves substrates after other amino acids. Caspase-3 has a preference for Asp in both P4 and P1, but it is unusual for substrate specificity to extend much further from the scissile bond. The peptidase with the most extended substrate specificity may be mitochondrial intermediate peptidase that removes an octapeptide targeting signal from the N-terminus of cytoplasmically synthesized proteins that are destined for import into the mitochondrial lumen.

A peptidase has a series of substrate-binding pockets to accommodate residues of the substrate. The S1 binding pocket accommodates residue P1, the S1′ binding pocket accommodates residue P1′, and so on. A binding pocket may contain several residues that interact with the substrate, and a single residue may take part in more than one binding pocket. Some peptidases bind the substrate at more than one binding site. A binding site away from the active site is described as an exosite. The presence of one or more exosites makes the peptidase very specific for a substrate, and it is not unusual for a peptidase with an exosite to cleave just one protein. Peptidases with such limited specificity include the blood coagulation enzymes. In some peptidases, additional substrate-binding sites are located on domains other than the peptidase unit. For example, the matrixins (family M10) interact with proteins of the extracellular matrix through the hemopexin-like domain that is C-terminal to the peptidase unit.

A proteolytic cascade occurs when one peptidase activates the next in a proteolytic pathway, and this in turn activates the next and so on. This is a mechanism to amplify the initial signal, because one peptidase molecule can activate many zymogen molecules. Examples of proteolytic cascades include blood coagulation, activation of digestive peptidases in the intestine, and apoptosis.

Drugs

The action of a peptidase can be neutralized by an inhibitor. Some inhibitors are very broad in their action and are capable of inhibiting many different peptidases, including peptidases of different catalytic types. Some inhibitors are assumed to be specific for a particular catalytic type but can inhibit peptidases of different types. Leupeptin, for example, is widely used as an inhibitor of serine peptidases from family S1, but it is also known to inhibit cysteine peptidases from family C1. Cysteine peptidase inhibitors such as

iodoacetic acid interact with the thiol of the catalytic cysteine. However, this reduction can occur on any thiol group and can affect other, predominantly intracellular, peptidases with a thiol dependency. One example is thimet oligopeptidase. Metal chelators such as EDTA can inhibit metallopeptidases but can also affect peptidases that have a requirement for metal ions that is independent of their catalytic activity, such as the calcium-dependent cysteine endopeptidase calpain 1.

Inhibitors which interact only with peptidases of one catalytic type include pepstatin (aspartic peptidases), E64 (cysteine peptidases from clan CA), diisopropyl fluorophosphates (DFP), and phenylmethane sulfonylfluoride (PMSF) (serine peptidases). Bestatin is a useful inhibitor of aminopeptidases.

Table 1 lists peptidases that are known or potential drug targets, alleviate disease symptoms, or aid disease identified from searching the literature from 2017 to 2019. In nearly all cases, the drug will be a synthetic peptidase inhibitor (Abbenante and Fairlie 2005).

Definition

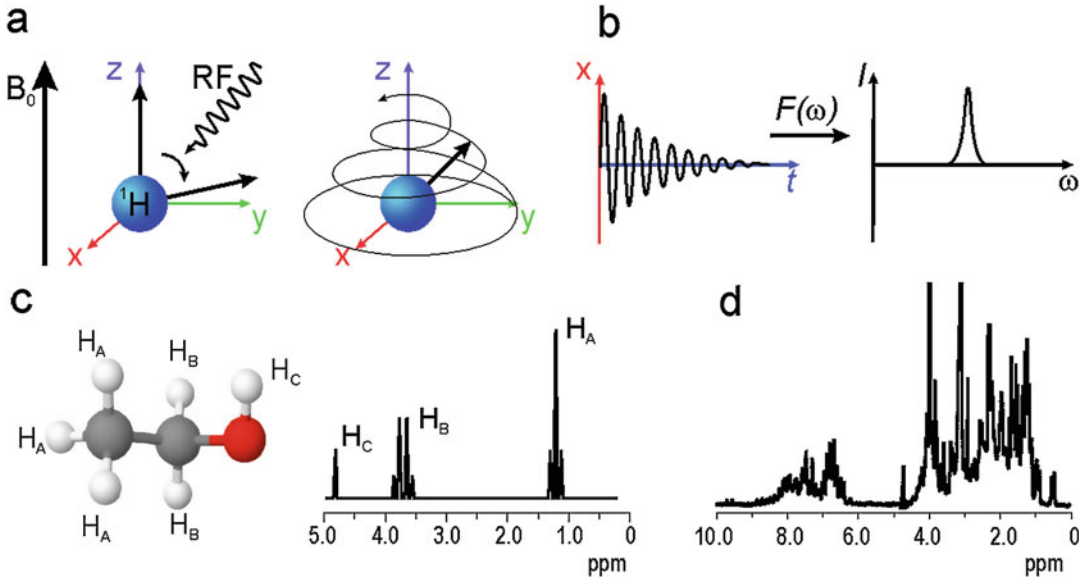
Nuclear magnetic resonance (NMR) is a spectroscopic technique detecting magnetic properties of atomic nuclei. All atoms that contain an odd number of protons and/or neutrons have a magnetic moment. This magnetic moment can be oriented and perturbed by an external magnetic field. In the presence of a magnetic field, the nuclear magnetic moment oscillates with a frequency (Larmor frequency) that depends on the external field strength as well as the gyromagnetic ratio of the nucleus, a fundamental property of atomic nuclei. Since the gyromagnetic ratio is constant for nuclei of the same type, the Larmor frequency can be used for highly precise measurement of the local magnetic field around nuclei and the magnetic coupling with nearby nuclei. Hydrogen nuclei are most commonly observed by NMR, but ^{13}C, ^{15}N, ^{31}P, and ^{19}F are also frequently used in life sciences, but in principle any nucleus with a magnetic moment can be observed. In some cases, the natural abundance of a magnetically active isotope is sufficient to measure its NMR signal. In other cases, specific, stable isotope enrichment is necessary. This is particularly useful for biomolecular NMR spectroscopy.

NMR spectroscopy is a nondestructive technique (for the sample) and does not rely on light or optical properties. Typically NMR is carried out in the solution state; however solid- and gaseous-state NMR is also possible.

Description

NMR techniques rely on polarizing the magnetic moments of the sample in a strong, external magnetic field. This is usually done by inserting the sample into a superconducting magnet or powerful electromagnet. The strength of the field determines the Larmor frequency of the nuclei. NMR spectrometers are characterized by the proton Larmor frequency (e.g., a 600 MHz spectrometer, 14.1 Tesla magnet, has a magnetic field that causes protons to oscillate at around 600 MHz). Depending on their gyromagnetic ratio, the frequencies of other nuclei will be different at the same field. For example, a 600 MHz ^{1}H spectrometer will have a ^{13}C frequency of 151 MHz. In the presence of an external magnetic field, the degeneracy of the nuclear spin energy levels is destroyed with a net population of spins slightly favoring the lower energy state(s), resulting in a net magnetic moment. The nuclear magnetization is diverted from its equilibrium state by intense radio-frequency pulses. The perturbed system returns to equilibrium, and a free induction decay (FID) signal is detected (Fig. 1a). A Fourier transform of the FID shows the resonance frequencies of nuclei present in the sample in an NMR spectrum (Fig. 1b). The resonance peaks in the spectrum have area proportional to the abundance of the nuclei. Therefore, peak integration can be used to measure relative abundance of particular nuclei in a small molecule. The position (chemical shift) of the resonance is usually given in ppm (parts per million) shift from a reference frequency. The advantage of a ppm scale over frequency units is that it is independent of the spectrometer frequency, therefore allowing easy comparison of data obtained on different spectrometers.

A molecule in NMR can be treated as "spin system"; this is a collection of magnetically



Nuclear Magnetic Resonance, Fig. 1 Principle of NMR. (**a**) Nucleus oriented along magnetic field B0 is diverted from equilibrium by an RF pulse. It then returns to equilibrium emitting decaying RF signal (FID). (**b**) The FID is recorded by a spectrometer. Its Fourier transformation gives a spectrum in frequency domain. (**c**) Ethanol molecule and its NMR spectrum. Each group of hydrogens resonates at different frequencies. Coupling between groups causes peak splitting. (**d**) Proton 1D spectrum of a small protein (SUMO). The resonances are highly overlapped making the interpretation difficult. Multidimensional NMR allows separating and identifying peaks overlapping in one-dimensional spectra

coupled nuclei. NMR allows measurement of through-bond coupling called scalar or J-coupling within the spin system. The magnitude of the J-coupling depends on the identities of the coupled nuclei as well as the bond geometry. Therefore, it provides essential information on molecular connectivity and bond properties. In addition, the nuclear Overhauser effect (NOE) is a through-space interaction and can be used to measure spin systems' proximity in space (Fig. 1c).

The possibility of magnetic excitation transfer between nuclei gives rise to multidimensional NMR spectroscopy. This allows the extraction of much more precise structural information from the sample. For example, in heteronuclear correlation experiments, one can observe connectivity between different nuclei (e.g., ^{1}H and ^{15}N). It is especially useful for the analysis of complex molecules like proteins (Fig. 1d). Such experiments can be coupled into multidimensional matrices allowing observation of multiple through-bond and space correlations.

Applications

Synthetic Chemistry Quality Control

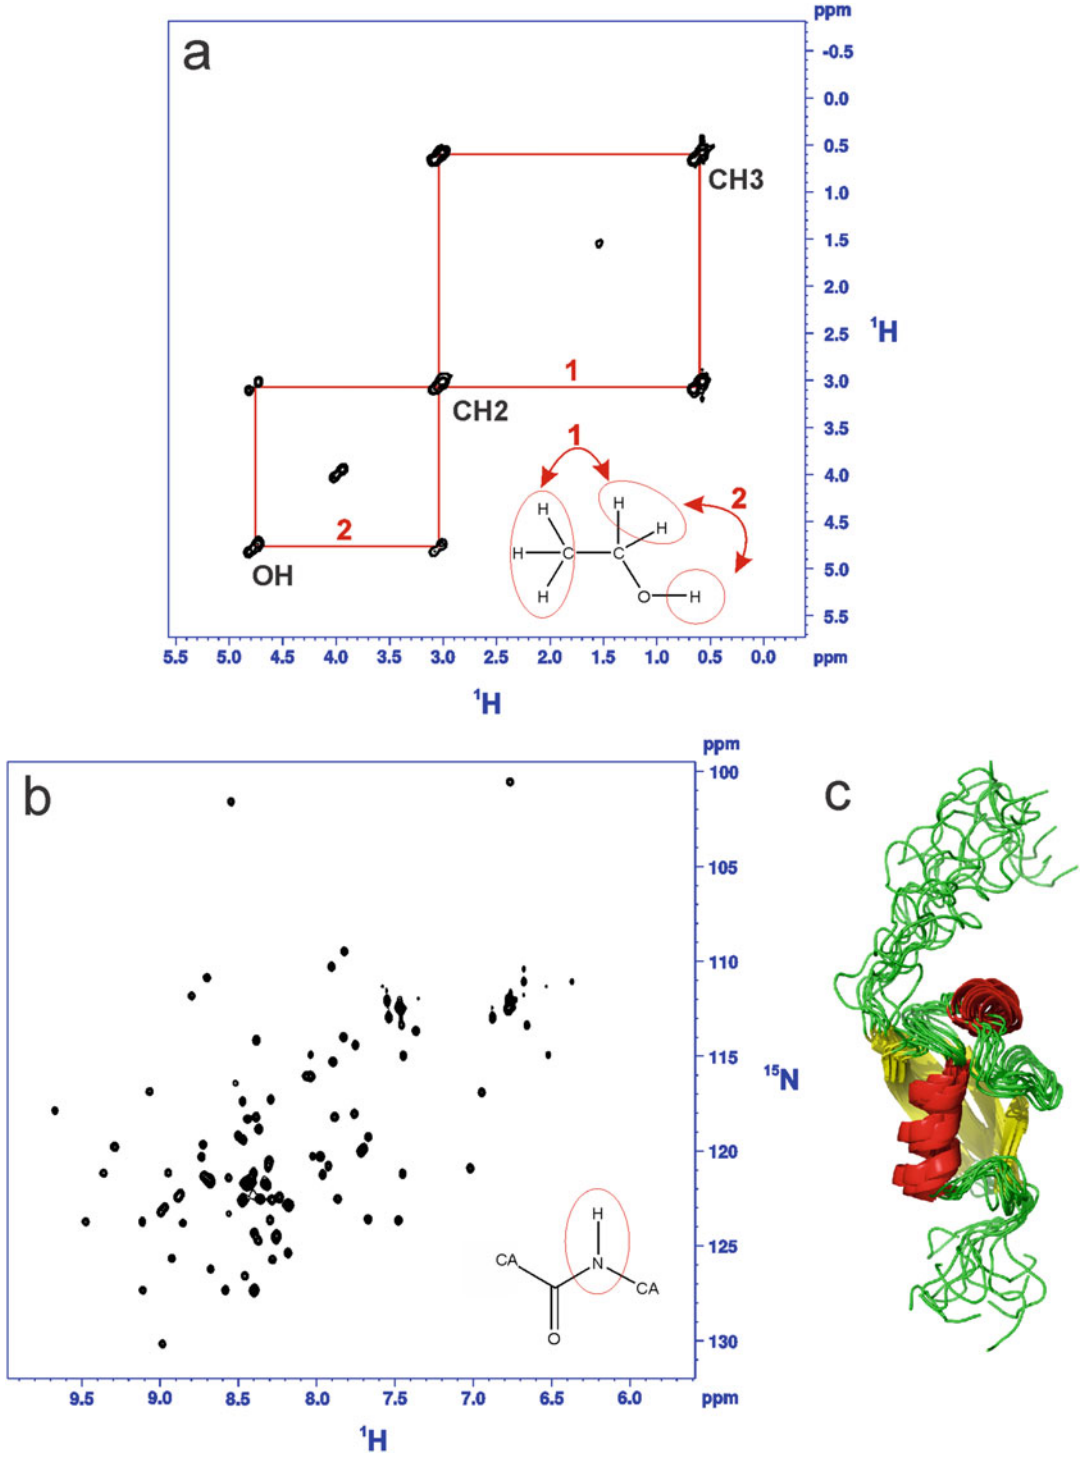
Synthetic organic chemistry and especially medicinal chemistry are the most popular areas for NMR application (Kiss et al. 2018). Simple one- or two-dimensional spectra give the chemist information about the identity and purity of the synthesized molecule (Pauli et al. 2014). Here, the principal information comes from proton, ^{1}H, and natural abundance, ^{13}C, spectra as stable isotope labeling is not feasible. In most cases distinct chemical moieties have resonances in different regions of the chemical shift scale (Fig. 1c). For example, protons belonging to aromatic systems have resonances located around 6–8 ppm, while saturated alkanes are visible between 0 and 2 ppm. Peaks in proton spectra have integrals that are directly proportional to the number of protons in each chemical environment, typically the number of hydrogens attached to one "heavy" atom. The adjacent groups of hydrogens in different chemical environments are coupled to each other; this causes splitting of the resonances within each group. The magnitude of the splitting is identical for both connected systems and characterizes bond type and geometry. To obtain more information about molecule connectivity, two-dimensional spectra can be used. This data usually allows the chemist to quantify the purity of a synthesized molecule and confirm its identity by comparing expected or predicted spectra with the measured result (Finch 2014). Most of the renowned medicinal chemistry journals require NMR characterization of the molecules reported. Usually at least assigned ^{1}H and ^{13}C spectra are required to prove compound identity.

Compound Identity Evaluation

NMR is one of the principal techniques for characterizing molecular identity. This is necessary especially for metabolite identification (Hamdam et al. 2013; Grillo 2015; Hollinshead et al. 2016; Nagana Gowda and Raftery 2015), characterization of degradation products, and evaluation of the identity of drugs and complex natural products, among other uses (Guleria et al. 2018; Beni et al. 2011; Holzgrabe and Malet-Martino 2011; Kiss et al. 2018; Rudszuck et al. 2019; Wang et al. 2013). Together with mass spectroscopy and sometimes elemental analysis, the chemist can analyze molecular connectivity and relative abundance. In most cases acquisition of multidimensional spectra is necessary to gather sufficient information to identify the molecule. The most useful spectra are as follows:

(i) COSY (COrrelated SpectroscopY) shows which signals arise from neighboring (up to four bonds) protons. The spectrum contains a proton 1D along its diagonal axis with cross-peaks (off-diagonal elements) appearing when there is spin-spin coupling between protons (Fig. 2a). COSY allows resolution of overlapping multiplets and tracing the carbon chain(s) of the molecule.

(ii) TOCSY (TOtal Correlated SpectroscopY) is similar to COSY but allows tracing coupling networks of any length as the intensity of cross-peaks is not related to the number of bonds connecting the protons. This experiment is particularly useful for large



Nuclear Magnetic Resonance, Fig. 2 Multidimensional NMR spectroscopy. (**a**) A COSY spectrum of ethanol. Peaks on spectrum diagonal are equivalent to 1D proton spectrum. Cross-peaks (outside diagonal) indicate through-bond coupling of protons. (**b**) An HSQC spectrum of a small protein (SUMO). Each peak relates to proton-nitrogen pair of the protein. The spectrum is unique to each protein and can be used as a "fingerprint" for

molecules containing multiple, separated coupling networks.

(iii) HSQC (Heteronuclear Single-Quantum Coherence) shows connectivity between two different nuclei. It is usually used to observe direct connectivity between ^{1}H-^{13}C and ^{1}H-^{15}N pairs. In these 2D spectra, one axis shows ^{1}H resonance frequency while the other ^{13}C (^{15}N) frequency. HSQC spectra allow determination of which hydrogen is directly bonded to which carbon (nitrogen) and therefore makes it possible to trace the connectivity between chemical groups that do not have direct hydrogen-hydrogen coupling (Fig. 2b).

(iv) NOESY (Nuclear Overhauser Effect SpectroscopY) is used for determining which resonances arise from protons that are close to each other (strength of the signal is proportional to the inverse sixth power of the distance between the nuclei) in space even if they are not bonded. A NOESY spectrum yields through-space correlations via spin-lattice relaxation. These spectra are usually recorded for hydrogen only. NOESY spectra can also detect chemical and conformational exchange. The 2D NOESY spectrum contains a 1D proton spectrum along its diagonal axis with cross-peaks indicating spatial proximity of resonances.

NMR is a nondestructive technique. This allows measuring the same sample multiple times. Measuring a sample after a certain period gives information about substance stability in solution when spectra taken at different time points are compared.

Protein Analysis

NMR experiments can provide significant information about protein properties (Zhuravleva and Korzhnev 2017). A one-dimensional proton spectrum of a protein allows estimation of how well folded the protein is, detection of aggregation, and the formation of higher-order complexes. The possibility of ^{15}N (or more seldom ^{13}C) labeling by recombinant production in isotopically enriched media allows heteronuclear correlation spectra (HSQC, Fig. 2b) of a protein to be recorded. HSQC spectra give a good measure of protein folding and allow easy observation of protein interactions with its ligand. The bigger the biomolecule, the more significant are the relaxation mechanisms leading to broadening of NMR resonance lines. This makes direct acquisition of spectra of a protein over approximately 40 kDa difficult. In such cases the use of higher field spectrometers (leading to better peak dispersion), selective labeling of a few atoms in a protein, deuteration, or special relaxation-insensitive experiments is necessary to obtain useful information. Correlation experiments can be extended into three-dimensional ^{1}H-^{15}N-^{13}C experiments. Those in turn enable tracing of residue connectivity and assignment of observed resonances to particular residues in a biomolecular sequence.

Investigation of Biomolecular Structure and Dynamics by NMR

One of the most prominent applications of NMR is structural investigation of biological macromolecules. While most of the published biomolecular structures were solved by X-ray crystallography (and, more recently cryo-EM), NMR structures complement this structural research. NMR has the advantage that it produces structures in solution without possible crystallization artifacts, can deliver structures of intrinsically disordered proteins or nucleic acids (Kellett et al. 2019; Schlundt et al. 2017), and can provide structures for biomolecules too small for cryo-EM techniques

Nuclear Magnetic Resonance, Fig. 2 (continued) identification and quality control. Folded proteins have good dispersion of resonances. When the protein is unfolded, peaks collapse toward single position around 8.5 ppm. (**c**) An example of NMR protein structure (SUMO). The calculated ensemble is converging where lots of NMR restraints are observed (structured elements). In the parts where little restraints are observed, the ensemble is dispersed (Bayer et al. 1998)

(Joshi and Vendruscolo 2015). The structural investigation of a biomolecule by NMR is a complex process (Arthanari et al. 2019). Initially a correlation spectrum is inspected for the presence of secondary structure and good resonance dispersion. Next 3D correlation experiments are recorded usually using a ^{13}C, ^{15}N double-labeled sample. This allows assignment of each resonance to an atom within a defined residue. When the assignment is complete, a set of experiments is selected that provides information on inter-atom distances (NOESY), bond angles (from coupling constants and/or chemical shifts), and orientation restraints (residual dipolar coupling). With all the structural data gathered, the structure is calculated by a software package that takes into account both the general geometry of biological macromolecules and experimental restraints. An ensemble of structures is generated (Fig. 2c). It converges when the experimental data is sufficient to determine a specific fold. Lack of measurable restraints will lead to significant dispersion of the ensemble and will indicate that the investigated molecule is flexible.

Both measured geometrical restraints and the general strength of through-space coupling (heteronuclear NOE experiment) can be used to evaluate biomolecule flexibility (Kovermann et al. 2016). It is also possible to measure relaxation of assigned atoms. Relaxation rates for different magnetization operators result from the intrinsic dynamic processes of the atoms under investigation and allow NMR to assess biomolecular dynamics across a range of timescales from ps to s or longer. Relaxation is faster in the case of rigid molecules and slower in the case of highly flexible molecules. Relaxation rates can thus report on the rigidity of biomolecules, the overall tumbling rate (correlation time), and local molecular dynamics. All these methods allow structural biologists to measure the degree of flexibility of parts of the molecule (e.g., loop closing an active site of an enzyme). These measurements can also be employed in evaluation of ligands causing allosteric or dynamic alterations of a biomolecule (Ambadipudi and Zweckstetter 2016; Skora and Jahnke 2015).

A very valuable tool for drug discovery but also a challenging task in NMR structural research is evaluation of protein-small-molecule structure (Erlanson et al. 2019). Quite often the size of the protein, complex abundance, or lack of access to stable isotope labeling will prevent acquisition of NOESY spectra giving distance restraints between ligand and protein. Several methodologies have been developed to solve this problem (attaching a paramagnetic atom to the proximity of a binding site (Nitsche and Otting 2018), per-atom analysis of STD-signal intensity, using chemical shifts to guide computational docking) (Ding et al. 2013; Sturlese et al. 2015; Wang et al. 2019). However, no generally accepted methodology exists at the moment.

Orthogonal Interaction Assays

NMR techniques are widely used for validation of hits produced by high-throughput screening (HTS) techniques (Li and Kang 2017; Wu et al. 2015). Most of the HTS assays involve an optical readout. Therefore, they are susceptible to false positives produced by highly absorbing or fluorescent compounds or impurities. Since NMR does not rely on optical properties but observes directly the magnetic field around atoms, it provides an excellent way to validate hits from other assays. Moreover, NMR observes protein in solution, without the need for immobilization and chemical labeling, in a buffer closer to the natural cellular environment. This eliminates several sources of erroneous measurement. NMR experiments usually require several minutes to several hours per sample. This makes them unsuitable to screen very large libraries, but primary hits from an HTS screen are usually in numbers suitable for NMR-based assays. This is especially true since the introduction of fully automated sample changers. Due to the fact that large biomolecules are difficult to observe by NMR (see Protein Analysis section), it is often easier to carry out ligand-observed experiments, where interaction with a larger biomolecule (protein) is inferred indirectly via the effect on the ligand signals. For smaller biomolecules (typically below 40 kDa), it is possible to observe interaction from both the receptor signals and the ligand signals. The experiments used for binding validation are identical to those used for NMR-based screening and are

described in the next section (Gossert and Jahnke 2016).

NMR-Based Screening

Until recently, NMR has been considered a low-throughput technique. This was caused by manual sample installation in most systems and the lengthy time required to prepare and execute experiments. Introduction of high-capacity sample changers (i.e., Bruker SampleJet), development of experiment automation software, and more time-efficient experiments have changed this situation (Sillerud and Larson 2012). It is now possible to measure several thousand experiments in a few days. This is still not sufficient for true HTS screening campaigns but satisfies the requirement of fragment and focused library screening (Harner et al. 2013).

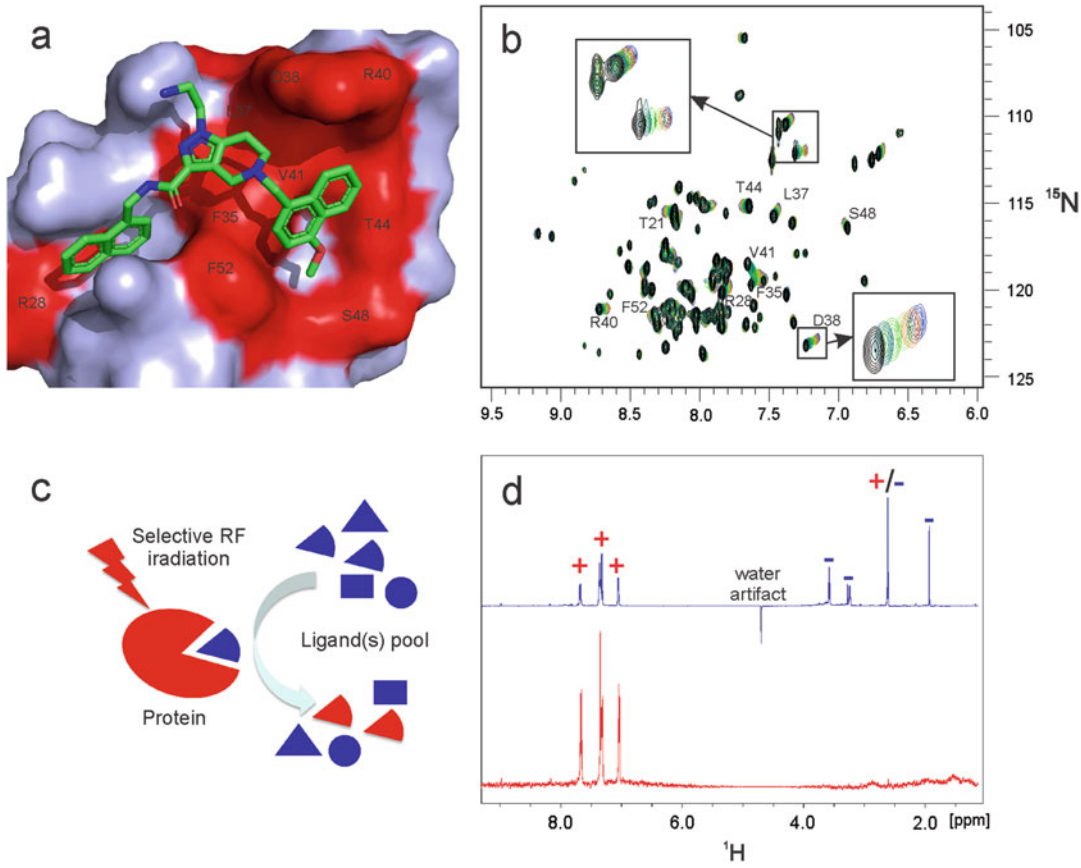
NMR is a method of choice for fragment screening (Kashyap et al. 2018). This is due to the fact that NMR experiments are sensitive to weak interactions in the high μM-low mM regime. Additionally, NMR experiments require relatively high concentrations of the observed molecule (tens to hundreds of μM); this is usually not a problem for small, highly soluble fragment molecules.

In order to reduce the number of experiments necessary to screen a library, the molecules are often pooled together into cocktails of up to tens of molecules. Molecules from cocktails evaluated as active are then measured individually. Some techniques allow direct identification of the active molecule in the cocktail by observation of its characteristic chemical shift.

In cases when direct observation of protein and ligand is not feasible because of low ligand solubility or lack of possibility for macromolecule labeling with stable isotopes, a reporter molecule that is easily detectable in NMR experiments can be used and displacement of the reporter from the molecule site of interest measured. Here, ^{19}F signals are often used as fluoride resonances, which are very easy to identify, and the ^{19}F spectrum does not contain any interfering signal from ligands, buffers, or the macromolecule.

The NMR experiments most commonly used for screening and orthogonal validation can be divided into three groups (Cala et al. 2014; Sugiki et al. 2018):

- Macromolecule-observed experiments – here the macromolecule (usually protein) is directly observed by NMR. Biomolecules in the native state contain only ^{1}H as an NMR-active nucleus. ^{1}H spectra of large molecules are usually heavily overlapped and difficult to interpret. Therefore, most biomolecule-observed experiments are conducted on stable isotope-labeled protein. ^{15}N or ^{13}C is usually used. The isotopes are introduced as components of defined media for recombinant expression. In the case of very large biomolecules, more sophisticated, selective labeling of certain residues or chemical moieties (i.e., methyls) can be applied using a suitable expression medium. The presence of two NMR-active nuclei allows recording of correlation spectra (HSQC), which are the most used for biomolecule-observed screening experiments. While it is theoretically possible to use ^{1}H-^{1}H experiments (COSY, NOESY) for screening, such experiments remain exceptional and are used primarily for DNA and RNA screening. Correlation spectra allow approximate mapping of the ligand binding site by comparing the position of peaks in the 2D spectrum for the biomolecule in the apo-form and after ligand addition (Fig. 3a, b). Spectral changes of resonances (shifts, intensities, splitting) indicate binding. If residue assignment is available, changes in the correlation spectra can be mapped onto the protein structure and allow approximate ligand placement. The biomolecule-observed experiments require a relatively large amount of materials. Typically, 0.5 mg of protein is required for a single experiment.
- In cases when isotopically labeled protein is not feasible or too expensive, NMR-based screening can be performed by observation of ligand. In this case only ligand hydrogen or fluorine nuclei are used and no special isotope labeling is necessary. Hydrogen-detected experiments are usually based on the altered magnetic properties of ligand that encountered the macromolecular receptor compared with



Nuclear Magnetic Resonance, Fig. 3 NMR of protein-ligand interactions. (**a**, **b**) A structure of a protein with inhibitor bound (Dawidowski et al. 2017). The residues in contact with the inhibitors have their resonances shifted in dose-dependent manner. Assigning of the peaks that change upon binding allows mapping of the binding site without crystal structure. (**c**, **d**) Principle of STD binding experiment. The ligand spectrum is observed as a standard proton 1D (blue) and STD (red). Protein is selectively excited by RF irradiation. The excitation is transferred to ligands (red) that bind briefly to the protein (+). Non-binding ligands (blue) give no signal on STD spectrum (−). The STD is one of a palette of ligand-observed binding experiments

ligand remaining free in solution. One of the most popular experiments is saturation transfer difference (STD, Fig. 3c, d), which uses selective magnetic excitation of protein only (Wagstaff et al. 2013). The excitation is transferred to a binding ligand. Fast exchange of the bound ligand with the pool of free ligand allows a pool of ligand, excited via binding to the protein, to build up. Then the 1H spectrum of the ligand under protein saturation conditions is compared to the one where the excitation signal does not "hit" the protein. The difference spectra show only those ligand resonances that come in contact with excited protein. Due to fast turnover of ligands in the binding site, the relative amount of protein to ligand can be very small (up to 1:1000), which makes the STD experiment particularly useful when only small amounts of protein are available. The WaterLOGSY (Dalvit et al. 2001) experiment is similar to STD; however excitation is directed toward water and then transferred to protein and ligand. The sign of magnetic polarization of the ligand is different for water-ligand and water-protein-ligand interactions. This difference can be measured and used for binding evaluation. When a small molecule contacts a macromolecule, it acquires

the relaxation properties of the macromolecule. This causes much faster relaxation of binding ligands when compared to non-binders, which translates to faster magnetization decay and broader resonance lines. Since linewidth is difficult to analyze directly, relaxation-sensitive experiments can be used to measure how fast the molecule is losing its magnetization due to contact with the protein. Similarly, an NMR sample can be placed in a magnetic field gradient and diffusion speed measured along the gradient. Bound ligand will diffuse much slower, and the difference can be observed.

- The interesting alternative to proton-observed screening experiments is ^{19}F NMR (Norton et al. 2016). Fluoride spectra are characterized by much large chemical shift dispersion (around 200 ppm compared to ~15 ppm for ^{1}H), much narrower spectral lines, and sensitivity comparable to ^{1}H spectroscopy. These factors make ^{19}F NMR attractive to screen mixtures on many compounds simultaneously, as there is little chance that the peaks will overlap. Direct identification of interacting ligand is possible simply by comparing the chemical shift of the "interacting" peak with the compound reference spectrum. Relaxation-sensitive experiments are usually chosen for screening. Of course, ^{19}F NMR requires special libraries where each compound contains at least one fluoride atom. Many vendors and pharmaceutical companies have already assembled such libraries with many thousands of compounds. In cases where the screened compounds do not contain fluoride, a fluorinated reporter molecule can be used. The requirements for such a molecule are specific interaction with the binding site of interest, at least one ^{19}F atom in the structure, and reasonably good solubility. It is also possible to introduce ^{19}F atom(s) into the protein structure in the proximity of the active site to observe ligand binding (Arntson and Pomerantz 2016).

Due to the versatility of experimental methodologies, NMR is one of the indispensable elements of target-oriented screening campaigns. It can also enable fast target identification for hits coming from phenotypic screening when the expected target macromolecule is available.

Pharmaceutical Relevance

NMR is one of the key techniques in the pharmaceutical sciences. It is indispensable for synthetic, medicinal chemistry, pharmacopoeic quality control, and metabolite analysis. Target-based drug discovery benefits from reliable, NMR-based orthogonal screening, binding site analysis, and structural biology data. The main drawback of NMR is the availability of sufficient sample quantities and stable isotope labeling. This is partially alleviated by increases in NMR spectrometer sensitivity (cryogenically cooled preamplifiers) and new experiment design. Development of new, sophisticated ligand binding evaluation approaches will certainly increase the role of NMR in structural analysis of biomolecule-ligand complexes. Development of in-cell NMR (Kang 2019; Luchinat and Banci 2016), while still in an early phase, offers opportunities to investigate biological systems in the native, cellular environment (Burz et al. 2019) and will enable phenotype-based cellular experiments by NMR.

Glossary Terms

Cytochrome P450 (CYP)	Family of hemeprotein monooxygenase enzymes that plays a central role in the oxidative metabolism of structurally diverse lipophilic steroids, fatty acids, drugs, and environmental chemicals. P450-catalyzed biotransformation of drugs is primarily carried out by 10–15 distinct human P450 enzymes, each encoded by a separate P450 gene.
Lithocholic acid	3α-hydroxy-5β-cholanoic acid, a hepatotoxic and cholestatic secondary bile acid which is formed by bacterial dehydroxylation of primary bile acids in the intestine.
Orphan nuclear receptor	Receptor protein belonging to the nuclear receptor superfamily whose physiological ligand has not been identified.
P450 induction	The process whereby cellular and tissue levels of one or more cytochrome P450 enzymes are increased in response to treatment of cells, or a whole organism, with certain drugs or environmental chemicals referred to as P450 inducers. P450 induction leads to an increase in the cell's capacity for P450-catalyzed oxidative metabolism of many xenochemicals, as well as endogenous steroidal and fatty acid P450 substrates.
Peroxisome proliferator chemicals	Chemicals that activate the nuclear receptor PPARα (peroxisome proliferator-activated receptor-α) and induce the enlargement and proliferation of liver peroxisomes in susceptible rodent species (e.g., rats and mice). Persistent exposure to peroxisome proliferator chemicals is closely linked to PPARα activation and liver tumor development in these species.
Phthalate esters	Di- and mono-esters of phthalic acid, an ortho-dicarboxylic acid derivative of benzene. These compounds are widely used as industrial plasticizers to coat polyvinylchloride surfaces of plastics used in food packaging and medical devices (intravenous drip bags, blood storage bags, etc.) and are common environmental contaminants. Several phthalate mono-esters are peroxisome proliferator chemicals and can activate the peroxisome proliferator-activated receptor PPAR.

Retinoid X receptor, RXR	Nuclear receptor that binds and is activated by certain endogenous retinoids, such as 9-*cis*-retinoic acid. RXR is the obligatory heterodimerization partner for a large number of non-classic steroid nuclear receptors, such as thyroid hormone receptor, vitamin D_3 receptor, peroxisome proliferator-activated receptor, and pregnane X receptor.

Definition

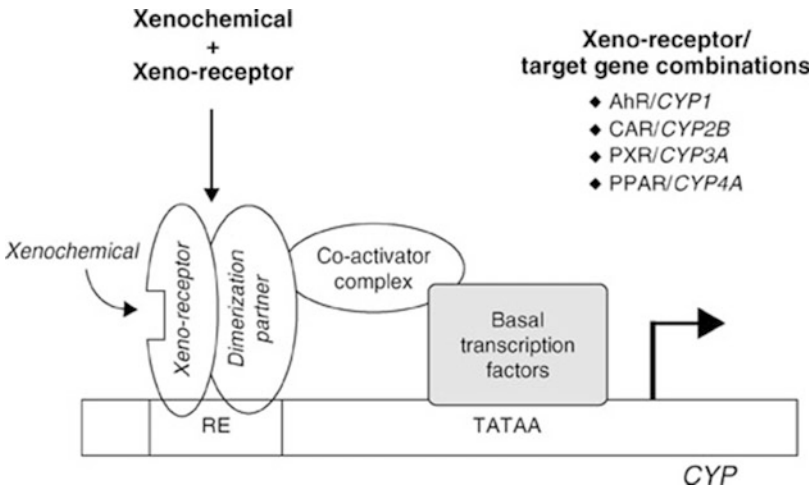
Cytochrome P450 (CYP) induction is the process whereby cellular or tissue levels of one or more P450 enzymes are increased as a result of de novo protein synthesis in response to treatment with certain drugs (e.g., phenobarbital and rifampicin) or exposure to environmental chemicals (e.g., dioxins and polychlorinated biphenyls), which are designated P450 inducers. This inductive response generally results from an increase in P450 gene transcription and leads to an increase in the capacity for P450-catalyzed oxidative metabolism of both xenochemicals (i.e., drugs and other foreign chemicals) and endogenous lipophilic substrates (i.e., steroid hormones, vitamins, fatty acids, and bile acids). Other drug-metabolizing enzymes, such as drug conjugation enzymes (e.g., glutathione *S*-transferases and UDP-glucuronosyltransferases), are also subject to induction by classic P450 inducers, whose pharmacological and toxicology effects are discussed here.

Basic Mechanisms

P450 induction can occur in many cell types and tissues but is most prominent in the liver, a major organ for metabolism of steroids, drugs, and environmental chemicals. Many of the inducible P450s are active catalysts of drug metabolism, and P450 induction typically enhances the capacity for chemical biotransformation, resulting in a shorter elimination half-life and more rapid clearance of the chemical from the body. Consequently, P450 induction can have a major impact on P450-dependent drug metabolism, pharmacokinetics, and drug-drug interactions; the toxicity and carcinogenicity of foreign chemicals; and the disposition and biological activity of endogenous steroids and certain other hormones. Although some P450 substrates also serve as P450 inducers, there is no necessary relationship between the ability of a chemical to induce a particular P450 enzyme and its ability to serve as a substrate for metabolism by that same P450.

At least 10 of the 57 known human P450s are subject to induction by xenochemicals. In most, but not all cases, the induction of P450 protein and enzyme activity occurs by a mechanism that involves increased transcription of the corresponding P450 gene. Members of four P450 gene families, *CYP* families 1, 2, 3 and 4, are induced by receptor-dependent transcriptional mechanisms (Fig. 1). P450 genes belonging to the *CYP1* gene family and the *CYP2S1* gene are induced by the aryl hydrocarbon receptor (AhR, also known as dioxin receptor), which is a member of the basic helix-loop-helix (bHLH)/periodic circadian protein (PER)-AhR nuclear translocator (ARNT)-single minded protein (SIM) superfamily of transcription factors (Rothhammer and Quintana 2019). In contrast, the induction of select genes from P450 families *CYP2*, *CYP3*, and *CYP4* is mediated by transcription factors from the nuclear receptor superfamily. The nuclear receptor known as constitutive androstane receptor (CAR, gene designation *NR1I3*) preferentially induces *CYP2B* genes (Kobayashi et al. 2015), whereas pregnane X receptor (PXR, gene designation *NR1I2*, also known as steroid and xenobiotic receptor and pregnane-activated receptor) preferentially induces *CYP3A* genes and peroxisome proliferator-activated receptor α (PPARα, gene designation *NR1C1*) preferentially induces *CYP4A* genes (Hakkola et al. 2018).

CAR is an orphan nuclear receptor that mediates the widely studied induction of *CYP2B* genes by phenobarbital, other "phenobarbital-like" lipophilic drugs, and other chemicals (Kobayashi et al. 2015). PXR activates *CYP3A* genes in response to diverse chemicals, including certain



Nuclear Receptor Regulation of Hepatic Cytochrome P450 Enzymes, Fig. 1 General mechanism for the direct transcriptional activation of *CYP* genes by xenochemicals that activate their cognate xeno-receptor proteins. In the case of AhR, the receptor's heterodimerization partner is Arnt, whereas in the case of the nuclear receptors CAR, PXR, and PPARα, the heterodimerization partner is RXR. The coactivator and basal transcription factor complexes shown are each comprised of a large number of protein factors

drugs, natural products, and natural and synthetic steroids (Chai et al. 2016). PPARα mediates the induction of fatty acid hydroxylases of the CYP4A family by many acidic chemicals classified as non-genotoxic carcinogens and peroxisome proliferators (Hakkola et al. 2018). These three xenochemical receptors are most highly expressed in the liver, where they may be activated by either by endogenous ligands or foreign chemicals, including many drugs and environmental pollutants. CAR and PXR are also expressed in the intestine, where they may also mediate P450 induction. The discovery of endogenous ligands for CAR (androstanes, which decrease basal receptor activity and serve as inverse agonists), PXR (certain pregnenolone derivatives, bile acids, and other steroids), and PPARα (specific prostaglandins and other fatty acid metabolites) suggests that these three nuclear receptors play an important role in modulating liver gene expression in response to endogenous metabolic or hormonal stimuli, in addition to their established role in modulating liver drug and xenochemical metabolism by induction of cytochromes P450 and other enzymes of foreign compound metabolism.

CYP1 Induction Via AhR

The AhR is localized in the cytosol in the basal state where it exists in a complex containing a dimer of heat shock protein 90 (hsp90), AHR-interacting protein (AIP; also known as the hepatitis B virus X-associated protein, abbreviated as XAP2), the co-chaperone p23 protein, and protein kinase SRC (Rothhammer and Quintana 2019). AhR is activated upon binding a ligand in the cytosol. The ligand-activated AhR translocates to the nucleus where it dissociates from the chaperone and co-chaperone proteins and heterodimerizes with a nuclear protein, AhR nuclear translocator (ARNT). The AhR-ARNT heterodimer binds to DNA enhancer sequences ("dioxin-response elements" or DREs) found upstream of *CYP1* and other AhR target genes and stimulates transcription of target genes, including those involved in biotransformation, cell proliferation, cell differentiation, and control of the immune responses. The overall pathway for AhR activation is conserved in many cell types and across species and accounts for the induction of *CYP1* genes by a large number of aromatic hydrocarbons, including important environmental carcinogens found in auto emissions and cigarette

smoke. Halogenated and polycyclic aromatic hydrocarbons are prototypic AhR ligands, but certain planar compounds, including dietary plant constituents, can also bind to AhR, although with varying affinities. AhR can also regulate gene expression without the direct involvement of DRE DNA-responsive elements, by mechanisms that include (i) interaction of AhR with various coactivators and corepressors, NF-κB, and the retinoblastoma protein; (ii) activation of various protein kinases; (iii) phosphorylation of AhR; and (iv) functioning as an E3 ubiquitin protein ligase to facilitate degradation of target proteins.

Role of CAR in CYP2B Induction and Other Phenobarbital Responses

The orphan nuclear receptor CAR is the key regulated transcription factor that mediates induction of liver *CYP2B* and other genes (Kobayashi et al. 2015). CAR is localized in the cytosol in the basal state (i.e., in the absence of a ligand or an activator), where it is in a complex with co-chaperone proteins Hsp90 and cytoplasmic CAR retention protein (CCRP). CAR is activated by dephosphorylation of Thr-38, which can be induced by direct binding of xenochemicals, such as 1,4-bis[2-(3, 5-dichloropyridyloxy)]benzene (TCPOBOP), a highly specific halogenated agonist of mouse CAR. CAR can also be activated by indirect activators, such as phenobarbital, which stimulates CAR Thr-38 dephosphorylation by disruption of signaling downstream of epidermal growth factor receptor (EGFR, see below). Thr-38 dephosphorylation dissociates CAR homodimers and induces translocation of CAR to the nucleus, where CAR binds to the nuclear receptor retinoid X receptor (RXR). The CAR-RXR complex recruits coactivators such as steroid receptor coactivator 1 (SRC1) and binds to specific DNA response elements to stimulate the transcription of a CAR target gene (e.g., *CYP2B*) (Fig. 1). RXR serves as a common heterodimerization partner for many nuclear receptors, including PXR and PPARα. Further, many activators of CAR can also activate PXR and/or PPARα.

Nuclear translocation of CAR is strongly enhanced in the liver in vivo following administration of phenobarbital. However, unlike classical nuclear receptor agonists, phenobarbital does not bind to the COOH-terminal ligand-binding domain of CAR. Other indirect activators of CAR include the flavonoids galangin, chrysin, and baicalein. Studies in the past decade have provided insights into the nuclear translocation of CAR by phenobarbital (Mackowiak and Wang 2016). The cellular events in the nuclear translocation of CAR by phenobarbital and other indirect inactivators of CAR include (1) binding to EGFR, resulting in inhibition of epidermal growth factor-mediated signaling; (2) dephosphorylation of a protein known as receptor for activated C kinase 1 (RACK1); (3) recruitment of protein phosphatase 2A to the CAR-Hsp90-CCRP complex; and (4) dephosphorylation of CAR.

Mouse *CAR* gene knockout studies demonstrate that CAR is essential, not only for induction of the highly inducible *CYP2B* genes but also for the multiple pleiotropic responses associated with exposure to phenobarbital and phenobarbital-like inducing agents. These include the induction of many genes involved in xenobiotic transport and biotransformation and repression of the expression of certain genes involved in energy metabolism. CAR is also required for various pathophysiological effects of phenobarbital in the liver (e.g., hepatomegaly, enhanced hepatocyte proliferation) and for toxicological or carcinogenic responses that are characteristic of phenobarbital-treated liver, including hepatotoxicity induced by acetaminophen and cocaine, and liver tumor promotion.

CYP3A Induction by PXR: Role in Metabolism of Xenochemicals and Endogenous Lipophilic Substrates

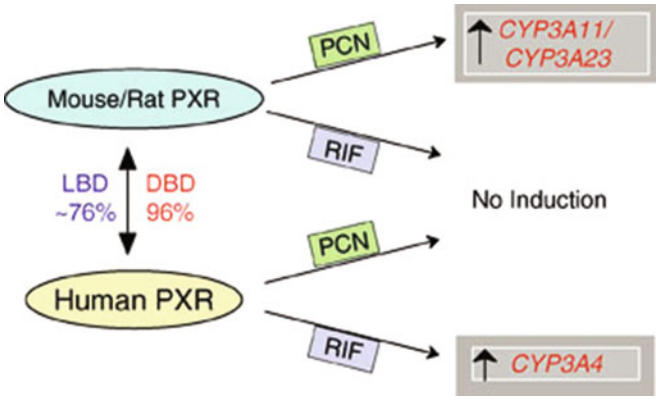
PXR is the major transcription factor that mediates the induction of CYP3A enzymes (Hakkola et al. 2018), most notably CYP3A4, the most abundant P450 enzyme in human liver. CYP3A4 is highly expressed in the liver and intestine, where it metabolizes structurally diverse drugs, environmental chemicals, endogenous steroid hormones, and lipophilic bile acids (Chai et al. 2016). The high level of expression of CYP3A4, coupled with its broad substrate specificity and

widespread inducibility following exposure to diverse steroids, antibiotics, and other pharmacological agents that activate PXR, gives rise to many CYP3A-based drug interactions.

PXR was initially thought to reside exclusively in the nucleus, but subsequent studies identified PXR in the cytosol. In contrast to CAR, PXR has little or no intrinsic basal transcriptional activity in the absence of ligand. Similar to CAR, the cytosolic form of PXR exists in a complex with co-chaperone proteins Hsp90 and CCRP (Mackowiak and Wang 2016). Upon direct binding by an agonist, the ligand-receptor complex dissociates from the co-chaperone proteins and translocates from the cytoplasm to the nucleus. Activated PXR, which is in a heterodimeric complex with RXR and binds various coactivators (e.g., steroid receptor coactivator 1), binds to specific DNA response elements in the promoter or enhancer regions of PXR target genes, enabling PXR to stimulate gene transcription. PXR activity may also be influenced by cellular signaling pathways that control posttranslational modifications, including phosphorylation, ubiquitination, acetylation, and sumoylation. Specific microRNAs (e.g., microRNA-148a-5p and microRNA-18a-5p) have been identified as posttranscriptional determinants in the expression and functionality of PXR.

Major species differences characterize the induction of CYP3A enzymes by drugs, steroids, and other chemicals (Chai et al. 2016). These species differences are a direct result of the species-dependent activation of PXR by individual PXR ligands (Fig. 2). Human PXR but not mouse PXR is activated by rifampicin and other xenochemicals that preferentially induce *CYP3A* genes in human cells and tissues, whereas mouse PXR but not human PXR is activated by the synthetic steroid pregnenolone 16α-carbonitrile (PCN). Mouse *PXR* gene knockout studies establish PXR as the major mediator of *CYP3A* induction by many xenochemicals. Moreover, a human pattern of *CYP3A* inducibility can be achieved when the endogenous mouse *PXR* gene is replaced by its human *PXR* counterpart. Mouse and human PXR exhibit an uncharacteristically high (~25%) divergence of amino acid sequence within the ligand-binding domain, suggesting that these rodent and human PXRs are unusually divergent orthologs whose evolution reflects their adaptation to the unique dietary constituents and distinct endogenous steroid profiles of each species.

PXR may serve as a broadly based "steroid and xenobiotic sensor" whose intrinsic physiologic function is to stimulate synthesis of CYP3A enzymes that catabolize endogenous steroidal



Nuclear Receptor Regulation of Hepatic Cytochrome P450 Enzymes, Fig. 2 Species-specificity of PXR's CYP3A induction response. Shown are the amino acid sequence identities of the COOH terminal-ligand-binding domain (LBD) and the central DNA-binding domain (DBD) of rodent and human PXR. *CYP3A11* and *CYP3A23* are mouse and rat P450 3A genes, respectively, whereas *CYP3A4* is a human P450 3A gene. *PCN* pregnenolone 16α-carbonitrile, *RIF* rifampicin

substrates (Chai et al. 2016). This possibility is supported by the striking responsiveness of PXR to endogenous steroids belonging to several distinct classes (pregnanes, estrogens, and corticoids) and by the catalysis by many CYP3A enzymes of 6β-hydroxylation reactions using diverse steroidal substrates, including androgens, corticoids, progestins, and bile acids. PXR plays a key role in bile acid homeostasis, as shown by the decreased production and increased hepatic uptake and detoxification of cholestatic bile acids, such as lithocholic acid, that is mediated by PXR. Activation of PXR by bile acids in liver leads to (1) decreased expression of *CYP7*, cholesterol 7α-hydroxylase, which catalyzes a key rate-limiting reaction of bile acid biosynthesis; (2) increased expression of the transporter *Oatp2*, which increases hepatic uptake of bile acids from the sinusoidal blood; and (3) induction of CYP3A enzymes that detoxify lithocholic acid by catalyzing its 6-hydroxylation.

PPARα: Xenochemical Induction of CYP4A Enzymes and Role in Rodent Hepatocarcinogenesis

CYP4A enzymes catalyze the oxygenation of biologically important fatty acids, including arachidonic acid and other eicosanoids. *CYP4A* gene transcription can be activated in both the liver and kidney by a range of acidic drugs and other xenochemicals, including hypolipidemic fibrate drugs, phthalate ester plasticizers used in the medical and chemical industries, and other environmental chemicals (Hakkola et al. 2018). These CYP4A inducers are classified as peroxisome proliferator chemicals because they markedly induce liver peroxisomal enzymes, leading to a dramatic increase in both the size and the number of liver cell peroxisomes.

PPARα is the nuclear receptor responsible for *CYP4A* induction, peroxisomal enzyme induction, and hepatic peroxisome proliferation (Hakkola et al. 2018). The tissue distribution of PPARα (liver >kidney >heart >other tissues) mirrors the responsiveness of these tissues to peroxisome proliferator chemicals. *CYP4A* induction in the liver and kidney and hepatic peroxisome proliferation are both abolished in *PPARα* gene knockout mice, demonstrating the essential role of PPARα for these responses in vivo. The general mechanism of PPARα activation is similar to that of other nuclear receptors. PPARα is found in the nucleus in the basal state as a complex with corepressor proteins. Ligand binding leads to dissociation of PPARα from its corepressor proteins, heterodimerization with RXR, recruitment of coactivators, and binding to functional DNA response elements, referred to as peroxisome proliferators response elements (PPREs), in the 5′-flank of *CYP4A* and other target genes, resulting in stimulation of gene transcription. PPARα-RXR complexes bound to PPREs can be synergistically activated by the combination of a PPARα ligand with the RXR ligand 9-*cis*-retinoic acid.

Persistent activation of PPARα can induce the development of hepatocellular carcinoma in susceptible rodent species by a non-genotoxic mechanism, i.e., one that does not involve direct DNA damage by peroxisome proliferator chemicals or their metabolites. This hepatocarcinogenic response is abolished in mice deficient in PPARα, underscoring the central role of PPARα, as opposed to that of two other mammalian PPAR forms (PPARγ and PPARδ), in peroxisome proliferator chemical-induced hepatocarcinogenesis. Other toxic responses, such as kidney and testicular toxicities caused by exposure to certain phthalate di-ester plasticizers, are not abolished in PPARα-deficient mice, raising the possibility that the latter toxicities may be mediated by PPARγ or PPARδ.

Pharmacological Relevance

Importance of Nuclear Receptors for Drug Metabolism and Drug Development

The identification of specific nuclear receptors as molecular targets of P450 inducers impacts drug metabolism and drug development in several important ways:

1. Drug interactions, often associated with interindividual differences in drug metabolism, are a major contributor to idiosyncratic drug responses, which can sometimes be fatal. P450 induction, especially the induction of CYP3A

enzymes via PXR, can contribute significantly to interpatient differences in drug metabolism. High throughput screens for P450 inducers that activate AhR, CAR, PXR, and PPARα have been developed and can readily be applied to characterize the P450 induction potential of drugs currently used in the clinic, as well as investigational drugs and lead compounds under development. These efforts may help to predict, and thereby avoid, drug interactions associated with P450 induction.

2. Interindividual differences in the function and expression of nuclear receptors and their accessory proteins, reflecting either genetic or epigenetic factors, may represent another set of determinants of interindividual differences in pharmacokinetics and possibly pharmacodynamics. Further elucidation of the factors that regulate cellular nuclear receptor levels (e.g., glucocorticoids, which increase expression of PXR in human hepatocytes) and the identification of genetic polymorphisms that impact receptor expression, ligand binding specificity or transcriptional activity are also likely to be important.
3. Receptor proteins involved in the induction of cytochromes P450 and other enzymes of drug metabolism may serve as novel drug targets. Examples of established nuclear receptor drug targets include PPARα, which is a target of hypolipidemic fibrate drugs, and PPARα, which is targeted by anti-type II diabetes drugs of the thiazolidinedione class. CAR and PXR are also therapeutic targets based on the role of CAR activators in the treatment of jaundice and PXR activators in the relief of cholestasis associated with hepatotoxic bile acids, hypercholesterolemia, and inflammatory bowel disease. PXR antagonists might be developed to block CYP3A auto-induction responses, which can substantially shorten the elimination half-life of a drug that simultaneously serves as a CYP3A inducer and a CYP3A substrate, which is a characteristic of several HIV-AIDS protease inhibitors and the anti-cancer drug ifosfamide. The finding that genes encoding liver and intestinal drug transporters are also targets of CAR and PXR (Hakkola et al. 2018) presents additional opportunities but also additional challenges in drug development.

Definition

The 14-3-3 s are a family of <30 kDa proteins that exist as homo- and heterodimers within all eukaryotic cells. 14-3-3 proteins bind target proteins containing phosphothreonine or phosphoserine motifs; however, exceptions do exist. The docking of 14-3-3 s to their target can (i) cause conformational changes in the target protein, (ii) block sequence-specific or structural features on the target protein, or (iii) function as a scaffold allowing other proteins to dock.

Basic Mechanisms

Recognizing Covalent Modifications

Evolution has provided the cell with a repertoire of 20 amino acids to build proteins. The diversity of amino acid side chain properties is enormous, yet many additional functional groups have been selectively chosen to be covalently attached to side chains, and this further increases the unique properties of proteins. These additional groups play a regulatory role allowing the cell to respond to changing cellular conditions and events. Known covalent modifications of proteins now include phosphorylation, methylation, acetylation, ubiquitylation, hydroxylation, uridylylation, and glycosylation, among many others. Intense study in this field has shown the addition of a phosphate moiety to a protein can result in several potential effects including control of enzymatic activity, the shuttling of proteins between cellular compartments, and regulation of proteolytic degradation. More recently the study of signal transduction events has provided a new understanding of the regulation of cellular activities by protein-protein interaction, and many of the covalent modifications mentioned above perform their function by providing specific docking sites for other proteins. Again, the field to protein

https://doi.org/10.1007/978-3-030-57401-7

phosphorylation was a forerunner in recognizing and characterizing this property of covalent modifications, and the 14-3-3 proteins were the first protein shown to specifically bind a phosphoserine or phosphothreonine motif. Thus, the generation of specific docking sites for other proteins is an additional, regulatory function for protein phosphorylation. Other phospho-specific binding modules that can be recognized by amino acid sequence within proteins include leucine-rich repeats (LRR), forkhead-associated (FHA), WW, FF, tetratricopeptide repeat (TPR), MH2, WD40, polobox, and BRCA1 carboxyl-terminal (BRCT) domains for serine and threonine phosphorylation and Src homology 2 (SH2) and protein tyrosine binding (PTB) domains for phosphotyrosine. It is possible that additional phospho-specific binding modules exist, although no new ones have been identified for several years now, suggesting the inventory is complete.

The 14-3-3 proteins were initially catalogued as abundant brain proteins and designated 14-3-3 based on their chromatography column elution fraction and position after starch gel electrophoresis (Bridges and Moorhead 2005). Defining the role for these proteins began many years later when they were identified initially as activators of tryptophan and tyrosine hydroxylases, and then as regulators of protein kinase C and the protein kinase Raf-1, and as a direct binding protein for the polyomavirus middle T antigen. This was followed by the key observation that binding of 14-3-3 to its target protein was dependent on the phosphorylation of the target protein. Since this discovery, 14-3-3 s have continuously surfaced as regulators of a multitude of phosphorylation-dependent cellular events (Yaffe 2002; Mackintosh 2004; Bridges and Moorhead 2005; Ballone et al. 2018).

14-3-3 Sequence Conservation, Structure, and Function

Cloning and genome sequencing has shown there to be multiple 14-3-3 genes in all eukaryotic organisms with 12 in *Arabidopsis*, 7 in mammals, and 2 in *Saccharomyces cerevisiae*, *C. elegans*, and *D. melanogaster*. No 14-3-3 or 14-3-3-like genes have been noted any archaeal or bacterial genomes. The *S. cerevisiae* 14-3-3 isoforms are encoded by *BMH1* and *BMH2*, and deletion of either does not cause growth defects, but the double deletion of both is lethal. The 14-3-3 s are highly conserved across species (Fig. 1a) with divergence occurring on the N- and C-termini. The 14-3-3 s have acidic pI values, are small in size (<28–32 kDa), and form homo- and heterodimers. More than 40 crystal structures have been elucidated for the unliganded form and 14-3-3 in complex with a small molecule and/or high-affinity phosphopeptide from a known target protein (Bridges and Moorhead 2005). Dimers form a cup shape with the most highly conserved amino acids lining the inside of the cup (Fig. 1b). It is this conserved inner surface that functions as docking site for the phosphoprotein(s). Each subunit has the ability to bind a phosphopeptide, and as shown in Fig. 1c, phosphopeptides dock in an extended antiparallel orientation. Residues equivalent to Lys ^{49}, Arg ^{56}, Arg ^{127}, and Tyr ^{128} of human 14-3-3ζ are completely conserved in every 14-3-3 known, and it is these residues that are responsible for direct interaction with the phosphate moiety of the bound phosphoprotein (Fig. 1c, d). It is interesting to note that crystallization of the nonsense-mediated decay regulatory protein, SMG7 (suppressor with morphogenetic effects on genitalia 7), revealed structural resemblance of one of its TPR domains to one monomer of a 14-3-3 protein, even with very limited (<10%) sequence homology. Additional work showed that this region, like 14-3-3, binds peptides in a phosphorylation-dependent manner.

When 14-3-3 s were first identified as phosphorylation-dependent binding proteins (note that a selection of non-phosphorylated targets are known), target protein phosphorylation sites were mapped, and it was immediately apparent that 14-3-3 s bound preferentially to specific phosphorylation motifs. The advent of oriented peptide libraries and their application to 14-3-3 binding specificity confirmed this first motif (RSX1, 2pSXP, where R is arginine, X is any amino acid, S is serine, pS is phosphoserine, and

P is proline) that is now described as mode I binding. The peptide library method also pulled out another high-affinity binding motif now designated mode II (RXXXpSXP).

In addition to these initially characterized 14-3-3 binding motifs, other studies identified 14-3-3 binding to the C-termini of proteins, and this mode, or mode III, is now recognized as a significant target for 14-3-3 s. This motif was first identified in the plant plasma membrane H^+-ATPase, where the C-terminal sequence QSYpTV-COOH was found to bind 14-3-3 resulting in relief of inhibition of the enzyme by the C-terminus. Binding and relief of inhibition are dependent upon phosphorylation of the second to last residue, in this case a threonine. In a genetic screen of random peptides aimed to identify C-terminal signal motifs that override endoplasmic reticulum (ER) retention of proteins destined for the cell plasma membrane, a group of C-terminal peptides that function through an interaction with 14-3-3 were identified, and this is much like the sequence of the H^+-ATPase C-terminal sequence. The genetic screen suggested preference for a hydrophobic amino acid at the C-terminus and a serine or threonine at −2 from the C-terminus. Further work has defined this binding motif as SWpTX $_{\{Pro\}}$-COOH (where pT is phosphothreonine, X is any amino acid except proline, and COOH is the carboxyl-terminus of the protein). Interestingly, a number of plasma membrane receptor proteins carry this motif.

Another novel 14-3-3 binding motif was uncovered during studies on histones and should be designated mode IV (Macdonald et al. 2005). Histones are among the most conserved proteins known with covalent modification of their tails, which includes lysine acetylation and methylation, arginine methylation, and seine phosphorylation, being responsible for altering access to DNA by charge neutralization and for generating high-affinity binding sites for other proteins. Acetylated lysine and methylated lysine residues are known to dock bromo- and chromodomains, respectively. Histone H3 is phosphorylated at Ser-

10 and 28, which are both preceded by the sequence for Ala-Arg-Lys (ARK). The precise function of this modification was unknown until the N-terminal 20 amino acids were synthesized as unmodified, acetylated (Lys-9 and 14), and acetylated plus Ser-10 phosphorylated peptides and were used for affinity chromatography with HeLa cell nuclear extracts. The only proteins found to bind specifically to the phosphorylated and acetylated (and not acetylated only) versions were 14-3-3 proteins ε, ζ, and γ. The crystal structure of 14-3-3ζ complexed with the acetylated and phosphorylated peptide (AR $_{Ac}$KpSTGG $_{Ac}$K, where $_{Ac}$K is acetylated lysine and pS is phosphoserine) revealed that the basic residues lining the binding pocket as shown in previous structures bind the phosphate moiety. Mode I and II binding motifs have a proline at +2 that allows the bound peptide or protein to change direction and exit the binding cleft. Here positions +2 and +3 have glycine residues that perform the same function. Interestingly, peptides with a glycine at the +2 position were identified as 14-3-3 binding in the original oriented peptide binding studies. The acetyl group at lysine 9 is folded back, and hydrogen bonded to the backbone amide. The exit from the cleft after the two glycines means that acetyl-lysine 14 is not in the binding cleft. Although making no contacts with 14-3-3, acetyl-lysine 14 is thought not to be accessible in any way to proteins that bind acetyl-lysine motifs, through motifs such as bromodomains. This structural study nicely demonstrates how 14-3-3 binding can mask another structural feature altering a property of the protein (see below for 14-3-3 roles).

Modes of Action

Early work on 14-3-3 proteins placed researchers in a peculiar position of trying to define the precise function of 14-3-3 s. This conundrum came from the large number of and apparently diverse types of target proteins. Continued work has brought more and more insights, and it is fairly well accepted that 14-3-3 s play potentially three functions when bound to a target. They are (i) 14-3-3 directed conformational changes, (ii) 14-3-3 blockage of sequence-specific or structural features, and (iii) scaffolding.

14-3-3 directed conformational changes. The 14-3-3 proteins are primarily α-helical and are thus described as rigid in nature. The 14-3-3 structure in the presence of phosphopeptides or the target enzyme serotonin *N*-acetyltransferase supports this notion as no change in 14-3-3 shape is observed in the co-crystals. This has led to the molecular anvil or clamping hypothesis for 14-3-3 function whereby the sturdy 14-3-3, upon binding certain targets, causes them to be reshaped and thus altering their function. This was first described for the enzyme serotonin *N*-acetyltransferase. Serotonin *N*-acetyltransferase is normally catalytically inefficient and after phosphorylation and 14-3-3 binding displays increased Vmax and increased substrate affinity. The binding of 14-3-3 causes a local alteration in enzyme, reshaping the active site. More recently the binding of 14-3-3 to chicken mannitol-1-phosphate dehydrogenase was shown to inactivate the enzyme upon completion of mannitol biosynthesis. This concept can also be extended to long-distance reshaping of proteins as well where it is thought that 14-3-3 binding can expose or hide protein features or motifs distant from the site binding. For instance, data now support the idea that 14-3-3 binding to several nuclear histone deacetylases (HDACs) causes exposure of a nuclear export sequence (NES) and shuttling from the nucleus.

14-3-3 blockage of sequence-specific or structural features. The physical association of 14-3-3 with a target can also mask or occlude sequence-specific motif or structural features. Examples include the masking of nuclear localization or export sequences, and as introduced above, it has been well characterized that the C-terminus of the plant plasma membrane H + -ATPase inhibits the activity of the enzyme. After phosphorylation on a mode III motif, 14-3-3 binding removes the tail of the enzyme, and the ATPase is activated. Another example of 14-3-3 function by sequence masking has been noted for several proteins synthesized in the endoplasmic reticulum (ER) and destined for the plasma membrane. Many proteins synthesized in the ER are retained there by a di-arginine motif that is "recognized" by the coat protein complex I (COPI) retention machinery. Using an affinity-binding method,

14-3-3 s were identified as interacting proteins for the dibasic motif of the C-terminus of the potassium channel α subunit, Kir6.2. 14-3-3 proteins do not recognize the monomeric form of the Kir6.2 tail but do bind the multimeric Kir6.2 complex and compete for binding to the dibasic region with the COPI machinery. This suggests that bound 14-3-3 masks the COPI interaction site and thus causes release of Kir6.2 from the ER.

Scaffolding. Because 14-3-3 s can potentially bind more than one phosphoprotein at once due to the presence of two phosphopeptide-binding sites in a dimer, it has been postulated that they play this role in vivo. Direct observation of this phenomenon is difficult to show, but data from several groups support this idea.

Binding Specificity Among 14-3-3 Isoforms

It is not clear why some organisms have two 14-3-3 isoforms while others have up to 12. Binding 14-3-3 inhibits the plant enzyme nitrate reductase, and there appears to be no selectivity between plant 14-3-3 isoforms; in fact yeast and human isoforms appear to work equally as well in vitro. The best example where selectivity has been demonstrated is human 14-3-3σ. 14-3-3σ preferential homodimerizes with itself, and crystallization revealed a structural basis for this isoform's dimerization properties as well as for its specific selectivity for target binding proteins. Here partner specificity is the result of amino acid differences outside of the phosphopeptide-binding cleft.

14-3-3 Interactome

In 2004, ~350 proteins had been identified in global 14-3-3 interaction studies with the most astounding thing to emerge being the vast repertoire of cellular processes that 14-3-3 plays a role in (Mackintosh 2004). Several early studies purified 14-3-3 as an effector molecule that regulated some assayable property of a protein, or 14-3-3 was simply found as a co-purifying protein with some specific target. One of the best-characterized examples is the purification of 14-3-3 as inhibitor of plant nitrate reductase. In the first global study to find new 14-3-3 interactors, yeast 14-3-3 s (BMH1 and 2) were coupled to a matrix, and a plant extract passed over this affinity column to allow proteins to bind. These were affinity eluted with mode I phosphopeptide and released proteins identified. This work found mostly higher abundance metabolic enzymes as the primary targets. Later studies have employed a similar approach or used specific human 14-3-3-isoforms. Identified targets include proteins involved in many metabolic pathways, protein trafficking, signal transduction, and transcriptional regulation. Prior to 2015, Scansite was used as the standard predictor to identify potential 14-3-3 binding sites based on mapped phosphorylation sites. This tool was developed using a limited number of known 14-3-3 binding sites that all essentially conformed to a mode I motif. By 2015, high-throughput mass spectrometry studies had catalogued more than 2000 phosphoproteins that dock 14-3-3 s. Using this updated dataset, a new 14-3-3 binding predictor was developed for a motif spanning from −6 to +4 around the phospho-binding site ((Madeira et al. 2015) and http://www.compbio.dundee.ac.uk/1433pred). At the time of publication (2015), this new software predicted the number of 14-3-3 binding sites in the human proteome to be 10,881 derived from 5483 proteins, constituting more than 9% of all serine/threonine phosphosites in the human proteome databases.

Pharmacological Intervention

The 14-3-3 s are abundant eukaryotic proteins that have emerged as key regulators of a vast number of cellular functions. Protein-protein interactions are a fundamental component of protein function and essentially all biological process. As a consequence, aberrant protein-protein interactions are often a component of disease states, and modulation of protein-protein association by small molecules (drugs) has emerged as a component of drug discovery programs. As the list of 14-3-3 interacting proteins grows, links with human disease are becoming clearer. Structural studies have defined the interaction surfaces of 14-3-3 s with several targets and have now placed them as potential drug targets. Modulation of 14-3-3-

client binding could be stabilizing or disruption of the interaction with the majority of small molecules binding in or near the interaction site of the two proteins. Given the wide variety and important roles played by 14-3-3 s in biological process, it is no surprise that natural products have evolved to control 14-3-3 partner association. Fusicoccin is a fungal metabolite that promotes the association of 14-3-3 with the plant plasma membrane H + -ATPase. Other complex stabilizers include cotylenin and mizoribine. In addition, high-throughput screening identified pyrrolidone1 as a molecule that stabilizes 14-3-3 H + -ATPase interaction. Several peptide- (R18 and ExoS) and non-peptide-based molecules have also been discovered that disrupt binding of 14-3-3 to clients (Ballone et al. 2018). Just as intriguing is the discovery that the key energy metabolite adenosine monophosphate (5'-AMP) has been shown to stabilize the association of 14-3-3 with the carbohydrate-response element-binding protein (ChREBP) in a phosphorylation-independent manner. The co-crystal structure shows that 5'-AMP occupies the same region as the phosphoserine or phosphothreonine of the phospho-ChREBP.

Opioid Systems

Rainer K. Reinscheid and Stefan Schulz
Institut für Pharmakologie und Toxikologie, Universitätsklinikum Jena, Friedrich-Schiller-Universität, Jena, Germany

Definition

The term "opioids" was traditionally used in a narrow sense for drugs derived from opium that produce a pharmacological effect similar to morphine. After cloning of all opioid receptors and ligand precursor proteins, the term is now referring to a gene family and corresponding drugs acting on opioid receptors. Opioids include all natural and synthetic ligands that interact with the four endogenous opioid receptors (MOP, DOP, KOP, NOP). Endogenous opioid ligands are peptides derived from the precursor proteins proopiomelanocortin (*pomc*), proenkephalin (*penk*), prodynorphin (*pdyn*), and pronociceptin/orphanin FQ (*pnoc*). Traditionally, opioid receptors had been characterized by pharmacological tools which identified only three binding sites, termed mu, delta, and kappa. These are still referred to as "classical opioid receptors" and are promiscuous for their endogenous ligands as well as most of the opium-derived alkaloids. The classical opioid receptors also share the common antagonist naloxone. The nociceptin/orphanin FQ (N/OFQ) system is pharmacologically separate, yet genetically part of the family.

Basic Characteristics

Receptor Subtypes and Opioid Ligands

The three classical opioid receptors mu, delta, and kappa were first defined as promoting the analgesic actions of morphine and its derivatives (Zöllner and Stein 2007). Later, morphine analogues and related synthetic compounds were used to further refine their pharmacological characterization and anatomical distribution. All endogenous ligands of the classical opioid receptors are peptides that share the aminoterminal

sequence Tyr-Gly-Gly-Phe, known as the canonical opioid motif. They are derived from three different precursor proteins (Table 1) and can activate all three classical opioid receptors promiscuously, yet with different potencies. The precursor proteins each harbor multiple active neuropeptides that are released by proteolytic processing. The pro-opiomelanocortin precursor (POMC) is unique in that it contains the opioid peptide β-endorphin together with adrenocorticotropin (ACTH) and the melanocyte-stimulating hormones (MSH) that act on a family of pharmacologically distinct receptors. (NB: The peptides endomorphin 1 and 2 are questionable as endogenous ligands since the human genome contains no equivalent sequences.)

Cloning of the delta opioid receptor in 1992 (Evans et al. 1992; Kieffer et al. 1992) allowed for the swift molecular identification of all three classical opioid receptors and produced an unexpected fourth new family member, originally termed ORL-1 (opioid receptor-like). ORL-1 did not bind and was not activated by any of the known endogenous or synthetic opioid ligands and was thus an orphan GPCR. In 1995, two groups simultaneously identified the endogenous ligand of ORL-1 and termed it nociceptin or orphanin FQ (N/OFQ) (Meunier et al. 1995; Reinscheid et al. 1995). N/OFQ does not bind or activate the three classical opioid receptors and contains distinct structural motifs that ensure and explain its pharmacological selectivity. However, N/OFQ contains the amino terminal sequence Phe-Gly-Gly-Phe and still bears significant homology to the endogenous opioid peptides, especially dynorphin A. It was suggested that the pro-N/OFQ precursor gene may have arisen through gene duplication of the prodynorphin precursor gene.

Opioid Systems, Table 1 Endogenous opioid precursors and ligands

Name	Encoded opioid peptides	Other peptides (active at different receptors)
Proopiomelanocortin	β-Endorphin	ACTH, MSH (α, β, γ)
Proenkephalin	Leu-Enkephalin, Met-Enkephalin	
Prodynorphin	Dynorphin A, Dynorphin B, α-Neoendorphin	
Pronociceptin/ Orphanin FQ	Nociceptin/ Orphanin FQ	Nocistatin (receptor unknown)

Cloning of the human genome ultimately confirmed the existence of only four genuine opioid receptor genes. Receptor subtypes that had been postulated based on pharmacological tools could not be identified at the genetic level and splice variants of the classical opioid receptors did not reproduce the subtype-specific pharmacology. Current hypotheses suggest tissue-specific interaction of certain opioid receptors with other proteins that might be responsible for the distinct pharmacology, although no such protein partners have been identified yet.

Selective agonists and antagonists exist for all four opioid receptors (Table 2). In vivo studies with knockout mice have demonstrated that all main effects of morphine are mediated exclusively by the MOP receptor, including residual analgesic effects of presumably selective compounds such as DPDPE or deltorphin in DOP knockout mice. In general, pharmacological separation exists between the classical opioid receptors (DOP, KOP, and MOP) and the NOP-N/OFQ system. Only at unphysiologically high concentrations some alkaloid opioids produce weak effects at NOP. However, recent medicinal chemistry efforts have discovered bifunctional compounds with dual MOP-NOP activity, such as cebranopadol and AT-121 (Ding et al. 2018).

Physiology

At the cellular level, all opioid receptors interact via $G_{i/o}$-types of G proteins with the same second messenger systems, resulting in inhibition of cyclic AMP accumulation, opening of GIRK potassium channels, inhibition of voltage-sensitive Ca^{2+} channels, and stimulation of common downstream kinases such as MAPK or c-src. Overall, activation of opioid receptors leads to reduced neuronal excitability through hyperpolarization.

At the organism level, all opioids produce some form of analgesia by inhibiting nociceptive

KOP (κ)	Visceral and central	None	Dysphoria	None
NOP	Spinal (central: reversal of MOP-mediated analgesia)	Profound	Anxiolysis	None

signaling pathways, either in the brain or periphery (Table 3). MOP carries all central and peripheral effects of morphine that also include therapeutically undesirable side effects such as respiratory depression, constipation, and addiction. DOP-mediated analgesia is mainly produced at the spinal cord level while central DOP activation was shown to produce antidepressant effects, a combination that may have therapeutic potential in the treatment of chronic pain states. DOP full agonists were found devoid of abuse liability but unfortunately produced seizures in animal models, which limited their further clinical development. KOP receptors are expressed both centrally and in sensory fibers innervating many internal organs, so that KOP agonists were found to mediate visceral and central analgesia. However, centrally active KOP agonists also produce significant dysphoria, which has hampered further clinical development. Activation of NOP receptors produces opposing effects on nociception, depending on receptor localization. At the spinal level, NOP agonists produce analgesia, whereas supraspinal administration of NOP agonists reverses effects of endogenous or exogenous opioids, including reversal of stress-induced analgesia. This complex interaction between NOP and MOP signaling has spawned interest into developing bifunctional compounds that may possess a larger therapeutic window with reduced side effect profile. In addition, NOP agonists are potent anxiolytics. Both MOP and NOP agonists also produce significant sedative effects.

Receptor Regulation

After agonist stimulation, all opioid receptors undergo desensitization, followed by internalization and eventual recycling or degradation. Desensitization is intimately linked to agonist-dependent phosphorylation of serine and threonine residues located in the carboxylterminal tail of the receptors. Different G protein-coupled receptor kinases (GRKs) have been identified for each opioid receptor, sometimes depending on

Opioid Systems, Table 4 Opioid receptor regulation

[a]Amino acid numbering refers to the most common isoforms of human opioid receptor proteins

agonist selection (Table 4). For each opioid receptor, individual "phosphorylation bar codes" were identified that depend on agonist efficacy (Kliewer et al. 2019; Mann et al. 2019; Miess et al. 2018). Phosphorylation always proceeds along a hierarchical pattern and partial agonists usually stimulate only phosphorylation of the primary serine (S) or threonine (T) residue (Table 4).

Recently, phosphorylation-dependent desensitization was demonstrated as a necessary prerequisite for the analgesic effects of MOP opioids and the subsequent development of tolerance, while not affecting reinforcement or respiratory depression and constipation, commonly produced by MOP agonists (Kliewer et al. 2019). Transgenic mice expressing phosphorylation-deficient MOP showed increased analgesic responses to morphine and fentanyl without developing analgesic tolerance after chronic opioid infusions for 1 week. However, nontolerant mice still displayed signs of opioid withdrawal, respiratory depression, and constipation, demonstrating that opioid tolerance and addiction involve separate physiological and molecular mechanisms.

Receptor phosphorylation is a prerequisite for recruitment of beta-arrestins which induce separate intracellular signaling cascades (mostly involving kinases). Arrestin binding to the phosphorylated GPCR is also necessary for receptor internalization. It was recently proposed that signaling through G proteins may be required for the analgesic effects of opioids while arrestin signaling may be involved in the majority of undesirable side effects including respiratory depression and addiction (Manglik et al. 2016). However, phosphorylation-deficient MOP can no longer recruit arrestins, yet the transgenic mice still display the full spectrum of opioid side effects, raising questions about this hypothesis (Kliewer et al. 2019).

Desensitization, phosphorylation, and internalization of other opioid receptors have also been investigated in vitro and in vivo. In general, phosphorylation-deficient opioid receptors no longer desensitize upon prolonged agonist exposure, are unable to recruit arrestins, and thus do not internalize. It remains to be seen whether this novel understanding of opioid receptor regulation can improve the development of future opioid analgesics.

Drugs

Therapeutic Applications and Abuse

Only alkaloid and synthetic MOP agonists are clinically used, primarily for control of severe pain. These include the common analgesics morphine, hydrocodone, oxycodone, codeine, fentanyl, methadone, and buprenorphine. Heroine is a more potent morphine analogue that is commonly abused by opioid addicts but has no clinical application. Prolonged administration of these compounds produces tolerance and strong

reinforcing effects, ultimately leading to addiction that is characterized by severe withdrawal symptoms upon cessation of drug intake. Weak partial agonists such as buprenorphine usually possess lower abuse liability and a reduced risk of fatal overdose, but are still addictive after prolonged administration.

In the last decade, massive over-prescription of opioid analgesics has led to the so-called "opioid crisis," in particular in the United States of America, with an estimated two to three million opioid-addicted Americans and an average of 130 deaths per day by accidental opioid overdose. This public health problem has rejuvenated the search for "safer opioids," especially devoid of the respiratory depressant effects of common opioid analgesics.

It was recently suggested that differential intracellular coupling pathways could separate analgesic effects from undesirable or potentially hazardous effects of MOP agonists. The concept of "biased signaling" posits that MOP agonists preferentially activating the G protein pathway should be mainly antinociceptive, while activation of the intracellular beta-arrestin pathway might be responsible for respiratory depression and constipation. Although it was possible to identify compounds inducing biased signaling at MOP in vitro (Manglik et al. 2016), clinical trials could not confirm the absence of undesirable side effects and failed to show therapeutic benefits compared to morphine. It is thus unclear at this time, whether the concept of biased signaling has any therapeutic potential or if it is an in vitro phenomenon that cannot be easily translated into a complex clinical application.

An alternative approach focuses on bifunctional ligands with agonist activity at both MOP and NOP, since co-administration of MOP and NOP agonists was found to reduce abuse liability while retaining analgesic drug effects. The first compound developed along this line was cebranopadol which is currently in clinical trials for treatment of chronic pain. Another promising candidate might be AT-121 which has partial agonist properties at both MOP and NOP and displayed no respiratory depressant or reinforcing effects in a primate model (Ding et al. 2018).

The diterpenoid (i.e., nonalkaloid) KOP agonist salvinorin A has recently entered the list of abused substances, mainly due to its hallucinogenic effects, although it also produces significant dysphoria and anhedonia. Salvinorin A has nanomolar affinity for KOP, but is also a partial agonist at dopamine D2 receptors, which may explain its atypical pharmacological effects in comparison to pure KOP agonists. Since selective DOP, KOP, and NOP agonists have no psychotropic effects, their abuse liability is considered low and no reports of illicit use have been published.

Synonyms

Cholesterol oxidation products; Oxygenated derivative of cholesterol; Oxygenated sterols

Definition and Introduction

Oxysterols are derived from cholesterol or related molecules and possess one or more additional oxygen-containing functional groups, which can exhibit potent biological activities. They tend to be more water-soluble than cholesterol by virtue of the additional polar functional groups which confer distinct physicochemical properties. Oxysterols are usually found at very low concentrations in biological samples (nM to μM), often at several orders of magnitude lower than cholesterol itself (Brown and Jessup 1999).

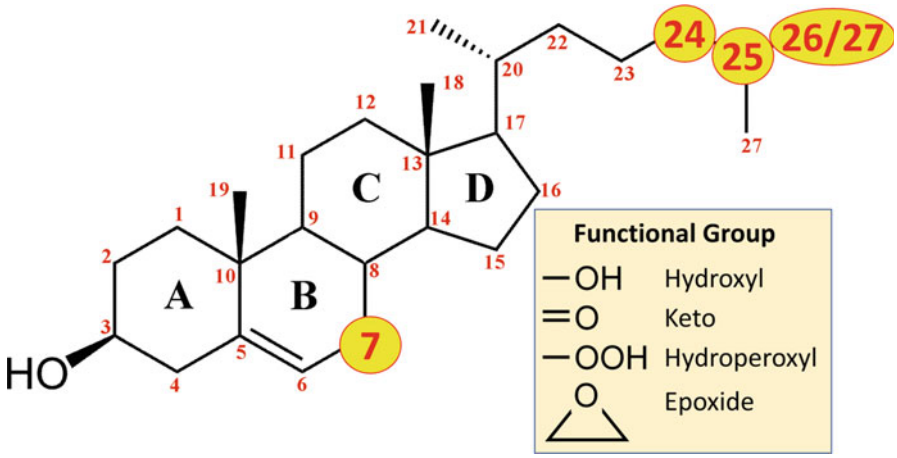
Initial interest in oxysterols stemmed from the idea that rather than cholesterol itself, some oxysterols control feedback regulation of cholesterol synthesis. Subsequent work indicated that oxysterols are likely to play only an auxiliary role in cholesterol homeostasis (Gill et al. 2008). However, work in the past decade has revealed important new roles for oxysterols in diverse fields, including immunity and development (Luu et al. 2016).

Nomenclature

The 27 carbons of cholesterol are numbered according to Fig. 1. In theory, many of these can be oxygenated to form distinct oxysterols. However, in practice the most commonly oxygenated sites are on carbons 7, 24, 25, and 26. Carbon-26 is more frequently referred to as 27 in the biological literature, and this nonsystematic name is used here for convenience. The oxygen-containing functional groups generally comprise hydroxyl, keto (oxo), hydroperoxyl, or epoxide groups. Primary oxysterols can be classified into side-chain (modified at C24, C25, or C27) or ring-modified (C7) oxysterols, while secondary oxysterols have more than one modification. Many of the individual oxysterol structures are provided in a recent review (Griffiths and Wang 2019).

General Principles of Oxysterols

In general, oxysterols can be made by both enzymic and nonenzymic means (**generators**). They can be



Oxysterols, Fig. 1 Numbered carbon structure of cholesterol showing where typical oxysterols are commonly oxygenated as well as the nature of the oxygen-containing functional group. Please note that more than one oxygenation can often occur, typically with oxygenation of the B-ring in addition to the side chain. Oxygenation at carbon-26 has most commonly been referred to as 27-oxygenated sterol, although it should be noted that this is a nonsystematic nomenclature

converted to other oxysterols (by **modifiers**) which can then have activities on various **effector** molecules. These three processes are summarized in the sections below with examples using the major players.

Generators

The oxidized low-density lipoprotein hypothesis of atherosclerosis led to considerable interest in free radical-mediated generation of oxysterols. Subsequently, interest shifted more to enzymic generation and modification of oxysterols. Many of the enzymes that generate oxysterols are cytochrome P450 monooxygenases, and three of these (CYP7A1, CYP7B1, CYP27A1) are pivotal in bile acid synthesis.

Free radical attack on unsaturated lipids can generate peroxyl radicals, resulting in oxysterol species like 7α-/β-hydroperoxycholesterol, which can decompose to 7α-/β-hydroxycholesterol and 7-ketocholesterol. This can occur in our bodies, and during processing of foods we then eat, although the contribution of dietary oxysterols to levels in humans is unclear (Brown and Jessup 1999). Originally, it was considered that many oxysterols that accumulate in disease states were produced by free radical attack. However, the source is now less certain as enzymic routes of generation are now known for many oxysterols which were previously thought to be exclusively nonenzymic in origin (e.g., 7-ketocholesterol).

Cholesterol 7α-hydroxylase (CYP7A1) catalyzes the first step in the classic bile acid synthesis pathway, producing 7α-hydroxycholesterol from cholesterol. CYP7A1 can also act on a precursor of cholesterol, 7-dehydrocholesterol, to make 7-ketocholesterol (Shinkyo et al. 2011). Consistent with this, patients who accumulate 7-dehydrocholesterol (due to a cholesterol synthesis defect, namely, Smith-Lemli-Opitz syndrome) also display elevated levels of 7-ketocholesterol.

Sterol 7α-hydroxylase (CYP7B1) is also a critical enzyme in bile acid synthesis, performing 7α-hydroxylation on side-chain oxygenated sterols like 27-hydroxycholesterol (Stiles et al. 2009).

Cholesterol 24-hydroxylase (CYP46A1) converts cholesterol into the more polar 24*S*-hydroxycholesterol (also known as cerebrosterol), providing the principal means by which excess cholesterol can be eliminated from the brain across the blood-brain barrier (Bjorkhem et al. 2019). In humans, CYP46A1 expression is restricted to the brain, whereas rodents have appreciable hepatic expression as well, highlighting that caution should be used when trying to extrapolate findings from mouse or rat models to humans.

Cholesterol 25-hydroxylase (CH25H) is not a cytochrome P450 but a microsomal di-iron-containing enzyme that converts cholesterol to 25-hydroxycholesterol. Its expression is dramatically induced in immune cells during inflammation (e.g., following treatment of macrophages with lipopolysaccharides) (Cyster et al. 2014).

Cholesterol 27-hydroxylase (CYP27A1) is a mitochondrial cytochrome P450, catalyzing the first step in the alternative bile acid synthesis pathway to produce 27-hydroxycholesterol from cholesterol (Bjorkhem et al. 2019). It can further oxidize the same carbon to ultimately produce cholestenoic acid. It is believed to be a significant mechanism by which cells (including macrophages) can eliminate excess cholesterol. Accordingly, patients deficient in this enzyme (cerebrotendinous xanthomatosis) have an abundance of cholesterol-filled macrophages (foam cells), despite having normal circulating cholesterol levels.

24*S*,25-Epoxycholesterol is made in a shunt in the cholesterol synthesis pathway but using the same enzymes (Gill et al. 2008). The key enzymes are squalene monooxygenase (or epoxidase) which introduces an epoxide group onto the isoprenoid squalene and the next enzyme, lanosterol synthase (or oxidosqualene cyclase), which then uses elegant molecular origami to fold the epoxide-bearing hydrocarbon into the four-fused ring structure characteristic of steroids. Partial inhibition of lanosterol synthase allows accumulation of mono-oxidosqualene which can be acted on again by squalene monooxygenase to introduce a second epoxide which ultimately becomes 24*S*,25-epoxycholesterol. This oxysterol can also be generated by the action of CYP46A1 on an immediate precursor of cholesterol, where CYP46A1 introduces the epoxide across the C24–C25 double bond of desmosterol. 24*S*,25-Epoxycholesterol plays a critical role in fine-tuning cell cholesterol homeostasis (Gill et al. 2008).

Modifiers

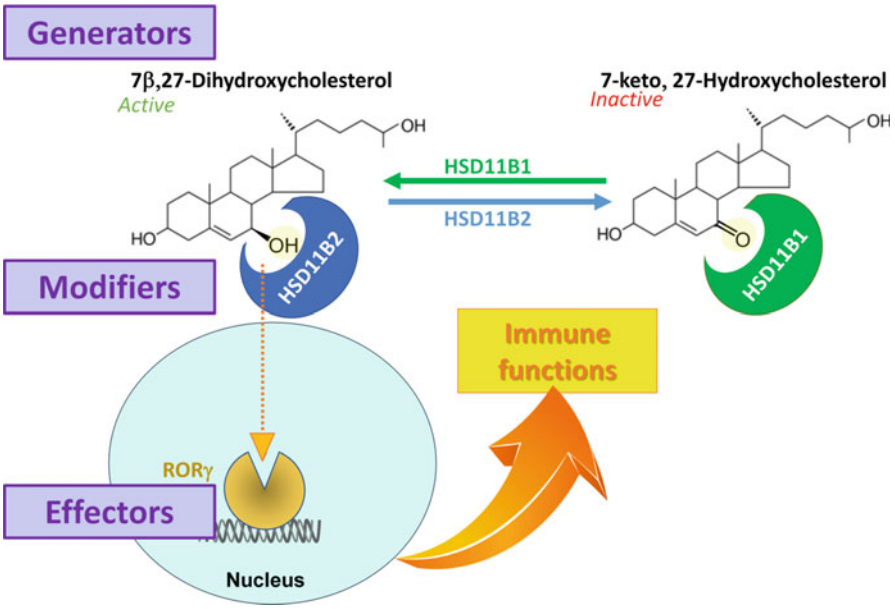
Oxysterols can be modified to other oxysterols which may alter their activities. Notable modifiers include members of the short-chain dehydrogenase/reductase superfamily such as the microsomally located enzymes HSD3B7, HSD11B1, and HSD11B2.

Hydroxy-Δ5-steroid dehydrogenase, 3β- and steroid delta-isomerase 7 (HSD3B7) is another enzyme involved in bile acid synthesis, oxidizing the 3β-hydroxyl to a keto group, as well as isomerizing the C5–C6 double bond to C4–C5. These modifications can deactivate the 7α,25-hydroxycholesterol ligand for the G-protein-coupled receptor, EBI2 (Cyster et al. 2014).

Hydroxysteroid 11β-dehydrogenase 1 (HSD11B1) functions mainly as an oxidoreductase and is best known for converting inactive cortisone to the active stress hormone cortisol in glucocorticoid target tissues. Cortisol is a ligand for both the glucocorticoid and mineralocorticoid receptors. In the context of oxysterols, HSD11B1 exhibits similar reactivity, reducing 7-ketocholesterol to 7-β-hydroxycholesterol (Mitic et al. 2013).

Hydroxysteroid 11β-dehydrogenase 2 (HSD11B2) functions as a dehydrogenase, deactivating cortisol to cortisone. HSD11B2 is highly expressed in mineralocorticoid target tissues, where it prevents cortisol acting as a ligand for the mineralocorticoid receptor. An analogous situation may exist with particular oxysterols. For instance, 7β,27-dihydroxycholesterol can activate the nuclear receptor RORγ (Fig. 2), but oxidation by HSD11B2 would be expected to produce an inactive 7-keto-derivative (Beck et al. 2019).

Esterification refers to the attachment of a fatty acid to the 3β-hydroxyl group of the sterol by an ester linkage. Like cholesterol, most oxysterols can be esterified in cells by either SOAT1 or SOAT2 (sterol *O*-acyl transferase 1/sterol *O*-acyl transferase 2, also known as ACAT1/ACAT2), or in the plasma by LCAT (lecithin cholesterol acyl transferase), where they can be transported mostly by lipoproteins. Esterification is another way that oxysterols are likely to be inactivated, as it is difficult to envisage an oxysterol ester binding to an effector, like a nuclear receptor, with the same affinity as an unesterified oxysterol ligand. It should be noted that most oxysterols found in the circulation and in diseased tissue are predominantly esterified (Brown and Jessup 1999), suggesting limited



Oxysterols, Fig. 2 **The origin and action of oxysterols generally involve three processes:** (1) **generation** of oxysterols from enzymic and nonenzymic reactions on cholesterol and related molecules; (2) **enzyme modifiers** convert specific oxysterols to active or inactive derivatives; (3) **effectors** transduce the biological effects of the oxysterols, often involving inducing particular transcriptional programs. The example given has been derived from Beck et al. (2019)

biological activity. Whether these esters can serve as stores of oxysterols, and how well they can then be liberated by sterol esterases, remains to be determined.

Other processes. As with cholesterol, oxysterols can be eliminated from cells by transporters like the ATP-binding cassette proteins ABCA1 and ABCG1. In humans, side-chain oxysterols like 24*S*-hydroxycholesterol can undergo reactions normally associated with hepatic metabolism of bile acids, steroid hormones, and drugs, such as sulfation and glucuronidation, which may facilitate their excretion from the body. Free radical-derived oxysterols, including 7-β-hydroxycholesterol and 7-ketocholesterol, are metabolized to unusual bile acids via novel branches of the alternative pathway (Griffiths et al. 2019).

Effectors

Oxysterols can have potent biological effects by binding to various effectors and eliciting a variety of transcriptional programs. These include nuclear receptors (LXRα/β, RORγ) which are ligand-activated transcription factors and G-protein-coupled receptors (GPCRs like EBI2 and Smoothened) which also transduce specific transcriptional programs, often in concert with small molecule activators.

Insig is like a brake for the activation of the SREBPs which are master transcriptional controllers of lipid metabolism. Binding of oxysterols to Insig (or cholesterol to Scap) prevents the proteolytic processing of SREBPs into active transcription factors and hence results in effective downregulation of lipogenic transcriptional programs. The oxysterols that can bind most avidly to Insig are those with oxygenated side chains like 25-hydroxycholesterol (Gill et al. 2008).

Liver X receptor α/β (LXRα/β) is a nuclear receptor where the endogenous ligands are oxysterols, with 24*S*-hydroxycholesterol, 27-hydroxycholesterol, and 24*S*,25-epoxycholesterol being particularly potent. Activation of LXRα/β favors cholesterol elimination from cells (for instance, through upregulation of *ABCA1* and *ABCG1*) and

from the body more generally by stimulating reverse sterol transport. LXRα/β activation also tends to dampen the immune response, providing one of the first glimpses into the importance of oxysterols in immunity (Spann and Glass 2013).

RAR-related orphan receptor gamma (RORγ) is another nuclear receptor and has been studied most with respect to the immune system. Notably in the thymus, RORγ promotes differentiation of thymocytes into a subclass of mature, pro-inflammatory T helper cells defined by their production of interleukin-17 (Th17 cells). A number of oxysterols can bind to RORγ, but 7α/β,27-dihydroxycholesterol is particularly potent. As shown in Fig. 2, oxidation by HSD11B2 of the 7β-hydroxy oxysterol to the 7-keto version will likely bar its ability to bind to and activate RORγ (Beck et al. 2019).

Epstein-Barr virus-induced G-protein-coupled receptor 2 (EBI2) is crucial for B-cell trafficking within lymphoid tissues and thus the humoral immune response in general, including antibody-mediated immunity. 7α,25-Dihydroxycholesterol is an especially potent ligand, binding to EBI2 at subnanomolar concentrations (Cyster et al. 2014).

Smoothened transduces the signal in the Hedgehog pathway of vertebrate development. Hedgehog binds to a multipass membrane receptor called Patched which then leaves the primary cilia where Smoothened is located. Various oxysterols can bind to Smoothened to activate it, upregulating a developmental transcriptional program. 24*S*,25-Epoxycholesterol is enriched in cilia from sea urchins and potently activates mammalian Hedgehog signalling by binding to Smoothened (Qi et al. 2019).

Oxysterols, Disease, and Concluding Remarks

Oxysterols have long been implicated in various diseases, including atherosclerosis, some cancers, and neurodegenerative diseases. Blood levels of certain oxysterols may be useful disease risk markers in some cases; however, it should be noted that accurately measuring oxysterol levels can be particularly challenging (Luu et al. 2016). In cell culture, oxysterols exhibit many properties that would be consistent with them contributing to pathogenesis. However, direct evidence of a particular oxysterol having a causal role in disease has been harder to attain. Specifically manipulating endogenous levels of a particular oxysterol is challenging, since the generation and metabolism of oxysterols share some of the same machinery as used in cholesterol, bile acid, steroid hormone, vitamin D, and xenobiotic metabolism. Oxysterol research has advanced significantly in recent years and continues to be a fruitful area of research.

Oxytocin

Maja Lozic and Mike Ludwig
Centre for Discovery Brain Sciences, University of Edinburgh, Edinburgh, UK

Synonyms

8-leucine-vasotocin; Pitocin (trade name); Syntocinon

Definition

Oxytocin is primarily involved in parturition and milk ejection, stimulating smooth muscle contraction in the uterus and mammary glands in female mammals. It is also known to contract smooth muscle in the male reproductive tract. Oxytocin is a peptide hormone secreted by the neurohypophysis and the hormonal targets for oxytocin in females are the myoepithelial cells that surround the alveolar channels in the mammary gland and the uterus and in males in the reproductive organs such as the seminal vesicles and epididymis. Oxytocin is also a neuropeptide, released into the brain and regulating sexual, maternal, social, and feeding behaviors. Several conditions are associated with altered oxytocin activity or effects. The main clinical disorder directly associated with altered circulating (neurohypophysial) oxytocin is preterm labor. Other conditions include a range of defects in social (e.g., autism spectrum disorders) and sexual behavior, which are primarily controlled by oxytocin released into the brain.

Basic Characteristics

Oxytocin is a small peptide hormone comprising nine amino acids arranged in cyclic form, which is maintained by a single disulfide bridge between cysteines 1 and 7. Together with the modified C-terminal amino acid, this confers resistance to rapid degradation in the blood stream, as well as providing a unique three-dimensional structure that complements the hormone-binding pocket of its receptor. In all mammals, oxytocin is very closely associated with the structurally related hormone vasopressin, both of which are derived by gene duplication from a common invertebrate ancestral hormone. Oxytocin is expressed as part of a polyprotein comprising more than one functional unit. Besides oxytocin, the gene also encodes a larger cysteine-rich polypeptide, neurophysin 1. Oxytocin mRNA encodes a pre-pro-polyprotein, which because of its N-terminal signal peptide is posttranslationally translocated into the lumen of the endoplasmic reticulum, where the signal is removed. The pro-polyprotein is then transferred to the Golgi apparatus and finally to acidic secretory vesicles. During this process, specific proteolytic enzymes cleave the oxytocin from neurophysin and catalyze C-terminal transamidation of the oxytocin, which remains associated with its neurophysin until released from the cell (de Bree 2000).

The principal sites of processing of the pre-prohormone into its final products are the cell bodies of the large magnocellular neuroendocrine neurones of the hypothalamus within the brain. These neurones produce either oxytocin or

vasopressin and are arranged symmetrically close to the third ventricle in two nuclei, the supraoptic nucleus and the paraventricular nucleus. The few thousand neurons located in both nuclei are characterized by long axons that project downwards out of the hypothalamus along the pituitary stalk ending in the posterior lobe of the pituitary gland (also called the neurohypophysis). From there the peptides are secreted into the blood after appropriate stimuli (Brown et al. 2013). Oxytocin secretion from the pituitary gland is triggered by the stimulation of the nipples, resulting in the milk-ejection reflex, and by the distension of cervix and vagina during labor. Oxytocin release in rodents and some other mammalian species is also stimulated by plasma hyperosmolality (high sodium) and hypovolemia, suggesting a regulatory role in natriuresis and blood volume for this hormone. Secretion also occurs during sexual arousal and ejaculation in many mammals, including in man. Oxytocin is also released during stress and (in some species) in response to food intake. Oxytocin secretion is suppressed by alcohol and opioids (Leng et al. 2012).

In addition, secretory granules containing oxytocin are released from the cell bodies and especially dendrites of the magnocellular neurons within the hypothalamus (Ludwig and Leng 2006). In the paraventricular nucleus, there are, as well as magnocellular neurons, smaller (parvocellular) oxytocin neurons that project not to the neurohypophysis but to sites in the caudal brainstem that are involved in the control of energy balance and to sites in the spinal cord involved in the control of erectile function and copulation (Argiolas and Melis 2013) and in the regulation of pain (Boll et al. 2018). Some scattered isolated neurones in the lateral and anterior part of the hypothalamus are between the paraventricular and supraoptic nucleus and some are located in the dorsomedial hypothalamic nucleus (Grinevich et al. 2016).

The anatomical distribution of oxytocin neurones and fibers is relatively consistent among mammals, but there is considerable species variation in oxytocin receptor expression and this is associated with differences in reproductive behavior. For example, in rodents oxytocin receptors are concentrated in brain regions involved olfactory processing, but in primates they are concentrated in regions in visual processing. Oxytocin (and vasopressin) are an integral part of the mammalian emotional circuitry and are associated with the emergence of social bonding, parental care, stress regulation, social communication, and emotional reactivity (Donaldson and Young 2008). Finally, several other organs, such as the gastrointestinal tract, heart, ovary, amnion, chorion, decidua, testis, epididymis, and prostate, have been reported to synthesize oxytocin (albeit at extremely low levels), suggesting a possible paracrine role for this hormone in these tissues.

Oxytocin Receptor Activation

Oxytocin elicits its physiological and pharmacological responses through the oxytocin receptor, a cell surface receptor belonging to the rhodopsin-like (type A) group of G-protein coupled receptors. So far, only one type of oxytocin receptor is known (but three different subtypes of vasopressin receptors). Due to its high sequence and structural homology with vasopressin, oxytocin has the ability to bind for all three types of vasopressin receptors, namely, V_{1a}, V_{1b}, and V_2 (Manning et al. 2012).

The oxytocin receptor is encoded by a single gene that is highly homologous across species, comprising three exons and in the human located on chromosome 3p25. In spite of the importance of the oxytocin receptor for the induction of labor and mammary function, little is known about the transcriptional regulation of the oxytocin gene. It is regulated by steroids such as estrogens, although probably in a nonclassical manner whereby activated estrogen receptors act indirectly via other transcription factors within the upstream promoter region of the gene. Other specific transcription factors such as MafF are also involved, acting within an intron of the receptor gene (Gimpl and Fahrenholz 2001). Moreover, DNA methylation within different regions of the gene appears to correlate with cell specificity of expression. There is evidence of physiological

redundancy in some functions; oxytocin and oxytocin receptor knockout mice appear to undergo parturition normally (Ratajczak and Muglia 2008).

Posttranslational modifications, localization in special plasma membrane compartments (lipid rafts or caveolae), and interactions with downstream signal transduction components modify oxytocin receptor signaling. Importantly, the oxytocin receptor responds to activation by oxytocin by rapid desensitization and internalization, as is typical for most hormones that are secreted in a pulsatile fashion. Up-regulation of the oxytocin receptor system in a cell requires either a delay in the desensitization process or simply an increase in the expression of the oxytocin receptor gene. At full-term pregnancy, the levels of oxytocin receptor gene transcripts appear to be increased almost 100-fold in the uterus.

The oxytocin receptor interacts with heterotrimeric G protein complexes (Gα, Gβ, and Gγ) and can be linked to multiple signaling pathways depending on the specific G protein complex involved (e.g., Gαq, Gαo, Gαi). Upon ligand binding to the complex, the β and γ subunits dissociate from the Gα-protein. Several different α-protein subforms can contribute to the composition of the complex. Depending on the type of Gα protein, the functional outcome of receptor activation can be stimulatory or inhibitory.

The main signaling pathway is the Gq/PLC/Ins3 pathway (Gimpl and Fahrenholz 2001; Arrowsmith and Wray 2014). Oxytocin receptor activation stimulates phospholipase C (PLC) resulting in the generation of inositol 1,4,5-trisphosphate (IP3) and 1,2-diacylglycerol (DAG). Whereas IP3 mobilizes Ca^{2+} from intracellular stores, DAG activates protein kinase C (PKC), leading to phosphorylation of a number of other downstream target proteins. In addition, Ca^{2+} influx through voltage-operated Ca^{2+} channels contributes to the full response after myometrial oxytocin receptor activation. The increase in cytosolic calcium concentration is the main trigger for smooth muscle contraction but also plays a role in neuronal oxytocin responses such as transmitter release (Busnelli and Chini 2018; Jurek and Neumann 2018). MAPK (ERK5) and the RhoA/Rho kinase pathways are also activated, contributing to increased prostaglandin production and direct contractile effect on myometrial cells. OTR activation also leads to activation of ERK1/2 in myometrial and endothelial cells (proliferation), an effect that involves the release from $G_{q/11}$ and transactivation of the EGFR. In decidua activation of oxytocin receptor induces PGF2α release, which enhances uterine contractions, cervical ripening, and luteolysis. This effect is G_i- and $G_{q/11}$-dependent and involves Ca^{2+}-mediated translocation of PLA_2 from the cytoplasm to cell membranes, in addition to the activation of PLA_2 by MAPK. When only a minor fraction of OTRs is located in lipid rafts (caveolae), they inhibit cell proliferation (via G_i, PLC, c-Src, PI3K, EGFR transactivation and persistent ERK1/2 activation), but when targeted to lipid rafts they have a strong mitogenic effect (via $G_{q/11,\ b/c}$ release, EGFR transactivation and transient ERK1/2 activation). Oxytocin receptor-activated ERK signaling is also involved in regulating selective behaviors in the brain, including social and maternal behaviors. In the cardiovascular system, oxytocin receptor is associated with the ANP-cGMP and NO-cGMP pathways, which reduce the force and rate of contraction and increase vasodilatation.

O

Oxytocin Effects

Parturition

Oxytocin is one of the most potent uterotonic factors, a property that is used today in the induction of birth. Shortly before the end of pregnancy (term), estrogen concentrations rise and there is functional progesterone withdrawal. Oxytocin receptors are up-regulated in the myometrial smooth muscle layers of the uterus and become sensitive to the increasing pulses of oxytocin released from the posterior pituitary. Labor and birth are a result of a positive feedback loop (Ferguson reflex) resulting in expulsion of the uterine contents. Part of this involves the induction of local prostaglandin-F2α expression in the myometrium, which, like oxytocin, causes smooth muscle contractility by mobilizing intracellular Ca^{2+} stores. Factors promoting

myometrial quiescence, such as progesterone and the hormone relaxin in most species (though not in humans), decrease. Uterine contractility, along with fetal movements, elicits the Ferguson reflex, whereby neuronal afferents from the cervix via the vagal and hypogastric nerves result in further activation of the magnocellular neurons in the hypothalamus.

In rats and other species, the magnocellular oxytocin neurones give rise to intense synchronized bursts of electrical activity, which cause the release of increasingly large secreted pulses of oxytocin. Activation of the magnocellular neurons also results in dendritic oxytocin release from the cells within the hypothalamus. Dendritic oxytocin release induces functional neuronal plasticity to further orchestrate the synchronization within the magnocellular nuclei. Oxytocin release in a pulsatile manner is important since continuous and sustained release of oxytocin leads to oxytocin receptor desensitization and a slowing of the birth process. Oxytocin is involved not only in the expulsion of the fetus at birth, but also subsequently of the placenta, and then critically ensures the contraction of the empty uterus and to separate the placenta from the womb. Therapeutically, oxytocin may be given to support this process, after giving birth if not before.

Lactation

Oxytocin is not involved in mammary gland development, nor in milk synthesis and secretion, but transgenic mouse studies have shown that oxytocin is essential for milk let-down in the mammary glands. Oxytocin is released from the posterior pituitary in response to suckling at the nipples, causing contraction of the smooth muscle cells surrounding the mammary alveoli and release of milk. As in the uterus, oxytocin receptors are increasingly expressed in the myoepithelial cells of the developing alveoli towards the end of pregnancy, and their responsiveness to oxytocin also increases. Studies in rats indicate that there are short bursts of electrical activity every 5–15 min in the magnocellular neurons of the hypothalamus, leading to pulses of oxytocin release from the posterior pituitary and release of milk to the suckling pups (Rossoni et al. 2008). This appears to be a feature common to all mammals; imaging in humans has shown a similar intermittent milk-release in response to continuous suckling. Oxytocin receptors in the mammary gland become desensitized if exposed to continuous oxytocin delivery, and require relatively high concentrations of oxytocin within a pulse.

Copulation

The oxytocin-dependent induction of smooth muscle contractility in the reproductive system is not limited to female mammals. In male mammals, pulses of oxytocin can be measured accompanying the contraction of smooth muscle cells in the epididymis and vas deferens, associated with ejaculation. Oxytocin produced locally within the testes is responsible for the slow peristaltic contractility of the seminiferous tubules associated with sperm release from the seminiferous epithelium. Oxytocin also promotes penile erection, through actions at the hypothalamus and spinal cord; the spinal effects are mediated by parvocellular oxytocin cells of the paraventricular nucleus, but the hypothalamic actions may reflect effects of dendritic release from magnocellular neurons (Argiolas and Melis 2013).

Hypothalamo-Pituitary-Gonadal Axis

Oxytocin not only has direct effects on receptors within the reproductive organs themselves, but also influences the hypothalamo-pituitary-gonadal axis. Activation of oxytocin receptors on the gonadotropin-producing cells of the anterior pituitary causes activation of phosphoinositide-3-kinase and intracellular Ca^{2+} release, which together interact with the GnRH-induced signaling activity in the same cells. Whether this oxytocin, like GnRH, arrives through the portal system from the hypothalamus or comes from the posterior pituitary is not known, but it does suggest that the hormones of the HPG axis can be modulated at times of high oxytocin expression, for example, at the end of pregnancy or during lactation.

Natriuresis

The magnocellular oxytocin neurons are, like vasopressin neurones, osmoreceptors; they

respond to increased osmotic pressure by releasing oxytocin, but oxytocin is released in a more sustained fashion than during uterine contraction and lactation, the circulating levels increasing without evident pulsatility (Leng and Russell 2019). In animal models, it has been shown that oxytocin can directly stimulate the kidney to increase Na^+ excretion (natriuresis), presumably via oxytocin receptors, though possibly also via vasopressin V1 receptors, with which oxytocin can interact weakly. However, much of this effect is due to the stimulation of cardiac atrionatriuretic peptide secretion, which in turn influences the kidney. The natriuretic response is species-specific, with humans and sheep exhibiting little effect compared to rodents.

Behavioral Effects of Oxytocin

Since oxytocin is largely unable to cross the blood–brain barrier, the various behavioral effects of oxytocin must be due to centrally released hormone, including that from the dendrites of the magnocellular neurones (Ludwig and Leng 2006). Moreover, such effects do not correlate with levels of oxytocin measured in blood, and these do not reflect the levels in cerebrospinal fluid. Central oxytocin is responsible for a range of maternal and affiliative behaviors: for example, in sheep oxytocin induces the bonding of a newborn lamb with its mother, while in the female prairie vole, it promotes monogamous pair-bonding. It is generally described as "anti-anxiolytic," encouraging more exploratory and olfactory behavior in laboratory animals. It is also linked to sexual responsiveness and behavior in female and male rats, respectively (Neumann and Landgraf 2012).

Cholecystokinin (CCK) can stimulate hypothalamic oxytocin secretion via CCK receptors on vagal efferents from the stomach. Since CCK is produced by the duodenum following a meal, these vagal actions evidently mediate a satiety reflex. It has been shown experimentally in rats that injection of oxytocin into the brain can suppress appetite, and there have been numerous claims of similar effects in humans (Leng and Sabatier 2017), though possibilities for therapeutic approaches using oxytocin in certain mental disorders are very limited, due to the difficulty of targeting the brain by a peptide that cannot cross the blood-brain barrier. Although it has been proposed that oxytocin applied as a nasal spray might circumvent this difficulty by reaching the brain directly across the nasal mucosa, the findings from such studies are not without substantial controversy (Leng and Ludwig 2016).

Drugs

Agonists

Oxytocin is a potent uterotonic, used in obstetrics as an intravenous infusion to induce labor in women with sufficiently ripened cervix, to augment hypotonic uterine contractions during labor, in the prevention and treatment of postpartum hemorrhage, and in the medical treatment of miscarriage (Molitch and Schimmer 2018).

The most common adverse effects following parenteral application of oxytocin are arrhythmias, headache, nausea, and vomiting. There are two caveats to intravenous application of oxytocin: rapid infusions can cause peripheral vasodilation, manifested in patients as hypotension followed by the reflex tachycardia due to the subsequent activation of baroreceptor reflex, whereas excessive doses of intravenously administered oxytocin may lead to uterine hyperstimulation and consequent complications for both mother and fetus. These complications include uterine rupture, impaired fetal oxygenation as a result of decreased uterine perfusion and cervical and/or fetal trauma during forced propulsion of fetus through the incompletely ripened cervix.

In recent years, a growing number of studies have speculated that oxytocin delivered nasally could be used as a possible treatment option for human conditions characterized by social deficits, such as autism spectrum disorder (Yamasue and Domes 2018). Further research directed towards unraveling the pharmacokinetic profile of intranasally applied oxytocin is yet to show if this approach may have any benefit in any psychiatric disorders.

Carbetocin is an oxytocin-derived analogue with a longer half-life than oxytocin itself. It is

used to prevent postpartum hemorrhage, especially in prevention of uterine atony after caesarean section. Unlike oxytocin, carbetocin can be applied parenterally in a single dose. It has also been shown to possess better tolerability and safety profile than oxytocin. Heat-stable formulation of carbetocin, which does not require cold-chain transport and storage, may be used to reduce the maternal mortality due to postpartum hemorrhage in less privileged parts of the world.

Antagonists

Discovered more than three decades ago, atosiban still remains the only oxytocin receptor antagonist that has found application in clinical medicine. For its ability to inhibit uterine contractions when given as an intravenous infusion, atosiban is used as a tocolytic in the acute treatment of preterm labor (Akerlund 2006). However, its lack of selectivity (atosiban shows even higher affinity for vasopressin V1a receptors than for oxytocin receptors) and its peptide nature make it unsuitable for prolonged maintenance treatment as a result of the limited oral bioavailability. A considerable effort has been made to identify novel, orally active, nonpeptide selective OTR antagonists.

Retosiban is an orally active, selective oxytocin receptor antagonist with tocolytic properties that shows high affinity for human oxytocin receptor (Ki = 0.65 nM). It is an antagonist at least 15-fold more potent on the oxytocin receptor than atosiban, with a better selectivity profile. Results from phase 2 clinical studies indicated that retosiban has a favorable safety and tolerability profile, but the phase 3 clinical studies have recently been terminated.

Epelsiban and ciglosiban are selective orally available oxytocin antagonists, suggested to be effective in the treatment of premature ejaculation.

The ability of oxytocin receptor antagonists to reduce the frequency of uterine contractions in nonpregnant women has been used in clinical studies as a potential means of increasing implantation and pregnancy rates prior to embryo transfer, in patients undergoing subfertility treatment through in vitro fertilization. However, randomized clinical trials have yet to provide reasonable grounds for using oxytocin receptor antagonists in assisted reproduction.

P450 Monooxygenase System

Ulrich M. Zanger
Dr. Margarete Fischer-Bosch Institute of Clinical Pharmacology, Stuttgart, Germany

Synonyms

Cytochrome P450 (CYP); Cytochrome P450 isozymes; Cytochrome P450 monooxygenases; Mixed-function oxidases

Definition

Cytochrome P450 (CYP) monooxygenases, also called mixed-function oxidases, are versatile hemoprotein enzymes that catalyze the cleavage of molecular oxygen to incorporate one oxygen atom into a substrate molecule and one atom into water (Ortiz de Montellano 2015). The general stoichiometry of the reaction is as follows (S-H, substrate):

$$NADPH + H^+ + O_2 + S\text{-}H \rightarrow NADP^+ + H_2O + S - OH$$

The numerous biotransformations catalyzed by cytochrome P450 enzymes include aromatic and aliphatic hydroxylations, epoxidations of olefinic and aromatic structures, oxidations and oxidative dealkylations of heteroatoms, and some reductive reactions. Cytochromes P450 of higher animals may be classified into two broad categories depending on whether their substrates are primarily endogenous or xenobiotic substances. Thus, CYP enzymes of families CYP1, CYP2, and CYP3 catalyze the phase I metabolism of most drugs and other xenobiotics, often a prerequisite for a phase II conjugation reaction and subsequent elimination from the body. Sometimes the product of CYP-catalyzed reactions can be pharmacologically active (in this case the substrate is termed a prodrug), or it may be carcinogenic or toxic. The CYP enzymes of families CYP4 to CYP51 primarily participate in various physiological pathways of fatty acids, eicosanoids, steroid hormones, bile acids, prostaglandines, and other endogenous compounds.

Basic Characteristics

Cytochrome P450 Electron Transport Systems

Cytochrome P450 monooxygenase function depends on electron transport chains, in which electrons are transferred from cellular pyridine nucleotides (NADPH/NADH) to the P450 heme moiety. In vertebrates, there are two principal types of P450 electron transfer chains. One is

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,

P450 Monooxygenase System, Fig. 1 P450 monooxygenase system. (**a**) Components of microsomal P450 monooxygenases. (**b**) Components of mitochondrial P450 monooxygenases

found in the endoplasmic reticulum (ER), the other in the mitochondrial inner membrane. The electron-donating protein of the ER system (Fig. 1a) is called NADPH-cytochrome P450 oxidoreductase (CPR). It consists of two domains with two different prosthetic flavin groups, FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide), which transfer two electrons acquired from NADPH directly, but only one at a time, to the P450 heme iron. CPR is bound to the ER membrane by its N-terminus with the bulk of the protein on the cytosolic side. In humans, CPR is encoded by a single gene (*POR*) on chromosome 7, which encodes a protein of 677 amino acids. The crystal structure of CPR has been determined. In certain reactions the second electron can be transferred via cytochrome b_5, a smaller heme containing protein (MW ~ 15 kDa), which usually accepts electrons from NADH via the flavoprotein NADH-cytochrome b_5-reductase.

In the mitochondria (Fig. 1b), the electron acceptor protein is also a flavoprotein termed NADPH-adrenodoxin reductase (MW ~ 50 kDa). It is present in the adrenal cortex and donates electrons not directly to P450 but to the smaller redox protein adrenodoxin (MW ~ 12.5 kDa). The two iron-sulfur clusters of this protein serve as electron shuttle between the flavoprotein and mitochondrial P450s.

Cytochrome P450 Structure

The name cytochrome P450 (P for pigment) derives from the unusual spectrum compared to other hemoproteins. Carbon monoxide strongly binds to the reduced (ferrous) heme iron inducing a strong absorption at 450 nm that was first discovered in 1958 and that can be used to quantitate cytochrome P450 via its reduced CO difference spectrum. The structural difference between cytochrome P450 and other hemoproteins is the

unusual fifth ligand to the heme iron, which is a histidine in other hemoproteins but a conserved cysteine thiolate in all P450s, located close to their C-termini. X-ray crystal structures available for bacterial and several human microsomal P450s have confirmed the role of the conserved thiolate ligand and provided deep insights into substrate binding and structural peculiarities (Guengerich et al. 2016). The many sequences available and the recent structural data indicate significant structural similarities between all P450s, which consist of about 500 amino acids and most likely evolved from a single common ancestor gene. Microsomal P450s are bound to the membrane by a single hydrophobic N-terminal transmembrane anchor in such an orientation that the heme moiety is colocalized with the CPR flavodomain at the cytoplasmic side of the ER. Mitochondrial P450s are synthesized as slightly larger precursors with an N-terminal signal sequence that is being cleaved off during translocation of the protein to the inner mitochondrial membrane.

Cytochrome P450 Gene Superfamily

Cytochromes P450 are the products of a gene superfamily with currently more than 50,000 known forms (isozymes) from all types of living organisms. Cytochrome P450 proteins are classified into families and subfamilies based on their sequence similarities. Any two forms with more than 40% identity at the amino acid level belong to the same family (indicated by an Arabic numeral), whereas they belong to the same subfamily (indicated by a capital letter) if they share more than 55% of identical amino acids. Individual isozymes of the same subfamily are distinguished by an additional Arabic number. Humans have 57 individual functional *CYP* genes that belong to 18 families and 43 subfamilies and that are located over all autosomal chromosomes. A particular aspect of mammalian cytochrome P450 systems is the high number of pseudogenes, which harbor mutations that prevent the expression of functional proteins. Humans have more than 25 *CYP* pseudogenes that make molecular genetic analysis complex due to their high sequence homology. Other mammals share the same 18 *CYP* families with humans, but the number of individual functional isozymes in each family or subfamily can be very different. Based on their role in metabolism, the 18 *CYP* families can be broadly classified into those catalyzing the metabolism of xenobiotics (families *CYP1*, *CYP2*, and *CYP3*) and those that are responsible for biotransformations of endogenous substances (families *CYP4* to *CYP51*; Table 1). Most *CYP* genes of the first category are polymorphic in the population, i.e., they harbor common genetic variants that may lead to polymorphic drug oxidation (Zanger and Schwab 2013). In contrast, mutations in CYPs catalyzing physiological reactions are usually rare as they may cause inherited metabolic disorders.

Human Drug Metabolizing Cytochromes P450

Typical characteristics of the drug-metabolizing P450s are their broad and overlapping substrate specificities and highly variable expression and function, both in terms of inter- and intraindividual variation, with tremendous influence on the pharmacokinetics of most drugs in clinical use. The in vivo activity of a specific P450 enzyme can principally be estimated by measuring metabolite concentrations of an ingested selective probe drug in urine, blood, or breath of patients. This is necessary because there are no reliable surrogate markers to estimate liver expression and activity. Three basic mechanisms are responsible for variability in the activity of drug-metabolizing enzymes: (i) genetic variation including common polymorphisms and rare mutations, as well as epigenetic variation; (ii) gene regulatory mechanisms that lead to enzyme induction or downregulation; and (iii) direct inhibition of enzyme activity. The importance of each type of variation differs substantially between different CYP enzymes (Fig. 2).

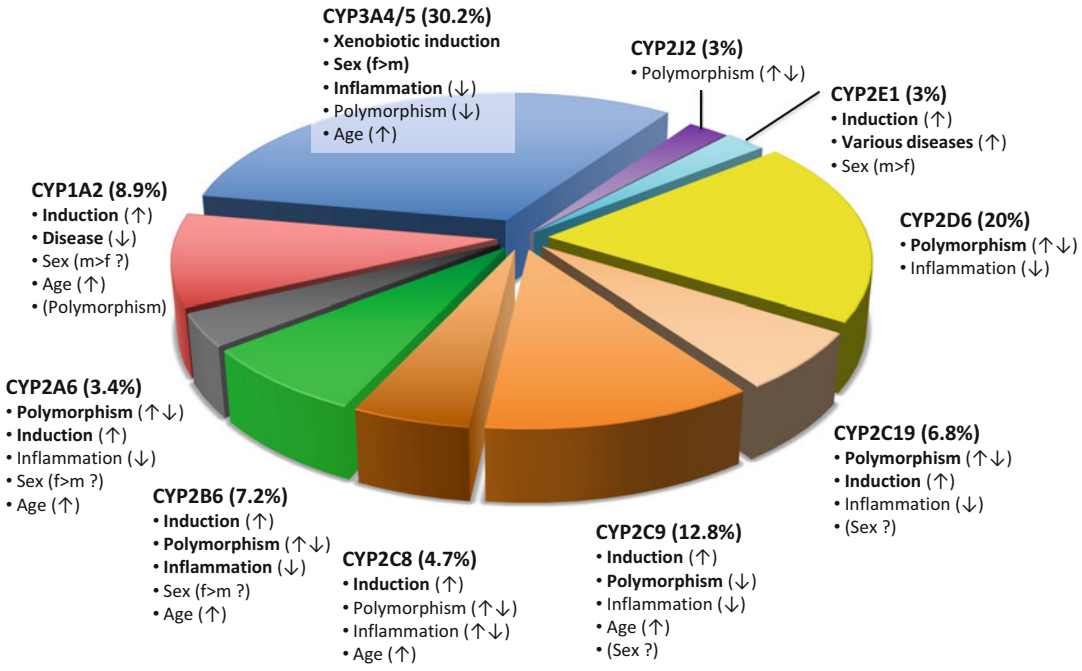
Genetic Variation in Drug-Metabolizing P450s

A genetic polymorphism is a difference in DNA sequence that has a frequency of at least 1% in a population. Many drug-metabolizing enzyme genes are highly polymorphic with consequences for expression and function of the gene product,

P450 Monooxygenase System, Table 1 P450 monooxygenase system. Overview of the cytochrome P450 superfamily in humans

Family	Subfamily, genes (P indicates pseudogenes, not all are shown)							Typical substrates/functions
CYP 1	A1	A2	A8P					PAHs, PCBs, estrogens, aromatic amines
	B1							PAHs, PCBs, retinoids
CYP 2	A6	A7	A13	A18P				Nicotine, coumarin, nitrosamines
	B6	B7P1						Cyclophosphamide, bupropion, efavirenz
	C8	C9	C18	C19	C23P			Taxol (C8), NSAIDS, warfarin (C9), omeprazole (C19)
	D6	D7P	D8P					Antidepressants, opioids, beta-blockers
	E1							Ethanol, halothane, acetone
	F1	F1P						Naphthalene, styrene
	G1P	G2P						No function
	J2							Arachidonic acid, ebastine hydroxylation
	R1							Vitamin D3 25-hydroxylase
	S1							All-trans retinoic acid, naphthalene
	T2P	T3P						No function
	U1							Arachidonic acid omega-hydroxylation
	W1							Bioactivation of procarcinogens
CYP 3	A4	A5	A5P3	A7	A43			Cyclosporin, antidepressants, testosterone
CYP 4	A11	A22						Medium- and long-chain fatty acids, arachidonic acid ω-hydroxylation
	B1							Inactive in humans
	F2	F3A	F3B	F8	F11	F12	F22	Medium- and long-chain fatty acids; arachidonic acid, leukotrienes, prostaglandines
	V2							ω-3 polyunsaturated fatty acids, medium-chain fatty acids, arachidonic acid
	X1							Unknown function
	Z1	Z2P						Medium-chain fatty acids, arachidonic acid (?)
CYP 5	A1							Thromboxane A2 synthase
CYP 7	A1							Cholesterol 7alpha-hydroxylase (→ bile acids)
	B1							Oxysterol 7alpha-hydroxylase
CYP 8	A1							Prostacyclin synthase
	B1							Steroid 12alpha-hydroxylase (→ cholic acid)
CYP 11	A1							Cholesterol side chain cleavage
	B1	B2						Steroid 11-β or 18 hydroxylase (→ cortisol, aldosteron)
CYP 17	A1							Steroid 17-apha hydroxylase/17–20 lyase
CYP 19	A1							Steroid aromatase (→ estrogens)
CYP 20	A1							Unknown function
CYP 21	A1P	A2						Steroid 21-hydroxylase
CYP 24	A1							Vitamin D degradation (24-hydroxylase)
CYP 26	A1							All-trans-retinoic acid hydroxylase
	B1							Retinoic acid hydroxylase
	C1							Retinoic acid hydroxylase
CYP 27	A1							27-hydroxylation in bile acid biosynthesis
	B1							Vitamin D3 1alpha-hydroxylase (kidney)
	C1							Unknown function
CYP 39	A1							24-Hydroxycholesterol 7-hydroxylase
CYP 46	A1	A4P						Cholesterol 24-hydroxylase
CYP 51	A1	P1	P2	P3				Lanosterol 14alpha-demethylase (cholesterol biosynthesis)

PAHs polycyclic hydrocarbons, *PCBs* polychlorinated biphenyls



P450 Monooxygenase System, Fig. 2 Major human drug-metabolizing P450s. Contribution (in %) of individual cytochrome P450 isoforms to the metabolism of 248 commonly used drugs. Only major pathways were considered. The legends indicate variability factors with direction of influence indicated (↑, increased activity; ↓, decreased activity; ↑↓, increased or decreased activity). Factors of controversial significance are shown in parentheses. (Reproduced with permission from Zanger and Schwab (2013))

such that they affect the disposition of drugs and xenobiotics (pharmacogenetics). The best studied example of a P450 genetic polymorphism is that of *CYP2D6* (Zanger and Schwab 2013). It results in four phenotypes in the population, termed ultrarapid (UM), extensive or normal (EM), intermediate (IM), and poor metabolizer (PM) phenotype. The PM phenotype is inherited as an autosomal recessive trait and affects about 5–10% of Caucasians who are unable to metabolize a range of drugs which are substrates for CYP2D6. For drugs with narrow therapeutic window, these individuals carry an increased risk to develop adverse drug reactions when given normal drug doses. Further examples for polymorphisms in *P450* genes are mentioned below. The Pharmacogene Variation Consortium (PharmVar) at www.PharmVar.org maintains a central repository for pharmacogene variation to facilitate CYP allele (haplotype) designation (Gaedigk et al. 2018).

Gene Regulatory Mechanisms in Drug-Metabolizing P450s

A variety of regulatory mechanisms are acting on different *P450* genes to regulate their constitutive expression and response to environmental stimuli. Members of the *CYP1* family and some other drug-metabolizing enzymes including some UDP-glucuronosyltransferases are collectively induced by polycyclic aromatic hydrocarbons (PAH) that serve as ligands to a specialized receptor called the aryl hydrocarbon receptor (AhR), which translocates to the nucleus following binding of ligand and another protein component called ARNT (AhR nuclear translocator). In the nucleus the complex binds to the DNA and activates transcription. Another regulatory mechanism is responsible for the 40–50-fold induction of CYP2B enzymes of humans and rodents following the administration of phenobarbital and other barbiturates. The orphan nuclear receptor CAR (constitutively activated receptor) plays a

central role in mediating the effect of phenobarbital that leads to the induction of human CYP2B6. PXR, another orphan nuclear receptor, binds a different range of ligands including the antibiotic rifampin and leads to the induction of a different profile of genes, in particular CYP3A4. Both CAR and PXR, as well as several other ligand-activated nuclear receptors, form heterodimeric complexes with the retinoic X-receptor, RXR, that subsequently translocate to the nucleus, bind to DNA elements, and activate transcription. Nuclear receptor-independent mechanisms to induce P450s are also known, e.g., the induction of the ethanol-oxidizing CYP2E1 enzyme by ethanol. The general feature of these regulatory mechanisms is that substrates induce their own metabolism.

Direct Inhibition of P450

Direct inhibition of P450 enzymatic activity is the most common reason for drug-drug interactions. P450 inhibitors can be either of the competitive- or of the mechanism-based type. Potent competitive inhibitors are often, but not always, substrates with high affinity for the enzyme. Mechanism-based or suicide enzyme inhibition occurs when a substrate is activated to a reactive intermediate that subsequently binds either to the P450 polypeptide or to the heme moiety, thereby inactivating it irreversibly. Examples for both types of inhibitors are known for almost every drug-metabolizing P450. Substances interfering with P450 enzyme activity may also originate from food, e.g., grapefruit juice contains CYP3A4 inhibitors that have significant effects on in vivo drug concentrations lasting several days (Flockhart 2007).

Drugs

Human Drug-Metabolizing CYPs

CYP1A1: Typical substrates are polycyclic aromatic hydrocarbons (PAHs) like benzo(a)pyrene or methylcholanthrene. The carcinogenicity of these substances depends on their metabolic activation by CYP1A1. Some of the PAHs that induce CYP1 enzymes via the Ah receptor are found in cigarette smoke and charred food. CYP1A1 is expressed at very low levels in the liver of uninduced individuals but is found in extrahepatic tissues including the placenta, lung, and lymphocytes. **CYP1A2** has a broader substrate specificity than CYP1A1, including many aromatic and heterocyclic amines, and is more abundantly expressed in the human liver. Typical substrates are caffeine, phenacetin, clozapine, estrogens, and others. Caffeine N3-demethylation can be used as a selective 1A2 marker activity, whereas 7-ethoxyresorufin O-demethylation or phenacetin O-demethylation reflects both CYP1A isozymes. Genetic polymorphisms have been found in all human *CYP1* genes, and their associations with various forms of cancer were intensely studied. The *CYP1A1/2* genes are located on chromosome 15.

CYP1B1 (chromosome 5) has been linked to primary congenital glaucoma. CYP1B1 is not regularly expressed in the liver but is often found in various kinds of tumors. It metabolizes retinoids and many aromatic amines and PAHs to potentially carcinogenic products.

The CYP2 family is the largest CYP family in humans, and it comprises about 16 functional genes and 11 pseudogenes.

CYP2A6 is the principal enzyme for nicotine metabolism. A selective probe drug for CYP2A6 is coumarin. Clinically important drug substrates are rare, but examples are tegafur, efavirenz, and letrozole. Genetic polymorphisms affect mainly expression levels. It has been suggested that smokers with genetically determined low CYP2A6 expression need to consume less nicotine to achieve the same satisfying blood levels of the drug.

CYP2B6 is the only functional isozyme of the 2B subfamily in humans, as *CYP2B7* is a pseudogene. Both genes are located within a large *CYP2* gene cluster on chromosome 19. CYP2B6 is highly variable owing to its inducibility by barbiturates and other drugs, but its expression and function are also affected by frequent genetic polymorphisms. Clinically important substrates are the cytostatic cyclophosphamide, the antidepressant bupropion, and the antiretroviral drugs used in HIV treatment, efavirenz and nevirapine. S-Mephenytoin *N*-demethylation and bupropion hydroxylation are selective marker activities that can be used both in vitro and in vivo.

The **CYP2C** subfamily comprises the four genes *CYP2C8*, *2C9*, *2C18*, and *2C19*, which are together localized on chromosome 10. The members of this subfamily show surprisingly large variation in substrate specificity and regulation. **CYP2C8** catalyzes taxol 6alpha-hydroxylation as a selective marker activity; other substrates include pioglitazone and amodiaquine. **CYP2C9** is very abundantly expressed in the human liver and has a broad substrate specificity accepting many weakly acidic substances like the hypoglycemic agent tolbutamide, the anticoagulant warfarin, the anticonvulsant phenytoin, and several NSAIDs (nonsteroidal anti-inflammatory drugs). **CYP2C19** substrates are S-mephenytoin, the 4-hydroxylation of which provides a very specific marker activity, the proton pump inhibitor omeprazole, the antimalarial proguanil, and diazepam. All *CYP2C* genes are genetically polymorphic. Clinically relevant are the two major variant alleles of CYP2C9, *2C9∗2* and *2C9∗3*, which are associated with decreased enzyme activity, as well as the genetic polymorphism of *CYP2C19*, also known as the S-mephenytoin polymorphism, which affects about 3–5% of Caucasians and up to 20% of Asian populations. **CYP2C18** appears to be expressed in the liver only as mRNA but not as a protein.

CYP2D6 is a very important enzyme for drug oxidation, although its expression in the liver is rather low. Substrates include antiarrhythmics (e.g., propafenone), antidepressants (e.g., amitriptyline, venlafaxine), antipsychotics (e.g., thioridazine), beta-blockers (e.g., metoprolol), opioids (e.g., codeine), and more. It was the first P450 for which a classical pharmacogenetic polymorphism became known. More than 100 functionally distinct alleles which are associated with either complete lack of function (null-alleles) or with decreased or increased enzyme activity are known (www.pharmvar.org). The individual inherited allele combination (genotype) determines whether an individual will have the ultrarapid metabolizer (UM), extensive (EM), intermediate (IM) or poor metabolizer (PM) phenotype. About 5–10% of Caucasians carry two null-alleles and are consequently PMs; about 10–15% are IMs carrying alleles with reduced function, and about 1–5% are UMs due to an allele with a duplicated functional gene. In other ethnic populations, these percentages can be very different. Thus, in Asians the PM phenotype has a frequency of only 0.5–1%, whereas in certain Arabian and Eastern African populations, the frequency of the UM phenotype can be as high as 30%. The phenotype can be determined either by using one of several available specific probe drugs, e.g., dextromethorphan or metoprolol, or it can be predicted by genetic diagnosis.

CYP2E1 metabolizes small molecules including ethanol, halogenated hydrocarbons like halothane, as well as small aromatic and heterocyclic compounds, many of which also act as inducers. For example, it is known that CYP2E1 is induced in alcoholics. Only few drug substrates of CYP2E1 are known, but the enzyme activates many xenobiotic metabolites to toxic intermediates. Chlorzoxazone 6-hydroxylation has been proposed as a marker activity. Polymorphisms in the *CYP2E1* gene seem to be of low significance, although some are believed to be associated with increased cancer risk.

CYP2F1 appears to be expressed preferentially in lung where it bioactivates the selective pneumotoxins 3-methylindole and naphthalene.

CYP2J2 is abundant in cardiovascular tissue and active in the metabolism of arachidonic acid to eicosanoids that possess potent anti-inflammatory, vasodilatory, and fibrinolytic properties. Polymorphic alleles with reduced function are known.

CYP2R1 is the principal hepatic enzyme for the hydroxylation of vitamin D to 25-hydroxyvitamin D. Inactivating mutations in CYP2R1 can lead to a certain form of vitamin D-deficiency rickets.

CYP2S1 appears to be expressed preferentially in respiratory tissues and the intestine. It is induced by dioxin and is able to activate and deactivate certain carcinogens.

CYP2U1 metabolizes arachidonic acid and has been linked to hereditary spastic paraplegia.

CYP2W1 appears to be expressed in the fetal colon and in colon tumors, but its functions are still unknown.

The **CYP3A** subfamily, in particular CYP3A4, plays a very important role due to its broad

substrate selectivity and because it is abundantly expressed not only in the liver but also in intestinal enterocytes. CYP3A4 makes significant contributions to the metabolism of more than half of all clinically used drugs including large molecules like the immunosuppressant cyclosporin A, macrolide antibiotics like erythromycin, or anticancer drugs like taxol and smaller molecules like benzodiazepines, HMGCoA reductase inhibitors, anesthetics, and many more. CYP3A4 expression levels are increased following exposure to a number of drugs that bind to the nuclear receptor PXR (pregnane X-receptor) which increases the rate of *CYP3A4* gene transcription. Furthermore, there are sex-related differences in CYP3A4 expression with women having significantly higher levels, which translate into higher in vivo clearance of several drug substrates. Although an allele (*CYP3A4*∗22) has been linked to lower activity, genetic polymorphism has not been found to be of major importance. In contrast, the expression of the two subfamily members, CYP3A5 and CYP3A7, is confined to a smaller fraction of the population who carry particular alleles of these genes. CYP3A7 is more abundantly expressed in the fetal liver than in adult liver. CYP3A43 was found to be expressed at very low levels.

CYPs in Physiological Pathways

The **CYP4** family comprises a large number of subfamilies and isozymes. The major substrates for CYP4A enzymes are fatty acids (ω-hydroxylation) and eicosanoids. Non-fatty acid substrates may be metabolized by specific CYP4A forms. For example, CYP4F2 is clinically relevant for warfarin dose adjustment. Expression of CYP4 enzymes is regulated by peroxisome proliferators like clofibrate (peroxisome oxidize fatty acids), drugs that bind to another nuclear receptor termed PPAR (peroxisome proliferator-activated receptor).

CYP5 synthesizes thromboxane A2, a fatty acid in the arachidonic acid cascade that causes platelet aggregation. Aspirin prevents platelet aggregation because it blocks the cyclooxygenases COX1 and COX2 which catalyze the initial step of the biotransformation of arachidonic acid to thromboxane and prostaglandins.

CYP7A1 catalyzes the 7α-hydroxylation of cholesterol, the first and rate-limiting step of bile acid synthesis. This is also the principal way to eliminate cholesterol. **CYP7B1** is primarily expressed in the brain and catalyzes the synthesis of various neurosteroids and also the 7α-hydroxylation of oxysterols.

CYP8A1 is the complementary enzyme to CYP5 in that it synthesizes prostacyclin in the arachidonic acid cascade. **CYP8B1** catalyzes the steroid 12alpha-hydroxylation in the cholic acid biosynthesis.

CYP11A1 is known as the mitochondrial side-chain cleavage enzyme that converts cholesterol to pregnenolone, the first step in steroid hormone biosynthesis. Steroid hormone levels are under tight endocrine control via the P450 enzymes involved in their biosynthesis, which are transcriptionally regulated by ACTH (adrenocorticotropic hormone) via intracellular cAMP. Genetic defects in CYP11A1 lead to a lack of glucocorticoids, feminization, and hypertension. **CYP11B1** is the mitochondrial 11 beta-hydroxylase that synthesizes cortisol and corticosterone. Genetic defects in this gene lead to congenital adrenal hyperplasia. **CYP11B2**, aldosterone synthase, hydroxylates corticosterone at C-18. The genetic deficiency of CYP11B2 is the cause of congenital hypoaldosteronism.

CYP17 is the 17alpha-hydroxylase and 17–20 lyase, two different reactions of the same substrate catalyzed by one enzyme and required for production of testosterone and estrogen, respectively. Defects in this enzyme affect development at puberty.

CYP19 is known as aromatase that synthesizes estrogen by converting ring A of the steroid nucleus into an aromatic ring. The lack of this enzyme causes a lack of estrogen and failure of women to develop at puberty. Because estrogens are involved in breast cancer development, CYP19 is an important target to develop specific anti-breast cancer agents (aromatase inhibitors) that inhibit the enzyme.

CYP21 catalyzes steroid C21 hydroxylation required for cortisol biosynthesis. Genetic defects in this gene cause congenital adrenal hyperplasia.

CYP24 is a 25-hydroxyvitamin D3–24-hydroxylase that degrades vitamin D metabolites.

CYP26 consists of three enzymes each representing a separate subfamily, all involved in retinoic acid hydroxylation. **CYP26A1** is an all-trans-retinoic acid hydroxylase which degrades retinoic acid, an important signaling molecule for vertebrate development. It acts through retinoic acid receptors.

CYP27A1 is a mitochondrial enzyme that catalyzes the side-chain oxidation (27-hydroxylation) in bile acid biosynthesis and the 25-hydroxylation of vitamin D_3. Because bile acid synthesis is the only elimination pathway for cholesterol, mutations in the *CYP27A1* gene lead to abnormal deposition of cholesterol and cholestanol in various tissues. This sterol storage disorder is known as cerebrotendinous xanthomatosis. **CYP27B1** is the 1alpha-hydroxylase of vitamin D3 that converts it to the active vitamin form. The function of **CYP27C1** is not yet known.

CYP46 is a brain enzyme and hydroxylates cholesterol at the 24-position, a reaction that appears to play a role for brain cholesterol homeostasis.

CYP51 catalyzes lanosterol 14alpha-demethylation required in the biosynthesis of cholesterol in a mammalian liver, but it is also expressed in the sperm where it synthesizes meiosis-activating sterols. This enzyme is evolutionarily highly conserved in plants, fungi and animals, and bacteria and may be the ancestor of all eukaryotic P450s. CYP51 enzymes are important targets for cholesterol-lowering drugs, antifungal agents like ketoconazole, and herbicides.

Definition

Peptides and Peptidomimetics

Peptides (derived from Greek language peptós "digested") are short chains of amino acids, typically comprising 2–50 amino acids, that are linked by peptide bonds. Peptides are naturally occurring biological molecules that are ubiquitous in all living organisms and display a large diversity of structures and biological effects. They are known to regulate most physiological processes in the body, acting as hormones, neurotransmitters, and antimicrobial agents. Peptides also mediate various essential biological functions, such as signal transduction, heart rate regulation, mating, chemotaxis, food intake, pain perception, growth development, and immunity to achieve homeostasis and maintain health. Like proteins, peptides are formed from transcription of a sequence of the genetic code, DNA; however, peptides are distinguished from proteins on the basis of size, being significantly shorter (oligopeptides (two to ten amino acids) and polypeptides (10–50 amino acids)), although the cutoff number of amino acids can be arbitrary (Lau and Dunn 2018).

Peptidomimetics are modified peptides whose essential elements (pharmacophore) mimic a natural peptide, designed to maintain the biological function of the natural peptide, while simultaneously removing their liabilities, such as their rapid metabolism, lack of receptor selectivity, and poor bioavailability. Peptidomimetics arise from the combination of chemical synthesis and employment of techniques from various other sciences offering preservation of the advantages of linear peptides, including high potency and low toxicity, and removing their disadvantages (Cunningham et al. 2017; Rubin et al. 2018; Rubin and Qvit 2018).

Peptides and peptidomimetics as drugs show unique characteristics and can be very effective. They are highly bioactive and very specific, demonstrate low toxicity, and in many cases are developed from natural endogenous scaffolds with known biological activity, thereby making them particularly attractive therapeutic agents. Over the years, peptides and peptidomimetics have been evolved as promising therapeutic agents in the treatment of different diseases (Rubin and Qvit 2016; Qvit et al. 2017; Lau and Dunn 2018) such as parasitic diseases (Qvit and Kornfeld 2016; Qvit et al. 2016c), cancer (Marqus et al. 2017), diabetes (Flatt and Conlon 2018), and cardiovascular diseases (Qvit et al. 2016a; Qvit et al. 2016b).

The Role of Peptides and Peptidomimetics in Drug Discovery

Over the past six decades, many scientific and technological tools have been improved remarkably in many various fields, contributing to innovation and progression in basic research, drug discovery, and drug development. Despite the various developments that have improved efficiency, reliability, and reproducibility, and in a much more cost-effective way, the research and discovery (R&D) productivity of the pharmaceutical industry has been declining. With every billion United States (US) dollars allocated to drug R&D, the number of approved drugs has halved approximately every 9 years since 1950, raising the estimated average cost per new approved drug to $1395 million (DiMasi et al. 2016). Scannell et al. coined this phenomenon as Eroom's Law (the reverse spelling of Moore – as in Moore's Law, which describes the doubling every 2 years from the 1970s to 2010 of the number of transistors which can be placed at a reasonable cost onto an integrated circuit) (Scannell et al. 2012).

Peptide therapeutics have played a notable role in medical practice since the isolation and commercialization of insulin, a 51-amino acid peptide, which was initially purified in 1921, reaching the first diabetic child for treatment with bovine insulin a year later and becoming the first commercially available peptide drug in 1923. Before insulin was discovered, there was no treatment for people with diabetes, other than to put patients on very strict diets that could buy patients a few extra years. Therefore, it is not surprising that insulin was considered a "miracle drug." The pioneering and extensive work on insulin's sequence, structure, and molecular pharmacology leads to several important accompaniments, including the introducing of the first recombinant drug, human insulin, in 1982. Since then there is a

constant increase in the number of peptides entering clinical studies, from 1.2 per year (1970s) to over 16.8 per year (2000s) (Kaspar and Reichert 2013). Importantly, peptides demonstrate superior success rates in transitioning from phase 1 to phase 2 trials (83%) compared to small molecules and biological drugs (63% and 77%, respectively) and in transitioning from phase 3 to regulatory review (68%, compared to 61% of small molecules and 63% of biological drugs). Overall, it is not surprising that the number of available therapeutic peptides and peptidomimetics is increasing, and currently, there are 60 approved peptide and peptidomimetic drugs in the market, about 155 peptide drugs are in clinical trials, and over 500 are in preclinical development (Fosgerau and Hoffmann 2015). In addition, four peptides reached global sales of over $1 billion in 2010, including glatiramer acetate ($4.0 billion), leuprolide acetate ($3.0 billion), octreotide acetate ($1.3 billion), and goserelin acetate ($1.1 billion). In the next section we will discuss the basic mechanisms and pharmacological intervention of three representative peptides: a hormone, somatostatin; a neurotransmitter, substance P; and antimicrobial peptides from the polymyxin family, polymyxin B and polymyxin E.

Somatostatin

Somatostatin ((SST) aka growth hormone-inhibiting hormone (GHIH)) is an endogenous cyclic peptide hormone that regulates the endocrine system. It was discovered in 1973, by the research group of Dr. Roger Guillemin (Brazeau et al. 1973), and in 1977 Dr. Guillemin shared the Nobel Prize in Medicine with Dr. Andrew V. Schally, for their discoveries concerning the peptide hormone production of the brain. It is initially secreted as a 116-amino acid precursor, pre-prosomatostatin, which undergoes endoproteolytic cleavage to prosomatostatin (92 amino acids). Prosomatostatin is further processed into two active forms produced by alternative cleavage, somatostatin-14 (SST-14) and somatostatin-28 (SST-28), which is an extended variant of SST-14 sequence, with the extension appended to the N-terminus. SST-14 is the predominant form in the brain, and SST-28 is mainly produced by intestinal enteroendocrine cells.

Basic Mechanisms

Somatostatin is a hormone produced by many tissues in the body, principally in the nervous and digestive systems, and it exhibits a large variety of actions in different organ systems throughout the body through binding to somatostatin-specific receptors that belong to the family of G protein-coupled receptors (GPCRs). Somatostatin receptors are members of the rhodopsin family of GPCRs and comprise five receptor subtypes (SSTR1-SSTR5), which are found in a variety of tissues, including the gastrointestinal (GI) tract and brain. SST-14 and SST-28 bind to SSTR1-SSTR4 with similarly high affinities (Kd values in the low nanomolar range); however SST-28 demonstrates about tenfold higher affinity for SSTR5 than to the other receptors (Kumar et al. 1997). Somatostatin release is stimulated by several nutrients, such as amino acids and glucose, as well as by stimulation of various hormones. It is secreted by the delta cells of the islets of Langerhans within the pancreas producing inhibitory effects on pancreatic endocrine and exocrine secretion. Somatostatin is also expressed throughout the gastrointestinal tract, reducing gastric secretions and the emission of gastrointestinal hormones. In addition, somatostatin is also generated by neurons in the anterior periventricular nucleus and arcuate nucleus within the hypothalamus, where it inhibits the release of growth hormone and thyroid-stimulating hormones from the anterior pituitary.

Pharmacological Intervention

Somatostatin's short circulating half-life ($t_{1/2}$ 1–3 min) limits its therapeutic potential. The development of ligands selective for each receptor subtype is important when producing new therapies to minimize interaction with other receptor subtypes and therefore reduce unwanted side effects. A common therapeutic use of somatostatin receptor agonists is their anti-secretory effect on neuroendocrine tumors.

Lanreotide (trade name: Somatuline) is a synthetic long-acting analogue of somatostatin with a significantly longer half-life (22 days), used to treat neuroendocrine tumors that secrete excessive amounts of growth hormone, other active hormones, or neuropeptides (Caplin et al. 2014). The Food and Drug Administration (FDA) approved lanreotide in 2007.

Octreotide (trade name: Sandostatin) is an octapeptide synthetic analogue of somatostatin that mimics natural somatostatin pharmacologically. It is a peptide analogue of somatostatin with longer half-life (1.7–1.9 h) compared to somatostatin, with pharmacological activity mimicking those of the natural hormone somatostatin; however it is a more potent inhibitor of growth hormone, glucagon, and insulin (Lamberts and Hofland 2019). It was first synthesized in 1979 by the chemist Wilfried Bauer and approved by the FDA in October 1988.

Pasireotide (aka SOM230, trade name: Signifor) is a cyclic hexapeptide synthetic analogue of somatostatin that resembles the native hormone in its ability to suppress levels and activity of growth hormone, insulin, glucagon, and many other gastrointestinal peptides. It is a long-acting molecule (half-life 12 h) that was approved as a drug for Cushing's disease by the European Medicines Agency (EMA) in October 2009 and by the FDA in December 2012. Pasireotide LAR (long-acting release) was approved by the EMA in November 2014 and by the FDA in December 2014 for treatment of acromegaly (Colao et al. 2014).

Substance P

Substance P is a undecapeptide of the tachykinin ((TK), aka neurokinin (NK)) family of neuropeptides that are evolutionarily the oldest neurotransmitters and are derived from the tachykinin-1 (Tac1) (aka preprotachykinin-A (PPTA)) gene. It was first identified in extracts of equine brain and intestinal tissue in 1931 (Euler and Gaddum 1931). Substance P is widely expressed throughout the animal kingdom, and it is abundant in the peripheral and the central nervous system (CNS), being the most abundant neuropeptide in the brain. The TK peptides are synthesized as large precursor proteins, which undergo posttranslational proteolytic processing by alternative mRNA splicing to generate the mature peptide products. TKs have an important role in health and disease (*e.g.*, cancer, inflammation, pain, and cardiovascular diseases) (Nässel et al. 2019).

Basic Mechanisms

Substance P biological activity is mediated by specific TK receptors that belong to the class of (rhodopsin-like) GPCRs. There are three main classes of neurokinin receptors: GPCR neurokinin-1 receptor (NK1R), NK2R, and NK3R, and substance P has the highest affinity to NK1R (affinity 0.05–0.5 nM), followed by NK2R and NK3R (Mantyh 2002). The various TKs have different binding affinities to the neurokinin receptors, yet all TK, sharing a common C-terminal amino acid sequence which essentially dictates their biological activity (Zieglgänsberger 2019). Substance P interaction with the neurokinin-1 receptor results in major downstream cellular actions, which include changes in fluxes of calcium (Ca^{2+}) and ERK, as well as phosphorylation of p21-activated kinase and nuclear factor kappa B (NF-κB) activation (Spitsin et al. 2018). There are two isoforms of NK1R, the full-length (NK1R-F, 407 amino acid residues) and truncated NK1R (NK1R-T, 311 amino acid residues), mediating the actions of substance P. NK1R-F is the predominant isoform in the central and peripheral nervous systems, while NK1R-T disrupts a vital receptor signaling motif resulting in decreased ligand binding affinity and thus lowering activity (Douglas and Leeman 2011). There are functional differences between NK1R-F and NK1R-T; herein we will focus on NK1R-F. Substance P activation of NK1R-F leads to the activation of several major signal transduction pathways, such as activation of phospholipase C (PLC) that causes phosphatidylinositol 4,5-bisphosphate cleavage to form diacyl glycerol (DAG) and inositol 1,4,5-trisphosphate (IP3) (Mizuta et al. 2008). NK1R-F activation also leads to calcium (Ca^{2+}) mobilization (release) and activation of protein kinase C (PKC) (Morris et al. 2006). NK1R-F signaling stimulates numerous downstream

mechanisms leading to diverse and sometimes cell type-specific effects that include inflammation, proliferation, anti-apoptosis, cellular growth, neuronal excitation, and migration, to mention a few (Martinez and Philipp 2016; Mashaghi et al. 2016).

Pharmacological Intervention

Substance P's role in pain, inflammation, cancer, depressive disorder, immune function, gut function, hematopoiesis, sensory processing, and hormone regulation has led to extensive research into the pharmacology and molecular biology of this signaling system as a therapeutic target. Structure-activity relationship (SAR) studies employing substance P fragments (Regoli et al. 1984), alanine-substituted (Couture et al. 1979), and D-amino acid-substituted analogs (Wang et al. 1993) have indicated that changes in the NH_2-terminal region have only minor effects on the peptide potency. Since substance P rapidly degrades both *in vivo* and *in vitro*, with a half-life of less than 2 min and 12 min, respectively, academic and industrial researchers are in search for metabolically stable analogues. Many potent and selective peptidomimetics and non-peptide TK receptor antagonists have been developed and proven effective in preclinical studies: herein we will describe some of these analogues.

Aprepitant (trade name: Emend) is a selective, high-affinity NK1R antagonist that is able to alleviate the emetic effects of substance P, which was initially approved as a drug in 2003. Oral aprepitant is effective in the prevention of acute and delayed chemotherapy-induced nausea and vomiting (CINV) associated with initial and repeat courses of highly emetogenic cancer chemotherapy when combined with a corticosteroid (*e.g.*, dexamethasone) and a serotonin 5-HT3 receptor antagonist (*e.g.*, ondansetron). Fosaprepitant for intravenous (IV) administration (Emend (US) and Ivemend (EU)) is a prodrug of aprepitant that is a well-tolerated substitute for oral aprepitant, with half-life of 9–13 h.

Netupitant/palonosetron (trade names: NEPA, Akynzeo) is a combination of netupitant, a small molecule antiemetic substance P analogue with high affinity to the NK1R antagonist, and palonosetron, a serotonin-3 ($5\text{-}HT_3$) receptor antagonist with a strong binding affinity for this receptor used as an antiemetic and antinauseant agent. It is an oral fixed-dose combination of netupitant/palonosetron for the prevention of acute and delayed CINV, with a half-life of 96 h, that was initially approved as a drug in 2014. Fosnetupitant is a prodrug form of netupitant approved as an alternative treatment option for CINV patients, with half-life of 80 h, that was initially approved as a drug in 2018.

Rolapitant (trade names: Varubi (US) and Varuby (EU)) is an oral potent and long-acting (169–183 h) NK1R highly selective antagonist. It is indicated in combination with other antiemetics for the prevention of delayed CINV, initially approved as a drug in 2015 (Goldberg et al. 2017).

Polymyxins

Polymyxins are an old class of non-ribosomal naturally occurring cyclic lipopeptides produced by the widely distributed Gram-positive spore-forming soil bacterium *Paenibacillus polymyxa*, which demonstrate narrow antibacterial spectrum against Gram-negative infections. Initially the polymyxin family was identified in the 1940s by three research groups concurrently (Ainsworth et al. 1947; Benedict and Langlykke 1947; Stansly et al. 1947). Members of the polymyxin family demonstrated unique characteristic by its specificity for Gram-negative bacteria (GNB), which distinguished it from previously reported antibiotics (Velkov et al. 2019).

At the beginning five different polymyxin molecules were known (polymyxins A, B, C, D, and E) differing in their amino acid sequences and fatty acid side chains. Later, several other members of the family were discovered, including polymyxin M, polymyxin S, and polymyxin T. Interestingly, polymyxins M and T are also active against Gram-positive bacteria. In 1963, the chemical structures for polymyxin B1, polymyxin B2, and colistin A (polymyxin E1) were determined, followed by that of colistin B (polymyxin E2) (Hayashi and Suzuki 1965). Polymyxin B and polymyxin E share an almost

identical primary amino acid sequence with the major difference present at position six, where polymyxin B contains D-phenylalanine, while colistin contains D-leucine (Velkov et al. 2010).

Polymyxin B is a cationic lipopeptide that binds the lipid-A portion of endotoxin, which was discovered and isolated from *Bacillus polymyxa* in the 1940s. It is a mixture of at least four closely related compounds, polymyxin B1 to B4; however polymyxin B1 and polymyxin B2 are the two major components (Rigatto et al. 2019). Polymyxin E (aka colistin) is a cyclic polypeptide antibiotic from *Bacillus colistinus* that was first described in 1950. At least 30 different components have been detected in colistin, which differ only in the fatty acid side chain components (Li et al. 2001).

Basic Mechanisms

Polymyxin B and colistin share the same mechanism of action; both have the diaminobutyric acid residues, which are positively charged, targeting the negatively charged bacterial cell membrane. They disrupt the bacterial cell membrane through interaction with anionic lipopolysaccharide and phospholipid molecules in the outer membrane of GNB, a detergent-like mechanism. The initial association of both peptides with the bacterial cell membrane occurs through electrostatic interactions between the cationic polypeptide and anionic lipopolysaccharides. They displace divalent cations, such as calcium (Ca^{2+}) and magnesium (Mg^{2+}), from the phosphate groups of membrane lipids, which stabilize the lipopolysaccharide membrane leading to derangement and an increase in the permeability of the cell envelope. The result of this process causes leakage of the cell contents and ultimately cell death (Gai et al. 2019).

Pharmacological Intervention

Polymyxin B and colistin became available clinically in the late 1950s and early 1960s. However, their use waned in the 1970s with the development of less toxic agents, such as extended-spectrum penicillins, due to their potential nephrotoxicity and neurotoxicity except for treatment of patients with cystic fibrosis. Currently they are used as a last therapeutic option for multidrug-resistant (MDR) Gram-negative organisms, caused by "superbugs" such as *Pseudomonas aeruginosa*.

Antibiotic resistance (AMR) causes higher medical costs, longer hospital stays, and increased mortality. It is estimated that a cumulative US $100 trillion of economic output is at risk due to AMR by 2050; moreso, about ten million people per year will die of AMR infections. Both polymyxin B and colistin are clinically available polymyxins that reemerged in clinical practice to treat infections caused by MDR GNB. The two clinically available polymyxins have very different pharmacological properties, as colistin is mainly administered intravenously to patients in an inactive prodrug form, colistimethate sodium (CMS) (Rigatto et al. 2019). Surprisingly, in several recent studies, polymyxin B and colistin demonstrated acceptable effectiveness and considerably less toxicity than that reported in old studies (Nation and Li 2017).

The most relevant clinical use of polymyxin B is for the treatment of infections caused by extensively MDR using polymyxin B sulfate (trade name: Polimixina B), which is the form available for IV administration, with half-life of 11.5 h. Colistin is available in two forms. First is colistin sulfate (trade name: Cortisporin-TC) for the treatment of acute or chronic infections due to sensitive strains of certain Gram-negative bacilli, with half-life of 5 h. In addition, it may be used for the treatment of lung infections due to MDR GNB in patients with cystic fibrosis. Colistin second form is colistimethate sodium ((CMS); trade name: Coly-Mycin M) which is an inactive prodrug of colistin less potent and less toxic than colistin sulfate, and it is used in parenteral formulations and can be administered intravenously, intramuscularly, or by nebulization, with half-life of 2–3 h.

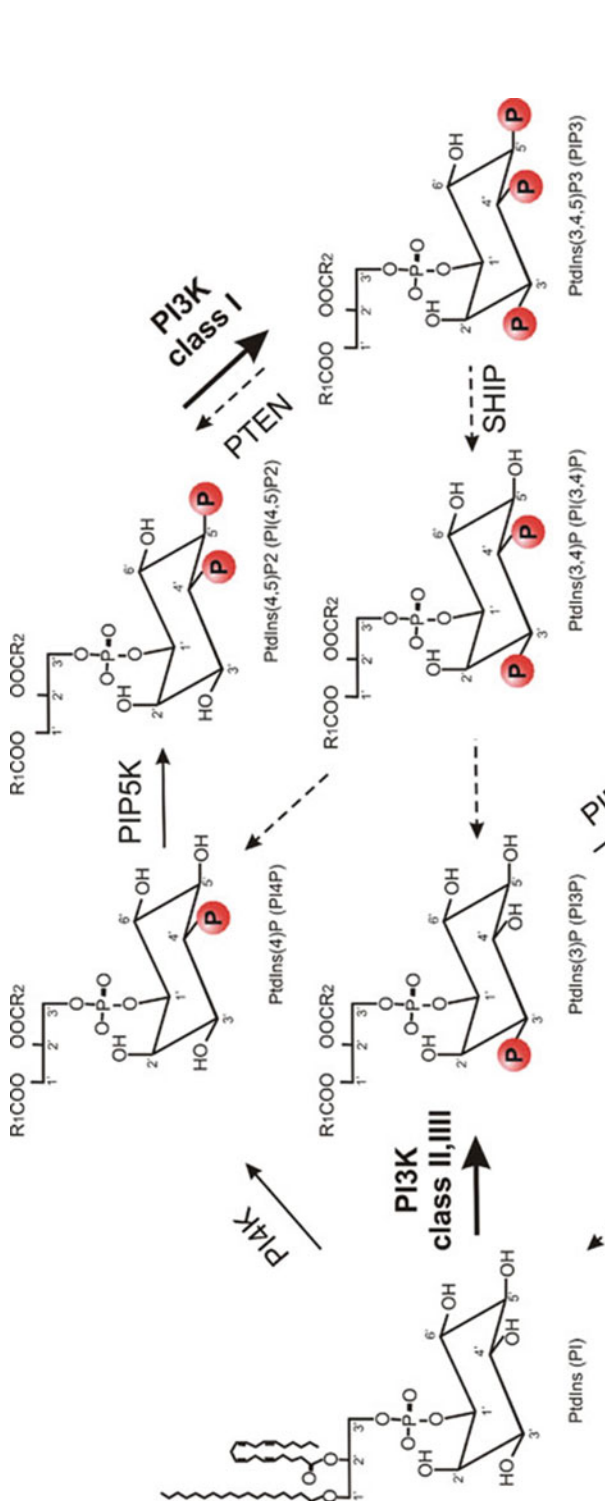
Definition

Phospholipid kinases comprise a family of enzymes that phosphorylate phosphatidylinositol (PtdIns) and phosphatidylinositides at positions 3′, 4′, and 5′ but not at positions 2′ and 6′ of the inositol ring (Fig. 1). PtdIns and its derivates are referred to as phosphoinositides or PIs. PIs represent approximately 1% of all membrane lipids such as those of the plasma, nuclear, and endomembranes. In unstimulated cells, more than 90% of all phosphoinositides correspond to unphosphorylated PtdIns, whereas the remaining 10% consist of roughly equal amounts of phosphatidylinositol 4-phosphate (PtdIns(4)P) and phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) (Loo et al. 2015). The remaining PIs, i.e., phosphatidylinositol 5-phosphate (PtdIns (5)P) and phosphatidylinositol 3,5-bisphosphate (PtdIns(3,5)P_2), are present in small quantities in cells (Shisheva 2008). Initially, it was assumed that these phosphoinositides function exclusively as precursors for signaling molecules. For instance, PtdIns(4,5)P_2 serves as a substrate for phospholipase C and phosphoinositide 3-kinases (PI3Ks). In addition, PtdIns(4,5)P_2 interacts with intracellular proteins in a regulatory manner, thereby affecting their endocytosis, trafficking, localization, and activity (Shisheva 2008). In resting cells, less than 0.25% of the PIs are 3′-phosphorylated. Stimulation of cells with ligands that activate, for instance, receptor tyrosine kinases or G protein-coupled receptors (GPCRs) results in the rapid and transient phosphorylation of PtdIns(4,5)P_2 to phosphatidylinositol 3,4,5-triphosphate (PtdIns (3,4,5)P_3). This 3′-phosphorylated phosphoinositide behaves as a typical second messenger. Hence, the responsible phosphoinositide 3-kinases are considered as important regulatory molecules of the cell and therefore targeted for pharmacological intervention.

Basic Characteristics

Cellular PI concentrations are under tight control by phospholipid kinases and phosphatases. Phospholipid kinases preferentially phosphorylate distinct positions of the inositol ring and hence are subdivided into phosphoinositide 3-kinases (PI3Ks), phosphoinositide 4-kinases (PI4Ks), and phosphoinositide 5-kinases (PI5Ks) that phosphorylate PIs on positions 3′, 4′, and 5′, respectively. In a canonical pathway, PtdIns(4,5)P_2 is generated from PtdIns(4)P by the enzymatic activity of phosphatidylinositol 4-phosphate 5-kinase (PIP5K) (Fig. 1). Maintenance of the plasma membrane pool of PtdIns(4)P and PtdIns (4,5)P_2 relevant for function and regulation of GPCRs and ion channels is preferentially controlled by the IIIα isoform of phosphatidylinositol 4-kinases (PI4Ks) and by the type 1 phosphatidylinositol 4-phosphate 5-kinases (PIP5Ks) (Loo et al. 2015). Two classes of PI4Ks are known that can be distinguished by their sensitivity toward Wortmannin. Interestingly, inducible PI4K IIIα knockout mice are lethal. A lethal phenotype was also reported for constitutive PIP5K and for global PIKfyve knockout mice. The latter produce phosphatidylinositol 5-phosphate (PtdIns (5)P) and phosphatidylinositol 3,5-bisphosphate (PtdIns(3,5)P_2) from PtdIns(3)P that have been implicated in regulation of endosomal trafficking and cellular signaling. The vital functions of these PI-forming enzymes question them as suitable drug targets for therapeutic intervention despite specific inhibitors are available and a rapidly growing number of mutations in PI-forming enzymes are correlated with human diseases.

3′-phosphorylated PIs function as important intracellular mediators or modulators of signaling processes and act as second messengers following stimulation of cells by a broad range of extracellular stimuli. They are involved in cell survival pathways, the regulation of gene expression, proliferation, cell metabolism, membrane trafficking, and cytoskeletal rearrangements involved in cell motility (Loo et al. 2015; Bilanges et al. 2019). Correspondingly, the enzymes producing 3′-phosphorylated PIs,, i.e. phosphoinositide 3-kinases (PI3K), have been linked to major human diseases and conditions such as cancer, nonmalignant overgrowth syndromes, immune dysfunction and inflammatory processes, diabetes, or aging. This has lead not only to the development of highly specific pharmacological tools to interfere with



Phospholipid Kinases, Fig. 1 Major phosphoinositide pathways in mammalian cells. All phosphoinositides are found in the cytosolic half of the lipid bilayer of the plasma or intracellular compartment membranes (left part). The different kinases acting on phosphoinositides in mammalian cells are shown in solid lines and the phosphoinositide 3-kinases in bold. The phosphoinositide counterpart pathways catalyzed by known phosphatases are represented by dashed lines. The best known phosphatases are PTEN (phosphatase and tensin homolog deleted on chromosome 10) and SHIP (SH_2 domain-containing inositol 5-phosphatase). For further information, see Rudge and Wakelam (2014)

Phospholipid Kinases, Table 1 Approved PI3K inhibitors for treatment in patients

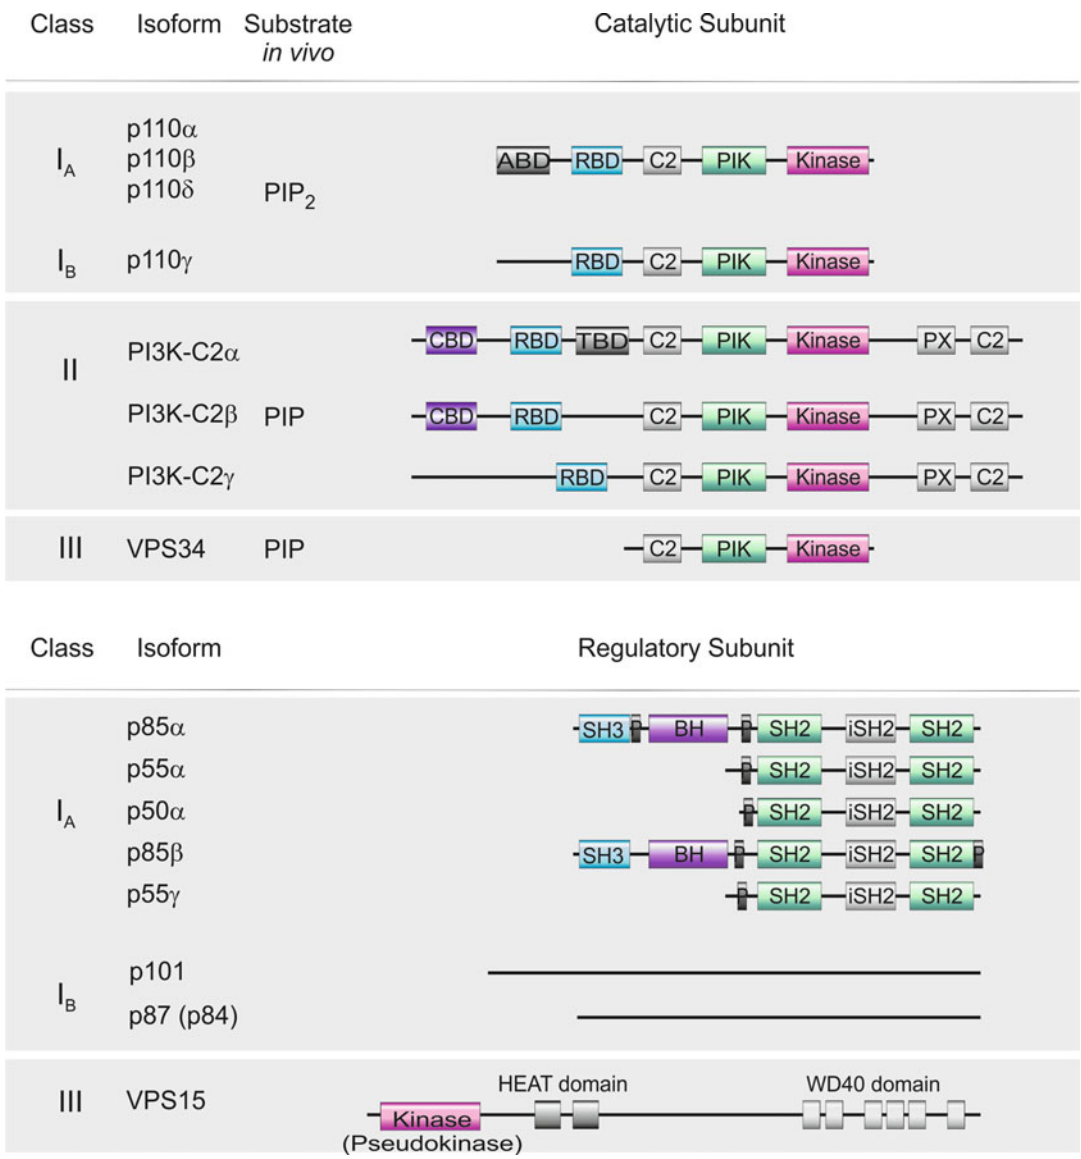
INN name	Drug name	Properties	Indication	Date of approval
Alpelisib	Piqray	PI3Kα inhibitor	Breast cancer in combination with endocrine therapy	2019
Copanlisib	Aliqopa	PI3K inhibitor (predominantly PI3Kα and PI3Kβ isoforms)	Relapsed follicular lymphoma	2017
Duvelisib	Copiktra	PI3Kδ and PI3Kγ inhibitors	Relapsed or refractory chronic lymphocytic leukemia (CLL), small lymphocytic lymphoma (SLL), follicular lymphoma	2018
Idelalisib	Zydelig	PI3Kδ inhibitor	Chronic lymphocytic leukemia (CLL), refractory follicular lymphoma	2014

PtdIns 3-dependent pathways but also to the application of PI3K-inhibiting drugs for the therapy of patients (Table 1).

Classification of PI3Ks

Based on substrate specificity and homology, mammalian phosphoinositide 3-kinases (PI3K) are divided into three classes (Fig. 2). Class I PI3Ks are heterodimeric enzymes composed of a 110 kDa catalytic subunit (with the isoforms p110 α, β, δ, or γ) that associates with a regulatory subunit. Although the class I PI3Ks are capable of phosphorylating PtdIns, PtdIns(4)P, and PtdIns (4,5)P_2 in vitro, it appears that they only use PtdIns(4,5)P_2 as a substrate in vivo (Bilanges et al. 2019). Receptor-induced formation of PtdIns(3,4,5)P_3 from PtdIns(4,5)P_2 seems restricted to the enzymatic activity of class I kinases, whereas the metabolites of PtdIns(3,4,5)P_3, PtdIns(3,4)P_2, and PtdIns(3)P are also produced by class II or class III PI3Ks.

Class I_A PI3K catalytic subunits are relatively unstable and form a complex with either one of five different regulatory subunits (p85α, p55α, p50α, p85β, or p55γ), which contain two src-homology 2 (SH2) domains (Fig. 2). These SH2 domains specifically recognize phosphorylated tyrosine residues that are present on activated growth factor receptors or on growth factor receptor substrates. This interaction results in a translocation of the cytosolic heterodimeric enzyme to the inner leaflet of the plasma membrane, thus bringing the catalytic subunit p110 close to its lipid substrate PtdIns(4,5)P_2. In addition, the interaction with the tyrosine-phosphorylated receptor induces a conformational change of p85, which disinhibits the enzymatic activity of the p110 catalytic subunit. The p85 subunits contain characteristic protein domains which allow multiple protein–protein interactions. For instance, the inter-SH2-region (iSH2) of p85 mediates the interaction with the catalytic p110 subunit. Interestingly, p85 seems to exist independently from p110 and may possess PI3K-activity independent roles such as cell migration and cytokinesis (Bilanges et al. 2019). All class I PI3Ks are also controlled by monomeric GTPases via a Ras-binding domain. Whereas p110α, p110γ, and p110δ bind monomeric Ras proteins, the p110β isoform preferentially interacts with Rac1 and Cdc42. In addition, p110β binds Rab5 by a discrete binding site within its helical domain which is required for autophagy (Bresnick and Backer 2019). Though the impact of the regulation by monomeric GTPases is currently not fully understood, it is assumed to contribute to subcellular localization and the signaling specificity of the different class I PI3Ks. PIK3β is somehow unique that it is not only controlled by growth factor-activated tyrosine kinases but also under the control of GPCRs via direct interaction with Gβγ dimers released from receptor-activated heterotrimeric G proteins. Accordingly, it is thought to act as a coincidence detector integrating signals



Phospholipid Kinases, Fig. 2 Classification of phosphoinositide 3-kinases. Shown are schematic representations of the catalytic (upper panel) and regulatory (lower panel) subunits of mammalian PI3Ks. Isoforms are subgrouped into three classes. Class I_A comprises the three catalytic members p110α, p110 β, and p110δ that are encoded by the *PIK3CA*, *PIKC3B*, and *PIKC3D* genes, respectively, and five regulatory p85 subunits encoded by three genes, i.e., *PIK3R1*, *PIK3R2*, and *PIK3R3*. The only catalytic class I_B subunit, p110γ, is encoded by the PI3KCG gene and associates with one of two regulatory subunits, p87 (also known as p84 and encoded by the P*IK3R6* gene) or p101 (encoded by the *PIK3R5* gene). Three enzymes belong to the class II termed PI3K-C2α, PI3K-C2β, and PI3K-C2γ that are encoded by the *PIK3C2A*, *PIK3C2B*, and *PIK3C2G*, respectively. The only class III PI3K catalytic isoform VPS34 (encoded by the *PIK3C3* gene) complexes with the regulatory VPS15 regulatory subunit (encoded by the *PIK3R4* gene). ABD indicates the binding site for the regulatory subunits. BH represents a BCR homology domain. The C2 domain is a membrane-binding domain that was first identified as a calcium-binding domain in protein kinase C (PKC), iSH2: inter-SH2 domain. The PIK (phosphoinositide kinase) domain is shared by all the lipid kinases. CBD (clathrin-binding domain), P (proline-rich region), RBD (Ras-binding domain), SH2 and SH3 (src-homology domains 2 and 3), and TBD (TACC3-binding domain) represent protein–protein interaction domains, PX: Phox homology domain

from different receptor classes. Little is known in molecular terms about the apparent preference of a given receptor for a class I_A-specific catalytic subunit. Class I_A PI3Ks are mainly involved in the regulation of cell growth, proliferation, metabolism, and immunity (Bilanges et al. 2019; Bresnick and Backer 2019). An increase of the class I_A PI3K activity has been found in a number of different human cancers, overgrowth, or immunodeficiency syndromes which lead to the development of PI3K-inhibiting drugs (Bilanges et al. 2019).

The class I_B PI3Kγ signals downstream of GPCRs and Ras (Nürnberg and Beer-Hammer 2019). It is a heterodimeric enzyme that occurs in two different variants. The only class I_B catalytic p110γ subunit is associated with one of two regulatory subunits, p101 or p87 (also known as p84). p101 and p87 are structurally distinct from class I_A PI3K adaptor proteins with an overall sequence similarity of 24%. Their structures have not been resolved so far. Similar to class I_A PI3Ks, unstimulated class I_B PI3Kγ is predominantly localized in the cytosol. Upon GPCR activation, Gβγ dimers and Ras directly bind PI3Kγ and induce a recruitment to the plasma membrane and a subsequent activation of PI3Kγ. The p87-containing PI3Kγ variant is less sensitive towards Gβγ than the p101-containing PI3Kγ variant. The physiological significance of this difference is not understood. In addition to its predominant expression in hematopoietic cells where it controls immune functions, PI3Kγ is also found in a broad range of other organs and tissues including cardiac, vascular, endocrine, and neuronal tissues. PI3Kγ dysfunction is also implicated in malignancy.

Two other classes of PI3Ks have been less intensively investigated. Class II PI3Ks comprise three members, PI3K-C2α, PI3K-C2β, and PI3K-C2γ (Margaria et al. 2019). The proteins are large monomeric enzymes of 170–210 kDa molecular weight that produce PtdIns(3)P and PtdIns(3,4)P_2 in vivo. They share overlapping functions but exhibit also distinct isoform-specific roles on membrane dynamics and trafficking most likely due to different subcellular expression profiles. In contrast to class I PI3Ks being mainly cytosolic, class II PI3Ks are predominantly found in membrane fraction of cells including plasma and various intracellular membranes. They respond to a wide array of stimuli, such as chemokines, insulin, and growth factors through mechanisms that are rather indirectly controlling cell signaling. A pivotal role was proposed for PI3K-C2α's enzymatic activity regulating primary cilium formation, vesicle trafficking, and cell migration. In contrast, PI3K-C2β governs selectively endosomal trafficking. Little is known about PI3K-C2γ that is predominantly expressed in the digestive system such as the liver, the pancreas, and the small intestine and in the exocrine tissue of the breast and the prostate. It has specific effects on cell metabolism through regulating endosomes. In addition, mutations of *PIK3C2G* have been linked to malignant tumors. Based on their pathophysiological roles, class II PI3Ks are considered as potential targets for anticancer therapies.

The vacuolar protein-sorting protein (VPS34) represents the only catalytic class III PI3K subunit which produces PtdIns(3)P (Bilanges et al. 2019). This PI is recognized by effector proteins harboring PtdIns(3)P-recognizing domains such as the Fab-1, YGL023, Vps27, and EEA1 (FYVE) domain, the phox homology (PX) domain, or the β-propellers that bind polyphosphoinositides (PROPPINS) domain. VPS34 was initially identified in *Saccharomyces cerevisiae*. The human orthologue, hVPS34, is 100 kDa of size and complexes with the VPS15 (also known as p150) adapter protein that has regulatory functions and is responsible for the membrane association of this PI3K. Of note, the N-terminal kinase domain of VPS15 includes a kinase-like structure that appears to be a pseudokinase. This region is important for the function of VPS34 due to its capacity to form multi-protein complexes (Ohashi et al. 2019). Two tetrameric class III PI3K-containing complexes have been defined that are designated complex I and complex II. In complex I, VPS34/VPS15 assembles with the accessory proteins VPS30 (also known as beclin 1, a Bcl-2-interacting protein) and ATG14L. It is involved in the regulation of autophagy, a conserved lysosomal degradation pathway. Complex II is composed of the UVRAG (UV irradiation resistance-

associated gene) protein instead of ATG14L and VPS34, VPS15, and VPS30. This complex plays roles in membrane trafficking including endocytic sorting. Interestingly, somatic mutations in the catalytic, regulatory, or accessory proteins of the complexes are linked to various human cancers such as esophageal, colorectal, bladder, and various forms of melanoma. VPS15 mutations have also been correlated with ciliopathy and neurodevelopmental disorders in humans. Because of its role in autophagy, type III PI3K is considered to be a potential therapeutical target for the treatment of malignancies (Shintani and Klionsky 2004).

Protein Kinase Activity of PI3K

In all known catalytic subunits of PI3K, the C-terminal kinase domains show considerable similarity with classical serine/threonine kinases (Nürnberg and Beer-Hammer 2019). Indeed, PI3Ks can function as dual-specific enzymes and exhibit a protein kinase activity in addition to their lipid kinase activity. This activity may have autoregulatory functions since for some enzymes their PI3K lipid kinase activity is modulated by autophosphorylation of the catalytic subunit p110 and/or by transphosphorylation of the associated regulatory p85. Accordingly, it became apparent that both enzymatic qualities, i.e., the lipid and the protein kinase activities, are required for certain physiological processes. For instance, the endocytosis of β-adrenergic receptors requires both lipid and protein kinase activities of PI3Kγ. Clear evidence for protein kinase-based independent downstream signaling pathways of PI3Ks is missing. Only very few protein substrates for PI3K have been described, and their physiological relevance remains to be determined.

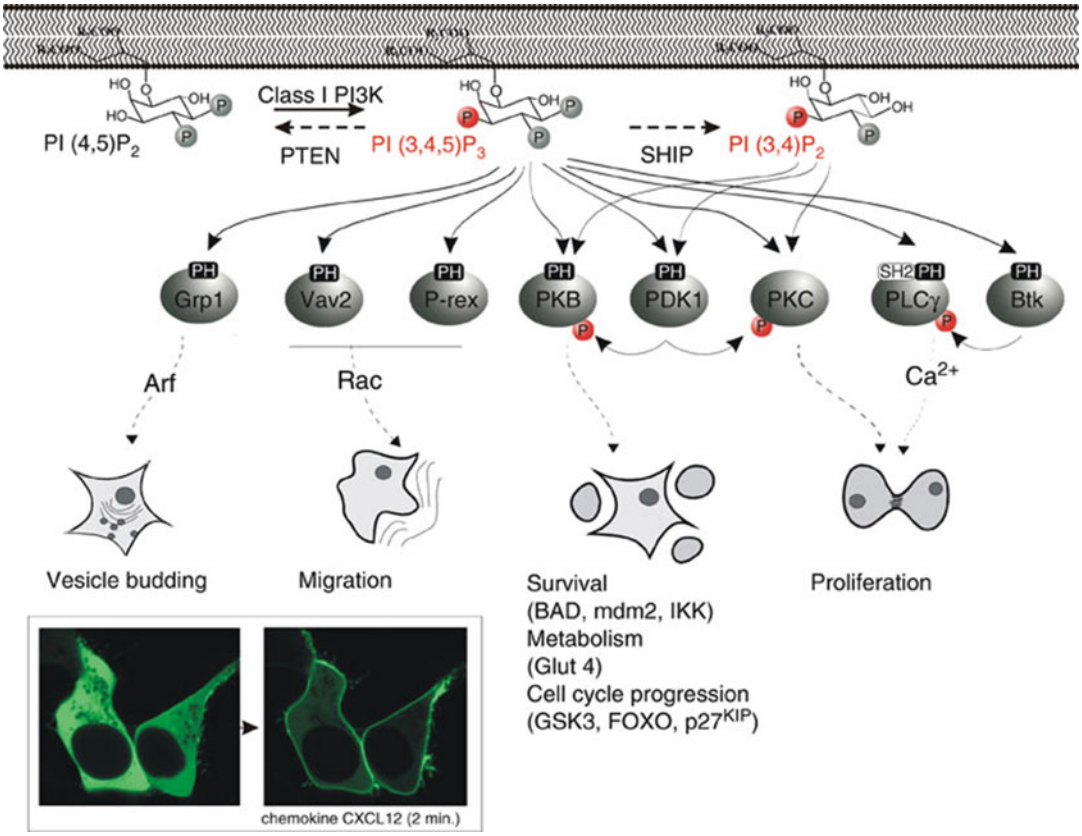
Nonenzymatic Roles of PI3K

Emerging evidence suggest that PI3Ks have also non-catalytic functions (Bilanges et al. 2019). They stabilize binding partners and orchestrate signaling complexes. Their roles as highly selective molecular scaffolds were detected when differential results became evident from genetically engineered mice lacking the kinase and from mice expressing a catalytically inactive point mutant of the same enzyme. These differences were not due to a redundancy of functions of related PI3K isoforms that may have jumped into the role of the deleted protein. Examples include nonenzymatic roles for PI3Kβ during glucose-stimulated insulin secretion or receptor-induced endocytosis and for PI3Kγ to ensure cyclic adenosine monophosphate (cAMP) homeostasis in the cardiovascular system (Bresnick and Backer 2019; Nürnberg and Beer-Hammer 2019). The class II PI3K-C2α stabilizes the mitotic spindle during metaphase in a non-enzymatic fashion (Margaria et al. 2019). In contrast to their lipid kinase functions that are controlled by upstream regulators, a demonstration of dynamic modulation of their scaffolding functions awaits further studies.

Downstream Effectors of PI3Ks

The importance of PI3Ks arises from the fact that numerous important signaling molecules need to be localized to the plasma membrane to fulfill their functions. Binding to 3′-phosphorylated phosphoinositides constitutes a major mechanism of membrane translocation for the signaling molecules. The prototypical phosphoinositide-binding domain is the pleckstrin homology-domain (PH-domain), which binds to the second messengers PtdIns(3,4,5)P_3 and PtdIns(3,4)P_2 with different affinities (Fig. 3). A PH-domain protein known to play a pivotal role in PI3K signaling is protein kinase B (PKB), also called *Akt* (Bilanges et al. 2019). Plasma membrane-recruited and plasma membrane-activated PKB triggers multiple signaling cascades implicated in an array of normal and pathophysiological cell processes, such as inflammation, metabolism, and tumorigenesis (Fig. 3).

Numerous other PH-domain-containing proteins are implicated in important physiological processes, such as the *g*uanosine nucleotide *e*xchange *f*actors (GEFs) Vav and P-Rex. GEFs



Phospholipid Kinases, Fig. 3 Role of PH-domain-containing effectors of class I PI3Ks in various cellular processes. Bottom left panel: visualization of the translocation of GFP-fused Grp1 PH-domain in living cells. Human embryonic kidney cells (HEK293) were stimulated with the chemokine CXCL12. The GFP-fused Grp1 PH-domain protein translocates from the cytosol to the plasma membrane, reflecting an increased PI3Kγ-mediated PtdIns $(3,4,5)P_3$ production. HEK293 were transfected with the chemotactic GPCR (CXCR4), PI3Kγ, and GFP-fused Grp1 PH-domain

exchange GDP for GTP and lead to an activation of small GTPases. Vav and P-Rex regulate the activity of the small GTPase Rho/Rac and are involved in cytoskeletal remodeling and cell motility. Grp1, a GEF for the small GTPase Arf, is necessary for vesicle budding (Fig. 3).

PtdIns(3)P generated by class II or III PI3Ks interacts with the FYVE zinc finger domains (acronym of FYVE: *F*ab1p, *Y*OTB, *V*ac1p, and *E*EA1) as well as PX domains (a domain originally identified as a common motif in the p40phox and p47phox of the neutrophil NADPH oxidase complex). Other phosphoinositide-binding domains have been identified. Among them are FERM domains (band four-point one, ezrin, radixin, moesin) that link cytoskeleton to the plasma membrane or ENTH domains (*e*psin *N*-*t*erminal *h*omology) that play a role in endocytosis.

Drugs

As described above, PI3K isoforms are critical for many signaling pathways in a highly selective manner that control growth and survival of the cells and metabolic and immunological functions of the organism. Consequently, PI3Ks are regarded as attractive drug target for cancer therapy and for the treatment of other human diseases. Whereas initial classical PI3K inhibitors such as Wortmannin and LY294002 show very little

selectivity for the different PI3K isoforms and display considerable off-target effects, nowadays a significant number of highly potent inhibitors have been developed. Major challenges for successful drug development of PI3K inhibitors are insufficient efficacy and serious unwanted drug effects (De Santis et al. 2019). The underlying reasons are manifold and often caused by mechanistically different developments of resistance and off-target toxicity. Pan-inhibitors, dual-specific inhibitors, or selective inhibitors are applied as part of a combination therapy, trying to increase therapeutic efficiency. Conversely, new classes of isoform-selective inhibitors are being designed to reduce off-target effects. Up to date, regulatory authorities have approved four PI3K inhibitors for treating patients suffering from various malignant tumors (Table 1). More are expected to come to the clinic in the future since a series of novel compounds are tested in clinical trials.

Physiology and Treatment of Hyperuricemia and Gout

Caroline Benn
LoQus23, Cambridge, UK

Synonyms

MSU; sUA; URAT1

Definition

Hyperuricemia is a condition characterized by abnormally elevated levels of serum urate (sUA), while gout, the most common form of inflammatory arthritis, arises from the subsequent deposition of urate crystals when concentrations become saturated (Dalbeth et al. 2019).

Hyperuricemia is commonly defined as a serum urate concentration >6.8 mg/dL, based on the *in vivo* solubility of urate above which crystal deposition may occur leading to gout. It should be noted that alternative definitions of hyperuricemia are sometimes applied, which needs to be considered during comparative data analysis (Stamp and Dalbeth 2017).

Gout has been defined as "a progressive metabolic disease characterized by symptomatic hyperuricemia and deposition of monosodium urate (MSU) crystals in joints and soft tissues due to an imbalance in uric acid uptake, synthesis or excretion" (Bardin and Richette 2014). Not all individuals with hyperuricemia go on to develop gout, and therefore gout represents a subset of individuals with symptomatic hyperuricemia.

Basic Mechanisms

Uric Acid

Uric acid is a weak diprotic acid with an aqueous pK_{a1} of 5.4 and pK_{a2} of 9.8. At physiological pH, uric acid is predominantly found as the deprotonated urate anion. The solubility of uric acid at normal physiological pH is around 6.8 mg/dL. The reference ranges for sUA are 3.5–7.2 mg/dL (210–430μmol/L) and 2.6–6.0 mg/dL (155–360μmol/L) in males and premenopausal females, respectively (Desideri et al. 2014). Notably, the upper limit of the normal male reference range includes concentrations that exceed the concentration at which uric acid precipitates. The normal range for serum urate concentrations in humans, and some other primates, is significantly above the typical mammalian range of 0.5–2.0 mg/dL (30–120μmol/L). Potential benefits of high sUA levels remain to be elucidated; however, hyperuricemia, in conjunction with genetic and/or environmental factors, can lead to significant health problems associated with urate crystal deposition.

Uric Acid Generation

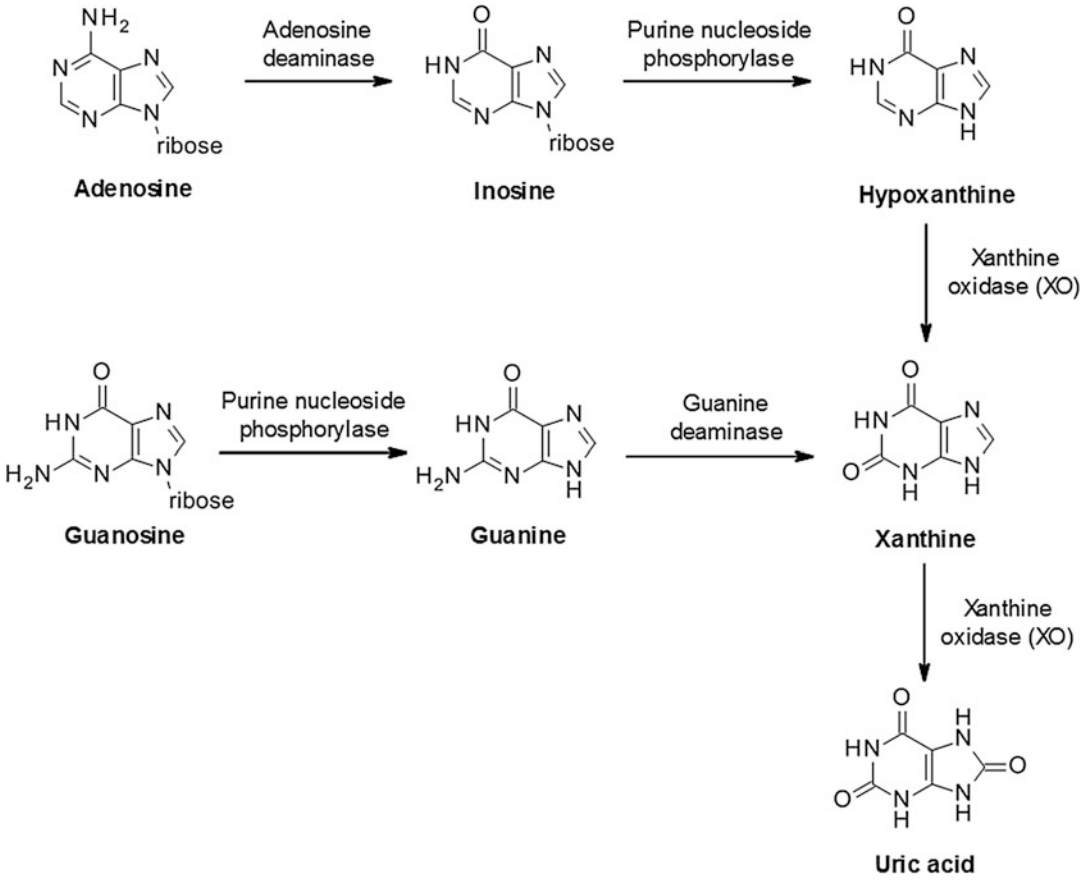
Uric acid is produced during the metabolism of both endogenous (daily synthesis rates of ~300–400 mg) and exogenous (dietary contribution, ~300 mg) purines within a total pool size of 1200 mg in healthy males (600 mg in females) on a purine-free diet. Uric acid biosynthesis is catalyzed by xanthine oxidase (XO/xanthine oxidoreductase/XOR), coded by the xanthine dehydrogenase gene *XDH* (Pacher et al. 2006). The enzyme is normally present as an inactive NAD-dependent cytosolic dehydrogenase precursor, which is processed by oxidation or proteolytic modification to form active enzyme. XO is widely distributed throughout various organs including the liver, gut, lung, kidney, heart, and brain as well as the plasma and is involved in two stages of uric acid generation: conversion of hypoxanthine to xanthine and subsequently xanthine to uric acid (Fig. 1).

Urate Crystal Formation

The initial clinical sign of an acute gout attack is severe disabling pain, usually involving a single joint, which typically spontaneously resolves over a period of a few days to weeks without intervention. Treatment with anti-inflammatory drugs such as colchicine, NSAIDs (nonsteroidal anti-inflammatory drugs), and corticoids will generally improve symptoms more rapidly. Upon resolution of an acute attack, the patient will enter a symptom-free interval; however flares can recur with increased frequency and duration if the underlying pathology is not addressed. If sUA (serum uric acid) values remain high, MSU (monosodium urate) crystal deposits can grow and expand to other sites leading to further inflammation and associated tissue/joint injury. A subset of individuals will transition to chronic tophaceous gout, characterized by nodular urate crystal deposits, recurrent flares, and concurrent arthritis (Bardin and Richette 2014).

While sustained hyperuricemia is a prerequisite of crystal formation, it is not possible to accurately predict which individuals will go on to develop gout, even for those with very high sUA. There is no global consensus on approaches for asymptomatic hyperuricemia nor in response to acute gout attacks. Different strategies are advocated by national or international guidelines, which range from reactive approaches to active sUA management in the absence of evoked symptoms.

The process of crystal deposition leading to gout is reversible by means of reducing sUA levels below its saturation point. The rate of crystal reduction will be modulated by both the total crystal load and reduction in sUA levels. Urate-lowering therapy (ULT) initiation generally leads to increased flare rate and associated pain,



Physiology and Treatment of Hyperuricemia and Gout, Fig. 1 Biosynthesis of uric acid from purines. Purine mononucleotides are catabolized to produce uric acid although the underlying pathway can vary in different tissues and cells

potentially as a direct consequence of urate crystal dissolution leading to the removal of a protein deposit protecting the underlying surface from attack by inflammatory cells. Treatment with anti-inflammatories alone may modulate the acute inflammatory response to crystals, but it is unlikely to alter crystal deposition and ongoing joint damage.

Uric acid urolithiasis refers to the development of a stone or calculus composed of significant amounts of urate in the renal pelvis, ureter, or bladder and is reported to account for 5.0–16.5% of all kidney stones. Uric acid solubility is modulated as a function of its weakly acidic pK_a, and hence, individuals with more acidic urine (pH 5.5) are more likely to have increased uric acid stone formation than individuals with a normal pH range (pH 6.0–6.5). Urinary alkalinization should therefore reduce stone growth/recurrence and promote stone dissolution.

Uric Acid Clearance

In most mammalian species, uric acid is further metabolized by the enzyme uricase to the more soluble allantoin which is subsequently excreted in the urine. However, humans and some higher-order primates lack a functional uricase enzyme, and therefore uric acid is the final breakdown product of the pathway. This discrepancy in uric acid handling between species represents a challenge in the preclinical evaluation of urate-lowering drugs during drug discovery. Urate elimination from humans occurs via two main routes; two-thirds is excreted in urine with normal

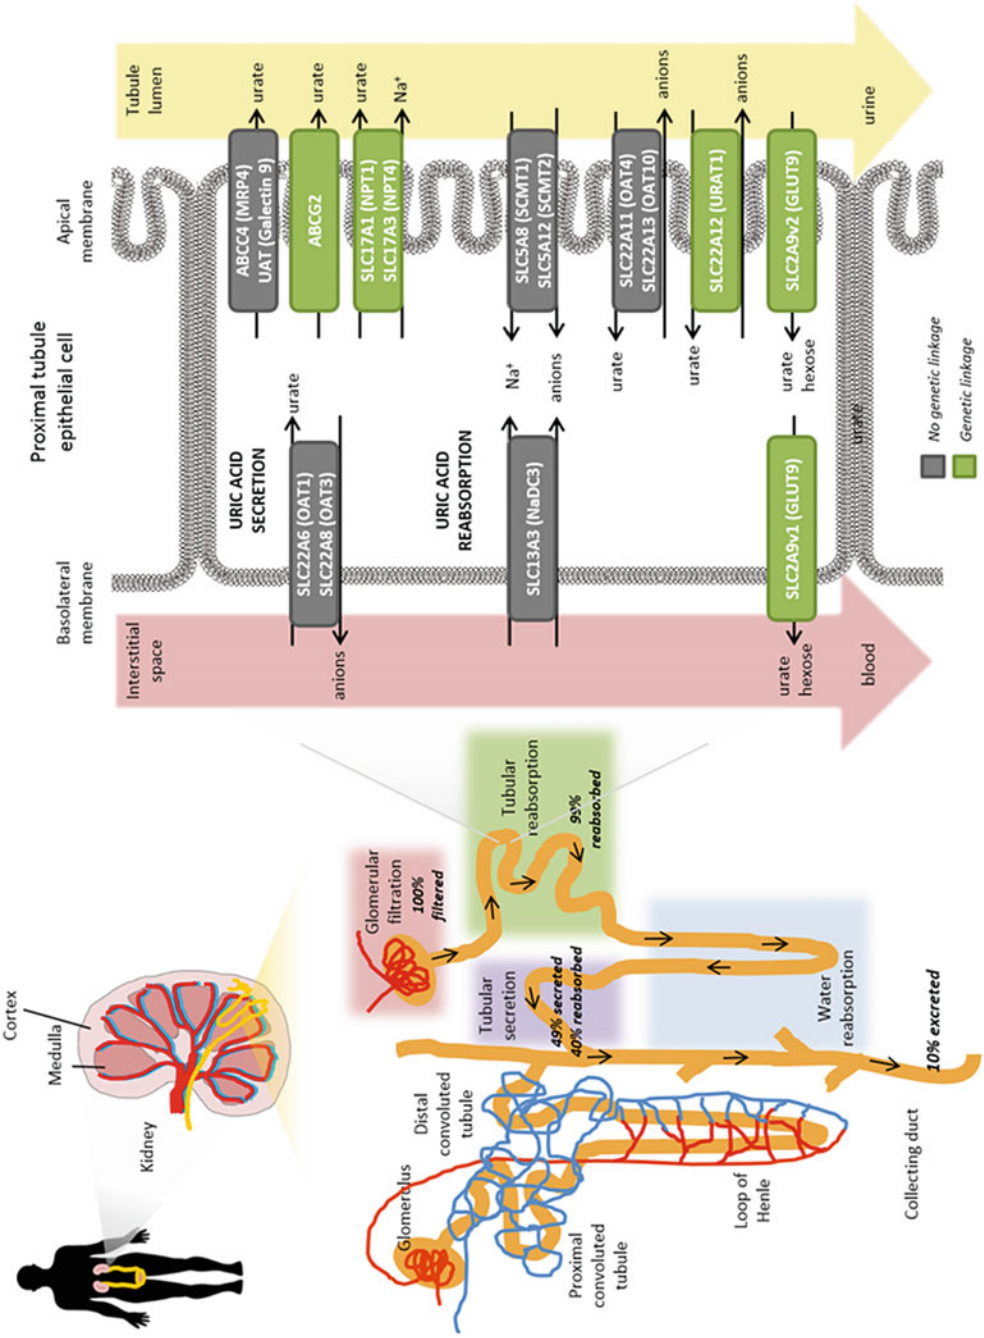
uricosuria levels of 620 ± 75 mg/day in adult, while the remainder is thought to be excreted via the gastrointestinal tract (Hyndman et al. 2016). Hyperuricemia may also be associated with hyperuricosuria (defined as urinary excretion of urate >800 mg/day in men and >750 mg/day in women). Urate elimination can also be quantified as clearance (normal males, 8.7 ± 2.5 mL/min) or as fractional excretion of urate (FEUA) which indicates the net urate excretion by the kidney (normal males, 7.25 ± 2.98%). Healthy subjects have an average FEUA in the range of 6–8%, whereas gout patients generally have average FEUA of 3–5%. These observations are consistent with the notion that decreased renal excretion or low FEUA represents a major contributor to hyperuricemia as opposed to increased generation of uric acid.

Despite the high fraction of renally excreted uric acid, the process is more complex than simple glomerular filtration, with approximately 91–95% of filtered urate being reabsorbed in the proximal tubule. Reabsorption is a key factor underpinning the comparatively high levels of circulating urate and is primarily mediated by transporters that exchange intracellular anions for urate. Reabsorption and secretion of urate predominates in the S1 and S2 regions of the proximal tubule although it is not clear whether the secretion happens concomitantly with reabsorption and/or if there is post-reabsorptive secretion within the tubule. Ultimately, around 3–10% of the filtered urate emerges in the urine. Several transporters playing a role in reabsorption and secretion have been identified, and some of these are genetically linked to hyperuricemia and gout (Köttgen et al. 2013; Hyndman et al. 2016) (Fig. 1).

URAT1 Is the Predominant Urate Reabsorption Transporter

URAT1 (*SLC22A12*) is the dominant apical (luminal) urate exchanger in the human proximal tubule. URAT1 is a 12-transmembrane domain protein, predominantly localized to the apical brush border membrane of proximal tubule epithelial cells in the kidneys. URAT1 has been reported to transport urate with a K_m of 371 ± 28μM as well as other organic anions such as orotate, salicylate, lactate, and nicotinate (Enomoto et al. 2002). URAT1-mediated urate transport is a tertiary active process dependent on sodium gradients initially established via basolateral Na^+K^+ATPases which actuate a number of apical Na^+-coupled organic anion transporters, in turn providing the driving force for urate reabsorption. Loss-of-function mutations of URAT1 are associated with FEUA of 40–100% and extremely low serum urate levels (average levels of 0.93 mg/dL). Additional urate transport pathways are inferred given that FEUA is <100% even in patients with complete URAT1 loss-of-function mutations. URAT1 is now a well-established drug target with a number of primary and secondary uricosurics (drugs capable of increasing FEUA) such as benzbromarone, probenecid, and lesinurad, known to derive at least part of their efficacy through this mechanism albeit, in earlier cases, this was not understood when they were developed. Interestingly, compounds such as pyrazinamide have been shown to trans-stimulate URAT1 activity to impact on vectorial transport of urate.

GLUT9 (*SLC2A9*) variants are strongly associated with both hyperuricemia and gout. GLUT9 appears to function predominantly as a facilitative urate uniporter with at least some additional capacity for hexose transport. GLUT9-mediated urate transport is voltage dependent, but independent of sodium, chloride, and other ions. GLUT9 is distinct from other members of the glucose transporter (SLC2) family due to its substrate specificity although it shares common structural features such as 12 transmembrane helices, cytoplasmic termini, and an N-linked glycosylation site. The short isoform (GLUT9a) appears to be expressed at both apical and basolateral membranes in proximal tubule epithelium cells (and indeed may contribute to the import of urate from the peritubular interstitium and thus facilitate renal urate secretion). The long isoform (GLUT9b) is predominantly expressed on the basolateral membrane and is the only known basolateral efflux transporter for urate. Interestingly, a positive relationship has been described between glycosuria and uricosuria suggesting that there could be interference between the tubular reabsorption of glucose and the tubular capacity to reabsorb urate.



Physiology and Treatment of Hyperuricemia and Gout, Fig. 2 (continued)

OAT4 (*SLC22A11*) and OAT10 (*SLC22A13*) have a range of organic anion substrates and are expressed on the apical membrane of proximal tubule epithelium cells together with URAT1 (*SLC22A12*). Both transporters have been demonstrated to exhibit low levels of urate transport capabilities.

Urate excretion transporters include ABCG2, and NPT1 (*SLC17A1*) and NPT4 (*SLC17A4*) are apical efflux transporters that are genetically associated with hyperuricemia and gout risk. OAT1 (*SLC22A6*) and OAT3 (*SLC22A8*) mediate the basolateral entry of urate into renal proximal tubule cells via the outwardly directed gradient for dicarboxylates, which in turn is generated by Na^+-dependent uptake. Thus, urate exchange is significantly trans-stimulated by dicarboxylates (Fig. 2).

Pharmacological Intervention

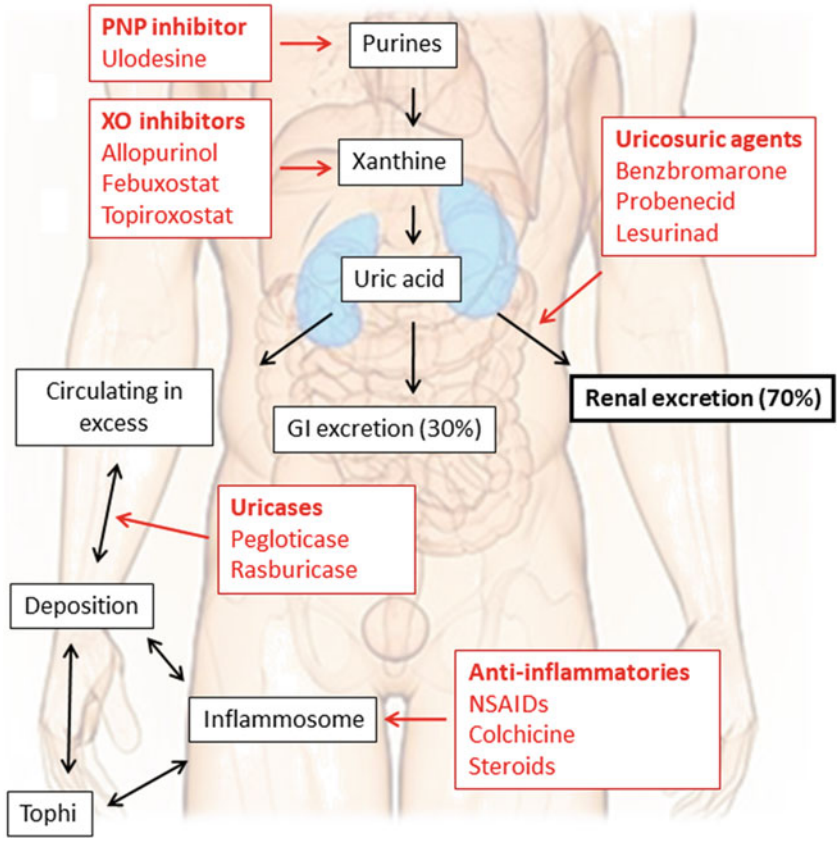
There are several approved ULT drugs which fall into three main classes: reduction of uric acid synthesis (xanthine oxidase inhibitors), increasing uric acid excretion (uricosurics, e.g., URAT1 inhibitors), and enabling systemic metabolic hydrolysis of uric acid (urolytics, e.g., recombinant uricases) (Figs. 3 and 4).

Xanthine Oxidase Inhibitors (XOi)

These reduce endogenous production of uric acid and thus lower sUA levels (Pacher et al. 2006). Inhibitors fall into two main classes: the classical purine analogs (including allopurinol) and more recently developed non-purine analog compounds such as febuxostat and topiroxostat.

Allopurinol was the first ULT to reach the market and remains the first-line therapy for hyperuricemia and gout. Allopurinol is a relatively weak competitive XO inhibitor and is rapidly metabolized to the more potent oxypurinol, an isostere of xanthine, which is then renally cleared. Allopurinol has been reported to possess additional pharmacology, such as decreasing blood pressure and creatinine levels, which supports the notion that XO inhibition can have effects independent of urate lowering. However, studies have suggested that less than 50% of patients taking the drug achieve a sUA level <6 mg/dL at an allopurinol dose of 300 mg/day although it is recommended to up-titrate allopurinol to 800/900 mg per day (depending on geography) until the target of sUA <6 mg/dL is achieved. Allopurinol has been associated with

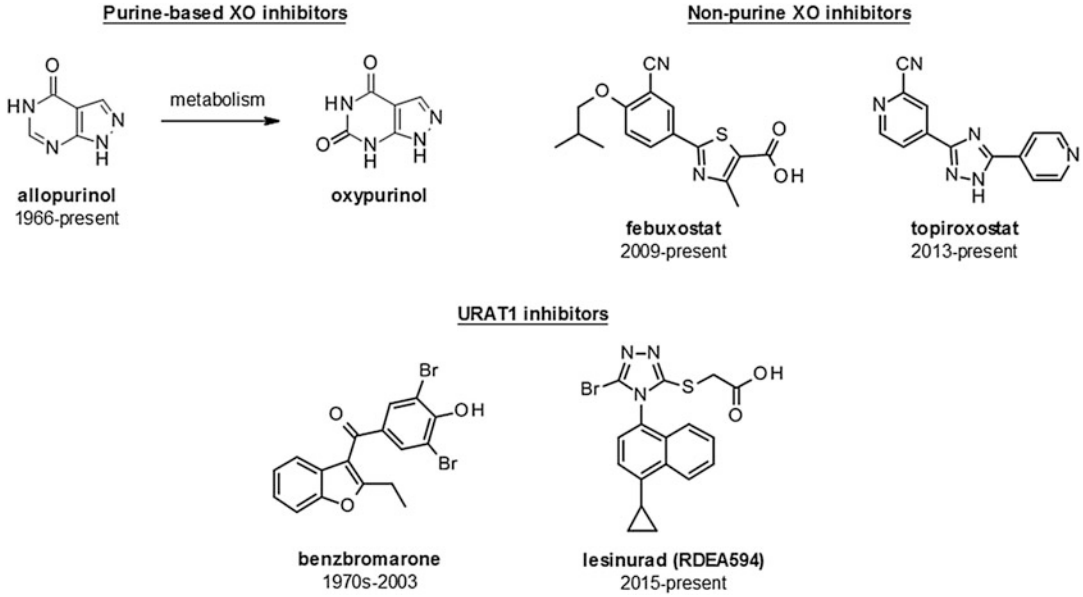
Physiology and Treatment of Hyperuricemia and Gout, Fig. 2 Role of transporters in the renal proximal tubule on urate handling. Within an individual nephron in the kidney (yellow), filtration of water and solutes occurs in the glomerular capsule from the afferent arteriole into the renal tubule (pink shading). Tubular reabsorption (green shading) is predominantly mediated by the proximal convoluted tubule, whereas tubular secretion extracts uric acid (and other substances) from peritubular capillaries (purple shading) and secretes them into the tubular fluid for urinary excretion. Urate transporters in renal proximal tubule epithelial cells actively mediate the secretion and reabsorption of urate. The balance between these processes determines the net excretion levels from the kidney. The anion transporters SLC22A6 (OAT1) and SLC22A8 (OAT3) localized on the basolateral membranes transport urate from the interstitial space in the blood depending on the gradients for exchanged anions but have not been shown to exhibit a genetic linkage with hyperuricemia or gout risk (gray box). On the apical membrane, ABCG2, SLC17A1 (NPT1), SLC17A3 (NPT4), ABCC4 (MRP4), and UAT (galectin 9) have all been shown to contribute to the secretory transport of urate into the tubule lumen and leading to urinary excretion; a number of these have been genetically associated with hyperuricemia and gout risk (green boxes). Exchange gradients upstream of urate anion exchange are enabled through the actions of SLC13A3 (NaDC3), SLC5A8 (SCMT1), and SLC5A12 (SCMT2). In renal reabsorption, the apical urate-anion exchanger SLC22A12 (URAT1) has been shown to play a predominant role in urate homeostasis, and indeed several variants have been identified to be associated with gout and hyperuricemia risk (green box). Additional contributions to urate reabsorption are mediated by SLC22A11 (OAT4) and SLC22A11 (OAT10) (gray boxes, not genetically associated with gout/hyperuricemia risk) and the short isoform of SLC2A9v2 (GLUT9, green box) on the apical membrane. The long isoform of SLC2A9v1 (GLUT9, green box) is the only known transporter to mediate basolateral efflux of urate back into circulation, which is in accordance with its genetic association for gout and hyperuricemia risk in addition to rare mutations associated with hypouricemia



Physiology and Treatment of Hyperuricemia and Gout, Fig. 3 Multiple points for rational pharmacological intervention (red boxes/text) to address hyperuricemia and gout. Biosynthesis of uric acid via purine catabolism to xanthine to uric acid can be targeted via purine nucleoside phosphorylase (PNP) or xanthine oxidase (XO) inhibition. Uric acid is predominantly cleared renally, with a significant proportion of the excreted uric acid being reabsorbed. It has been reported that underexcretion of uric acid contributes notably to hyperuricemia and gout; and this is the mechanism targeted by uricosuric agents. Uricases are synthetic recombinant enzymes that metabolize circulating uric acid. All aforementioned approaches are disease-modifying in contrast to symptomatic management approaches such as anti-inflammatories

several adverse effects including gastrointestinal effects, rash, Stevens-Johnson's syndrome, and allopurinol hypersensitivity syndrome in 2–8% of patients. Complications can also arise when patients have renal impairments.

Febuxostat is a selective, non-purine, inhibitor of XO approved by the FDA in 2009 for management of patients with hyperuricemia in patients with gout but not for asymptomatic hyperuricemia. Febuxostat has a reported IC_{50} of 1.8 nM, which is significantly more potent than allopurinol (IC_{50} 7.8μM), and consequently has been shown to be more efficacious at doses of 80 or 120 mg for achieving target urate levels of <6 mg/dL vs. allopurinol at 100–300 mg daily. Interestingly, gout flares on commencement of treatment have been reported to be more frequent with febuxostat than with allopurinol, likely due to the more rapid and pronounced sUA reduction. Febuxostat clearance is predominantly via hepatic metabolism which suggests the potential at least for broader prescribing with respect to impaired renal function though this has not been fully assessed in the clinic. In addition, febuxostat has been reported to have fewer drug-drug interactions than allopurinol and is better tolerated in patients with allopurinol hypersensitivity syndrome.



Physiology and Treatment of Hyperuricemia and Gout, Fig. 4 Structures of launched (marketed and withdrawn) drugs for the management of hyperuricemia. Purine-based (allopurinol and oxypurinol) and non-purine-based (febuxostat and topiroxostat) XO inhibitors are shown with dates of approval for clinical use. URAT1 inhibitors are represented by benzbromarone (withdrawn in 2003) and lesinurad (RDEA594).

Topiroxostat (FYX-051) is a structurally distinct, non-purine, selective XO inhibitor which was approved for use only in Japan in 2013. Topiroxostat has been shown to inhibit xanthine oxidase via formation of a hydroxylated 2-pyridine metabolite that forms a covalent linkage to the molybdenum via oxygen and also interacts with amino acid residues in the solvent channel.

Uricosurics

The underlying cause of hyperuricemia in a notable subset of patients appears to be due to renal underexcretion of uric acid (Ichida et al. 2012). This suggests the application of uricosuric agents to increase renal urate excretion as a rational approach for the treatment of hyperuricemia. However, by enhancing the renal clearance of uric acid, uricosurics may increase the risk of renal adverse events (e.g., nephrolithiasis). Uricosurics are currently recommended as a second-line therapy when target sUA levels are not reached, particularly as add-on therapies in combination with XO inhibitors. Combination therapy with uricosuric agents and XOi have been suggested to provide enhanced urate lowering and potentially more rapid resolution of tophi.

Several drugs, including probenecid, sulfinpyrazone, fenofibrate, and losartan, were serendipitously discovered to have uricosuric properties although the underlying pharmacology was not initially understood. Probenecid was originally introduced to prolong the action of antibiotics by reducing their renal clearance and functions as a nonselective inhibitor of organic anion transporters. URAT1 has now been demonstrated to be one of the molecular targets of probenecid. However, its lack of selectivity and subsequent potential for drug-drug interactions limit its clinical use as a uricosuric.

Benzbromarone, the first drug specifically developed for its uricosuric properties, was discovered and developed without any understanding of its pharmacology at a molecular level (Lee et al. 2008). Benzbromarone, first marketed in 1976, has subsequently been shown to be a potent URAT1 inhibitor (IC_{50} 22 nM). Benzbromarone is effective as a single-agent ULT although, like allopurinol, it requires dose titration from 50 to

200 mg to achieve maximum efficacy. Unlike allopurinol, benzbromarone could be used in patients with renal impairment though caution was advocated by clinicians where there was history of renal calculi. Benzbromarone was not approved in the USA and was withdrawn from the market in many other countries in 2003 following reported incidents of idiosyncratic hepatotoxicity.

Lesinurad is the first novel uricosuric to reach the market since benzbromarone. The primary mechanism of action of lesinurad derives from inhibition of URAT1, although it is also reported to be an inhibitor of OAT4 which could also potentially contribute to its efficacy. 200 mg dose of lesinurad received FDA approval at the end of 2015 for use in combination with a xanthine oxidase inhibitor for the treatment of hyperuricemia associated with gout in patients who have not achieved target serum uric acid levels with a xanthine oxidase inhibitor alone (Pérez-Ruiz et al. 2019). Further optimization of the RDEA594 (lesinurad) template culminated in the development of RDEA3170 (verinurad) which reportedly has a URAT1 IC_{50} of 25 nM (compared to 3.4 uM IC_{50} of lesinurad against URAT1) and is currently in clinical trials. Additional uricosurics in development have been reported including arhalofenate, FYU-981, and URC-102 (Benn et al. 2018). Another interesting molecule for which development has been terminated is PF-06743649 which was a dual URAT1/XO inhibitor. Ulodesine (BCX4208) is also noteworthy as it represents a novel mode of action, outside of XO inhibitors, uricosuric and uricolytic agents. This is a potent purine nucleoside phosphorylase (PNP) inhibitor acting upstream of xanthine oxidase inhibitors.

Urate Hydrolysis by Uricases

Humans, and some primate species, differ from other mammals by the lack of a functional uricase enzyme. Therapies based on the intravenous administration of a functional recombinant uricase enzyme have been developed which enable an immediate and significant reduction of sUA levels (Benn et al. 2018). Pegloticase, a PEGylated recombinant uricase, was approved in 2010 for limited-patient use in the treatment of chronic refractory gout in patients with tophaceous deformities and complications or where XOi and uricosurics are contraindicated. However, likely due to the very rapid urate reduction caused by administration of pegloticase, its application has been associated with significant prevalence of acute flares. Additionally, while pegloticase has been used effectively in the clinic, it is also prone to immunogenic infusion reactions with a significant portion of the patients receiving pegloticase developing antibodies within the first few months of treatment. A non-PEGylated uricase, rasburicase, has also been approved for specifically treating hyperuricemia associated with tumor lysis syndrome as its quick mode of action and short half-life relative to pegloticase (8 h vs. 12 days) aligns well with this particular application. However, rasburicase also causes high rates of immunogenic infusion reactions, methemoglobinemia, hemolysis, and anaphylaxis in patients which limit its more general use.

Conclusions

High levels of circulating uric acid have been associated with the increased risk for developing gout and kidney stones. Gout is the most common form of inflammatory arthritis with well-studied epidemiology. The natural history of gout can be summarized as asymptomatic hyperuricemia, acute gouty arthritis, intercritical period, and chronic tophaceous gout, with diagnosis based on both laboratory and radiological features. Gout is an eminently curable condition with approaches that include management of the inflammatory pain associated with flares, urate-lowering therapies that address the underlying cause, as well as other approaches such as improved patient education. If the treatment paradigm shifts further toward active management of hyperuricemia, we anticipate that patients will benefit from more facile methods for determining uric acid concentrations in biofluids together with increased availability of mobile applications for disease management.

The role of genetic predisposition is becoming more evident, and new insights into the pathophysiology of hyperuricemia and gouty arthritis (both acute and chronic) allow for an even better understanding of the disease. The identification of the URAT1 transporter and its role in urate reuptake from the proximal tubule has shed light on the pharmacology of a number of clinical uricosuric compounds and enabled the development of a new generation of specifically targeted molecules. This has been exemplified by development of lesinurad and verinurad in addition to other agents whereby drug discovery efforts have leveraged the measurement of URAT1-mediated transport as a functional primary pharmacology assay (Storer et al. 2016; Benn et al. 2018). Other transporters genetically linked with urate homeostasis such as GLUT9 may provide further targets for novel drug development in the future. In this context it is worth mentioning that determining requisite potency levels for advancing a compound can be hampered by the lack of a valid preclinical model. In addition, direct clinical PK/PD comparison can be challenging, due to complicating factors such as active metabolites, active renal excretion (which may imply that ultrafiltrate concentrations in the proximal tubule significantly differ from unbound plasma), and organic anion transporter polypharmacology. Nonetheless, there is genuine potential for further drug development to lead to better management in patients with hyperuricemia, gout, and associated conditions in the coming years.

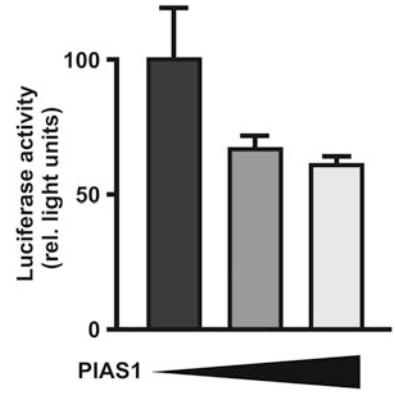
Definition

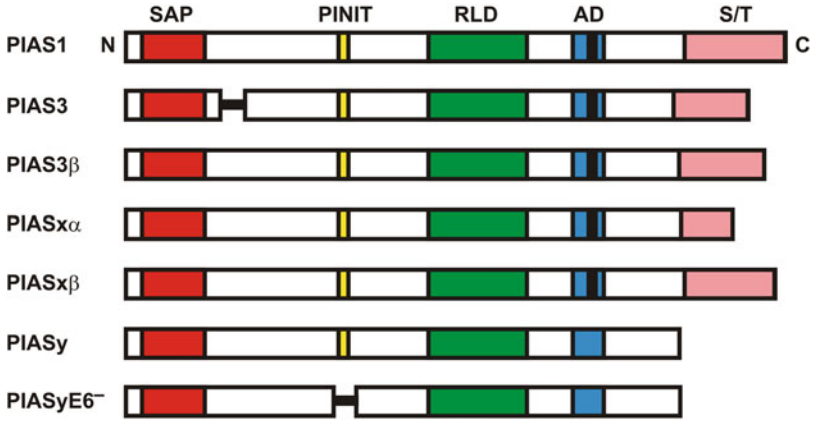
PIAS (*p*rotein *i*nhibitors of *a*ctivated *S*TATs) proteins were first discovered in yeast two-hybrid screens as interacting molecules with STAT transcription factors. The mammalian family consists of the founding member PIAS3, which was described as a repressor of STAT3, and three additional members, PIAS1, PIAS2 (also known as PIASx with α and β splice variants, termed ARIP3 [androgen receptor-interacting protein 3] and Miz1 [Msx-interacting zinc finger]), and PIAS4 (also known as PIASy), respectively. Despite their name, PIAS proteins do not selectively inhibit STAT-mediated cytokine signaling (Fig. 1), but function as transcriptional co-regulators in diverse pathways either by activating or repressing gene expression (Palvimo 2007). PIAS proteins have been shown to interact with a broad range of transcription factors unrelated to STATs, such as p53, c-Jun, SMAD, β-catenin/lymphoid enhancer factor 1, NF-κB p65, nuclear hormone receptors, and other proteins. PIAS proteins have been identified as SUMO E3 ligases, which catalyze the covalent addition of small ubiquitin-like modifier (SUMO) to different target proteins acting in these pathways. Some reports demonstrated that the effect of PIAS proteins on substrate function can also be exerted by mechanisms independent of their SUMO ligase activity (Rytinki et al. 2009). PIAS proteins are thought to act as adapter proteins, thereby regulating transcription through several mechanisms, which include inhibition of DNA-binding activity of transcription factors, recruitment of transcriptional corepressors, sequestration of transcription factors in distinct subcellular or subnuclear compartments, and epigenetic modification. Given their function in both SUMOylation-dependent and SUMOylation-independent processes, PIAS proteins are involved in a broad spectrum of biological processes, including embryonic development, innate and adaptive immune responses, hematopoiesis as well as spatial learning and long-term memory.



PIAS Proteins, Fig. 1 Reporter gene assay using an interferon-γ-driven artificial promoter demonstrating the inhibitory transcriptional activity of increasing concentrations of PIAS on STAT1 signal transduction by an unknown mechanism

Domain Structure and Function

With the exception of a variable carboxy-terminal region, all mammalian PIAS proteins share a high degree of sequence homology and a common domain structure (Fig. 2). The overall sequence identity at the amino acid level is more than 40%. PIAS1 with a length of 651 amino acid residues is the largest member, whereas PIASy lacking the C-terminal serine-/threonine-rich domain is the smallest. In the amino-terminus of all PIAS proteins, a SAP domain is located which contains an LXXLL amino acid motif (where X denotes any amino acid residue). The acronym refers to three defining members of the class of SAP-containing proteins, namely, scaffold attachment factor (SAF), apoptotic chromatin condensation inducer in the nucleus (ACINUS), and PIAS, and has been



PIAS Proteins, Fig. 2 Domain structure of PIAS proteins. For abbreviations see text

suggested to confer binding to chromatin structures. The SAP domain of PIAS1 and PIASy has been shown to bind synthetic (A+T)-rich DNA sequences *in vitro*, suggesting that it targets PIAS proteins to the nuclear matrix. The PINIT (Pro-Ile-Asn-Ile-Thr) motif is present in all PIAS proteins except the splice variant PIASyE6-, which lacks exon 6. Mutation in the PINIT motif results in disrupted nuclear localization of PIAS3, suggesting a role in nuclear retention (Heppler and Frank 2017). Another conserved domain is the RING-finger-like domain (RLD), which resembles the zinc-binding RING fingers found in a subclass of ubiquitin E3 ligases, except for a different spacing of the zinc-coordinating residues. And indeed, the RLD domain has been shown to confer E3 ligase activity for SUMO modification. The carboxy-terminus of PIAS proteins contains a highly acidic domain (AD) with a putative SUMO-interaction motif (SIM, except for PIASy, in which the SIM is missing), which modulates their enzymatic activity, as well as a serine-/threonine-rich domain (S/T rich).

Characteristics of PIAS Proteins

PIAS proteins have been described as adapter molecules that function as E3-like ligases in enhancing the interaction between the SUMO-conjugating enzyme Ubc9 and its respective substrates (Rabellino et al. 2017). PIAS proteins facilitate the formation of an isopeptide bond between the C-terminus of SUMO and the ε-amino group of a lysine residue in the target protein. SUMOylation has been suggested to regulate a variety of cellular processes, such as modulation of transcriptional activity, targeting of proteins to subnuclear structures, and protein stability. PIAS might repress or stimulate gene expression, depending on the target gene and the transcriptional cofactors involved. The molecular mechanisms of PIAS-mediated gene regulation include inhibition of DNA-binding of transcription factors as well as the recruitment of co-regulators, such as histone deacetylases, p300, or CPB (cyclic AMP-responsive element-binding [CREB] protein). It was shown that PIAS-dependent SUMOylation is involved in the repair of DNA double-strand breaks (DSBs) (Zlatanou and Stewart 2010). This function of PIAS proteins in homologous recombination repair (HRR) and nonhomologous end joining (NHEJ) may be mediated through their ability to effectively promote the relocalization of 53BP1 (p53-binding protein 1) and/or BRCA1 (BReast CAncer 1, early-onset) to sites of DNA breaks. Sequestering transcription factors in subnuclear structures has been proposed as another mechanism for PIAS action. The role of SUMOylation in these processes is currently unclear and needs further attention.

PIAS1 knockout mice show increased protection against pathogenic infection, but are otherwise viable (Sharrocks 2006). PIASy-deficient mice display no obvious phenotype with normal distribution of lymphocyte populations, but the absence of PIASy expression had a modest effect on myeloid cell differentiation and Wnt signaling.

In cells derived from *Pias1*-, *Piasx*-, or *Piasy*-mutated mouse lines, the overall SUMOylation patterns of cellular proteins were not reduced as compared to cells from wild-type animals, demonstrating the functional redundancy among the mammalian PIAS proteins at an organismic level.

Drugs

Specific antagonists of PIAS proteins are not available. The engagement of PIAS proteins in different signal pathways suggests that inhibition of PIAS might cause pleiotropic effects. Due to the promiscuous actions of PIAS, the pharmacological reactions resulting from blockade of PIAS functions are currently far from been predictable. Moreover, the response may differ depending on which member of the PIAS family is preferentially targeted.

Synonyms

Placebo response

Definition

The placebo effect is the reduction of a symptom or a change in a physiological parameter, when an inert treatment (the placebo) is administered to a subject who is told that it is an active drug with specific pharmacological properties. The placebo effect, so far considered a nuisance in clinical research when a new treatment has to be tested, has now become a target of scientific investigation to better understand the physiological and neurobiological mechanisms that link a complex mental activity to different functions of the body. Usually, the terms placebo effect and response are used interchangeably by clinical researchers who run clinical trials and by neuroscientists who want to understand the underlying mechanisms. It is important to realize that there is not a single placebo effect but many, which occur through different mechanisms in different conditions, systems, and diseases (Benedetti et al. 2005; Colloca and Benedetti 2005; Colloca et al. 2004).

Basic Mechanisms

Methodological Considerations

The identification of a placebo effect is not easy, and its study is full of drawbacks and pitfalls. In fact, the effect which follows the administration of a placebo can be due to many factors, such as spontaneous remission, i.e., natural history (natural course of a disease or a symptom), regression

to the mean (statistical phenomenon which assumes that individuals tend to receive their initial symptom assessment when the symptom is near its greatest intensity and that their symptom level is likely to be lower when they return for a second assessment), symptom detection ambiguity, and biases. All these phenomena need to be ruled out by means of control groups. The possibility of spontaneous remission can be discarded by means of a no-treatment group, which gives us information about the natural course of a symptom. Regression to the mean can be controlled by using an experimental model in healthy volunteers. Symptom detection ambiguity and biases can be avoided by using objective physiological measurements. It is also important to rule out the possible effects of co-interventions. For example, the mechanical insertion of a needle for the injection of an inert substance may per se induce analgesia, thus leading to erroneous interpretations. Furthermore, the therapeutic outcome of a clinical trial and its interpretation can be affected by the Hawthorne effect, that is, the change in behavior of the patients who are aware of being part of a controlled study (Benedetti et al. 2016).

When all these phenomena are ruled out and the correct methodological approach is used, striking placebo effects can be detected which are mediated by psychophysiological mechanisms worthy of scientific inquiry (de la Fuente-Fernández et al. 2001; Petrovic et al. 2002). Therefore, it is this psychological component that represents the real placebo effect.

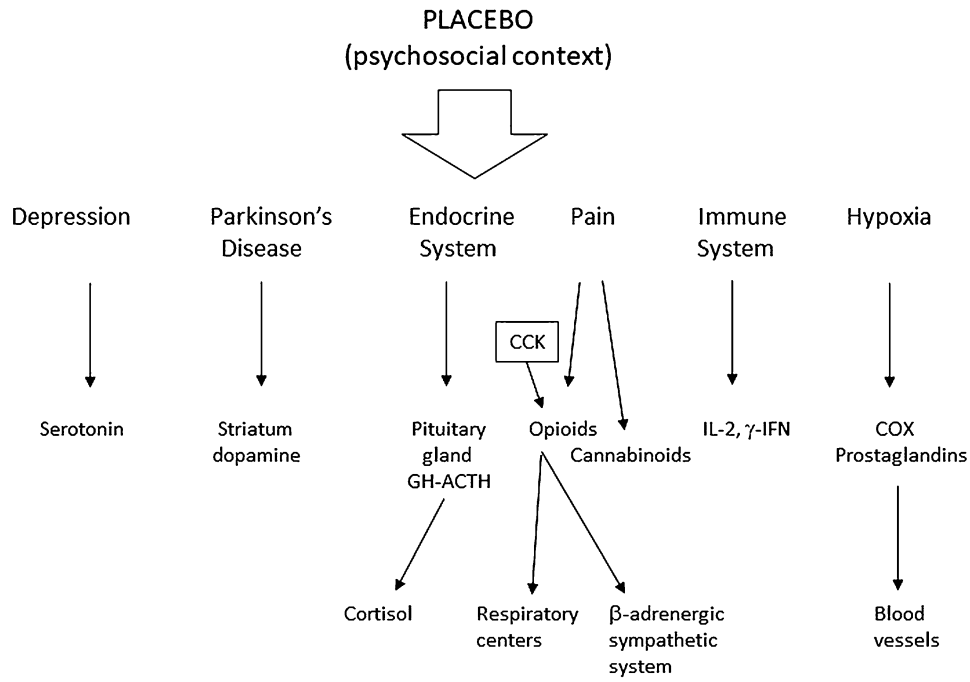
Psychological Mechanisms

The placebo effect is basically a context effect, whereby the psychosocial context (e.g., the therapist's words, the sight of complex machines, and other sensory inputs) around the medical intervention plays a crucial role. Today we know that the context may produce a therapeutic effect through at least two mechanisms: conscious anticipatory processes and unconscious conditioning mechanisms. In the first case, expectation (anticipation of an event; according to expectation theories, expecting an outcome affects the outcome itself) and anticipation of clinical benefit has sometimes been shown to induce a real clinical improvement. In the second case, contextual cues (e.g., color and shape of a pill) may act as a conditioned stimulus that, after repeated associations with an unconditioned stimulus (the active pharmacological agent contained in the pill), is capable alone of inducing a clinical improvement. In the case of pain and Parkinson's disease, it has been shown that expectations play a crucial role, even though a conditioning procedure is performed.

Neurobiology of Placebo Analgesia

The neural mechanisms underlying the placebo effect are only partially understood, and most of our knowledge comes from pain, Parkinson's disease, hypoxia, and immune and endocrine responses, whereas we have only a few pieces of information for other conditions such as depression (Fig. 1). In each of these conditions, different mechanisms seem to take place, so that we cannot talk of a single placebo effect but many.

As to pain and analgesia, in the studies so far performed, there is a general agreement that the endogenous opioid peptide systems play an important role in some circumstances. There are several lines of evidence indicating that placebo analgesia is mediated by a descending pain-modulating circuit which uses endogenous opioids as neuromodulators. This evidence comes from a combination of both imaging and pharmacological studies. In fact, by using positron emission tomography (PET), it was found that the very same regions of the brain in the cerebral cortex and in the brainstem are affected by both a placebo and the opioid agonist remifentanil, thus indicating a related mechanism in placebo-induced and opioid-induced analgesia (Petrovic et al. 2002). In particular, the administration of a placebo induces the activation of the rostral anterior cingulate cortex (rACC), the orbitofrontal cortex (OrbC), and the brainstem. Moreover, there is a significant covariation in activity between the rACC and the lower pons/medulla at the level of the rostral ventromedial medulla (RVM) and a subsignificant covariation between the rACC and the periaqueductal gray (PAG), thus suggesting that the descending rACC/PAG/RVM pain-modulating circuit is involved in placebo analgesia. In another



Placebo Effect, Fig. 1 Cascade of events that may occur during a placebo procedure in different systems and diseases. In pain, both opioid and cannabinoid mediators can be released through the activation of a descending inhibitory network. The respiratory centers may be inhibited by opioid mechanisms as well. The beta-adrenergic sympathetic system is also inhibited during placebo analgesia, although the underlying mechanism is not known (reduction of the pain itself and/or direct action of endogenous opioids). Cholecystokinin (CCK) counteracts the effects of the endogenous opioids, thus antagonizing placebo analgesia, and is also a mediator of the hyperalgesic nocebo effect. Placebos may also affect hormone secretion, like growth hormone (GH), adrenocorticotropic hormone (ACTH), and cortisol, as well as some immune mediators, such as IL-2 and γ-IFN. In Parkinson's disease, placebos induce dopamine release in the striatum, whereas in depression they affect the same brain regions that are affected by serotonin reuptake inhibitors, thus suggesting the involvement of serotonin in the placebo effect in depression. Under hypoxic conditions, placebos may also modulate cyclooxygenase (COX) activity, thereby affecting prostaglandins synthesis

study with functional magnetic resonance imaging (fMRI), it was shown that placebo administration produces a decrease of activity in many regions involved in pain transmission, such as the thalamus and the insula.

The studies with PET and fMRI tell us that placebo analgesia and opioid analgesia share a common neural mechanism and that pain transmission is inhibited by placebos. Recently, a meta-analysis of brain imaging studies has shown that placebo analgesia, while not directly affecting areas involved in pain processing, activates a complex network of areas that influence pain-related regions (Zunhammer et al. 2018).

In support of the involvement of endogenous opioids in this descending circuit, there are several pharmacological studies which show that placebo analgesia is antagonized by the opioid antagonist naloxone. In addition, it has been shown that the endogenous opioid systems have a somatotopic organization, since local placebo analgesic responses in different parts of the body can be blocked selectively by naloxone. A recent PET study used in vivo receptor binding to show that placebos induce the activation of *mu* opioid receptors in different brain areas, like the dorsolateral prefrontal cortex, nucleus accumbens, insula, and rACC.

The placebo-activated endogenous opioids do not act only on pain transmission but on the respiratory centers as well, since a naloxone-reversible placebo respiratory depressant effect has been

described. Likewise, a reduction of beta-adrenergic system activity, which is blocked by naloxone, has been found during placebo analgesia. These findings indicate that the placebo-activated opioid systems have a broad range of action, influencing pain, respiration, and the autonomic nervous system, though it is not known whether they act only through a descending modulating network. The placebo-activated endogenous opioids have also been shown to interact with endogenous substances that are involved in pain transmission. In fact, on the basis of the anti-opioid action of cholecystokinin (CCK), CCK-antagonists have been shown to enhance placebo analgesia, thus suggesting that the placebo-activated opioid systems are counteracted by CCK during a placebo procedure.

It is important to point out that some types of placebo analgesia appear to be insensitive to naloxone, thus suggesting that neuromodulators other than opioids can be involved in some circumstances. For example, if a placebo is given after repeated administrations (preconditioning) of the non-opioid painkiller ketorolac, the placebo analgesic response is not blocked by naloxone but by rimonabant, a CB1 cannabinoid receptor antagonist, which suggests the involvement of endocannabinoids in placebo analgesia.

Furthermore, by using high-altitude hypoxia as a model, it has been found that, similar to aspirin, a placebo can modulate cyclooxygenase activity and the synthesis of prostaglandins and thromboxane in hypobaric hypoxia headache (Benedetti et al. 2014).

Interestingly, although genetic studies are still at the beginning, it has been recently observed that placebo responsiveness is associated with specific genetic polymorphisms in the irritable bowel syndrome (Hall et al. 2012).

Parkinson's Disease

The release of endogenous substances following a placebo procedure is a phenomenon which is not confined to the field of pain, but it is also present in motor disorders, such as Parkinson's disease. As occurs with pain, in this case patients are given an inert substance (placebo) and are told that it is an antiparkinsonian drug that produces an improvement in their motor performance. A study used PET in order to assess the competition between endogenous dopamine and ^{11}C-raclopride for D_2/D_3 receptors, a method that allows identification of endogenous dopamine release (de la Fuente-Fernández et al. 2001). This study shows that placebo-induced expectation of motor improvement activates endogenous dopamine in the striatum of Parkinsonian patients. As this occurs in both the dorsal and ventral striatum, a region involved in reward, it has been argued that the expectation-induced release of dopamine in Parkinson's disease is related to reward mechanisms.

Placebo administration in Parkinson patients affects the activity of the neurons in the subthalamic nucleus, a brain region belonging to the basal ganglia circuitry and whose activity is increased in Parkinson's disease. Verbal suggestions of motor improvement during a placebo procedure are capable of reducing the firing rate and abolishing bursting activity of subthalamic nucleus neurons, and these effects are related to clinical improvement (Benedetti et al. 2005).

Immune and Endocrine Responses

Placebo responses in both the immune and endocrine system can be evoked by pharmacological preconditioning. In fact, after repeated administrations of drugs, if the drug is replaced with a placebo, immune or hormonal responses can be evoked that are similar to those obtained by the previously administered drug. For example, immunosuppressive placebo responses can be induced in humans by repeated administration of cyclosporine A (unconditioned stimulus) associated with a flavored drink (conditioned stimulus), as assessed by interleukin-2 (IL-2) and interferon-γ (IFNγ) mRNA expression, in vitro release of IL-2 and IFNγ, and lymphocyte proliferation. Likewise, if a placebo is given after repeated administrations of sumatriptan, a serotonin agonist of the 5-HT $_{1B/1D}$ receptors that stimulates growth hormone (GH) and inhibits cortisol (glucocorticoids) secretion, a placebo GH increase and a placebo cortisol decrease can be found. These studies support a conditioning mechanism in both immunosuppressive and hormonal placebo responses.

Depression

Depressed patients who receive a placebo treatment show both electrical and metabolic changes in the brain. In the first case, placebos induce electroencephalographic changes in the prefrontal cortex of patients with major depression, particularly in the right hemisphere. In the second case, changes in brain glucose metabolism were measured by using PET in subjects with unipolar depression. Placebo treatments are associated with metabolic increases in the prefrontal, anterior cingulate, premotor, parietal, posterior insula, and posterior cingulate cortex and metabolic decreases in the subgenual cingulate cortex, parahippocampus, and thalamus. Interestingly, these regions are also affected by the selective serotonin reuptake inhibitor, fluoxetine, a result that suggests a possible role for serotonin in placebo-induced antidepressant effects.

Nocebo Effect

The nocebo effect, or response, is a placebo effect in the opposite direction. For example, administration of an inert substance along with verbal suggestions of pain increase may induce a hyperalgesic effect. In this case, anticipatory anxiety may play a fundamental role. Nocebo hyperalgesia has been found to be blocked by proglumide, a non-specific CCK-A/CCK-B receptor antagonist. This suggests that expectation-induced hyperalgesia is mediated, at least in part, by CCK. These effects of proglumide are not antagonized by naloxone; thus endogenous opioids are not involved. Since CCK plays a role in anxiety and negative expectations themselves are anxiogenic, proglumide is likely to act on a CCK-dependent increase of anxiety and pain during the verbally induced negative expectations. Although, mainly due to ethical constraints, the nocebo effect has not been investigated in detail, as has been done for the placebo effect, it shows the powerful effect of the top-down modulation of pain. In other words, cognitive and emotional factors can modulate pain perception in opposite directions.

Nocebo effects represent a source of confusion and misinterpretation in clinical trials, and adverse events described in informed consent forms can actually lead to negative outcomes. For example, in clinical trials for anti-migraine drugs, it has been shown that the adverse events described specifically for each anti-migraine drug out of three different classes (nonsteroid anti-inflammatory, triptans, and anticonvulsants) corresponded to the adverse events observed in each respective placebo arm (Amanzio et al. 2009).

Studies on nocebo effect in depression showed similar effects. Indeed, in a study on the rates of adverse events in serotonin reuptake inhibitor (SSRI) trials, a total of 143 placebo-controlled trials were analyzed showing that the reported rate of adverse events was influenced by their assessment, so that a more systematic assessment led to higher rates in comparison to a less systematic assessment (Rief et al. 2009).

Pharmacological Relevance

Implications for Clinical Trials

According to the classical methodology of clinical trials, any drug must be compared with a placebo in order to assess its effectiveness. If the group that takes the drug shows a larger clinical improvement than the group that takes the placebo, the drug is considered to be effective. However, in light of the recent advances in placebo research, some caution is necessary in the interpretation of some clinical trials. In fact, by considering the complex cascade of biochemical events induced by placebo administration, any drug that is tested in a clinical trial may interfere with these placebo-/expectation-activated mechanisms, thus confounding the interpretation of the outcome of a clinical trial. As we have no a priori knowledge of which substances act on placebo-activated endogenous opioids, dopamine, and serotonin – and indeed almost all drugs might interfere with these neurotransmitters – one way to eliminate this possible pharmacological interference is to make the placebo-activated biochemical pathways "silent." This can be achieved by the hidden administration of drugs.

Hidden Administration of Drugs

It is possible to eliminate the placebo (psychosocial) component and analyze the pharmacodynamic effects of a treatment, free of any

psychological contamination, by administering drugs covertly. In this way, the cascade of biochemical events triggered by a placebo procedure can be eliminated. To eliminate the psychosocial context in which a treatment is given and thus the placebo component of the treatment, the patient is not made aware that a medical therapy is being carried out. To make this possible, drugs are administered through hidden infusions by machines. A hidden drug infusion can be performed through a computer-controlled infusion pump that is pre-programmed to deliver the drug at the desired time. It is crucial that the patient does not know that any drug is being injected, so that he or she does not expect anything. The computer-controlled infusion pump can deliver a drug automatically, without a doctor or nurse in the room and without the patient being aware that a treatment has been started (Colloca et al. 2004).

The analysis of different treatments, either pharmacological or not, in different conditions has shown that an open (expected) therapy that is carried out in full view of the patient is more effective than a hidden one (unexpected). Whereas the hidden injection represents the real pharmacodynamic effect of the drug, free of any psychological contamination, the open injection represents the sum of the pharmacodynamic effect plus the psychological component of the treatment. The latter can be considered to represent the placebo component of the therapy, even though it cannot be called placebo effect, as no placebo has been given. It is important to realize that, by using hidden administration of drugs, it is possible to study the placebo effect without the administration of any placebo.

For example, in a postoperative setting, it has been shown that the analgesic dose used to reduce pain by 50% was higher in hidden compared to open administrations of four different painkillers (buprenorphine, tramadol, ketorolac, metamizol) and the reported pain was higher after a hidden analgesic infusion compared with an open one (Benedetti et al. 2011).

Brain imaging studies have shown different activities for open and hidden administrations of analgesic drugs. Indeed, it has been observed that the open infusion of the analgesic remifentanil (told remifentanil, gets remifentanil) induced stronger analgesic effects than its hidden infusion (told saline, gets remifentanil), and these effects were associated with activity in the dorsolateral prefrontal cortex and pregenual anterior cingulate cortex. Interestingly, the negative expectation of drug interruption (told interruption, gets remifentanil) completely blocked the analgesic effects of remifentanil and was associated with activity in the hippocampus (Bingel et al. 2011).

Prefrontal Control and Placebo Response

A common finding across different neuroimaging studies on placebo analgesia is the predominant activity of prefrontal regions, like the dorsolateral prefrontal cortex, suggesting their crucial role in placebo responses. Data coming from studies on patients' neuroimaging and neuromodulation support this idea.

Since in patients affected by Alzheimer's disease the frontal lobes appear to be severely compromised, this neurodegenerative disorder has been used as a model to test placebo responsiveness. Indeed, in these patients, it has been found that placebo analgesia is positively correlated with cognitive status and functional connectivity between different brain areas, and, conversely, the more impaired the prefrontal activity, the smaller the observed placebo response (Benedetti et al. 2006). More recently, it has been shown that stronger placebo analgesia is associated with increased mean fractional anisotropy values within white matter tracts connecting the PAG with rACC and dorsolateral prefrontal cortex (Stein et al. 2012). Finally, in healthy volunteers, repetitive transcranial magnetic stimulation (rTMS) has been used to inactivate the left and right prefrontal cortex during placebo analgesia, and this prefrontal inactivation resulted in a complete blockade of the placebo response (Krummenacher et al. 2010). Therefore, these studies confirm that the placebo response is directly correlated to prefrontal control: when this activity is abolished, there is no placebo response.

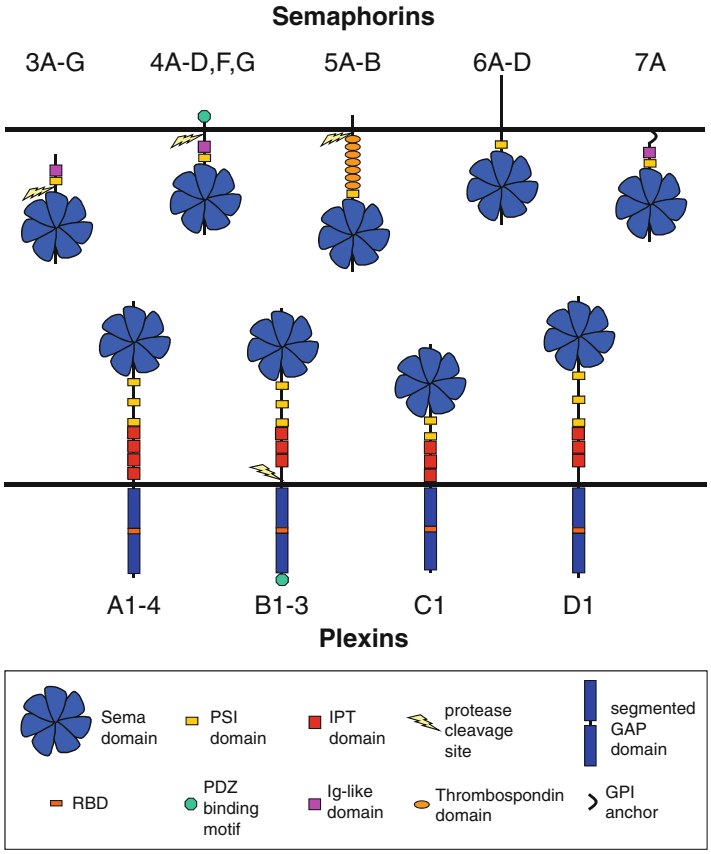
Definition

Plexins comprise an evolutionary conserved and widely expressed family of transmembrane

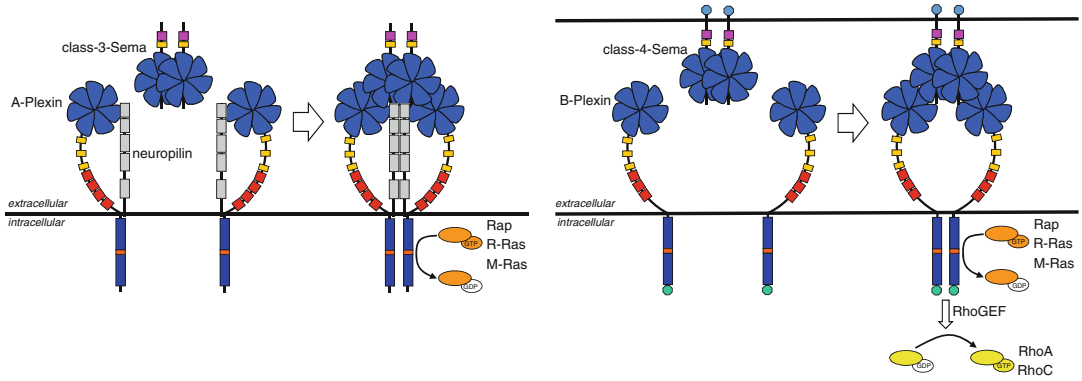


Plexins, Fig. 1 Mammalian plexins and their semaphorin ligands. The mammalian plexins are grouped into four subfamilies (**A**–**D**). The mammalian semaphorin family is divided into five classes (3–7). Both plexins and semaphorins are characterized by the presence of an extracellular sema domain, which contains a seven-blade β-propeller. In addition, all plexins share a highly conserved intracellular moiety that carries a segmented GAP domain and a Rho GTPase binding domain (RBD). Additional domains include PSI (plexin, semaphorin, integrin) domains and IPT (Ig-like, plexins, and transcription factors) domains. The plexins of the B-family have a PDZ binding motif at their C-terminus. Some plexins and semaphorins exhibit protease cleavage sites. While class-3-semaphorins are secreted, classes 4–6 are transmembrane proteins. Class-7-semaphorins are attached to the plasma membrane by a GPI-anchor. Class-5-semaphorins are characterized by seven thrombospondin domains

proteins that serve as receptors for semaphorins. They regulate key cellular functions such as morphology, proliferation, differentiation, and migration and play a pivotal role in cell-cell communication. On the basis of homology, they are grouped into four subfamilies (A–D). Semaphorins are a large family of secreted and membrane-associated proteins. In the mammalian system, five structurally different classes of semaphorins (3–7) have been found (Fig. 1). While the semaphorin-plexin system was initially discovered as a regulator of axonal guidance in the developing nervous system, it has become clear that its physiological and pathophysiological relevance is much larger including the cardiovascular, immune, renal, and bone system as well as cancer (Worzfeld and Offermanns 2014).

Basic Mechanisms

Both plexins and semaphorins are structurally characterized by the presence of an extracellular sema domain, which contains a seven-blade β-propeller (Fig. 1) (Worzfeld and Offermanns 2014). The sema domain of semaphorins mediates



Plexins, Fig. 2 Mechanism of semaphorin-plexin signaling. Binding of a semaphorin homodimer to two plexin monomers induces plexin dimerization and downstream signaling. For class-3-semaphorins, neuropilins are required to stabilize the assembly

Plexins, Table 1 Plexins and their respective ligands

Receptor	Ligand
Plexin-A1	Class-3-semaphorins[a], Sema5A, Sema5B, Sema6C, Sema6D
Plexin-A2	Class-3-semaphorins[a], Sema6A, Sema6B
Plexin-A3	Class-3-semaphorins[a], Sema5A, Sema5B
Plexin-A4	Class-3-semaphorins[a], class-6-semaphorins
Plexin-B1	Sema3C[a], Sema4A, Sema4D
Plexin-B2	Sema4A, Sema4B, Sema4C, Sema4D, Sema4G, angiogenin
Plexin-B3	Sema4A, Sema5A
Plexin-C1	Sema4D, Sema7A, viral semaphorins
Plexin-D1	Class-3-semaphorins[a], Sema3E[b], Sema4A

[a]When plexin is in a complex with neuropilin
[b]Independently of neuropilins. Angiogenin = Angiogenin-1 = Ribonuclease 5 = RNase 5

the formation of semaphorin homodimers (Fig. 2). So far, there is no evidence for semaphorin heterodimers or for functional semaphorin monomers. The extracellular domain of plexins forms an autoinhibited ring-like conformation. In contrast to the sema domain of semaphorins, the sema domain of plexins is monomeric and does not dimerize. The cytoplasmic moieties of plexins (~600 amino acids) are highly conserved and do not show homology to any other known protein. The interaction between semaphorins and plexins is mediated by the sema domains (Table 1). The semaphorin-plexin binding interface is relatively large, and the binding specificity critically relies on insertions in the β-propeller of the sema domains. Each subunit of a semaphorin dimer binds a monomeric plexin, thereby inducing the formation of plexin dimers and plexin downstream signaling (Fig. 2). Class-3-semaphorins require neuropilins as co-receptors, which stabilize the binding of a class-3-semaphorin to its plexin receptor. Other functionally relevant co-receptors for plexins of the B- and D-subfamily include the receptor tyrosine kinases ErbB-2 and Met. Since semaphorins are found both in a membrane-bound form and in a soluble form, plexins can interact with semaphorins on different cells or with semaphorins in solution (Jongbloets and Pasterkamp 2014). In addition to interactions between semaphorins and plexins in *trans* (i.e., the semaphorin and the plexin being on different cells), there is evidence that semaphorins and plexins can also interact in *cis* (i.e., on the same cell). These *cis* interactions can induce plexin signaling in *cis* and/or alter the binding of semaphorins and plexins in *trans*. Furthermore, it has become clear that transmembrane class-4- and class-6-semaphorins can also serve as receptors, rather than ligands, and signal in a reverse manner upon binding of plexins. The semaphorin-plexin system therefore constitutes a bi-directional signaling system.

Activation of plexins results in the induction of a multitude of signaling pathways. Among the central downstream players in plexin signaling are small GTPases (Pascoe et al. 2015). All

plexins contain a GTPase-activating protein (GAP) domain within their cytoplasmic portion, which catalyzes the guanine nucleotide exchange of Rap proteins. This domain also mediates the deactivation of R-Ras and M-Ras; however, plexins do not exhibit direct GAP activity toward R-Ras and M-Ras, and the precise molecular mechanism underlying plexin-mediated R-Ras and M-Ras deactivation remains unclear. Inhibition of Rap and R-Ras by plexins has been suggested to result in the inhibition of integrin signaling. In addition to the GAP domain, the intracellular portion of all plexins carries a Rho GTPase binding domain (RBD) through which Rac1 and Rnd1 can interact with plexins. The functional consequences of these interactions are not entirely understood. Plexins of the B-subfamily carry a PDZ-binding motif at their C-terminus, which mediates a stable interaction with the Rho guanine nucleotide exchange factors (RhoGEFs) LARG and PDZ-RhoGEF. Activation of B-plexins results in the activation of RhoA and RhoC via this pathway. Furthermore, a series of kinases have been implicated as effectors or modulators in signaling of particular plexins. These kinases involve receptor tyrosine protein kinases (Met, ErbB-2), cytosolic tyrosine protein kinases (FAK, Pyk2, Fes, Fyn, Src, Syk), cytosolic serine/threonine protein kinases (PKA, Akt, MAP kinases, Raf, GSK3β), and lipid kinases (PI3K). It has to be noted that plexin signaling is highly versatile and complex and that activation of the same plexin can evoke different and sometimes even opposing cellular responses, depending, e.g., on the association of the plexin with different co-receptors.

Semaphorins and plexins were first described to be involved in the guidance of axonal growth cones during development. Semaphorin 3A (formerly collapsin-1) was in fact one of the first repulsive axonal guidance factors described. Various semaphorins have been shown to induce axonal growth cone repulsion via activation of plexins. However, in some cases, semaphorins can also attract axons. In addition to axon guidance, plexins regulate multiple other aspects of neural circuit assembly, in both the central and peripheral nervous systems, including neuronal morphogenesis, synapse assembly, and synaptic refinement (Koropouli and Kolodkin 2014). Plexins have been suggested to play a role in various neurological diseases, such as Hirschsprung's disease, autism, epilepsy, and neurodegenerative diseases; however, evidence for an involvement of plexins in these diseases is mostly correlative so far (Van Battum et al. 2015). Experiments in animal models of disease demonstrate that interfering with semaphorin-plexin signaling improves regeneration after central nervous system trauma and may be of relevance in the treatment of pathological pain and aberrant fear.

Semaphorins and plexins are of also of vital importance in the cardiovascular system, where they control vascular patterning and remodeling (Corà et al. 2014). Similar to the situation in the nervous system, semaphorin-plexin signaling directs the behavior of specialized endothelial cells at the tip of navigating vascular sprouts. This is the case not only during development but also under pathophysiological conditions at adult stages. For example, class-3-semaphorins, in particular semaphorin 3E, activate Plexin-D1 expressed on endothelial cells to repel growing endothelial sprouts and to regulate endothelial tip cell fate. The anti-angiogenic effect of semaphorin 3E-Plexin-D1 signaling may hold therapeutic potential in microvascular diseases, for example, in patients with diabetic retinopathy, where damage to the microvasculature triggers compensatory hypervascularization. In addition to effects on the vasculature, semaphorins and plexins have also been shown to control multiple aspects of cardiac morphogenesis including myocardial compaction and trabeculation, cardiac-outflow tract development, and autonomic innervation of the heart.

Semaphorins and plexins have been found to be expressed by different cell types of the innate and adaptive immune system, e.g., macrophages, dendritic cells, and T and B lymphocytes, and have emerged as central players in immune cell communication (Nishide and Kumanogoh 2018). They control various functions of immune cells, including immune cell activation, differentiation, motility, migration, and trafficking. As shown

in preclinical animal models of disease, the semaphorin-plexin system is also of major importance in inflammatory and autoimmune diseases. For example, semaphorin 3A promotes the migration of dendritic cells from the periphery to the draining lymph nodes via Plexin-A1, downregulates T cell proliferation via Plexin-A4, and activates macrophages via Plexin-A4. Another example for an important immune semaphorin is semaphorin 4D (also known as CD100), which was the first semaphorin to be characterized for its role in the immune system. Semaphorin 4D expressed on T cells activates Plexin-B1 on microglia to promote neuroinflammation in an experimental autoimmune encephalomyelitis mouse model. Furthermore, semaphorin 4D has been shown to act as a receptor for plexins and to mediate reverse signaling in γδ T cells of the skin and intestinal epithelium; activation of semaphorin 4D supports skin wound healing and ameliorates colitis in mouse models. On B cells and dendritic cells, semaphorin 4D induces its effects via a non-plexin receptor, CD72.

Loss of bone tissue is a hallmark of several bone disorders, in particular of osteoporosis. The semaphorin-plexin system exerts decisive functions in the communication of different types of bone cells and regulates both bone formation and bone resorption (Verlinden et al. 2016). In mice, semaphorin 3A is expressed by osteoblasts and neurons. Through its receptor Plexin-A1, semaphorin 3A promotes bone formation by enhancing the differentiation of osteoblasts and by inhibiting the differentiation of osteoclasts. Alternatively or additionally, semaphorin 3A may increase bone mass indirectly by modulating sensory innervation of bones. Another semaphorin, semaphorin 4D, is expressed on osteoclasts and decreases bone formation by interfering with osteoblast differentiation via activation of Plexin-B1 on osteoblasts.

In the kidney, the semaphorin-plexin system plays an important role both in glomerular and in tubular diseases (Xia and Worzfeld 2016). Several class-3-semaphorins have been found to be expressed in podocytes, and podocyte expression of a particular class-3-semaphorin, semaphorin 3A, is upregulated in diabetic humans and mice. In mice, genetic inactivation of semaphorin 3A or its receptor Plexin-A1 in podocytes, or pharmacological inhibition of semaphorin 3A, ameliorates diabetic nephropathy, presumably through normalization of the slit diaphragm. Class-4-semaphorins and their receptors, B-plexins, have been demonstrated to be expressed in tubular epithelial cells and to be required for kidney repair after acute kidney injury in mice. Moreover, semaphorin 3A has been proposed as a biomarker of tubular injury.

Plexins are of central importance in cancer and can mediate both tumor-promoting and tumor-suppressive effects (Gurrapu and Tamagnone 2019). The expression of several semaphorins and plexins has been found to be dysregulated in human cancers. In various types of cancer cells, plexins control critical cellular properties such as proliferation, apoptosis, migration, invasion, and/or epithelial-to-mesenchymal transition. The semaphorin ligands binding to plexins on cancer cells can be derived from cancer cells (including autocrine signaling loops) or from other cell types in the tumor microenvironment. Conversely, semaphorins expressed by cancer cells can impact on cells of the tumor microenvironment. Among the best-characterized effects of semaphorins in the tumor microenvironment are those on endothelial cells, where semaphorins can induce both anti-angiogenic (class-3-semaphorins) and pro-angiogenic (class-4-, class-5-, and class-6-semaphorins) responses. Moreover, the semaphorin-plexin system conveys information between different types of cells in the tumor microenvironment. For example, semaphorin 4D produced by tumor-associated macrophages acts on endothelial cells to induce tumor angiogenesis. Finally, the ability of the semaphorin-plexin system to signal both in a forward and in a reverse manner potentially enables bi-directional communication among cancer cells or between cancer cells and cells of the tumor microenvironment.

Pharmacological Intervention

The semaphorin-plexin system has been shown to play multiple roles in various organ systems.

Accordingly, most semaphorins and plexins have been validated as potential drug targets in animal models of diseases – including cancer, multiple sclerosis, spinal cord injury, osteoporosis, microvascular diseases, diabetes, and asthma – using genetic (knockout/knockdown) and/or pharmacological approaches (Worzfeld and Offermanns 2014). These pharmacological approaches to block, activate, or modulate semaphorin-plexin signaling comprise small molecules, peptoids, peptides, recombinant proteins (recombinant semaphorins or recombinant plexins acting as ligand traps for semaphorins), and antibodies. Hitherto, the pharmacological agent most far advanced in clinical development is an anti-semaphorin 4D antibody, which has completed phase I clinical trials in patients with advanced solid tumors and in patients with multiple sclerosis. This monoclonal semaphorin 4D antibody, pepinemab (VX15/2503), is currently being tested in further phase I clinical trials in combination with immune checkpoint inhibitors (ipilimumab or nivolumab) in patients with melanoma, head and neck squamous cell carcinoma, and pancreatic or colorectal cancer and in a phase Ib/II clinical trial in combination with immune checkpoint inhibitors (avelumab) in patients with non-small cell lung cancer.

Definition

Prodrugs are molecules with little or no pharmacological activity in their own right before they are converted to the active drug. Prodrug strategies can be considered a chemistry-enabled tool to overcome deficiencies in the physicochemical properties of a molecule that limit its formulation options or result in suboptimal bioavailability or safety profile and, consequently, pharmacological response.

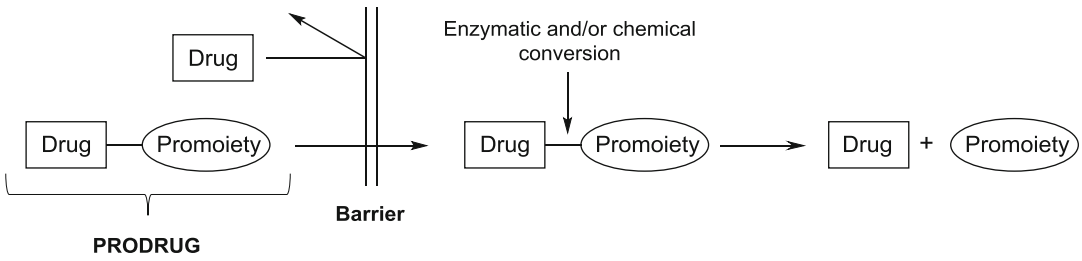
Basic Mechanisms

In most cases, prodrugs are molecules consisting of a chemical group, a promoiety, that is attached to a parent drug via a covalent bond. This attachment must be reversible so that the promoiety is cleaved off by a chemical or enzymatic process or a combination of the two to liberate the pharmacologically active drug in the body (see Fig. 1 for the simplified prodrug concept and Fig. 2 for a representative prodrug example). Some literature uses a term bioprecursor prodrug in order to refer to a more complex prodrug molecule that lack an obvious promoiety but form the active compound through rearrangement such as intramolecular reaction or oxidation (Fig. 2). Codrugs, on the other hand, are inactive molecules that consist of two pharmacologically active drugs that are coupled together, and each is the promoiety for the other. Upon conversion, codrugs liberate both active drugs simultaneously (Fig. 2).

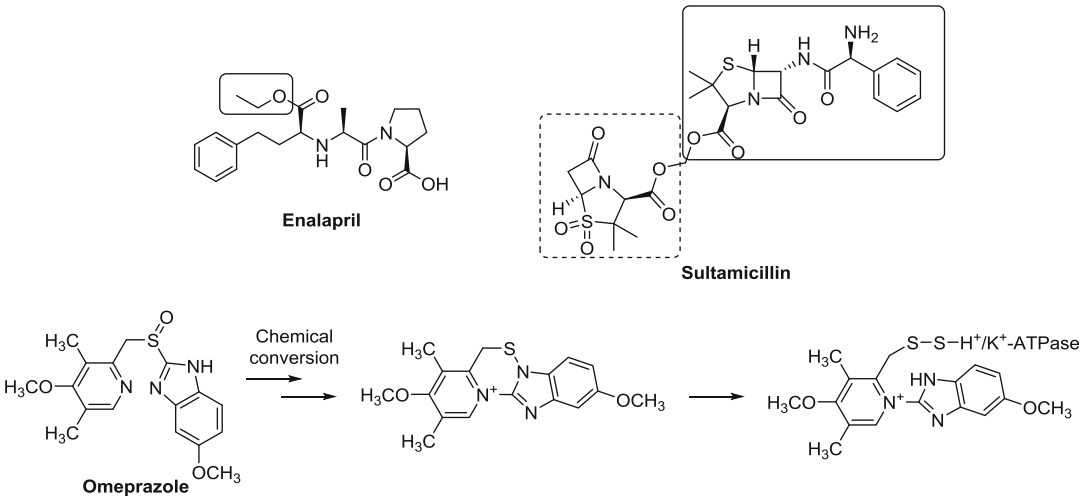
Common functional groups on parent drugs that can be contemplated to chemical modification to prepare prodrugs include such as hydroxyl (-OH), carboxyl (-COOH), as well as basic and acidic NH groups. Prodrugs produced via these modifications include, for example, esters, carbonates, carbamates, amides, phosphates, as well as various *N*-acyl derivatives and *N*-Mannich bases. Also, modification of phosphate (-OPO$(OH)_2$) and phosphonate (-CPO$(OH)_2$) groups has resulted in various experimental and clinically approved phosphate and phosphonate nucleoside prodrugs. Some of the prodrug strategies used in marketed prodrugs are listed in Table 1. It is not surprising that the most common prodrug structures are those requiring a hydrolytic bioconversion in vivo by ubiquitous hydrolases.

Pharmacological Relevance

An increase in the number of druggable targets has substantially expanded the chemical property space for new drug candidates. Consequently, contemporary molecules suffer often from undesirable physicochemical properties that create challenges for their delivery to their biological targets in the body and lead to poor pharmacological response. Also, several drugs already on the market possess suboptimal pharmacology due to same reasons. In these respects, temporary structural modifications by various prodrug strategies can intentionally be used to overcome deficiencies in physicochemical properties such as polarization, electronic factors including ionization constant (i.e., pK_a), topological and steric factors, hydrophobicity and hydrogen bonding that lead to better biopharmaceutical properties such as



Prodrugs, Fig. 1 A simplified representation of the prodrug concept. The drug-promoiety molecule is the prodrug that is inactive or very weakly active pharmacologically. In broad terms, the barrier can be thought of as any liability for a parent drug that prevents its optimal pharmaceutical or pharmacological performance



Prodrugs, Fig. 2 Examples of prodrugs, bioprecursor prodrugs and codrugs. Enalapril is an ethyl ester prodrug of enalaprilat (promoiety circled). Omeprazole is a bioprecursor prodrug that is converted into its active sulfenamide metabolite, which binds covalently to the proton bump (H^+/K^+-ATPase). Sultamicillin is a codrug, which liberates both the β-lactam antibiotic ampicillin (closed circle) and β-lactamase inhibitor penicillanic acid sulfone (dotted circle)

Prodrugs, Table 1 Examples of prodrug strategies for the most common functional groups on parent pharmacologically active drugs

Functional group	Prodrug strategy		Representative prodrugs
Carboxylic acid R-COOH	R-O-CO-R_1	Esters	Enalapril
	R-O-CO-CH(R_1)-O-CO-R_2	Double esters	Cefuroxime axetil
Hydroxyl R-OH	R-O-CO-R_1	Esters	Abiraterone acetate
	R-O-CO-NR_1R_2	Carbamates	Irinotecan
		Phosphates, phosphonooxymethylethers	Tedizolid phosphate, fospropofol
Amine R-NR_1R_2	R-NR_1-CO-R_2	Amides	Midodrine
	R-NR_1-CO-O-R_2 R-NR_1-CO-O-CH(R_2)-O-CO-R_3	Carbamates	Gabapentin enacarbil
	R-NR_1-CHR_2-O-CO-R_3	*N*-acyloxyalkylamines	Aripiprazole lauroxil
		Phosphates, phosphoramidates	Fosphenytoin, fosaprepitant
Phosphate or phosphonate 		Carbonyloxymethyl	Tenofovir disoproxil
		ProTide phosphoramidates/ phosphoamidates	Sofosbuvir, tenofovir alafenamide

P

Prodrugs, Table 2 Prodrugs can be used to address the following barriers to improve drug delivery and pharmacological response

Formulation and administration
• Inadequate aqueous solubility for liquid dosage forms
• Inadequate shelf-life for solid or liquid dosage forms
• Pain or irritation after local administration
Absorption
• Inadequate dissolution rate due to low aqueous solubility
• Poor membrane permeation and low oral or topical (e.g., dermal, ocular) bioavailability due to poor lipophilicity
• Inadequate stability in the gastrointestinal tract or during the first-pass metabolism
Distribution
• Lack of site-specificity (e.g., poor brain distribution or tumor targeting)
• Need to decrease plasma protein binding or deposition in lipophilic compartments
Metabolism and excretion
• Lack or need of site-specific biotransformation
• Short duration of action
Toxicity
• Lack of site-directed delivery or site-specific transformation
• Need to temporarily mask a reactive, inherently active, functional group

solubility, permeability or partitioning, or better chemical or enzymatic stability, or targeting and, consequently, more favorable pharmacological response (Table 2). Today, the interest in prodrug strategies is evident because approximate 10% of all marketed drugs worldwide can be considered prodrugs.

Improving Solubility

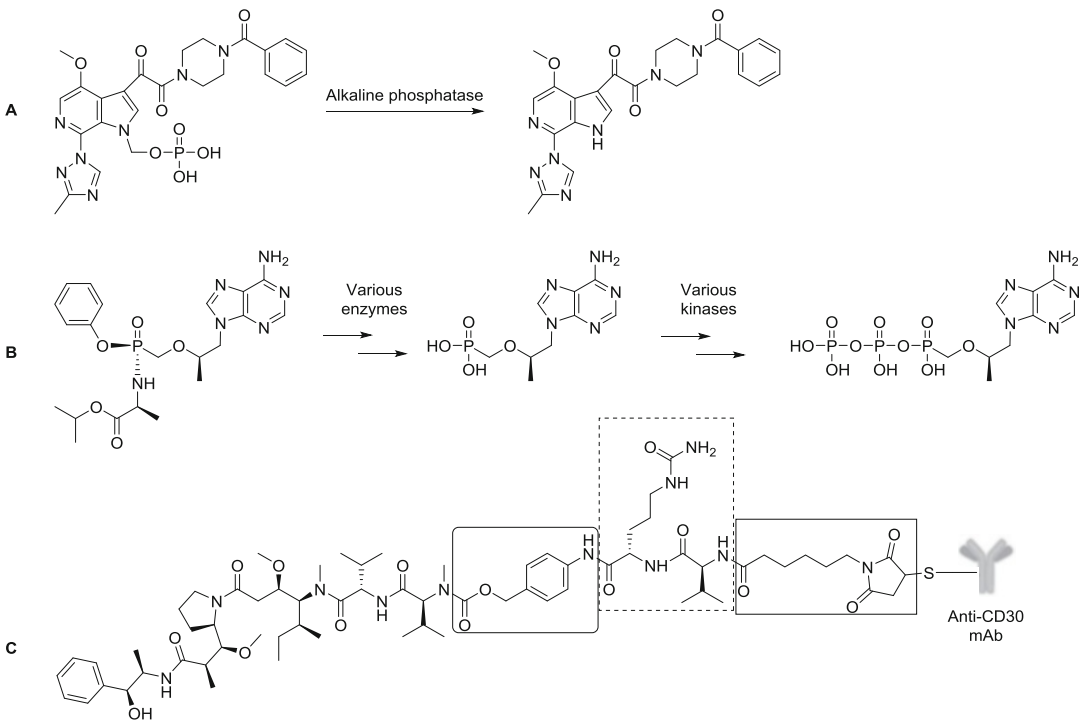
Poorly soluble oral drug may face low and variable oral bioavailability, which leads to unpredictable pharmacological response. Improved solubility can be achieved by attaching an ionized or a polar promoiety, such as phosphate, amino acid or sugar moiety, or by using a promoiety that disrupts the crystal packing of the drug (for example, by blocking intramolecular hydrogen bonding).

Currently, phosphate prodrugs are the most commonly used strategy for improving the aqueous solubility of oral drugs as the increase in solubility imparted by the two negative charges of the phosphate group is often several orders of magnitude (phosphate group has two pK_a values, ca. 2 and 7, which are substantially charged negatively when pH is higher than the pK_a). This is demonstrated by fostemsavir (Fig. 3) that has aqueous solubility of over 500-times higher (>11 mg/ml vs. ~20 μg/ml in the pH range of 2–8 at room temperature) than that of temsavir. The phosphate prodrug strategy successfully overcame dissolution- and solubility-limited absorption as a major barrier to achieving optimal systemic exposure of the parent HIV-1 attachment inhibitor temsavir.

Water-soluble oral prodrugs are usually designed to undergo conversion in proximity to the site of absorption (i.e., typically small intestine) by intestinal enzymes to release the parent drug. Therefore, increasing water-solubility by promoieties is best suited for highly permeable drugs having facile absorption in the intestine after being liberated from the prodrug in order to avoid precipitation.

Improving Permeability

Permeability across any biological membrane is challenging for polar and charged drugs. This usually leads to low and variable absorption and, consequently, to low bioavailability and low exposure for specific target organs. Most frequently enhancement in permeability has been attempted to solve by increasing the lipophilicity of the parent drug by masking its polar and ionized groups. Hydrophilic hydroxyl, carboxyl, phosphate, or amine groups can be converted to the more lipophilic alkyl or aryl esters or *N*-acyl derivatives, which are then converted back to the parent drugs in the body usually by ubiquitous esterase or peptidase activity. As an example, the ethyl ester prodrug oseltamivir is readily absorbed after oral administration resulting in approximately 80% oral bioavailability in humans, whereas its pharmacologically active parent drug oseltamivir carboxylate showed only negligible bioavailability (<5%) in preclinical species. After oral absorption, oseltamivir undergoes bioconversion to its neuraminidase enzyme inhibitor parent drug and ethanol predominantly by human



Prodrugs, Fig. 3 (**a**) Water-soluble prodrug fostemsavir undergoes bioconversion to pharmacologically active temsavir by alkaline phosphatase. (**b**) Tenofovir alafenamide is a lipophilic phosphoramidate prodrug of tenofovir that efficiently delivers this compound to the hepatocytes where, after cleavage by various cytosolic enzymes, it is readily phosphorylated twice to generate the pharmacologically active form. (**c**) Antibody-drug conjugate (ADC) brentuximab vedotin contains a CD30-specific antibody that is attached to an antimitotic agent monomethyl auristatin E (vedotin) via a cathepsin B labile peptide bond that is between the dipeptide valine-citrulline (dotted circle) and *para*-amino benzyloxycarbonyl (closed circle on the left) moieties. The maleimidocaproyl spacer (closed circle on the right) provides space for enzymatic cleavage

carboxylesterase 1. Many successful angiotensin-converting enzyme (ACE) inhibitors, such as enalapril, are also ethyl esters of their respective pharmacologically active carboxylate forms (Fig. 2). More recent ethyl ester prodrugs in clinical use are sacubitril and telotristat etiprate, which are lipophilic prodrugs of the endopeptidase inhibitor sacubitrilat and the serotonin synthesis inhibitor telotristat, respectively.

Much of the prodrug research has recently been focusing on enabling oral bioavailability of various nucleoside analogues that have demonstrated their effectiveness in the treatment of cancer and various infections. To become pharmacologically active, nucleoside analogues must undergo the stepwise addition of phosphate groups to form active nucleoside triphosphates in the body. Because the first phosphorylation step is often limiting, nucleoside analogues are frequently administered as their monophosphorylated forms or are structurally modified to possess a phosphonate moiety, both of which can further be turned into lipophilic prodrug forms. Representative examples are phosphoramidate ProTide prodrugs tenofovir alafenamide (Fig. 3) and sofosbuvir, which are efficiently delivered to the cytosol of hepatocytes after oral administration. After cleavage of promoieties, representative triphosphorylated forms are generated providing inhibitory effect against hepatitis B virus and hepatitis C virus, respectively, for tenofovir alafenamide and sofosbuvir.

Better Targeting

Drug targeting can be achieved in general either by site-directed delivery or site-specific

transformation of a prodrug. While site-directed drug delivery consists of the selective or primary delivery of the intact prodrug to the site of drug action, in site-specific transformation the prodrug can be widely distributed in the body, but it releases the active drug predominantly at the desired site by a selective activation reaction.

Selective delivery can be possible using drug conjugation strategies, wherein the drug is conjugated to a macromolecule carrier that recognizes target-specific markers, such as antigens or receptors. Macromolecules typically cannot penetrate healthy membranes, but because the membranes of cancerous tissues are leaky, macromolecules can enter the tumor microenvironment from the bloodstream. Therefore, macromolecular prodrugs are usually designed to improve drug targeting to a tumor. This has been experimented with various nonbiodegradable polymers such as *N*-(2-hydroxypropyl)methacrylamide (HPMA) and polyethylene glycol (PEG) as well as biodegradable polymers such as polyglutamic acid (PGA), dextrin, and hyaluronic acid that have been used to form macromolecular prodrugs with some anticancer agents and tested in clinical trials. Also, some antibody-drug conjugates (ADCs) consisting of a monoclonal antibody linked to an active drug via a cleavable bond can be regarded as macromolecular prodrugs. For example, brentuximab vedotin consists of a CD30-specific antibody that is attached to an antimitotic agent monomethyl auristatin E (known as vedotin) via the plasma-stable dipeptide valine-citrulline linker (Fig. 3). This linker is designed to be site-selectively cleaved by the proteolytic enzyme cathepsin B once the ADC has been internalized by CD30 expressing tumor cells through endocytosis and then releasing vedotin.

On the other hand, the site-specific transformation of the prodrug can be achieved either by: (i) exploiting endogenous enzymes or physiological conditions of target tissue and/or cells, such as pH or hypoxia, (ii) delivering genes that encode prodrug-activating enzyme into target tissue (e.g., virus-directed enzyme prodrug therapy (VDEPT) and gene-directed enzyme prodrug therapy (GDEPT)), or (iii) delivering prodrug-activating enzyme into target tissue via monoclonal antibodies (e.g., antibody-directed enzyme prodrug therapy (ADEPT)). While most of these strategies are still experimental, a successful example of drug targeting via site-selective transformation can be provided by previously described phosphoramidate prodrugs tenofovir alafenamide and sofosbuvir. These prodrugs are efficiently translocated to the cytosol of their target cells, hepatocytes in the liver where, after removal of promoieties and consequent release of the monophosphate, the monophosphate is readily site-selectively phosphorylated twice to generate the pharmacologically active triphosphate forms.

Another example of where site-specific transformation has resulted in the marketed prodrug is given by the proton pump (H^+/K^+ ATPase) inhibitor omeprazole (Fig. 2). As the weakly basic drug (pK_a is 3.97) omeprazole is not protonated at physiological pH, allowing it to be absorbed and distributed into the secretory canaliculus of the parietal cells. In the acidic conditions of parietal cells (pH of 1–2), omeprazole becomes protonated and accumulates inside the canaliculus of the cell. Protonation also initiates the site-specific chemical transformation of omeprazole into its active metabolite, which binds to the thiol of a cysteine residue of the H^+/K^+ ATPase. This irreversible binding inhibits the ability of parietal cells to secrete gastric acid. The fact that omeprazole and other proton pump inhibitors (e.g., lansoprazole, pantoprazole, and rabeprazole) are only effective on H^+/K^+ ATPases, which contain highly acidic compartments that non-gastric H^+/K^+ ATPases lack, corresponds their excellent safety profiles. Therefore, proton pump inhibitors are transformed into their active species only under highly acidic conditions at the site of action.

Proprotein-convertases subtilysin/hexin type 1-9 (PCSK 1-9)

Definition

Proprotein convertases is a family of serine proteases that catalyze the cleavage of specific peptide bonds. This cleavage results in activation of several cellular and extracellular proteins such as hormones, receptors, growth factors, metalloproteinases, and viral and bacterial proteins, among others. Inhibition of the enzymatic activity of PCs constitutes a valuable therapeutic tool for several diseases ranging from cancer, inflammation, viral and bacterial infections to endocrine imbalances, and hypercholesterolemia.

Basic Characteristics

Many proteins are synthesized as inactive precursors, which need to be activated to display full activity. Proteolysis at specific sequences separates the active protein from the prodomain and constitutes one of the main activation mechanisms in mammalian cells. According to their structure, and recognition sequence, the PCs can be classified into kexin-like, pyrolysin-like, or proteinase-like (Seidah and Prat 2012).

The kexin-like subfamily has seven members, PSCK1 to 7, which recognize and cleave at the C-terminus of the sequence K/R-X_n-K/R, where n is 2, 4, or 6. The basic amino acids at the positions indicated (lysine and arginine) are essential for PC recognition. In fact, the former name for the probably best characterized member of PCs, furin (PCSK3), PACE (for paired basic amino acid cleaving enzyme) highlights the specific PC activity. Although the enzymatic activities of these seven kexin-like proteases are somewhat overlapping, each PC shows differential substrate specificity, tissue localization, and patterns of expression. For instance, furin PCSK5 and 6 are ubiquitous, whereas SPCK4 is restricted to the testes and PCSK1 and 2 to the neuroendocrine tissues (Seidah and Prat 2012).

In contrast, PCSK8 and PCSK9 cleave at nonbasic residues and play important roles in cholesterol and lipid metabolism and LDL functionality, respectively. The pyrolysin and proteinase-like recognize the sequences R-X-(L/V/I)-X and V/I/L-F-A-Q, respectively, both essentially nonbasic sequences. PCSK9 is the sole member of the subfamily of proteinase-like PCs and presents a unique behavior regarding the sequence specificity, ability to self-activate by intracellular proteolytic activity, and the lack of substrates, other than itself. After autocatalytic cleavage, the prodomain acts as a chaperone and remains attached to the catalytic site, preventing further enzymatic activity. This PC is also unusual in its crucial role in the regulation of cholesterol levels, its impact on hypercholesterolemia, sepsis, and inflammation. PCSK9 is mainly expressed in the liver, kidney, and small intestine (Seidah and Prat 2012).

Several protein-based and small molecule inhibitors have been designed in order to block the active site of these enzymes. Interference with the stability of furin mRNA, utilizing small hairpin RNA, constitutes the bases of the clinical trial

FANG-VIGIL to prevent furin translation and furthering cancer cell sensitivity to the host's immune system. Other strategies, including nanobodies, have been assayed to abolish PC activities targeting not the active site, but the P domain, necessary for stability (Klein-Szanto and Bassi 2017). Undoubtedly, the development of PCSK9 inhibitors to facilitate the LDLR internalization and cleavage has changed the therapeutic horizons for the treatment of hypercholesterolemia. Two PCSK9 inhibitors are commercially available and used successfully in patients who are refractory to statins or presenting with LDLR mutations in some cases of familial hypercholesterolemia.

PCs and Cardiovascular Diseases

PCs have been implicated in several cardiovascular diseases, such as coronary artery disease (CAD), atherosclerosis, and hyperlipidemia. Furin is associated with the stimulation of several pathways associated with CAD, and its expression increases with the severity of vascular and cardiac valves' lesions. Furthermore, heightened furin expression correlates with negative cardiovascular manifestations observed in patients with type II diabetes (Yakala et al. 2019).

On the other hand, PCSK6 (PACE4) contributes to lower blood pressure. This PC has been identified as the protease that activates the protein Corin, a membrane protease synthesized as a zymogen in the cardiomyocytes. Proteolytic activity of Corin leads to the activation of Atrial Natriuretic Peptide, a key regulator of blood pressure, stimulating diuresis and salt elimination (CHen et al. 2015). PCSK6 inhibition leads to salt-dependent hypertension, precluding it from consideration as a therapeutic target for inhibition. Nevertheless, PCSK6 negative association with hypertension may stimulate new strategies aiming at stabilizing this protein, increasing its expression in cardiomyocytes, or increasing its activity. The design of small molecule agonists specific for this PC may not be out of consideration.

Hypercholesterolemia constitutes a risk factor for the development of atherosclerotic cardiovascular disease (ACVD). Statins are the gold standard for the prevention of ACVD and the treatment of hypercholesterolemia. However, these compounds present serious side effects and may not be well tolerated by a subset of patients. In this context, inhibition of PCSK9 proved to be a successful strategy to decrease the levels of circulating cholesterol associated with low density lipoproteins (LDL-C). Excess of circulating LDL-C binds to its receptor (LDLR) on the surface of cells, prompting their internalization and recycling to the plasma membrane to continue the clearance of LDL-C from circulation. In the presence of PCSK-9, the LDLR remains tightly attached to this PC, not only preventing its recycling, and hence, clearance of LDL-C, but also carrying this receptor to the lysosomes. Once in the lysosomes, LDLR is degraded. PCSK9 inhibitors interfere with this association, stimulating LDLR-mediated internalization of cholesterol and recycling. Two monoclonal antibodies, evolocumab and alirocumab, are already in the market to treat cases of hypercholesterolemia refractory to statins (Seidah 2016).

PCs and Cancer

PCs overexpression has been documented in several cancers including breast, lung, head and neck, ovarian, endometrial, prostate, gastric and colon, among others (Jaaks and Bernasconi 2017). Increased expression of these PCs results in the acquisition of cancerous properties, such as increased proliferation, migration, invasion, and metastasis. PCSK3, PCSK 6, and PCSK5 are the major PCs implicated in cancer.

Inhibition of these PCs in vitro and in vivo decreases the maturation of several substrates necessary for cancer cell proliferation, invasion, and metastasis, including growth factors and their receptors (proliferation, angiogenesis, and lymphangiogenesis), matrix metalloproteinases (invasion and metastasis), and cell adhesion molecules (invasion) (Klein-Szanto and Bassi 2017).

PCs and Viral/Bacterial Infections

Several bacteria produce diseases through the action of exotoxins, extracellular proteins secreted by pathogenic bacteria, capable of producing tissue-specific damage. Most of these exotoxins consist of a catalytically active

A subunit and a membrane-bond B subunit which mediates the attachment and translocation of the A subunit. Once on the surface or in the endoplasmic reticulum of the target cell, the A subunit needs to be separated by limited proteolysis form the B subunit, a process catalyzed by Furin. Free exotoxin A is transported to the nucleus, where it stimulates the transcription of genes, resulting in stalling protein synthesis. Furin activates several exotoxins, including Diphtheria toxin, Pseudomonal exotoxin A, Shiga-like toxins, and anthrax toxins (Braun and Sauter 2019).

Proteolytic activity represents a crucial step for viral maturation, attachment, fusion, infection, and release from the infected cells. Proteins in the envelope or capsid of several viruses, including Papilloma-, Herpes-, Flavi-, Corona-, Paramyxo- (Braun and Sauter 2019), and Retroviruses, contain sequences recognized by PCs. PCs, such as furin, interact with viral proteins during their transit through the secretory pathway, whereas other viral proteins are processed extracellularly. Upon cleavage, these viruses enhanced their pathogenicity and their success in infecting other cells (Sathananthavathi et al. 2019; Izaguirre 2019).

Drugs

PCs play pivotal roles in several physiological and pathological processes. It is not surprising that several strategies came out to inhibit their activity for research and clinical purposes. As the first subfamily of PCs characterized, the kexin-like PCs were extensively studied as targets for inhibition. However, two inhibitors for PCSK9 have completed all the stages of basic and clinical investigation and are now currently used in the treatment of hyperlipidemia.

Inhibitors of Kexin-Like PCs

Small Molecule Inhibitors

These agents usually contain a cleavage site for PCs, RR/KXR, blocking the active site, hence functioning as competitive inhibitors. The high polarity of these molecules and, in some agents, its toxicity, limits their application to research. Examples of these agents include chloromethylketones, ploy-D-arginines, and streptamine derivatives. However, most of these compounds exhibit a K_i in the micromolar range, suggesting their possible future application (Klein-Szanto and Bassi 2017).

One of the first small molecule inhibitors developed was decanoyl-RVKR chloromethyl ketone (Dec-RVKR-CMK) (Angliker 1995). This inhibitor contains the recognition sequence for the kexin-like PCs (RXR/KR) with the C-terminal substitution of a chloromethyl residue that makes this inhibition irreversible by covalent attachment to the PC. In addition, the decanoyl moiety increases the cell permeability for this highly charged tetra peptide. Although this compound is toxic and does not have major selectivity for the different PCs, it represents an invaluable tool for research in the field.

The neuroendocrine PCs, PCSK1 and 2, have been implicated in glucose metabolism, PCSK1 and, in less measure, PCSK 2 activate insulin in the pancreatic β-cells, whereas PCSK2 converts inactive pro-glucagon to glucagon in α cells. A small allosteric inhibitor, RJC00847, has been developed that selectively inhibits PCSK2, but not PCSK1. This inhibitor may represent a lead to develop new strategies to treat some cases of hyperglycemia.

Peptides

Drugs with the active site for the PCs containing a protein scaffold proved to be effective (Ki in the nanomolar order) and less toxic than the small molecules inhibitors. However, their high molecular weight has limited the internalization into the cells. Specific pro-domains from PCs and derivatives of the α1-antitrypsin are representatives of this type of strategies (Jean et al. 1998).

PCSK9 Inhibitors

The developments occurring in the field of inhibition of kexin-like PCs translated into the search for PCSK9 inhibitors. Surprisingly the synthesis and production of anti-PCSK9 antibodies that

Proprotein Convertases, Table 1 Main inhibitors for PCs, their pharmacological mechanism of actions and main uses

Piperidine carboxamides	PCSK9	Translation inhibitor	Hypercholesterolemia	Londregan et al. (2018)
Inclisiran	PCSK9	siRNA	Hypercholesterolemia, dyslipidemia	Nishikido and Ray (2018)

completely blocked its functions represented the most far-reaching approach in blocking PC activity. Two antibodies are commercial and currently used in the treatment of hypercholesterolemia with excellent results.

Evolocumab and Alirocumab

Monoclonal antibodies Evolocumab (Rephata) and Alirocumab (Praloent) (Stein et al. 2012) specifically and effectively bind to PCSK9 in the extracellular milieu preventing its binding to the LDLR, increasing LDLR recycling to the membrane, enhancing LDL-C clearance. These drugs are administered as intramuscular injections once or twice a month. Concomitant treatment with statins these antibodies showed a significant reduction in the circulating levels of LDL-C (Stein et al. 2012).

Translator Inhibitors

A new family of drugs, the N-(piperidin-3-yl)-N-(pyridin-2-yl) piperidine/piperazine-1-carboxamides ("piperidine carboxamides") selectively blocks the translation of PCSK9 by preventing the binding of ribosomes to this PCs' mRNA. These new small molecule compounds are formulated as prodrugs, which achieve full activity in the liver, where most PCSK9 is produced. Some of these compounds showed an advance in safety, stability, and potency properties compared with other drugs currently in use. This is a novel approach and may open new venues in the field of small molecule inhibitors (Londregan et al. 2018).

Small Interference RNA

A clinical trial to silence the expression of PCSK9 using injectable siRNA is underway. The drug, Inclisiran, degraded the cellular PCSK9 mRNA, preventing protein synthesis. The side effects seem to be very benign. Furthermore, the drug would require two or three applications per year only, probably reducing the high costs associated with the monoclonal antibodies (Nishikido and Ray 2018) (Table 1).

[2]Department of Cardiology, Karolinska University Hospital, Stockholm, Sweden

Synonyms

Immunoresolvents; Specialized pro-resolving lipid mediators; SPMs

Definition

Pro-resolving mediators are endogenous signaling molecules that act as "stop signals" to terminate an inflammatory reaction when no longer needed to promote the return to a normal tissue state (Serhan 2014). This resolution of inflammation is achieved through both anti-inflammation and an active pro-resolution. The anti-inflammatory actions during the resolution of inflammation include counter-regulating pro-inflammatory signals and limiting immune cell infiltration. At the same time, active pro-resolving actions lead to the apoptosis and efflux of inflammatory cells and the promotion of macrophage uptake mechanisms to clean up the site of inflammation. Hence, anti-inflammation and pro-resolution are not equivalent processes. While both processes aim to limit inflammation, the pro-resolving mediators activate specific receptors to promote processes that facilitate tissue repair and return to homeostasis. Pro-resolving mediators hence act to reprogram the inflammatory response and actively promote tissue repair.

Basic Characteristics

Inflammation is a protective response mounted by the host in response to infection and tissue injury and is normally self-limiting, that is, inflammation

resolves to bring the tissue back to homeostasis. Classically an inflammatory response is hence divided into two phases, the initiation and the resolution phase. In fact, chemical signals produced during the early initiation phase play a pivotal role in turning on the subsequent resolution response (Sugimoto et al. 2016). However, in the case of a failure in the resolution of inflammation, the "stop signals" will lack and the inflammation turns into a chronic response (Bäck et al. 2019).

Pro-resolving mediators exhibit key characteristics allowing them to turn off the inflammatory reaction and subsequently turn on the "cleanup" phase required to return to homeostasis and regain physiological function of the tissue. These characteristics include (1) inhibiting neutrophil trafficking, (2) promoting macrophage differentiation towards an alternatively activated "repair" phenotype (i.e., M1 to M2 switching), (3) promoting neutrophil apoptosis, (4) enhancing phagocytosis of apoptotic cells (efferocytosis) and microbes, and (5) activating structural cells to promote tissue regeneration and repair (Sugimoto et al. 2016). In addition to these fundamental properties, each individual mediator may have other specific actions that are receptor-, cell-, location-, and time-specific.

The mediators involved in resolution of inflammation are a growing class and comprise several chemically distinct molecules that include bioactive lipid mediators as well as resolver proteins and peptides. Gaseous molecules, autacoids like purine, and neuromodulators released by the vagus nerve (Dalli et al. 2017) have also emerged as players in the resolution response.

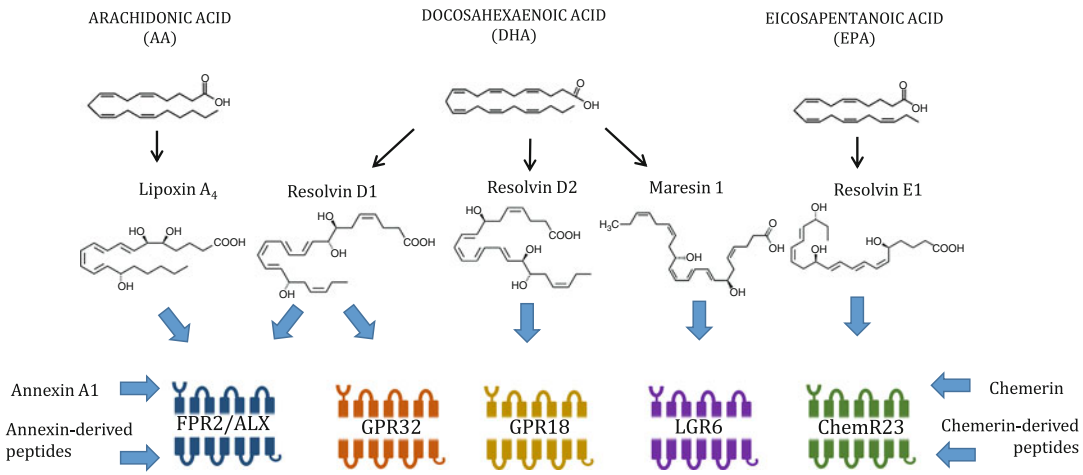
Specialized Pro-resolving Lipid Mediators

The term specialized pro-resolving lipid mediators (SPMs) has been introduced to denote a specific class of pro-resolving mediators formed by enzymatic conversion of polyunsaturated fatty acids (PUFAs). SPMs are comprised of several structurally distinct families, which include the lipoxins from the omega-6 metabolome and resolvins, protectins, and maresins from the omega-3 metabolomes.

Lipid mediators are tightly linked to the initiation, maintenance, and resolution of inflammation. During an inflammatory response, bioactive lipid mediators are produced by variety of cell types, where innate immune cells like macrophages and neutrophils are considered to be their primary source. First, prostaglandins and leukotrienes are produced from the omega-6 PUFA arachidonic acid (AA) by cyclooxygenases (COX) and 5-lipoxygenase (5-LO), respectively. These pro-inflammatory lipid mediators promote the recruitment and activation of immune cells at the inflammatory site to regulate and amplify the inflammatory cascade. Subsequently, AA metabolism is skewed towards production of lipoxins (Fig. 1) via two sequential lipoxygenase steps. This lipid mediator class switch involves upregulation of 15-LO (a key biosynthetic enzyme necessary for the production of lipoxins and other SPMs), transcellular biosynthesis (in particular neutrophil-platelet interactions involving platelet 12-LO), and a change of subcellular 5-LO activity. Whereas 5-LO located on the nuclear membrane primarily converts AA to the pro-inflammatory leukotriene B_4 (LTB_4), a cytoplasmic localization of 5-LO may favor the biosynthesis towards lipoxin A_4 (LXA_4). Furthermore, SPMs can inhibit the cellular translocation of 5-LO to the nucleus, resulting in a pro-resolving amplification loop (Fredman et al. 2014).

In addition to changes in LO metabolism, also an altered COX metabolism will take part in the lipid mediator switch towards SPMs. Of note, aspirin acetylation of COX-2 not only blocks the formation of prostaglandins but also alters the COX-2 enzymatic activity towards intermediates that serve as substrates for stereoisomers of lipoxins, referred to aspirin-triggered lipoxins (ATL). The ATLs share their biological activity with their isomeric counterparts but are more resistant to metabolic inactivation.

Resolvins, protectins, and maresins are synthesized from omega-3 PUFAs (Fig. 1). Resolvins derived from eicosapentaenoic acid (EPA) are indexed with an E (e.g., RvE1; Fig. 1) and are



Pro-resolving Mediators, Fig. 1 Pro-resolving mediators and their receptors. Lipoxin A_4 is derived from arachidonic acid, whereas D- and E-series resolvins are formed from metabolism of the omega-3 polyunsaturated fatty acids docosahexanoic acid (*DHA*) and eicosapentanoic acid (*EPA*), respectively. The figure depicts five receptors for pro-resolving mediator receptors; ALX/FPR2 for lipoxin A_4, D-resolvins, and annexins, GPR32 and GPR18 for D-resolvins, LGR6 for maresin 1, and ChemR23 for E-resolvins and chemerins. (Adapted from Pirault and Bäck 2018)

formed through initial production of 18R-hydroxy-EPA (18-HEPE) by acetylated COX-2 or cytochrome p450, which is then further converted to RvE1 or RvE2 via 5-LO or to RvE3. Docosahexaenoic acid (DHA) is converted to D-series resolvins (RvD1 through RvD6), protectins, and maresins. The metabolism of DHA into SPMs is initiated by 15-LO and then leads to either RvDs via subsequent 5-LO conversion or protectins via its epoxide intermediate. Similar to the lipoxins, D-series resolvins and protectins also include metabolically more stable aspirin-triggered stereoisomers. On the other hand, maresins (e.g., MaR1; Fig. 1) are produced via 12-LO metabolism of DHA.

More recently, peptide-containing SPMs originating from DHA have also recently be uncovered to specifically activate tissue regeneration. These SPMs have been collectively denoted Conjugates in Tissue Regeneration (CTRs) and denoted MCTR, PCTR, and RCTR according to their basic structure being maresin, protectin, or resolvin, respectively (Dalli et al. 2017). Finally, SPM biosynthesis from the omega-3 PUFA docosapentenoic acid (DPA) was discovered. These pro-resolving mediators are produced through similar enzymatic pathway as their DHA counterparts and have consequently been denoted $\text{resolvins}_{\text{n3DPA}}$, $\text{protectins}_{\text{n3DPA}}$, and $\text{maresins}_{\text{n3DPA}}$ (Hansen et al. 2018).

Protein and Peptide Pro-resolving Mediators

In addition to lipid-derived SPMs, several proteins and peptides have emerged as pro-resolving mediators. In particular, annexin A1 (AnxA1) is a 37 kDa protein-induced protein, which is induced by glucocorticoids to mediate anti-inflammatory effects by inhibiting prostaglandin and leukotriene formation through blocking of phospholipase A2 (Perretti and D'acquisto 2009). However, AnxA1's biological activity, as well as that of bioactive peptides that comprise its N-terminal region, has now been extended to promote neutrophil apoptosis and macrophage efferocytosis, contributing to tissue repair while also limiting neutrophil recruitment in vivo (Perretti and D'acquisto 2009), hence fulfilling the abovementioned characteristics of a pro-resolving mediator. Other protein and peptide mediators considered to promote resolution include IL-10 (Bäck et al. 2019), chemerin (Carracedo et al. 2019b), and chemerin-derived peptides, as well

as melanocortins, adrenocorticotropic hormone (ACTH), and galectins.

Pro-resolving Receptor Signaling

The G-protein-coupled receptors (GPRs) identified for pro-resolving mediators represent phylogenetically different families, of which most belong to classes still officially annotated as orphan receptors (Table 1). Apart from the D-series resolvins and LXA_4 being the hitherto sole agonists paired with GPR32 (Pirault and Bäck 2018), the pro-resolving mediators share other GPRs with diverse agonists having a number of more or less specific biological actions. Finally, the molecular structural similarity of the SPMs with pro-inflammatory lipid mediators has particular implication for their receptor signaling, as exemplified by the inhibition of LTB_4 responses by means of RvE1 acting as a partial agonist at the BLT1 receptor (Bäck et al. 2014).

As illustrated in Table 1, the GPRs for pro-resolving mediators represent classes of receptors associated with inflammation (formyl peptide receptors (FPR), chemerin receptors), regeneration (leucine-rich repeat-containing GPRs; LRG), and pain (cannabinoid signaling), all of which are strongly linked to the pro-resolving response. This promiscuity of the GPRs towards their ligands also implicates complex biological agonist interactions. The different ligands may signal differential and even opposite downstream responses through the same receptors by means of, for example, specific receptor binding sites, allosteric modulation, partial agonism/antagonism, conformational changes, and receptor dimerization (Bäck et al. 2014).

Pro-resolving Mediators, Table 1 Receptors for pro-resolving mediators

Receptor family	Receptor	Agonists
Formyl peptide receptors (FPR)	FPR2/ALX	LXA4, ATL, D-series resolvins
		Annexin A1 and annexin-derived peptides
Chemerin receptors	ChemR23	RvE1
		Chemerin and chemerin-derived peptides
Orphan receptors	GPR32	D-series resolvins, LXA4
Orphan receptors, similar to cannabinoid receptors	GPR18	RvD2
		Anandamide
Orphan receptors; leucine-rich repeat-containing GPRs (LGR)	LGR6	MaR1
		R-spondin 1-4

Abbreviations: *GPR* G-protein-coupled receptor, *LXA4* lipoxin A4, *ATL* aspirin-triggered lipoxin, *RvE1* resolvin E1, *RvD2* resolvin D2, *MaR1* maresin 1

Pro-resolving lipoxins, resolvins, and annexins share the FPR2/ALX receptor with pro-inflammatory amyloidogenic and bacterial peptides. Since the downstream receptor signaling differs between different classes of FPR2/ALX agonists (Hanson et al. 2013), the tissue ligand concentrations may determine receptor activation to either resolve or enhance a local inflammatory response (Petri et al. 2015). Another GPR for pro-resolving mediators closely linked to an inflammatory modulation is the chemokine-like receptor ChemR23, also referred to as chemerin receptor 1 and resolvin E1 receptor ERV1 (Laguna-Fernandez et al. 2018). Although chemerin in general is considered to be a pro-inflammatory ligand, chemerin and certain chemerin-derived peptides transduce similar pro-resolving signaling patterns as RvE1 through this receptor (Carracedo et al. 2019b). Lack of ChemR23 increases the pro-inflammatory state of macrophages and abrogates RvE1-induced phagocytosis (Laguna-Fernandez et al. 2018), supporting that ChemR23 primarily acts to resolve inflammation. Nevertheless, in vivo models of genetic ChemR23 deletion have generated contradictory results on inflammatory and metabolic phenotypes, hence reinforcing the complex interaction between signaling of inflammation and its resolution through the same receptor (Carracedo et al. 2019a).

As mentioned above, pro-resolving mediators mediate antinociception, and it is therefore interesting that RvD2 shares the orphan GPR18 with some of the endocannabinoids. In addition to possible antinociceptive effects, GPR18 also transduces RvD2-induced effects in macrophages,

including M2 differentiation and reduced inflammasome activation. The beneficial effects of RvD2 are largely lost in mice lacking GPR18, supporting that GPR18 is directly involved in the pro-resolving response to RvD2 (Pirault and Bäck 2018).

The most recently identified GPR for pro-resolving mediators is LGR6 from the receptor family for R-spondins, which are regulators of the Wnt/β-catenin signaling pathway and mediate regenerative responses. The intracellular signaling response and the phagocytic activity of the pro-resolving mediator MaR1 were enhanced by LGR6 overexpression and diminished by LGR6 knockdown in vitro (Chiang et al. 2019*)*, but the in vivo consequences for of MaR1 signaling through LGR6 remain to be explored.

Taken together, instead of signaling through a common receptor family, the cellular effects of pro-resolving mediators are hence transduced through several GPRs, representing diverse phylogenic and functional classes. The differential and in part opposing downstream signaling of different ligands at these receptors adds another complexity to the overall effects of the pro-resolving mediators, which may be highly dependent on the conditions and the models used to study their effects. This should be taken into consideration when interpreting the somewhat contradictory findings reported from receptor knockout studies and ligand-receptor interaction studies.

Gaseous Pro-resolving Signaling

In addition to pro-resolving mediators of lipid and protein/peptide structures signaling through GPRs, certain gaseous molecules dissolved in extracellular fluids can diffuse over cell membranes to directly affect cellular function to promote the resolution of inflammation (Wallace et al. 2015). In particular, nitric oxide (NO) in addition to its vasoactive effects also serves to regulate immune cells and increase apoptosis of inflammatory cells. Further, hydrogen sulfide (H_2S) alters, for example, intracellular calcium and cAMP and has been shown to reduce inflammatory activation of macrophages and increase efferocytosis (Wallace et al. 2015). Finally. macrophage expression of heme oxygenase-1 (HO-1) is a source of carbon monoxide (CO), which may contribute to limiting leukocyte infiltration, increasing phagocytosis, and suppressing cytokine production (Wallace et al. 2015). In addition, an increase in SPMs has been observed after CO exposure (Chiang et al. 2013), indicating that pro-resolving signaling pathways are interdependent (Bäck et al. 2019).

Pathophysiology and Therapeutic Potential

It is now appreciated that excessive or uncontrolled inflammation is an underlying component of many widely occurring pathologies and diseases. Evidence that such chronic inflammation is associated with a failure in the resolution of inflammation has emerged from studies in, for example, cardiovascular diseases (Bäck et al. 2019; Carracedo et al. 2019a), arthritis (Arnardottir et al. 2016), obesity, periodontal disease, and aging (Arnardottir et al. 2014). Emerging evidence from both human and animal studies suggests that this underlying failed or impaired resolution mechanism may, at least in part, reflect a reduced production of pro-resolving mediators and/or reduced expression or signaling through pro-resolving receptors. Indeed, disturbed balance between pro-resolving and pro-inflammatory mediators is emerging as a potential maker of non-resolving inflammation (Thul et al. 2017).

Pathophysiology and Therapeutic Potential

While current therapeutic approaches treating inflammation by focusing on suppressing or inhibiting pro-inflammatory mediators are effective in relieving the gross signs and symptoms, side effects in terms of possible immunosuppression and increased risk of infections should be considered. Therefore, triggering pro-resolving mediators to prevent the transition into chronic

inflammation without blunting the acute response to injury and infection has the potential to resolve inflammation without causing immunosuppression. Such therapeutic strategies include targeted delivery of pro-resolving mediators and omega-3 PUFA supplementation to enhance SPM formation. Defining appropriate dosage and formulation in clinical trials will be crucial to define the therapeutic potential of pro-resolving mediators.

Definition

Prostanoids are a group of biologically active lipid mediators. The group consists of prostaglandins and thromboxane A_2. Prostanoids are not stored in cells. Instead, they are formed ad hoc in the cell via several enzymatic steps after exposure to physical, chemical, or hormonal stimuli and are then released. They play an important role in nearly every tissue and are critically involved in, e.g., inflammatory and hemostatic processes as well as in the regulation of smooth muscle tone. Because of their diverse physiological functions, prostanoids are also of pharmacological relevance, and many important drug classes, in particular nonsteroidal antiphlogistics as well as most non-opioid analgesics, act through inhibition of prostanoid formation.

Basic Characterization

Biosynthesis and Degradation

The decisive step in the biosynthesis of prostanoids is the release of the substrate arachidonic acid by phospholipids of the cell membrane. The formation of arachidonic acid is mainly catalyzed by the cytosolic phospholipase A_2, which translocates to the cell membrane after increase in intracellular Ca^{2+} concentrations. Apart from $cPLA_2$, which is important for the acute release of arachidonic acid, several other PLA_2 isoforms are, in part, induced by chronic cell activation. Arachidonic acid released by PLA_2 is relatively quickly metabolized to prostanoids by cyclooxygenases. In general, the activation of PLA_2-dependent release of arachidonic acid is the rate-limiting step of prostanoid biosynthesis.

Formation of Prostanoids

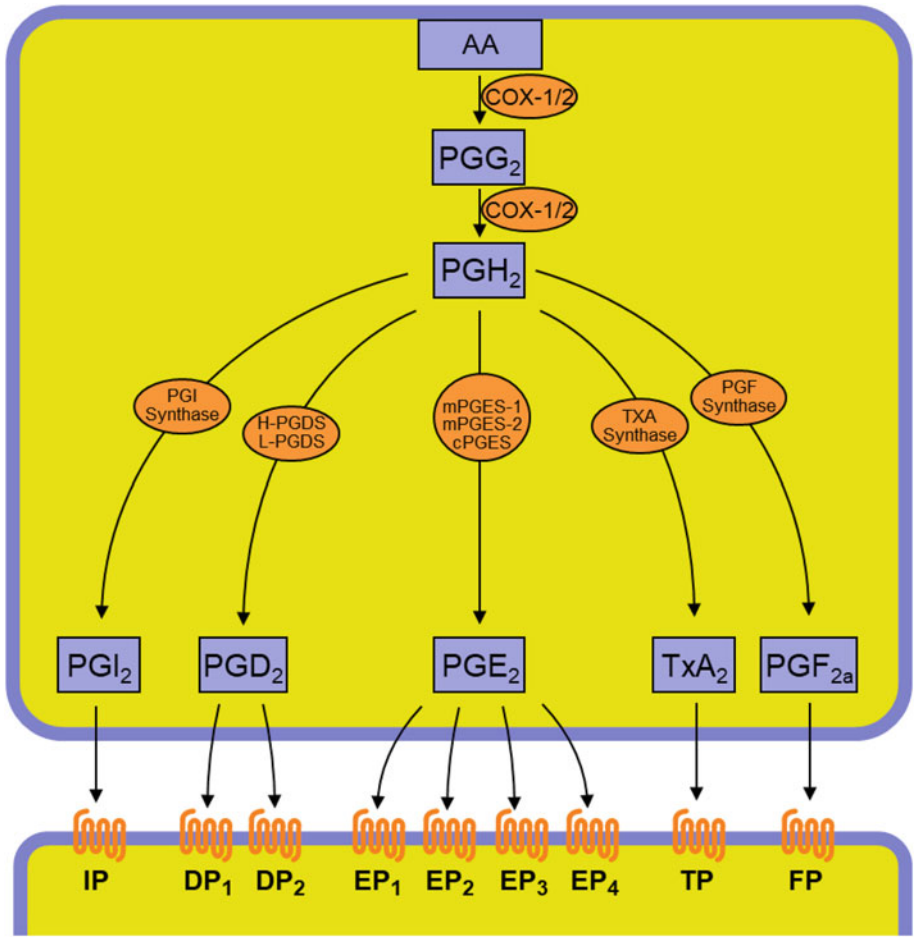
The synthesis of prostanoids from arachidonic acid is initially mediated by cyclooxygenase (COX), which, via the cyclic endoperoxide prostaglandin G_2 (PGG_2), turns arachidonic acid into the progenitor of all prostanoids, prostaglandin H_2 (Fig. 1).

Cyclooxygenase has two isoforms: COX-1 and COX-2. While COX-1 is constitutively expressed in most cells, the expression of COX-2 is induced by various humoral and mechanical factors. COX-2 is also constitutively expressed in different areas of the kidney and the brain as well as in the endothelium of blood vessels.

Cyclooxygenases form PGH_2, which, via different isomerases and synthases, is then further metabolized into the biologically active prostanoids prostaglandin E_2 (PGE_2), prostaglandin I_2 (prostacyclin, PGI_2), prostaglandin D_2 (PGD_2), prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and thromboxane A_2 (TXA_2). Which prostanoids a cell synthetizes depends on the expression of the respective prostanoid synthases.

Many cells are capable of forming PGE_2. Three different PGE_2 synthases are known: two membrane PGE_2 synthases (mPGES-1 and mPGES-2) as well as one cytosolic synthase (cPGES). Similar to COX-2, the PGE_2 synthase mPGES-1 is induced by various stimuli in different tissues, and, in most instances, its presence is associated with COX-2. In contrast to mPGES-1, cPGES and mPGES-2 are constitutively expressed in most tissues and are not primarily coupled to COX-2. Especially cPGES metabolizes mainly PGH_2 generated by COX-1.

PGD_2 formation is induced by two different PGD_2 synthases: As its name already suggests, the hematopoietic prostaglandin D_2 synthase (H-PGDS) is mainly found in the hematopoietic system as well as in the immune system and has been shown to occur in mast cells, TH2 cells, as well as microglia. The so-called lipocalin-type prostaglandin D_2 synthase (L-PGDS) is expressed in the central nervous system and in the heart and testis.



Prostanoids, Fig. 1 Synthesis of several biologically active prostanoids and their receptor targets

According to the current state of knowledge, $PGF_{2\alpha}$, TXA_2, and PGI_2 are each formed by a specific synthase. While TXA_2 and $PGF_{2\alpha}$ synthases are mainly associated with COX-1, the PGI_2 synthase appears to often be co-expressed with COX-2.

Degradation of Prostanoids

Most prostanoids are inactivated rather quickly after their formation, typically within seconds or minutes, and that fact restricts their impact on their immediate site of formation. Some prostanoids, like TXA_2, degrade spontaneously with a half-life of 30 s, while others are broken down very fast by specific enzymes. Prostanoids entering the systemic circulation will get almost completely inactivated during the first passage of the pulmonary circulation.

Effects of Prostanoids

Prostanoids mainly mediate their manifold effects by activating G-protein-coupled receptors (Hirata and Narumiya, 2011; Biringer, 2021; Woodward et al., 2011). While prostanoids like TXA_2 and PGI_2 act through only one receptor, other prostanoids, e.g., PGE_2, have several receptor types for the activation of different G-proteins and secondary signaling transduction pathways (see Table 1).

PGE_2

In most areas of the vascular system, PGE_2 exerts vasodilatory effects by activating G_s-coupled EP_2 and EP_4 receptors. COX-2-dependently formed PGE_2 also plays a special role in

Prostanoids, Table 1 Formation sites, receptors, and effects of some biologically active eicosanoids

Prostanoid	Formation site(s)	Receptor	Expression	Effector	Effects (examples)
Thromboxane A_2 (TXA_2)	Platelets, macrophages	TP	Platelets, smooth muscle	Gq/11/ PLC↑ G12/13, RhoA	Activation of platelets, smooth muscle tone ↑
Prostacyclin (PGI_2)	Vascular endothelium	IP	Platelets, smooth muscle, nociceptive neurons	Gs/AC↑	Inhibition of platelets, smooth muscle tone ↓
Prostaglandin E_2 (PGE_2)	Widely spread	EP_1	Kidney, lung, stomach	Gq/11/ PLC↑	Smooth muscle tone↑, gastric HCO_3 secretion ↑
		EP_2	Uterus, vessels	Gs/AC↑	Vasodilation
		EP_3	Widely spread	Depending on splice variant: Gs/AC↑ Gi/AC↓ $Gq_{/11}$/ PLC↑	Mediating fever reaction, increasing uterus tone, duodenal HCO_3 secretion↑
		EP_4	Widely spread	Gs/AC↑	Keeping open the ductus arteriosus Botalli
Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)	For example, uterus	FP	Smooth muscle, corpus luteum	Gq/11/ PLC↑	Smooth muscle tone ↑
Prostaglandin D_2 (PGD_2)	Mast cells, brain	DP_1	Vessels	Gs/AC↑	Smooth muscle tone ↓
		DP_2	Monocytes, basophils, eosinophils	Gi/AC↓, PLC↑	Chemotaxis

PLC phospholipase C-β; *AC* adenylyl cyclase

keeping open the ductus arteriosus Botalli before birth by activating EP_4 receptors.

PGE_2 is one of the key mediators in acute local inflammatory responses that cause local vasodilation as well as edema formation (Dennis and Norris, 2015; Ricciotti and FitzGerald, 2011; Wang and DuBois, 2018). During inflammatory responses, PGE_2 also sensitizes peripheral nerve endings and has pronociceptive effects on the dorsal horn of the spinal cord. In addition, PGE_2 is the central mediator of fever reaction and, by activating EP_3 receptors in the hypothalamus, leads to changes in the set point of the body temperature.

PGE_2 has inhibitory effects on the differentiation of B-lymphocytes into antibody-producing plasma cells, and it blocks mitogen-induced proliferation of T-lymphocytes.

While leading to contractions of the uterine musculature in the pregnant myometrium, PGE_2 exerts relaxing effects on the nonpregnant uterus.

Together with PGI_2, PGE_2 plays an important role in maintaining the physiological functions of the mucosal membrane in the gastrointestinal tract. PGE_2 has cytoprotective effects, in particular on the gastric mucosa, as it promotes the formation of mucus and bicarbonate as well as encourages the blood flow while at the same time inhibiting the secretion of H^+ ions.

Regarding the kidney, prostanoids such as PGE_2 and PGI_2 have various functions:

- PGE_2 inhibits water resorption through ADH and promotes renal blood flow.

- Together with PGI_2, PGE_2 is also involved in the stimulation of renin release in the context of the tubulo-glomerular feedback mechanism.

TXA_2 and PGI_2

TXA_2 and PGI_2 are antagonistic mediators in the vessel wall.

TXA_2 formation depends on COX-1. It is produced by platelets after activation and leads to vasoconstriction as well as to increased platelet activation. In contrast to TXA_2, the formation of PGI_2 is COX-2-dependent and induced by endothelial cells under the influence of the shear forces of the flowing blood. It counteracts TXA_2 effects by relaxing vascular smooth muscle and inhibiting platelet function. Apart from vascular smooth muscle cells, TXA_2 contracts and PGI_2 relaxes also bronchial and uterine smooth muscle.

Similar to PGE_2, PGI_2 stimulates circulation in the kidney and is involved in the release of renin from cells of the juxtaglomerular apparatus.

Again similar to PGE_2, PGI_2 also plays an important role in acute local inflammatory processes by locally inducing vasodilation and edema formation as well as by sensitizing peripheral nociceptive nerve endings.

PGD_2

PGD_2 is formed and released by, e.g., mast cells. It has vasodilatory effects and inhibits platelet functions. Together with leukotrienes, PGD_2 also induces bronchoconstriction. There are reports of chemotactic effects on eosinophils and TH2-lymphocytes. In the central nervous system, PGD_2 is believed to play a role in sleep induction.

$PGF_{2\alpha}$

$PGF_{2\alpha}$ is formed in the uterus where it induces strong contractions in the normal as well as in the pregnant myometrium. $PGF_{2\alpha}$ also leads to the contraction of smooth muscle cells in the vascular system of pulmonary arteries and veins.

As for the eye, $PGF_{2\alpha}$-mediated contraction of the trabecular network results in improved chamber drainage and, consequently, in reduced intraocular pressure.

Drugs

Due to the very diverse physiological and pathophysiological functions of eicosanoids, inhibition of their formation as well as of the effects they mediate constitute an effective therapeutic approach. In this context, nonsteroidal antiphlogistics are most significant, as they inhibit cyclooxygenases and thereby possess antiphlogistic, antipyretic, and analgesic characteristics, which are all important factors in the treatment of different types of pain and chronic inflammatory diseases. The cyclooxygenase blocker acetylsalicylic acid (aspirin), given at low doses, is an important antiplatelet therapeutic principle and the basis treatment for secondary prophylaxis in cardiovascular disease.

The direct application of prostanoid and prostanoid derivates can also be an effective treatment under certain conditions. However, their systemic administration is often afflicted by a relatively short effect duration and the occurrence of unwanted side effects.

Alprostadil (PGE_1) has strong vasodilatory effects and is injected intraarterially or intravenously when treating advanced stages of chronic arterial occlusion disease. Its vasodilatory effect is also exploited to treat erectile dysfunction. Here, PGE_1 is administered intracavernously or transurethrally. In recent years, however, this principle of action has been mostly substituted by PDE-5 inhibitors, which allow oral administration. PGE_1 can also be utilized to temporally keeping open the ductus arteriosus Botalli in newborn infants.

Epoprostenol, the sodium salt of PGI_2, the PGI_2 derivate iloprost, and the PGI_2-receptor (IP) agonist selexipag all possess strong vasodilatory effects and can be used to treat serious forms of primary pulmonary hypertension. Iloprost is also given in the treatment of advanced stages of thrombangiitis obliterans.

With regard to perinatal care, in particular PGE_2 (dinoprostone) and $PGF_{2\alpha}$ are utilized for their contractile effects in the pregnant uterus. Local administration of PGE_2 as vaginal gel or vaginal pill is used as birth-inducing measure. Uterine atony postnatally can be treated with $PGF_{2\alpha}$.

The PGE_1 derivates misoprostol and gemeprost as well as the PGE_2 derivate

sulprostone are used to induce abortion. Misoprostol affects the acid and mucus secretion in the gastrointestinal tract and can thereby be given together with COX inhibitors to prevent ulcer formation.

Various $PGF_{2\alpha}$ derivates, such as latanoprost, travoprost, tafluprost, or bimatoprost, are of ophthalmological relevance and are used to decrease the intraocular pressure in the treatment of primary open-angle glaucoma.

Protease-Activated Receptors (PARs)

Xu Han, Sahana Aiyer, Jeeda Ismail and Marvin T. Nieman
Department of Pharmacology, Case Western Reserve University, Cleveland, OH, USA

Synonyms

Thrombin receptor

Definition

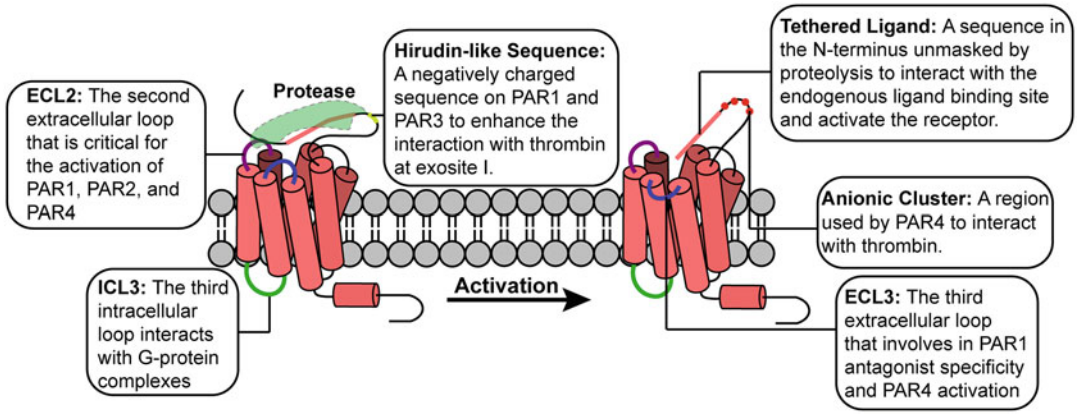
Protease activated receptors (PARs) are a unique set of G-protein coupled receptors (GPCRs) that play a significant role in hemostasis, vascular biology, inflammation, and cancer. There are four members of the PAR family, PAR1-4. PAR1 was discovered 30 years ago and was originally classified as the thrombin receptor on platelets (Vu et al. 1991). Soon after this original discovery, the other family members were identified with important signaling roles in cells such as fibroblasts, myocytes, platelets, neutrophils, and endothelial cells (Adams et al. 2011; Han and Nieman 2020). PARs signal through classical G-protein (Gαq, Gα12/13, and Gαi) and arrestin pathways depending on the cellular context. Understanding how PARs function at the molecular level can be instrumental in developing therapies that target this family of receptors. Here, we will describe unique features of PARs and the pharmacological approaches that have been used to inhibit or modulate PAR activity. By delving into the PAR antagonists that have been developed in preclinical studies, more can be learned to help develop therapies to put into clinical use.

Basic Characteristics

The Tethered Ligand Activation Mechanism

PARs are the primary means by which proteases mediate intracellular signaling. The activation of PARs occurs by cleavage of the N-terminus to produce a tethered ligand that intramolecularly binds to the ligand binding site (Han and Nieman 2020) (Fig. 1). This activation mechanism differs from other GPCRs that are typically activated by a free ligand. Since the sequence of the tethered ligand of each PAR is different, the shape of the endogenous ligand binding sites on the extracellular side of the receptors should also be distinct. The soluble activation peptides mimicking the tethered ligands generally do not cross react between PAR subtypes, which further supports unique binding sites. These data support the concept that it is possible to design peptide mimetics and small molecule antagonists to target each PAR specifically.

The endogenous ligand binding sites have not been fully defined, but there are common themes across PARs. The available structural data from PAR1 and PAR2 in complex with inhibitors do not



Protease-Activated Receptors (PARs), Fig. 1 General mechanism of the tethered ligand-mediated PAR activation. The regions that are critical for the receptor activation and downstream signal transduction are highlighted

reveal how the endogenous tethered ligand interacts with the receptor (Cheng et al. 2017; Zhang et al. 2012). However, experiments with selective point mutations show a key role for extracellular loop 2 (ECL2) in PAR1, PAR2, and PAR4. As additional tools and techniques become available, a more complex model for PAR activation is emerging. For example, hydrogen deuterium exchange studies recently demonstrated an essential role for ECL3 in PAR4 activation (Han et al. 2020a).

The list of proteases that activate PARs continues to grow (Zhao et al. 2014). These proteases rely on a variety of mechanisms such as exosites, cofactors, and membrane localization to ensure efficiency and specificity of substrate proteolysis. For example, PAR1 is an excellent thrombin substrate because it has a hirudin-like sequence that interacts with thrombin's exosite I to increase cleavage efficiency (Han et al. 2020b). In contrast, activated protein C (APC) requires the endothelial protein receptor (EPCR) as a cofactor for efficient cleavage of PAR1. In addition, proteases can have unique recognition sites on PARs that generate a panel of tethered ligands through distinct cleavage sites. This increases the diversity of signaling from individual PAR subtypes within a given cell through biased agonism (Zhao et al. 2014).

Due to the unique, irreversible activation mechanism of PARs, desensitization and internalization are key processes that terminate PAR signaling. Activated PARs do not recycle to the plasma membrane following internalization; they are sent to the lysosome for degradation. These termination events are dependent on G-protein coupled receptor kinase (GRKs), second messenger kinases, and β-arrestin (Grimsey et al. 2014).

Protease Activated Receptor Subtypes

In the 1980s, thrombin was a known potent agonist of platelets but its mechanism of platelet activation was still unknown (Han et al. 2019). In an effort to elucidate the mechanism of thrombin-mediated platelet activation, Vu and colleagues identified PAR1 as the "thrombin receptor" or coagulation factor 2 receptor (F2R) through expression cloning (Vu et al. 1991). Soon thereafter, the other family members were discovered. The amino acid sequence homology between PARs is 27–36% and is primarily in the conserved transmembrane domains similar to most GPCRs. The genes for human PAR1 (F2R), PAR2 (factor 2 receptor like 1 or F2RL1), and PAR3 (F2RL2) are located in a cluster on chromosome 5 (5q13) (Kahn et al. 1998). In contrast, the gene PAR4 (F2RL3) is a more distant relative and is located on chromosome 19p12 (Jin et al. 2016). Although PARs are widely expressed, there are important species differences that impact preclinical drug development (Han et al. 2020b).

PAR1

PAR1 is an efficient thrombin substrate due in large part to a hirudin-like sequence that interacts with thrombin's exosite I to facilitate cleavage of the PAR1 N-terminus at Arg^{41} (Han and Nieman 2020). Once activated by thrombin, PAR1 elicits a rapid signal that is quickly terminated. There is now a growing list of proteases that activate PAR1 including Activated Protein C (APC), Matrix metalloproteases (MMP1 and MMP13), proteinase 3, Cathepsin G, plasmin, elastase, Factor VIIa, and Factor Xa (Zhao et al. 2014). Some of these proteases cleave PAR1 at noncanonical sites, generating unique ligands that give rise to distinct downstream signaling. This is known as biased signaling and can lead to opposite cellular responses. For example, thrombin-mediated activation of PAR1 on endothelial cells results in increased permeability while activation by APC is barrier protective. Furthermore, MMP1 cleavage of PAR1 promotes RhoA activation and p38 phosphorylation (Austin et al. 2013). The diversity in signaling from PAR1 activation has been exploited with allosteric modulators and parmodulins to direct signaling through cytoprotective pathways in preclinical studies. These are discussed below.

PAR2

PAR2 was discovered in 1995 as a trypsin receptor and was the second PAR to be cloned (Yau et al. 2013). PAR2 is widely expressed on the surface of endothelial cells, epithelial cells, fibroblasts, nerves, immune, and inflammatory cells. The expression level of PAR2, however, varies depending on the specific cell type, disease conditions, or even environmental stimuli, such as LPS and dietary fats. Over the years, both the list of the proteases that activate PAR2 and its roles in physiological and pathological conditions continue to grow.

PAR3

The signaling roles of PAR3 remain controversial. In most cells, PAR3 does not signal on its own; it instead serves as a cofactor to modulate the activation and activity from other PARs (Han and Nieman 2020). Given the limited signaling activities of PAR3, it is understudied and only a few pharmacological agents have been developed targeting PAR3.

PAR4

The functional studies of PAR4 have primarily focused on its role in hemostasis and thrombosis since PAR4 was first identified on human platelets and is one of the key receptors mediating thrombin signaling in platelet activation. However, PAR4 is widely expressed in many human tissues such as the kidney, pancreas, lungs, thyroid, and small intestine. The physiological roles of PAR4 in these other tissues are an emerging topic of research.

PAR4 was initially considered a low affinity backup thrombin receptor on platelets because it is a less efficient thrombin substrate (Han et al. 2019). It is now recognized that PAR1 and PAR4 cooperate to mediate thrombin's full signaling profile in platelets. Specifically, PAR1 responds to subnanomolar thrombin and triggers a rapid and transient downstream signal. In contrast, PAR4 requires a ~10-fold higher concentration thrombin for proteolysis and leads to a sustained downstream signal. The sustained signaling from PAR4 results in stable platelet function, increased procoagulant potential, and increased platelet spreading and adhesion (Han et al. 2019). A goal of targeting PAR4 therapeutically is to spare the immediate PAR1 response, but block the sustained PAR4 signaling (Wong et al. 2017). In principle, this would prevent thrombosis and spare hemostasis. An important concept is that although thrombin cleaves both PAR1 and PAR4, the sequences of the unmasked tethered ligands are different. This implies that the location and the shape of the endogenous ligand binding sites of the two receptors are also distinct and can be individually targeted (Hamilton and Trejo 2017).

Drugs

The tethered ligand activation mechanism presents unique challenges to targeting PARs therapeutically. The tethered ligand cannot diffuse from the receptor, which creates an entropy-driven high affinity interaction that is difficult to

block. Three strategies have been used to interfere with PAR signaling (Fig. 2): antibodies that block proteolytic activation, allosteric modulators, and orthosteric antagonists (Tables 1, 2 and 3). Each strategy is discussed below.

Blocking Antibodies

Antibodies that prevent engagement of the protease with the PAR exodomain were the first tools developed to specifically target PAR1 activation and have since been used to inhibit PAR2 and PAR4 (Hung et al. 1992a, b; Hamilton and Trejo 2017; French et al. 2018). The typical strategy is to target an epitope near the protease cleavage site to sterically prevent proteolysis and subsequent receptor activation. However, antibodies that interfere with other recognition sites have also proven successful. For example, antibodies that block the hirudin-like sequence on PAR1 from interacting with thrombin's exosite I inhibit PAR1 activation (Hung et al. 1992a, b). Similarly, blocking the anionic cluster in PAR4 is effective at blocking both mouse and human PAR4 activation (Mumaw et al. 2014). To date, inhibitory antibodies have not been developed for clinical use. However, these reagents have been essential in preclinical models and as laboratory tools to monitor receptor cleavage.

Allosteric Modulators

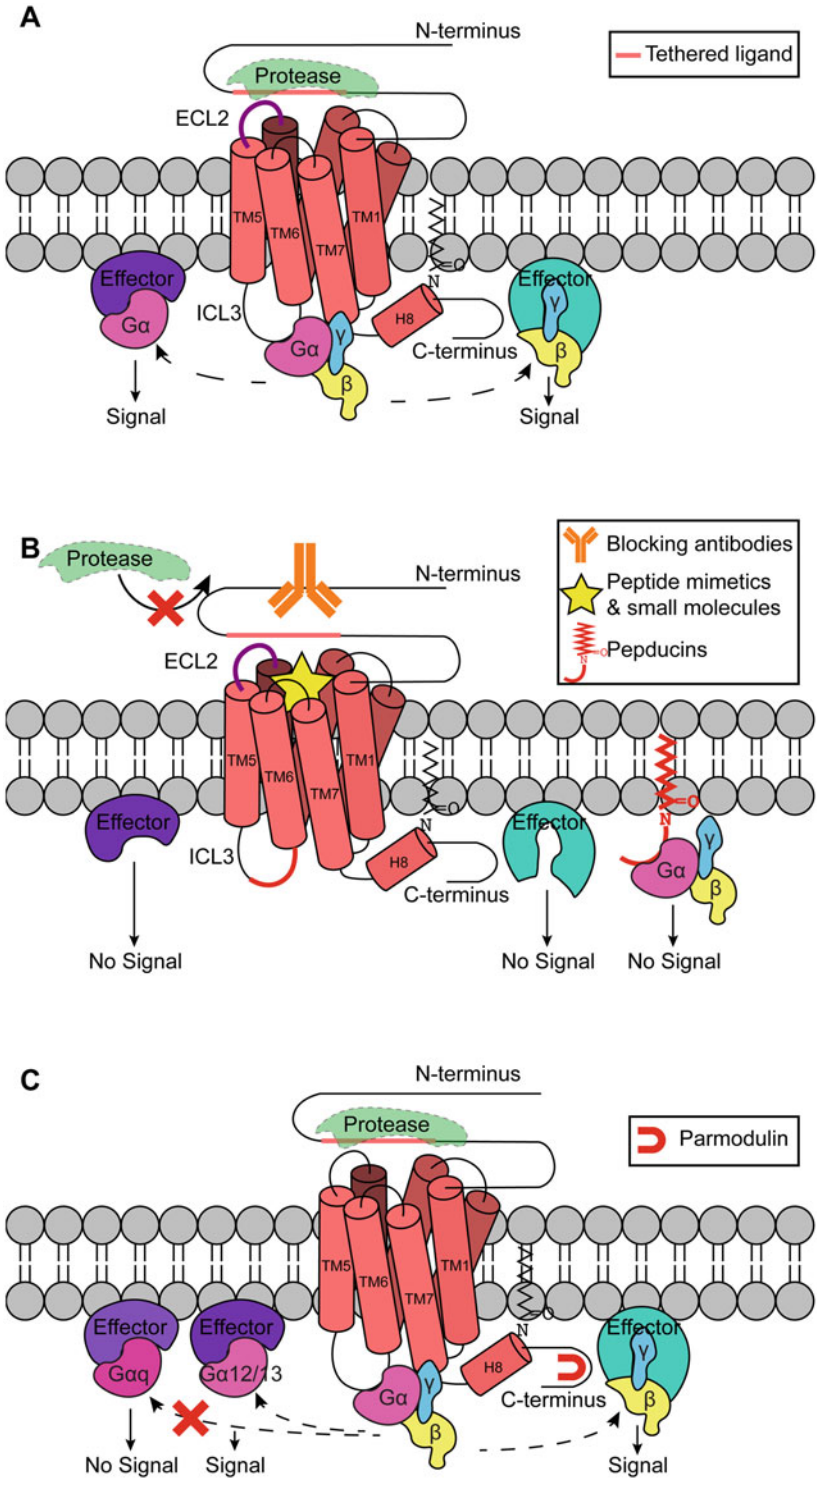
Pepducins are lipidated peptides that mimic intracellular loop 3 (ICL3) of the receptor and disturb the interaction between the receptor and G-proteins (Covic et al. 2002; Hamilton and Trejo 2017). Pepducins have been developed to target PAR1, PAR2, and PAR4. To inhibit signaling, pepducins enter the cell membrane via the lipid moiety, translocate to the intracellular surface, and interfere with G-protein coupling. A PAR1 pepducin, PZ128, has finished two clinical trials. The first trial, NCT01806077, is a Phase 1 study that evaluated the pepducin efficacy in patients with heart disease risk factors (Gurbel et al. 2016). The second trial, NCT02561000, evaluated PZ128 as an antithrombotic therapeutic in the Thrombin Receptor Inhibitory Pepducin-Percutaneous Coronary Intervention study (Rana et al. 2018).

Parmodulins target the 8th helix on the cytoplasmic face of PAR1 (Flaumenhaft and De Ceunynck 2017). Parmodulins do not alter the endogenous ligand binding site located on the extracellular face of the receptor. This property allows some receptor signaling that helps to restrict intracellular calcium flux mediated by the PAR1-Gq axis but has limited effects on RhoA activity by the PAR1-G13 axis (Flaumenhaft and De Ceunynck 2017). Parmodulins are able to block the PAR1-mediated proinflammatory effect in endothelium without altering the APC-mediated cyto-protective pathways.

Small Molecule Antagonists

PAR1

PAR1 antagonists can also be designed by targeting the interaction between the tethered ligand and the ligand binding site. Such antagonists can be divided into: peptidomimetics based on the tethered ligand and nonpeptide small molecules. By modifying the activation peptide at the R1, R2, R3, or R4 position, high affinity PAR1 antagonists such as BMS-200261, RWJ-56110, and RWJ-58259 could be generated (Han and Nieman 2020). These modifications disturb the crucial interaction between the tethered ligand and ligand binding site to produce antagonists that are widely utilized for *in vitro* and *in vivo* experiments. Nonpeptide small molecule inhibitors express improved pharmacokinetic profiles and pharmacodynamic profiles. FR171113 was one of the nonpeptide PAR1 antagonists discovered first, functioning by inhibiting thrombin-or PAR1-AP-induced ERK1/2 activation as well as PAR1-AP- and thrombin-induced guinea pig platelet aggregation *in* vitro (Han and Nieman 2020; Kato et al. 1999). Other nonpeptide small molecule inhibitors include SCH-79797 and its N-methyl analog that are widely used in both *in vitro* and *ex vivo* experiments due to their high specificity and selectivity for PAR1. SCH-79797 also functions as an antagonist in the *in vivo* rodent models (Ahn et al. 2000). However, Lee and Hamilton reported that this molecule drastically changed the morphology and function of platelets independently of PARs (Lee and



Protease-Activated Receptors (PARs), Fig. 2 PAR antagonist mechanism. (**a**) Upon enzymatic cleavage, the tethered ligand activates PARs intramolecularly. G-protein complexes are recruited to the intracellular side

P

Hamilton 2013). These effects were seen at SCH-79797 concentrations required for the full inhibitory effect of PAR1, raising major suspicion on the use of the molecule as a PAR1 antagonist.

Vorapaxar (SCH-530348) is a small molecule PAR1 antagonist found to have a significant oral antiplatelet effect (Morrow et al. 2012; Scirica et al. 2012; Tricoci et al. 2012). Voraxapar was able to block human platelet aggregation induced by 10 nM thrombin or 15μM high affinity thrombin receptor activating peptide in preclinical *in vitro* experiments. It plays a major role in the oral antiplatelet effect due to its high oral bioavailability in several species such as the rat and monkey. In May 2014, the FDA approved vorapaxar as a novel antiplatelet therapeutic to treat patients with a history of myocardial infarction or peripheral arterial disease (Baker et al. 2014). To reduce further risk of thrombotic cardiovascular damage, vorapaxar can be administered with aspirin and/or clopidogrel. Although vorapaxar has major oral antiplatelet effects, it has severe limitations such as the increased risk of bleeding in the brain of patients with a history of stroke, transient ischemic attack, intracranial hemorrhage, or a bodyweight <60 kg. These limitations offset any therapeutic benefits, prompting the search for more novel PAR1 antagonists. New PAR1 antagonists are crucial since PAR1 still has potential as a target for therapeutics.

PAR2

Although PAR2 plays critical roles in inflammation, pain sensation, cancer, and other pathologies, the development of the antagonist targeting PAR2 has not progressed as far as PAR1 (Yau et al. 2013). Two peptide antagonists of PAR2, FSLLRY-NH_2 and LSIGRL-NH_2, blocked trypsin-induced PAR2 signaling but not PAR2-AP (SLIGRL-NH_2)-induced PAR2 activation (Al-Ani et al. 2002). This again highlights that the proteolysis-mediated structural rearrangement of PARs is different from the activation peptide-mediated PAR activation. Several small molecules or peptidomimetic PAR2 antagonists have been reported. The first PAR2 antagonist showed proof of principle, but all have limitations. ENMD-1068 has extremely low potency in vitro (Kelso et al. 2006). K12940 and K-14585 only block the binding of 2-furoyl-LIGRL-NH_2 (a PAR2 peptide agonist) to the receptor but are incapable of inhibiting protease-mediated PAR2 signaling (Goh et al. 2009). Triptolide was not selective to PAR2 and also inhibited neurokinin receptor 1 (NK1) activation (Hoyle et al. 2010).

The first potent, small molecule targeting PAR2, GB88, was released in 2012 and is effective against all known PAR2 activators, including proteases, activation peptides, and nonpeptide agonists (Suen et al. 2012). In additional studies, GB88 and its derivatives including AY117 were shown to be biased ligands (Yau et al. 2013, 2016). GB88 and AY117 were found to inhibit trypsin or 2f-LIGRLO-NH_2-induced calcium mobilization and proinflammatory cytokine release via PAR2 (Yau et al. 2013). This series of PAR2 antagonists also showed anti-inflammatory effect both in vitro and in vivo. Using a similar strategy, Boitano et al. created another PAR2 antagonist, C391, from the PAR2 agonist, 2-furoyl-LIGRLO-NH_2 (Boitano et al. 2015). C391 is a potent and specific PAR2 antagonist that inhibits both PAR2-mediated calcium mobilization and MAPK signaling.

Solving the crystal structure of PAR2 in 2017 led to the most recent breakthrough on PAR2 antagonist development, which yielded the design of the AZ series (Cheng et al. 2017; McIntosh et al. 2020). The crystal structure of PAR2-AZ8838 complex at 2.8 Å uncovered the binding site of this competitive antagonist, while the

Protease-Activated Receptors (PARs), Fig. 2 (continued) of the receptors to further relay the protease signals. (**b**) There are three general strategies for PAR inhibition. Blocking antibodies target the exodomain of PARs to block the protease from interreacting with the receptor. Peptide mimetics and small-molecule compounds are designed to target the ligand binding site, which prevent the interaction between the tethered ligand and PARs. Pepducins act as intracellular modulators that interfere with the G-protein signaling. (**c**) Parmodulin bind to the C-terminus of PARs to redirect PAR signaling

Protease-Activated Receptors (PARs), Table 1 PAR1 antagonists

Name	Chemical structure	Mechanism of Action	Comments	Clinical Trial	References
Vorapaxar		Irreversible orthosteric antagonist, compete directly with endogenous tethered ligand	Thrombin $IC_{50} = 10$ nM, PAR1-AP ([^{3}H] haTRAP) $IC_{50} = 15$ nM	FDA approved (2014)	Tricoci et al. (2012), Morrow et al. (2012), Scirica et al. (2012) and Baker et al. (2014)
FR171113		Competitive Antagonist	Thrombin $IC_{50} = 0.29\mu M$, PAR1-AP (SFLLRN) $IC_{50} = 0.15\mu M$		Kato et al. (1999)
SCH-79797		Competitive Antagonist	PAR1-AP ([^{3}H] haTRAP) $IC_{50} = 70$ nM for binding, $IC_{50} = 300$ nM for platelet aggregation		Ahn et al. (2000)

structure of PAR2-AZ3451 at 3.6 Å resolution revealed that AZ3451 served as an allosteric inhibitor for PAR2. So far, only the AZ3451 has been tested in vivo and showed to be a therapeutic agent for osteoarthritis (Cheng et al. 2017; Huang et al. 2019; McIntosh et al. 2020). The PAR2 inhibitor I-287 selectively inhibits Gαq and Gα12/13 signaling while leaving the Gi/o signaling and β-arrestin2 engagement untouched (Avet et al. 2020). Interesting, although only a subset of PAR2 downstream signaling were inhibited, I-287 treatment still showed an anti-inflammatory effect in vivo. Both the observations from the AZ3451 and I-287 highlighted the potential of specifically regulating PAR function using allosteric inhibitors.

PAR4

Until recently, the development of small molecule PAR4 antagonists has received less attention than PAR1 or PAR2. The initial PAR4 antagonists were based on indazole, indole, imidazole, [1,3,4] thiadiazole (IDT), quinoline, and quinoxaline analogues (Hamilton and Trejo 2017; Liu et al. 2021). YD-3 was the first small-molecule PAR4 antagonist that inhibited GYPGKF-mediated activation of washed human platelets at an IC_{50} of 0.13μM (Wu et al. 2000, 2002). Although it showed some selectivity of PAR4 over PAR1, YD-3 has a couple limitations that restricted its preclinical usage. The synthetic strategy of YD-3 is complicated and the synthesis is inefficient since 20% of the final yield is the inactive isomer. Using YD-3 as the lead compound and replacing its indazole core with indole, ML-354 was selected from Vanderbilt University's (VU) sample library as a potent PAR4 antagonist (Temple et al. 2016; Young et al. 2010). Although ML-354 has an IC_{50} of 140 nM to AYPGKF-stimulated washed platelets, this compound has a high toxicity and a poor drug metabolism and pharmacokinetics (DMPK) profile. In 2016, one of the derivatives of ML-354, VU0661259, was reported (Temple et al. 2016). This was the first highly selective PAR4 antagonist that inhibited γ-thrombin-mediated PAR4 activation along with a reasonable pharmacological profile. However, this compound is a mixed competitive/non-competitive PAR4 inhibitor, which limited the in vivo application. The biggest breakthrough on PAR4 antagonist development occurred in 2017, in which Bristol Myers Squibb (BMS) disclosed the patent of BMS-986120 (Wilson et al. 2018; Wong et al. 2017). Containing an IDT core, BMS-986120 is a high selective small-molecule PAR4 antagonist

Protease-Activated Receptors (PARs), Table 2 PAR2 small-molecule antagonists

that also shows saturable and reversible binding properties to PAR4. Wong et al. also demonstrated that inhibition of PAR4 is a safer antiplatelet strategy with low bleeding risk and a wider therapeutic window compared to the current standard care. Both BMS-986120 and its derivative, BMS-986141, were in clinical trials and showed promising outcomes as a PAR4 antagonist.

Single Nucleotide Polymorphisms (SNPs)

SNPs have been identified in PAR2 and PAR4 that impact receptor functions. PAR2 has a well-characterized polymorphic variant at residue 240 within ECL2 where phenylalanine is replaced by a serine (PAR2-F240S) (Compton et al. 2000). The minor allele frequency for this polymorphism is 0.084. PAR2-F240S has a significantly decreased sensitivity toward trypsin (~3.7-fold), and PAR2-activation peptides, SLIGKV-NH2 (~2.5-fold) and SLIGRL-NH2(~2.8-fold), and an increased sensitivity to a selective PAR2 agonist, trans-cinnamoyl-LIGRLO-NH2(~4-fold). Furthermore, PAR2-F240S also has constitutive activity (Ma and Burstein 2013). These data point to Phe240 in ECL2 as a key residue in PAR2 activation and this polymorphism may impact the response to PAR2 therapeutics. This has yet to be demonstrated empirically.

Protease-Activated Receptors (PARs), Table 3 PAR4 small-molecule antagonists

Name	Chemical structure	Mechanism of Action	Comments	Clinical Trial	References
YD-3		Competitive Antagonist	First non-peptide PAR4 antagonist. PAR4-AP (GYPGKF) $IC_{50} = 130$ nM		Wu et al. (2000, 2002)

VU0661259		Mixed Competitive/ Non-competitive Antagonist	PAR4-AP (AYPGKF) $IC_{50} = 180$ nM, γ-Thrombin $IC_{50} = 4.35\mu M$		Temple et al. (2016)
BMS-986120		Reversible competitive Antagonist	PAR4-AP (Ala-(L-4-F-Phe)-Pro-Gly-Trp-Leu-Val-Lys-Asn-Gly) $IC_{50} = 0.56$ nM, γ-Thrombin $IC_{50} = 7.3$ nM	Phase I trial completed	Wong et al. (2017) and Wilson et al. (2018)
BMS-986141		Reversible competitive Antagonist	PAR4-AP (Ala-(L-4-F-Phe)-Pro-Gly-Trp-Leu-Val-Lys-Asn-Gly) $IC_{50} = 0.45$ nM, γ-Thrombin $IC_{50} = 2.1$ nM	Phase II trial completed	Wong et al. (2017)

PAR4 has four well-characterized sequence variants that change the receptor function, A120T, Y157C, F296V, and P310L (Han and Nieman 2020). The PAR4-A120T variant is the only that has correlated with a differential response to an antagonist. This residue is located in the middle of TM2. PAR4-120T is a hyperreactive PAR4 compared to PAR4-120A, which is also associated with a higher platelet reactivity, increased sensitivity to thrombin, resistance to desensitization, and increased *ex vivo* thrombus formation. More importantly, this alternation of PAR4 function between the two sequence variants may impact the efficacy of PAR4 specific inhibitors or even other antiplatelet compounds. The hyperreactive PAR4 (PAR4-120T) not only showed a higher resistance to YD-3, a selective PAR4 antagonist, but also demonstrated less inhibitory effects of the P2Y12 inhibitor and COX2 inhibitor (Han and Nieman 2020). The precise molecular mechanism of how changing a single residue from alanine to threonine in TM2 can alter PAR4 function is not clear. Based on the amide-HDX study, the 120 position is close to the endogenous ligand binding site of PAR4. This may imply that switching threonine to alanine could affect the shape of the ligand binding site, which further impacts the ligand-receptor interaction and the antagonist-receptor interaction (Han et al. 2020a).

Future Directions

The tethered ligand-mediated receptor activation of PARs provides the opportunity to target each receptor individually while also set up a unique challenge for the antagonist to compete with the entropy-driven high affinity between the tethered ligand

and the receptor. Current drug developments of therapeutic targets of PAR1, PAR2, and PAR4 show great potential. Even though the first member of this family, PAR1, was discovered 30 years ago, this is a promising time for PAR research. The PAR1 antagonist vorapaxar was approved by the FDA in 2014. PAR1 pepducin, PZ128, and the PAR4 antagonists BMS-986120 and BMS-986141 showed promise in the preclinical setting.

Looking forward, there is still a lot of work that needs to be done for PAR antagonist development as well as for the molecular mechanism of PARs in general. Large-scale clinical trials are still needed for the PAR4 antagonists to identify the target patient population so the effects of these therapeutics are still up in the air (Han et al. 2019). A better understanding of how the PAR4 polymorphisms influence effectiveness of the therapeutics and how these remedies will be used with existing antiplatelet and anticoagulation therapies are also needed (Han et al. 2019). Also, when targeting PARs therapeutically, it is important to consider their physiological roles in numbers of tissues and the effects of disrupting their signaling pathways (Han et al. 2019). Using PAR1 as an example, the role of PAR1 on hemostasis is always primarily being considered; thus, antagonists targeting PAR1 have been majorly tested as antiplatelet therapies. However, PAR1 is widely expressed in many different tissues and inhibiting PAR1 may affect other tissues. Therefore, when designing PAR inhibitors, blocking potentially protective signaling pathways needs to be balanced with blocking harmful pathways (Han et al. 2019).

Not every drug candidate is suitable enough to be tested in clinical trials. In fact, most of the PAR antagonists are only usable in preclinical studies. Either way, these PAR antagonists still serve as probes to help scientists understand the specific roles of PARs on different tissue as well as enrich the knowledge of the tethered ligand activation mechanism. Even with more than 20 years of study, there is not a full understanding of the contributions of PAR1 and PAR4. Hence, the development of pharmacological tools for PAR research, including more appropriate animal models and more PAR modulators with a different mechanism of actions, is still required.

Proteasome Inhibitors

Lloyd D. Fricker
Department of Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

Bortezomib (Velcade); Carfilzomib (Kyprolis); Ixazomib (Ninlaro)

Definition

Proteasomes are large multicatalytic protein complexes that function in the degradation of proteins into peptides. Drugs that inhibit one or more of the proteasome's catalytic subunits include bortezomib (Velcade), carfilzomib (Kyprolis), and ixazomib (Ninlaro). These drugs are used to treat multiple myeloma and mantle cell lymphoma, and they are being investigated for other diseases.

Mechanism of Action

As their name implies, proteasome inhibitors target the proteasome. More specifically, they target one of the proteolytic subunits within the proteasome, thereby reducing the ability of the proteasome to cleave cellular proteins into peptides (Fricker 2020). While this is ultimately toxic to all cells, some cell types show elevated sensitivity to proteasome inhibition. Sensitive cells include some types of white blood cells, especially those that are abnormal in cancer such as multiple myeloma and mantle cell lymphoma (Gandolfi et al. 2017). The specific downstream pathway that leads from proteasome inhibition to cell death is not known with certainty, and a variety of mechanisms have been proposed (Fricker 2020). These potential mechanisms are discussed below following discussion of the proteasome.

Proteasome Composition and Diversity

Proteasomes exist in a wide variety of forms and are found in virtually every human cell in the body (Collins and Goldberg 2017). The simplest form of the proteasome is termed the "20S proteasome core particle" and consists of two inner rings of β subunits and two outer rings of α subunits. Each ring consists of seven different α or β subunit proteins. The α subunits are named α1 to 7 and are generally the same in every cell in the body with the exception of the α4S subunit that is unique to spermatozoa. In contrast, some of the seven β subunits in each ring are variable with cell type. Three of the seven β subunits are catalytically active as proteases: β1, β2, and β5. In some cell types, especially immune system cells, the three active subunits are replaced with variants: β1i, β2i, and β5i (Goldberg et al. 2002). In thymocytes, another β5 variant is found, named β5t (Murata et al. 2018). Each variant is catalytically active and confers a slight difference to the substrate specificity of the resulting proteasome. The β5, β5i, β5t, and β1i subunits cleave proteins at hydrophobic amino acids, the β1 subunit cleaves at acidic amino acids (Asp or Glu), and the β2 and β2i subunits cleave at basic amino acids (Lys or Arg). The other four β subunits (β3, β4, β6, and β7) are catalytically inactive and are common to proteasomes in all cell types throughout the body. The catalytically inactive β subunits are evolutionarily related to the active subunits but lack either the critical active site threonine or other important residues (Fricker 2020).

In addition to the diversity of the proteasome that arises from differences in the catalytically active β subunits, there are two other sources of diversity in the proteasomes (Morozov and Karpov 2018). One source of diversity is through posttranslational modifications such as phosphorylation, N-acetylation, glycosylation, myristylation, poly-ADP ribosylation, and ubiquitination. These modifications can affect proteasome assembly, stability, activity, and sensitivity to proteasome inhibitors (Morozov and Karpov 2018). Another major source of proteasome diversity is the presence of cap proteins that serve to bind protein substrates and deliver them into the catalytic core of the proteasome (Collins and Goldberg 2017; Morozov and Karpov 2018). There are several different regulatory complexes, and each 20S proteasome core can bind two regulatory complexes, one at each end. These regulatory cap proteins may be identical or different. Furthermore, the 20S core can exist with only one regulatory complex or no complexes (i.e., the free 20S core particle). The largest regulatory complex is the 19S proteasome activator, also known as PA700. The 19S proteasome activator is responsible for the recognition of ubiquitinated proteins, removal of the ubiquitin chains, and the unfolding and translocation of the protein into the 20S core. There are two different 11S proteasome activators, also known as PA28, PA26, and REG, that differ in their

subunits (α/β vs γ). Neither of the 11S proteasome complexes can bind ubiquitinated proteins or use ATP to unfold proteins. Another regulatory subunit is PA200; this also does not bind ubiquitin or ATP. Thus, the diversity of the regulatory complexes has a large impact on the types of cellular proteins cleaved by the proteasome. Only proteasomes with the 19S proteasome activator can bind and unfold ubiquitinated proteins. Proteasomes containing the other regulatory complexes, or those without any regulatory complexes, are thought to primarily cleave peptides and small unfolded or misfolded proteins (Collins and Goldberg 2017; Morozov and Karpov 2018). All proteasome forms are inhibited by the proteasome inhibitors, albeit with difference in potency (Morozov and Karpov 2018).

Downstream Pathways that Contribute to Cell Death

Protein degradation is an important regulatory event that plays an essential role in many processes. Removing unfolded or otherwise damaged proteins is needed to maintain cells in a healthy state. In addition, many cellular pathways include one or more proteins that function as inhibitors to prevent activation of the pathway, and proteasome-mediated removal of the inhibitor protein(s) is required for subsequent activation. As such, there are many possible ways that blocking the proteasome can contribute to cell death. Cellular proteins cleaved by the proteasome that could contribute to cell death upon proteasome inhibition include NF-κB, p53, cyclin, and cyclin-dependent kinases (Heine et al. 2018). Proteasome inhibitors also cause the accumulation of unfolded and misfolded proteins which trigger the unfolded protein response and apoptosis (Zang et al. 2012). The extrinsic caspase-8 pathway and intrinsic caspase-9 pathways have also been proposed to be involved in cell death caused by exposure to a proteasome inhibitor (Gandolfi et al. 2017). While evidence supports each of these pathways, a major problem is that the concentrations of bortezomib required to alter protein levels in each of these studies are generally much higher than the doses used clinically. Studies that incubate cells with high concentrations of bortezomib for 1–2 days do not reflect the concentration and time course of bortezomib in clinical scenarios. For example, subcutaneous administration of bortezomib results in peak plasma levels of ~25–50 nM for 1–2 h, while intravenous injection causes peak plasma levels of ~250–500 nM for only ~5 min, after which the levels rapidly drop as bortezomib distributes to tissues (Schwartz and Davidson 2004).

Because the levels of cellular proteins do not change rapidly with clinically relevant concentrations of the drugs, it is possible that an alternative mechanism accounts for the downstream effects and cell death. One alternative mechanism involves the peptides that are proteasome products, rather than the proteins that are proteasome substrates (Fricker 2020). The levels of proteasome products show rapid changes when cells are exposed to low concentrations of drugs. These proteasome products are peptides formed upon degradation of the protein. Most of these peptides are not stable within cells and are rapidly degraded by cytosolic peptidases. Because of their high turnover, these peptides are rapidly altered by drugs that inhibit the proteasome and block their production. If these peptides are biologically active, they could contribute to the downstream mechanism of action of the proteasome inhibitors (Fricker 2020).

Classes of Drugs

Proteasome inhibitors can be classified by the chemical moiety that binds to the proteasome. The first synthetic compounds designed to inhibit the proteasome contained an aldehyde group that bound to the active site threonine residue in the β1, β2, and/or β5 subunits (Wilk and Orlowski 1983). However, these aldehyde-based inhibitors were not very selective and inhibited a wide range of cellular proteases. Replacing the aldehyde with a boronate residue conferred greater selectivity (Teicher et al. 1999). Alternatively, natural compounds found to inhibit the proteasome contained other chemical moieties, such as epoxyketones or β-lactone γ-lactams, and these groups also conferred selectivity to the proteasome. Synthetic

drugs using each of these active site "warheads" have been developed (Teicher and Anderson 2015). All of these drugs show greatest activity toward the β5 subunit and the related β5i subunit and weaker potency as inhibitors of the β1 or β2 subunits.

Boronates

Bortezomib was the first proteasome inhibitor to be used clinically (Adams and Kauffman 2004). This compound contains a boronate group that binds to the active site threonine on the β subunits. Because the peptide-based backbone of bortezomib is hydrophobic, this compound is most effective at inhibiting the β5 subunit. Bortezomib is an order of magnitude less potent as an inhibitor of the β1 subunit and two orders of magnitude less potent at the β2 subunit.

Another boronate-containing proteasome inhibitor is ixazomib citrate (Gandolfi et al. 2017). This drug was the third proteasome inhibitor to be used clinically. It is an orally administered prodrug that is converted into the active form (ixazomib) by plasma enzymes. In contrast, all other proteasome inhibitor drugs currently on the market require intravenous or subcutaneous administration.

A third boronate-containing proteasome inhibitor is delanzomib (Zangari and Suva 2016). This drug is currently in clinical trials. Delanzomib is related to bortezomib with a peptide-like backbone and a boronate warhead.

Epoxyketones

Epoxomicin is a natural product isolated from *Streptomyces* extracts. This compound was found in a screen for antitumor activity, and further studies found that epoxomicin has anti-inflammatory properties (Hanada et al. 1992). The structure of epoxomicin consists of a peptide backbone with an epoxyketone group. This epoxyketone moiety forms a covalent bond with the active site threonine and leads to irreversible inhibition. While epoxomicin is commonly used in the laboratory to inhibit the proteasome, it was not developed as a drug.

The first clinically useful proteasome inhibitor containing the epoxyketone moiety is carfilzomib (Kuhn et al. 2007). A drug in development, oprozomib, is structurally related to carfilzomib with a peptide-like backbone and an epoxyketone warhead.

Bicyclic β-Lactone γ-Lactams

The first natural product found to inhibit the proteasome was lactacystin. This compound spontaneously hydrolyzes to the active form, clasto-lactacystin β-lactone, which forms a covalent bond with the active site threonine of the proteasome β5 subunit. Although lactacystin is not suitable as a drug, another natural product proteasome inhibitor named marizomib is being developed as a drug. Marizomib also has a bicyclic β-lactone γ-lactam moiety and is an irreversible inhibitor of the proteasome.

Clinical Use (Including Side Effects)

All of the proteasome inhibitor drugs are effective in treating multiple myeloma and mantle cell lymphoma. Bortezomib is typically used in combination with lenalidomide (a thalidomide analogue) and dexamethasone (a glucocorticoid). The three-drug combination with bortezomib is more effective than the two-drug combination lacking bortezomib. Other bortezomib-containing three-drug combinations found to be effective contain dexamethasone and either thalidomide or cyclophosphamide in place of lenalidomide. Likewise, three-drug combinations in which carfilzomib or ixazomib is substituted for bortezomib have also been found to be more effective than the two-drug combinations lacking the proteasome inhibitor. Patients who develop resistance to bortezomib often show responses to carfilzomib or ixazomib (Gandolfi et al. 2017).

Common side effects to bortezomib include peripheral neuropathy, skin rash, fatigue, nausea, vomiting, diarrhea or constipation, and thrombocytopenia. Rarer but potentially serious side effects include heart failure and other cardiovascular events. Carfilzomib and ixazomib produce similar side effects as found with bortezomib, although the relative incidence of each side effect varies among the drugs (Gandolfi et al. 2017).

In addition to the use of proteasome inhibitors for treating multiple myeloma and mantle cell

Proteasome Inhibitors, Table 1 Proteasome inhibitors

Drug	Molecular class	Inhibition	Comment
Bortezomib	Boronate	Reversible	1st proteasome inhibitor drug

Ixazomib citrate	Boronate	Reversible	Prodrug of ixazomib
Marizomib	β-Lactone γ-lactam	Irreversible	Currently[a] in clinical trials
Oprozomib	Epoxyketone	Irreversible	Currently[a] in clinical trials
Delanzomib	Boronate	Reversible	Currently[a] in clinical trials

[a]in 2020

lymphoma, these drugs are in clinical trials for patients with other types of tumors. For example, marizomib is being tested for glioblastomas based on the ability of this drug to cross the blood-brain barrier (unlike bortezomib). Marizomib was found to be effective in treating glioblastoma in animal studies (Manton et al. 2016). Proteasome inhibitors are also being investigated as immunomodulators (Table 1).

Protein Kinase C

Alexandra C. Newton
Department of Pharmacology, University of California at San Diego, La Jolla, CA, USA

Synonyms

C kinase; PKC

Definition

Protein kinase C (PKC) is an enzyme family whose members are activated by agonists that cause receptor-mediated generation of lipid second messengers. The activated enzymes transduce information from such agonists by phosphorylating relevant downstream substrates.

Basic Characteristics

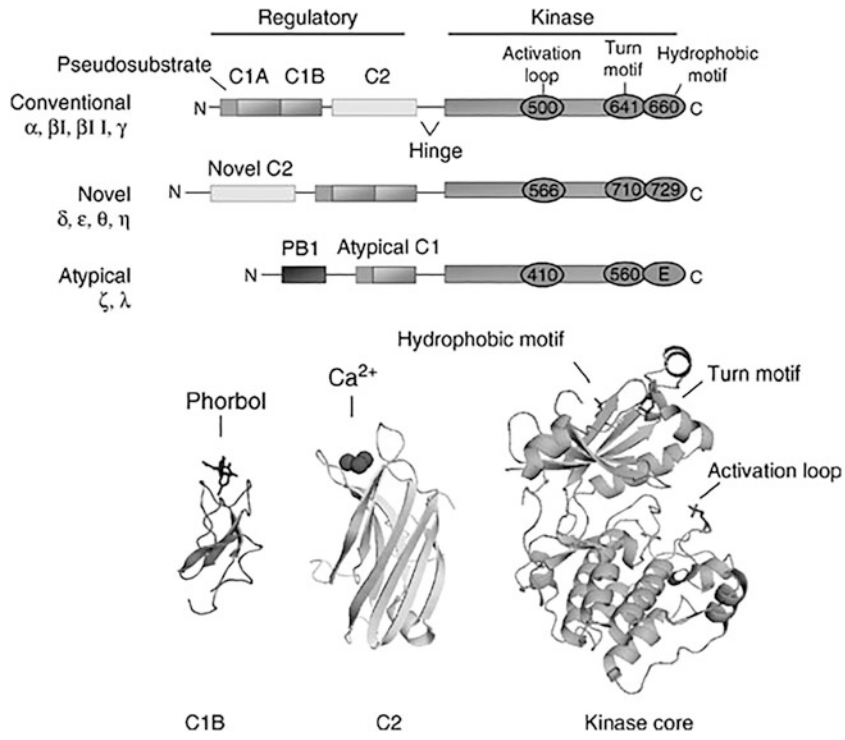
PKC is a family of enzymes whose members play central roles in transducing information from external stimuli to cellular responses. Members of this family of serine/threonine kinases respond to signals that cause lipid hydrolysis. PKC isozymes phosphorylate an abundance of substrates, leading to both short-term cellular responses such as regulation of membrane transport and long-term responses such as memory and learning. They generally function as tumor suppressors, with loss-of-function mutations associated with diverse cancers. Conversely, gain-of-function mutations have been identified in degenerative diseases. Thus, homeostatic control of PKC is essential to avoid pathophysiologies.

The PKC Family

There are nine genes encoding PKC isozymes in mammals, and they fall into three classes: conventional (α, β (with two common splice variants, βI and βII) and γ), novel (δ, ε, η, and θ), and atypical (ζ and ι/λ) PKC isozymes (Newton 2018). As shown in Fig. 1, all isozymes comprise an N-terminal regulatory moiety and a C-terminal kinase core. The regulatory moiety contains two important functional segments: an autoinhibitory pseudosubstrate sequence that allosterically regulates access to the substrate-binding cavity and one or more membrane-targeting modules. It is the nature of the membrane-targeting modules that defines the classes of PKC isozymes. All PKC isozymes have a version of the C1 domain, the diacylglycerol sensor. This domain binds diacylglycerol, the natural agonist, as well as phorbol esters, potent functional analogues, in all isozymes except atypical PKC isozymes. For these isozymes, an impaired ligand-binding pocket does not support the binding of diacylglycerol or phorbol esters, and, as a consequence, the hallmark of atypical PKC isozymes is their complete lack of response to phorbol esters. Rather, these isozymes are regulated by binding protein partners through their PB1 (for Phox and Bem1p) protein interaction domain. Conventional and novel PKC isozymes have a C2 domain. For conventional PKC isozymes, this domain binds phosphatidylinositol-4,5-bisphosphate in the plasma membrane in a Ca^{2+}-dependent manner, serving as a plasma membrane-sensing module. An impaired Ca^{2+}-binding pocket in the novel PKC isozymes makes them unresponsive to Ca^{2+}. In one novel isozyme, PKC δ, phosphorylation on tyrosine controls protein interactions of this domain.

Regulation

PKC isozymes are regulated by three mechanisms: phosphorylation, second messenger binding, and protein–protein interactions. First, a series of ordered phosphorylations renders newly synthesized PKC catalytically competent. The upstream kinase, phosphatidylinositol-dependent kinase-1 (PDK-1), phosphorylates the activation loop of PKC, triggering phosphorylation at two conserved sites in the C-terminus, the turn motif and the hydrophobic motif, by a mechanism that is facilitated by mTORC2. Phosphorylation of the hydrophobic motif occurs via intramolecular autophosphorylation. The positions of these sites on structure of the kinase domain of PKCβII are shown in Fig. 1. These phosphorylations are essential to lock PKC in a stable and autoinhibited



Protein Kinase C, Fig. 1 Domain structure of PKC family members showing regulatory modules (pseudosubstrate sequence and C1, C2, and PB1 domains) and the kinase core. Shown below are the structures of the C1 domain of PKCδ with bound phorbol, the C2 domain of PKCβ with bound Ca^{2+}, and the kinase domain of PKCβII solved by Grant and coworkers (Grodsky et al. 2006) with three processing phosphorylation sites labeled. Figure adapted from (Newton 2003)

conformation. Second, the mature, fully phosphorylated species of PKC is allosterically activated following engagement of the membrane-targeting modules to the membrane. For conventional PKC isozymes, Ca^{2+} pretargets PKC to the membranes by binding the C2 domain and increasing this domain's affinity for anionic lipids. At the membrane, the C1 domain binds diacylglycerol, an event that provides the energy to release the autoinhibitory pseudosubstrate sequence from the substrate-binding cavity. Novel PKC isoforms respond to diacylglycerol alone because their C1 domain has a sufficiently high-affinity binding to diacylglycerol such that pretargeting by the C2 domain is not required. Third, scaffold proteins position PKC near its activators or substrates, allowing specificity in signaling by distinct isoforms.

Signaling by PKC is terminated by concentrations of its ligands dropping to basal levels (i.e., Ca^{2+} and diacylglycerol). Prolonged activation also results in the dephosphorylation and degradation of PKC. Dephosphorylation is controlled, in part, by PHLPP (for PH domain leucine-rich repeat protein phosphatase), which dephosphorylates the hydrophobic motif of conventional and novel PKC isozymes, initiating their downregulation.

Function in Health and Disease

Conventional and novel PKC isozymes generally function to suppress proliferative and survival pathways, with recent evidence converging on roles as tumor suppressors (Newton 2018). Analysis of somatic mutations throughout the PKC family has revealed that the majority are loss of function. In contrast, germ-line mutations that enhance activity are associated with degenerative diseases such as Alzheimer's disease and cerebellar ataxia. For a number of cancers, including pancreatic and colon, patients with high levels of PKC have significantly better prognosis than those with relatively low levels. One exception is PKCι, an

atypical PKC, which functions as an oncogene in cancers such as that of the lung (Yin et al. 2019).

Because the levels of PKC in cells control the amplitude of PKC signaling pathways, defects in PKC regulation that result in altered levels of the kinase are associated with disease. One mechanism that controls the levels of PKC is a quality control pathway by which the phosphatase PHLPP regulates how much newly synthesized PKC progresses to the stable, phosphorylated form: low levels of the phosphatase allow more accumulation of phosphorylated (and thus stable) PKC, whereas high levels promote dephosphorylation and degradation of PKC. This quality control mechanism is particularly important in pancreatic cancer, where patients with low PHLPP and high PKC have considerably better prognosis than ones with high PHLPP and low PKC (Baffi et al. 2019).

Drugs

Activators

Conventional and novel PKC isozymes are potently activated by phorbol esters, heterocyclic compounds found in the milky sap exuded by plants of the Euphorbiaceae family. This sap was used medicinally as a counterirritant and cathartic agent over the millennia; we now know that the active ingredients, phorbol esters, specifically bind to the C1 domain, the diacylglycerol sensor described above. In fact, their ability to recruit PKC to membranes is so effective that phorbol esters cause maximal activation of conventional PKC isozymes, bypassing the requirement for Ca^{2+}. This module is found in a number of other proteins in addition to PKC, so the profound effects of phorbol esters on cells are mediated by other proteins as well. Bryostatins are another class of compounds that bind to the C1 domain and result in acute activation of PKC. Note that these molecules are not readily metabolized and result in the constitutive activation of PKC, triggering PHLPP-mediated dephosphorylation and subsequent downregulation. Thus, while these molecules acutely activate PKC isozymes, they cause the chronic loss of the enzymes. This paradox accounted for confusion as to whether to inhibit or activate PKC in cancer therapies.

Inhibitors

A number of inhibitors directed toward the active site of PKC have been developed (Yin et al. 2019). While these failed in clinical trials for cancer (where, in general, PKC activity should be restored, not inhibited), they may prove useful for neurodegenerative diseases, where inhibiting overly active PKC could be beneficial.

Phosphoprotein phosphatase

Definition

Protein phosphatases are a group of enzymes that catalyze the removal of a phosphate group from substrate proteins, opposing the action of protein kinases.

Basic Mechanisms or Characteristics

Widespread Protein Phosphorylation

The covalent modification of proteins is a common mechanism to control protein function. Dozens of protein covalent modifications are known, with phosphorylation, acetylation, ubiquitination, and methylation being regarded as the most common. Reversible protein phosphorylation was discovered when elucidating the mechanisms that control mammalian glycogen-metabolizing enzymes (Brautigan and Shenolikar 2018) (Moorhead et al. 2007). In eukaryotes, protein phosphorylation occurs predominantly on the hydroxy amino acids, serine (~86%), threonine (~12%), and tyrosine (~2%), generating stable phosphate esters (Brautigan and Shenolikar 2018). Mass spectrometry-based phospho-proteomic studies have revealed that phosphorylation on serine, threonine, and tyrosine residues is also common in prokaryotes. Phosphorylation can occur on several additional amino acid side chains, forming phosphoramidate bonds in phospho-His, phospho-Lys, and phospho-Arg and a phosphorothioate bond with Cys (phospho-Cys). Histidine and aspartate phosphorylation were first discovered in prokaryotes, as part of their two-component basic stimulus-response systems. The recent development of phosphohistidine-specific antibodies has revealed that phosphorylation on histidine is more prevalent in eukaryotes than originally thought. Quantitative mass spectrometry has established that protein phosphorylation occurs on at least 75% of all human proteins with most having multiple phospho-sites (Brautigan and Shenolikar 2018). Given the prevalence of protein kinases and phosphatases across eukaryotes, it is likely that this mechanism of protein regulation is equally widespread in all eukaryotes.

Protein Phosphatases and Kinases

The phosphorylation status of any given amino acid within a protein is governed by the balance of activities of the protein kinase(s) and phosphatase (s) that target that specific residue. With ~98% of human protein phosphorylation on serine and threonine residues, it is no surprise that of the more than over 500 catalogued protein kinases, ~428 are predicted to be serine/threonine-specific, with ~90 being tyrosine-specific protein kinases. Notably, there is a similar number of predicted tyrosine phosphatases (~109) as kinases, but only ~38 serine/threonine phosphatases (Shi 2009). As detailed below, several of the PPP family serine/threonine phosphatase catalytic subunits are used in multiple holoenzyme complexes where the additional subunits provide substrate specificity. Our current knowledge about the number of additional subunits or holoenzyme complexes roughly balances the number of serine/threonine protein phosphatases and kinases (note that most protein kinases and phosphatases have multiple substrates *in vivo*).

The protein kinases belong to one large gene family, while the protein phosphatases are believed to have evolved four times, producing four separate gene families. Like the protein kinases, protein phosphatases were first characterized during the study of glycogen metabolism using in vitro biochemical assays. Extra-mitochondrial serine/threonine protein phosphatase activity was defined as type one (PP1) if abolished by the endogenous inhibitor proteins I-1 or I-2 and called type two if insensitive to I-1 or I-2. Type two activity was further designated PP2A, PP2B, and PP2C if the in vitro activity did not require metal ions, was calcium stimulated, or was dependent on magnesium for activity, respectively (Brautigan and Shenolikar 2018). Subsequent cloning and genomic analysis revealed additional related PPP members, classified as shown in Table 1. PP7 is unique to plants and green algae and contains several insertions in the catalytic region with currently unknown function. Protein phosphatases with EF-hand motifs (PPEFs) are distributed widely in eukaryotes and are also called rdgC (for the *Drosophila* mutant retinal degeneration C). PP2B is also known as

Protein Phosphatases, Table 1 A summary of the protein phosphatases found in humans. calcineurin and has been renamed PP3. PP2C has been reclassified to the PPM family.

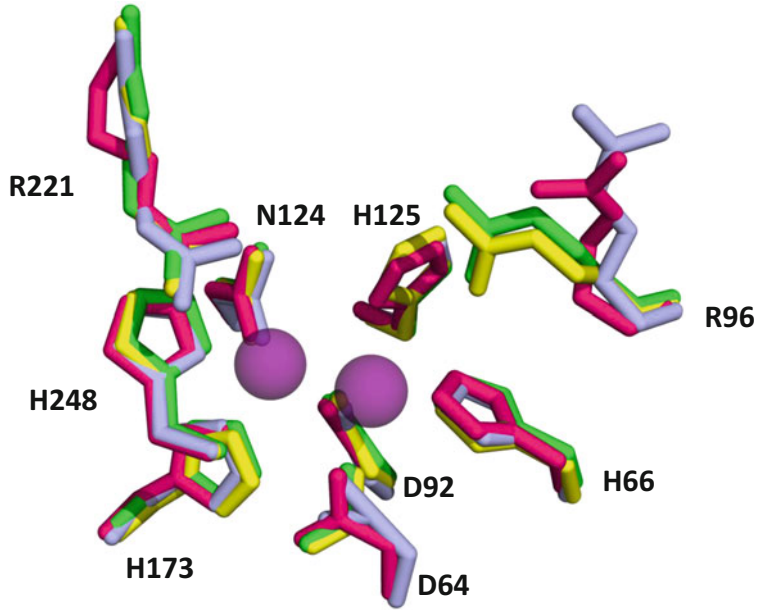
The discovery of tyrosine phosphorylation and then tyrosine-specific protein kinases led to the discovery of the tyrosine-specific protein phosphatases or phosphotyrosine phosphatases (PTPs). Studies on RNA-polymerase II led to the discovery of an additional serine/threonine phosphatase that controls the dephosphorylation of the C-terminal tail (CTD) of the polymerase. This enzyme was the founding member of a small family of related enzymes termed FCP/SCP (TFIIF-associating CTD phosphatase/small CTD phosphatase). Table 1 is completed with the haloacid dehalogenase or HAD family sharing the same catalytic mechanism as FCP/SCP (Moorhead et al. 2007).

PPP Family of Protein Phosphatases

The phosphoprotein phosphatase family (PPP) are serine/threonine-specific enzymes (Table 1) that all contain a series of completely conserved catalytic residues, several of which coordinate binding of two metal ions (Fig. 1). These metals (thought to be Zn^{2+}, Fe^{2+}, or Mn^{2+}) play a key catalytic role by activating a water molecule for nucleophilic attack on the substrate phosphoryl group, leading to the release of phosphate. A substrate peptide based on the phosphorylation site of the PP5 substrate Cdc37 provided the first clue about the active site plasticity of the PPP enzymes (Oberoi et al. 2016). By altering the phospho-site on Cdc37 to a phospho-mimic and tethering residues 5–20 surrounding this phospho-site to PP5, it was clear that this substrate binds the active site using



Conserved Active Site Residues in PPP

Protein Phosphatases, Fig. 1 Members of the phosphoprotein phosphatase (PPP) family have conserved active sites. Human PP1 (green, PDB code 4MOV), PP2A (light blue, 2 IE4), PP2B (red, 4F0Z), and PP5 (yellow, 1S95) crystal structures were aligned and superimposed using the PyMOL Molecular Graphics System, version 2.2.0 (Schrödinger, LLC). The side chains of nine conserved active site residues were extracted from each structure and drawn in stick representation. Residues on the image are numbered following the canonical human PP1 sequence. The equivalent residues for PP2A, PP2B, and PP5 are tabled below the structure. Purple spheres represent the positions of the two metal ions coordinated in the PP1 active site, which are very similar the positions of metal ions taken in the other structures

all the same conserved active site residues found in all PPP enzymes (with the exception of a single PP5-specific change [N308D]) (Fig. 1). The observation that a number of water molecules occupy the active site with the substrate peptide likely explains how PP5 and other PPPs can accommodate so many substrates with differing side chains, as the water molecules can play a role in molding them to a conserved active site.

As noted above, PPP catalytic enzymes, although serine/threonine-specific, tend to be promiscuous and thus have their activity controlled or directed by additional binding proteins. Research that started with PP1 and PP3 (PP2B) and more recently with PP2A and PP4 have uncovered short linear motifs or SLiMs that direct protein/protein interactions between catalytic and regulatory subunits and help recruit substrates to the active site. Protein phosphatase SLiMs tend to be short (four to eight amino acids), reside in intrinsically disordered regions, and have a few key interacting amino acid side chains. Each will be discussed below, and it is expected that additional SLiMs will be discovered for the remaining PPP enzymes. To date only PP5 and PP7 do not have characterized regulatory subunits, although PP5 does have an N-terminal extension that contributes to its regulation.

PP1

PP1 was originally discovered as the protein phosphatase that resides on mammalian glycogen particles to control the activity of the glycogen metabolic enzymes in response to hormonal signals and cellular needs. PP1 has no affinity for glycogen, and the glycogen-bound enzyme in muscle was found to co-purify with a regulatory protein termed G_M. Identification of a different protein that directs PP1 activity toward smooth muscle myosin (MYPT1) led to the concept of PP1 targeting or regulatory subunits. This in turn led to the identification of a PP1 regulatory subunit binding motif, or SLiM, designated the RVxF motif. This motif is somewhat degenerate ([KR][KR][VI]{FIMYDP}[FW], with amino acids {FIMYDP} not accommodated at the indicated position), is found in nearly all PP1 interactors, and has been characterized in over 200 human proteins. In addition to regulatory proteins, this motif is also found in some PP1 substrates, facilitating direct recruitment of the phosphatase. Additional, much less frequently occurring PP1 binding motifs have now been identified and include the G/SILK, MyPhoNE, and SpiDoC motifs (Brautigan and Shenolikar 2018). PP1 regulatory subunits target PP1 to specific locations in the cell to be in the vicinity of substrates and also control the substrate specificity of the somewhat promiscuous, although serine/threonine-specific, PP1 catalytic subunit.

PP2A/4/6

Phylogenetic analysis of the PPP catalytic subunits from any eukaryotic organism always groups PP2A, PP4, and PP6 together, indicating they are more like each other than any other PPP enzyme and likely evolved from a common ancestral phosphatase. PP2A, PP4, and PP6 are all exquisitely sensitive to okadaic acid, which means that early studies that attributed effects of okadaic acid on cellular processes to PP2A function may have been erroneous, as the effects could have been due to the inhibition of PP4 or PP6 complexes.

PP2A is relatively abundant, regulates an extraordinary range of cellular processes, and is composed of three subunits. The PP2A core enzyme is the catalytic subunit (PP2AC) and a scaffolding A or PR65 subunit, which is composed solely of HEAT repeats. Humans express two versions of each of these subunits. The core then associates with one of several B subunits that belong to four sequence unrelated families: B (also known as B55 or PR55), B′ (B56 or PR61), B″ (PR48/PR72/PR130), and B‴ (PR93/PR110). Each B subunit family protein is expressed from two to five genes with several generating splice variants. It is the B subunits that confer substrate specificity on PP2A holoenzyme complexes. The PP2A catalytic subunit is reversibly methyl-esterified on its carboxy-terminal leucine (as are PP4 and PP6). Methyl-esterification and demethylation are controlled by leucine carboxyl methyltransferase (LCMT-1) and PP2A methylesterase (PME-1), both of which appear to be specific for the enzymes PP2A, PP4, and PP6 (Brautigan and Shenolikar 2018). For PP2A, it is currently thought that this covalent modification controls the association of the PP2A core with B subunits and possibly the incorporation of metal ions into the active site.

PP4 is a predominantly nuclear serine/threonine phosphatase composed of a catalytic subunit (PP4C) and two regulatory subunits (R2 and R3, with A and B versions of R3) (Ueki et al. 2019). R3 is composed of ARM/HEAT repeats and an N-terminal EVH1 domain. It has been established that the EVH1 region recruits PP4 substrates that house the SLiM FXXP. Recent *in silico* and proteomic analysis has uncovered many new potential substrates for PP4 that have the FXXP SLiM (Ueki et al. 2019).

PP6, also a serine/threonine phosphatase, exists as a trimer in cells. Three related human proteins, SAPS1, SAPS2, and SAPS3 (Sit4-associated proteins, also called PPP6R1, PPP6R2, and PPP6R3), associate with the PP6 catalytic subunit. A common N-terminal region of each, known as the SAPS domain, is required to associate with PP6C. Mass spectrometry analysis of PP6 complexes uncovered three ankyrin repeat-containing proteins as regulatory proteins for PP6, and there are three in humans which can form trimers with PP6C and SAPS: ANKRD28, ANKRD44, and ANKRD52 (Brautigan and

Shenolikar 2018). To date no SLiM has been identified for PP6 substrates.

PP3 (PP2B/Calcineurin)

PP3 was originally termed PP2B/calcineurin and identified as a Ca^{2+}-stimulated phosphatase activity *in vitro*. Purification from the skeletal muscle and brain uncovered a catalytic A subunit and Ca^{2+} binding (EF-hand) B subunit. After binding Ca^{2+} PP3 can be further activated by binding Ca^{2+}-calmodulin. In the absence of Ca^{2+}, PP3 is inactive, due to an autoinhibitory region from the A subunit docking at the active site. Upon Ca^{2+} and Ca^{2+}-calmodulin binding, this autoinhibitory peptide is removed from the active site, allowing substrates to dock for dephosphorylation. The best characterized substrate for PP3 is the T-cell transcription factor, NFAT (nuclear factor of activated transcription), which when dephosphorylated shuttles from the cytosol to the nucleus to initiate an immune response. Detailed studies of PP3 and NFAT identified a SLiM on NFAT that binds PP3 (the PIXIXIT motif, where X can be any amino acid). This SLiM has subsequently been identified on most PP3 substrates. A second substrate-recruiting site has also been found in many PP3 substrates and is known as LXVP (Brautigan and Shenolikar 2018).

PP5

PP5 is somewhat unique among the PPP enzymes because it has no known regulatory subunits. This enzyme has an N-terminal extension composed of tetratricopeptide repeats (TPR) that fold back and inhibit the enzyme, with a key glutamate (E76) extending into the active site to act as a phosphomimic. How PP5 and likely all PPP enzymes dock substrates was revealed when the substrate peptide Cdc37 was linked to the tail of PP5 and co-crystalized (described above in the PPP introduction) (Oberoi et al. 2016).

PPM Family of Protein Phosphatases

The PPM enzymes were originally identified and named based on the need to add exogenous Mg^{2+} to enzyme assays to detect their activity. Purification, cloning, and genomic analysis revealed that the PP2C enzymes have a unique sequence, evolving independently of the PPP family enzymes, and they were thus renamed the Mg^{2+}/Mn^{2+}-dependent protein phosphatases (PPM) (Brautigan and Shenolikar 2018). This class also includes the mitochondrial pyruvate dehydrogenase phosphatases. Like the PPP enzymes, the metal ions activate a water molecule to drive catalysis. To date, no regulatory or accessory subunits are known for PPM enzymes, but most have additional domains outside of the catalytic core. There are 16 members (Table 1) in the human family, and most plant genomes have many more (e.g., there are more than 80 PPMs in *Arabidopsis thaliana*).

PTP Family of Protein Phosphatases

With the discovery of tyrosine phosphorylation in 1979 and the identification of tyrosine-specific protein kinases, the search began for tyrosine-specific protein phosphatases. The first, PTP1B, was discovered in 1988 and is now known to counter insulin and leptin signaling. Members of the PTP family (Table 1) all share a conserved PTP domain and catalytic signature designated CX_5R, with the C and R being critical for catalysis (Moorhead et al. 2007). Subsequent cloning and genomic analysis identified many more PTP family members, including the first mitogen-activated protein kinase phosphatase (MAPKP) that was the founding member of the dual-specificity phosphatase subfamily known as the DUSPs (Table 1). They are considered "dual-specificity" because all protein phosphatases characterized before this were specific for serine/threonine or tyrosine, while these enzymes could dephosphorylate the TxY motif of MAPK activation loops. Members of this subfamily are placed here based on amino acid sequence. Characterization has confirmed they are phosphatases, although many act on non-protein substrates (RNA, glycogen, starch, phosphoinositides; Moorhead et al. 2007) or dephosphorylate serine or threonine residues on proteins.

Aspartate-Based Family of Protein Phosphatases

Eukaryotic RNA-polymerase II is hyper-phosphorylated in a C-terminal repeat of the sequence YSPTSPS (on serine 2 and 5) during

elongation of transcripts and is dephosphorylated to initiate another round of transcription. A biochemical search for an activity that would dephosphorylate the C-terminal tail of RNA-polymerase II identified FCP, a serine/threonine phosphatase (Moorhead et al. 2007). The human genome has seven related, but smaller, versions of FCP designated SCP (small CTD phosphatase). FCP/SCP have no additional subunits, but do have accessory domains outside the catalytic core. To date, their only known substrate is RNA-polymerase II. Unlike the other protein phosphatases, FCP/SCP catalysis is driven by aspartates in the motif DXDXT/V.

Chronophin is also an aspartate-based protein phosphatase and belongs to the HAD family of proteins (Table 1). To date, chronophin's only known substrate is cofilin, a regulator of actin dynamics. It is postulated that other HAD family members could be protein phosphatases, although these enzymes are currently only known to target cellular metabolites, not proteins.

Pharmacological Intervention

The biological importance of the PPP family phosphatases is highlighted by the widespread production of an enormous array of potent and chemically diverse small-molecule inhibitors of PPP enzymes by a wide range of organisms. Some degree of specificity exists between inhibitors (microcystin, nodularin, okadaic acid, tautomycin, fostriecin, and others) and the PPP enzymes they target. Potent inhibition has been described for PP1, PP2A, PP4, PP5, and PP6, and only very weak inhibition of PP3 (PP2B) and PP7 (Brautigan and Shenolikar 2018). These molecules have no effect on PPM, PTP, and aspartate-based family enzymes. As such, they have proven to be useful research tools for implicating specific types of protein phosphatases in specific cellular events (although caution needs to be taken when interpreting these results (Brautigan and Shenolikar 2018)) and for locking the phospho-status of proteins in extracts for analysis. In addition, conjugation of microcystin to affinity matrices has facilitated the purification and analysis of microcystin-sensitive protein phosphatase complexes.

From a pharmaceutical industry perspective, the serine/threonine protein phosphatases were initially not thought to be ideal drug targets due to their broad substrate specificities. This view is changing, with the realization that the activity of holoenzyme complexes can be controlled with high specificity by targeting the regulatory rather than the catalytic subunits. This can include activating or inhibiting activity against a specific substrate, as required. PP3 (PP2B), in contrast, can be directly inhibited by two natural products that target the active site and have proven to be invaluable for organ transplants. These two bacterially produced molecules, FK506 and cyclosporin, bind the proteins FKBP12 and cyclophilin, respectively, and the drug-protein complexes in turn bind PP3 (PP2B). This abolishes the ability of PP3 (PP2B) to dephosphorylate the key T-cell transcription factor NFAT, which prevents its translocation to the nucleus and initiation of an immunogenic gene response, thereby preventing organ rejection.

Aberrant tyrosine phosphorylation has been linked to multiple human diseases, including cancer, diabetes, neurodegenerative and infectious diseases, and autoimmune disorders, and the tyrosine kinases have been key therapeutic targets for decades. Their counterpart PTPs have also been linked to a wide range of diseases and thus represent novel drug targets. The PTPs all share a common catalytic mechanism requiring the signature C and R amino acids of the CX_5R motif. The PTPs have, to some degree, evolved unique active sites to accommodate novel substrates that can be exploited for drug targeting. One recent novel approach to develop selective inhibitors of PTPs was to develop bivalent ligands that dock the active site and a secondary binding pocket (He et al. 2013). Although no PTP inhibitors are in the clinic as yet, selective inhibitors have been produced for PTP1B, TC-PTP, SHP2, Lyp, mPTPA, HePTP, PTPβ, PTPγ, MKP-3, CD45, Cdc25, YopH, PTPRO, VHR, MKP-1, and mPTPB (He et al. 2013; Stanford and Bottini 2017).

As we gain a better appreciation of the physiological significance and complexity of phosphatase regulation, these previously "undruggable" enzymes have become more approachable and now represent a significant pool of molecular targets that can be exploited therapeutically.

S-Nitrosation

Definition

Protein S-nitro(sy)lation is a reversible posttranslational modification, resulting from the covalent attachment of a nitric oxide (NO)-related group to the thiol (or, perhaps more properly, thiolate anion, S^-) of a specific cysteine residue. Similar to other posttranslational modifications, S-nitrosylation can regulate the enzymatic activity, conformation, binding properties, or intracellular localization of a protein. In the setting of normal/low levels of NO, the resulting protein S-nitrosylation mediates physiological signaling pathways, often critical for cellular homeostasis and survival. However, high levels of NO, as seen in many disease or inflammatory states, can result in aberrant protein S-nitrosylation of cysteine residues not normally modified in healthy cells, resulting in dysfunctional or deleterious cell function. Note that the term "S-nitros*ylation*" was adopted to reflect the biological actions of NO on redox-sensitive proteins, akin to phospho*rylation* and methy*lation*, through modification of the sulfur (S) atom of a cysteine residue. Nitrosylation can also refer to direct addition of NO to a metal center, such as ferrous heme in a metalloprotein. In addition, another form of reactive nitrogen species (RNS), peroxynitrite ($ONOO^-$), can induce nitration of tyrosine residues, also affecting protein function and structure (Ischiropoulos et al. 1992). Thus, metal nitrosylation and tyrosine nitration are clearly distinct from S-nitrosylation of cysteine residues. The first protein whose activity was shown to be regulated by S-nitrosothiol formation on critical cysteine residues (and thus to be S-nitrosylated) was the *N*-methyl-D-aspartate (NMDA)-type of glutamate receptor (NMDAR) in the brain (Lipton et al. 1993).

Basic Characteristics

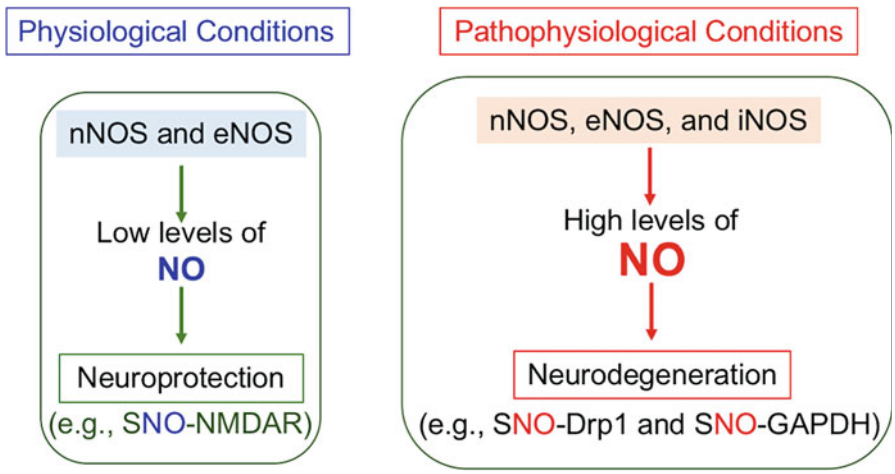
Generation of NO in Mammalian Cells

Many mammalian cells constitutively produce moderate but sufficient levels of NO to regulate physiological processes such as dilation of blood vessels, cardiac contractility, and memory formation in the brain. NO production in mammalian cells entails activation of a family of NO synthases (NOSs) that converts L-arginine to

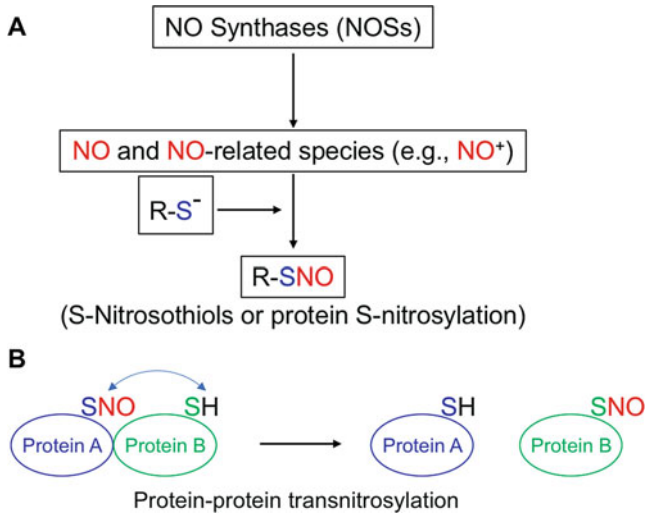
L-citrulline and NO (in the presence of low arginine levels, reactive oxygen species (ROS) are produced instead of RNS). Three NOS members exist in mammals: neuronal NOS (nNOS or NOS1), inducible NOS (iNOS or NOS2), and endothelial NOS (eNOS, NOS3, or cNOS). nNOS and eNOS activities are stimulated by intracellular calcium, whereas iNOS generates NO in a calcium-independent manner. For example, in the case of nNOS in the brain, mild activation of NMDARs at neuronal synapses triggers calcium influx that moderately activates nNOS, which exists in a protein complex tethered to the NMDAR via PDZ domains in PSD-95. The physiological production of NO supports synaptic plasticity and neuronal survival through various protein S-nitrosylation reactions, although S-nitrosylation-independent effects of NO (e.g., via activation of guanylate cyclase and formation of guanosine-3′,5′-monophosphate [cGMP]) also mediate various biological effects (Fig. 1). In contrast, excessive activation of NMDARs, particularly extrasynaptic receptors, causes pathological production of RNS including NO, contributing to aberrant protein S-nitrosylation reactions that can result in protein misfolding, mitochondrial dysfunction, transcriptional dysregulation, synaptic damage, and other neurotoxic events, thus contributing to various neurodegenerative diseases (Nakamura et al. 2013). Consistent with these findings, genetic ablation of nNOS ameliorates neuropathological features seen in mouse models of not only NMDA toxicity but also ischemia and Parkinson's disease (PD).

Protein S-Nitrosylation

As delineated above, protein S-nitrosylation results from the targeted covalent attachment of NO-related species to a specific thiol group (RSH or, more properly, thiolate anion, RS^-), forming an S-nitrosothiol (R-SNO or SNO-protein) (Fig. 2a). The chemical intermediate thought to be involved in S-nitrosothiol formation is nitrosonium cation (NO^+), which is not, however, present in a free



Protein S-Nitrosylation, Fig. 1 NO-dependent signaling pathways under physiological and pathophysiological conditions. At physiological levels, NO generally supports normal neuronal signaling and function, in many cases enhancing neuronal survival in the brain. In contrast, excessive production of NO from iNOS, eNOS, or nNOS can contribute to protein misfolding, mitochondrial/bioenergetic dysfunction, ER stress, synaptic injury, and other forms of neuronal damage in neurodegenerative disorders. Physiologically produced NO provides neuroprotection in part through protein S-nitrosylation of the NMDAR (forming SNO-NMDAR). Additionally, non-S-nitrosylation pathways, such as activation of soluble guanylate cyclase (sGC) to produce cGMP, may mediate some neuroprotective actions of NO. Under pathophysiological conditions, high levels of NO contribute to neurodegeneration via aberrant protein S-nitrosylation (e.g., formation of SNO-Drp1 and SNO-GAPDH). Notably, a full S-nitrosylation motif (SNO motif) is typically needed near the target cysteine to form an S-nitrosothiol at physiological levels of NO (see main text for details); however, excessive production of NO-related species can cause aberrant S-nitrosylation even if a partial SNO motif is present and potentially in the absence of nitrosylating enzymes



Protein S-Nitrosylation, Fig. 2 Mechanisms for production of S-nitrosylated proteins. (**a**) In mammalian cells, NO synthases (NOSs) produce NO, allowing subsequent formation of NO-related species. Protein S-nitrosylation emerges from a chemical reaction between thiolate anion (RS^-) and NO-related species that have an S-nitrosylating activity (such as NO^+). (**b**) Protein-protein transnitrosylation entails transfer of an NO group from one protein to another protein. Importantly, direct protein-protein interaction is required for transnitrosylation reactions to occur, because such a protein complex provides a platform for enzymatic denitrosylation from one protein and S-nitrosylation of another recipient protein

state at physiological pH. For donation of NO-related species in cells, a transition metal is probably required to facilitate electron transfer. As an alternative mechanism for R-SNO formation, direct chemical reaction between a thiyl radical (RS·) and ·NO has been suggested (Tannenbaum and White 2006).

Protein S-nitrosylation can also be accomplished via transfer of an NO-related species from one thiol group to another thiol (Nakamura et al. 2013). This process is known as trans(S-) nitrosylation and likely represents a key mechanism for generation of SNO-proteins in vivo. In general, S-nitrosylating enzymes (or nitrosylases) facilitate donation of NO-related species to a protein, while denitrosylating enzymes catalyze removal of NO. Several enzymes that participate in other reactions have been reported to mediate denitrosylation as well (e.g., S-nitrosoglutathione reductase (GSNOR) and thioredoxin) (Sengupta and Holmgren 2013; Benhar et al. 2009; Smith and Marletta 2012). In the case of trans-nitrosylation, the protein donating NO acts as the nitrosylase, and the protein accepting NO as the denitrosylase (Fig. 2b).

Other chemical reactions can occur following protein S-nitrosylation. For example, if S-nitrosylation occurs on one of vicinal thiols, it will facilitate disulfide bond formation (Cho et al. 2009; Nakamura et al. 2013). Chemically speaking, although dependent on the local redox milieu, the NO group in the R-SNO is often a good "leaving group." As NO leaves, it may facilitate reaction of ROS with the remaining free sulfhydryl group to produce additional oxidation products, such as sulfenic (R-SOH), sulfinic ($R-SO_2H$), and sulfonic ($R-SO_3H$) acid derivatives (Nakamura et al. 2013). Importantly, these other oxidation products may also promote aberrant protein activity, misfolding, or aggregation. In fact, since the higher oxidation states (i.e., $R-SO_3H$) represent irreversible reactions, the abnormal effect on the target protein may be permanent.

Specificity of Protein S-Nitrosylation

S-Nitrosylating and denitrosylating enzymes facilitate protein S-nitrosylation and denitrosylation, respectively, and the local redox environment also exerts a strong influence, as alluded to above. Several additional factors have been proposed for

specific targeting of S-nitrosothiol (-SNO) formation to a specific cysteine residue (Hess et al. 2005; Lipton et al. 1993; Nakamura et al. 2013; Smith and Marletta 2012). A major determinant of SNO specificity involves the presence of nucleophilic amino acid residues (e.g., lysine, histidine, aspartate, and glutamate) flanking or in proximity to the target cysteine, constituting a "SNO motif," which facilitates reaction of the target thiol with an NO-related species (Hess et al. 2005; Stamler et al. 1997). In this scenario, sidechains of the nucleophilic amino acids (typically acidic or basic) lower the pKa of the target cysteine thiol to enhance SNO formation (Stamler et al. 1997; Hess et al. 2005).

While a full SNO motif is typically required for a target cysteine to form an S-nitrosothiol at physiologically low levels of NO-related species, excessively high levels of NO, as occur in neurodegenerative disorders, can result in S-nitrosylation of cysteine residues that have only a partial SNO motif, thus promoting "aberrant" protein S-nitrosylation under these conditions. Intramembrane localization of a target protein can also affect specific SNO formation. In this regard, the hydrophobic environment present in lipid membranes can promote nitrosylation by NO or other hydrophobic NO-related species. Additionally, localization of a target cysteine near NOS can facilitate S-nitrosylation because of the local increase in NO concentration.

As outlined above, transnitrosylation represents an important mechanism for cellular SNO formation and transfer from one protein to another. In this case, precisely regulated transfer of the NO proceeds only when a specific protein-protein interaction occurs (Fig. 2b). For example, interaction of a SNO-protein with its binding partner protein can lead to specific S-nitrosylation of the acceptor protein and denitrosylation of the donor protein.

Examples of Neuroprotective Signaling Pathways Triggered by S-Nitrosylation in the Brain: S-Nitrosylation of NMDARs

Physiological levels of NO typically afford neuroprotection. For example, addition of an NO groups can act as neuroprotective agent via S-nitrosylation of NMDARs, DJ-1, or caspases. Here, we review the effect of S-nitrosylation of NMDARs. Hyperactivation of NMDARs (especially extrasynaptic, as opposed to synaptic, NMDARs) has been shown to trigger ROS/RNS generation and to activate downstream enzymatic cascades that contribute to neuronal and synaptic damage in a wide range of neurodegenerative diseases, including Alzheimer's disease (AD), PD, and stroke. Our group and subsequently others have shown that physiological levels of NO-related species can prevent excessive activation of this receptor via S-nitrosylation of multiple NMDAR subunits, thus mediating the neuroprotective action of NO (Choi et al. 2000; Lipton et al. 1993; Lipton 2006, 2007). In contrast, a decrease in S-nitrosylation of NMDARs has been reported to exacerbate neuropathology in a mouse model of prion disorders.

NO-related species can S-nitrosylate NMDARs at multiple cysteine residues on different NMDAR subunits (Lipton 2006, 2007; Lipton et al. 1993). These include Cys744 and Cys798 on the GluN1 (formerly termed NR1) subunit, and Cys87, Cys320, and Cys399 on the GluN2A (formerly NR2A) subunit. Note that high ambient oxygen levels facilitate the formation of an intramolecular disulfide bond between Cys744 and Cys798 on GluN1, thus preventing S-nitrosylation of these sites; however, under relatively hypoxic conditions, as seen in the normal brain, the free thiol groups on these GluN1 cysteines are maintained. This renders these GluN1 cysteine residues vulnerable to S-nitrosylation, as observed in the X-ray crystal structure of GluN1. Notably, S-nitrosylation of Cys744 and Cys798 on GluN1 by themselves exerts little effect on the electrophysiological activity of the NMDAR; however, formation of S-nitrosothiol on the GluN1 subunit increases the sensitivity of cysteine residues on GluN2A to S-nitrosylation (i.e., at Cys87, Cys320, and Cys399). Hence, Cys744 and Cys798 on GluN1 act as a redox sensor via an apparent allosteric influence on GluN2A nitrosylation status (Choi et al. 2000; Lipton et al. 1993; Lipton 2006, 2007). Poly-S-nitrosylation of the GluN2A subunit inhibits excessive NMDAR activity, thus limiting ion influx, and representing a negative feedback mechanism for the NMDAR-nNOS-NO pathway (Choi et al. 2000).

Examples of Neurodegenerative Signaling Pathways Triggered by Aberrant S-Nitrosylation in the Brain: S-Nitrosylation of Drp1 and GAPDH

As alluded to above, excessive production of NO-related species can result in aberrant S-nitrosylation of a large number of proteins. In the brain, this contributes to the development of neurodegenerative pathology, including mitochondrial dysfunction, protein misfolding, and synaptic damage. Aberrantly S-nitrosylated proteins include SNO-Drp1 (dynamin-related protein 1), SNO-GAPDH (glyceraldehyde-3-phophate dehydrogenase), SNO-PDI (protein disulfide isomerase), SNO-MMP9 (matrix metallopeptidase 9), SNO-MEF2C (myocyte enhancer factor 2C), SNO-PINK1 (PTEN-induced kinase 1), SNO-Parkin, and SNO-XIAP (X-linked inhibitor of apoptosis) to name but a few. In this chapter, we highlight the pathological consequences of SNO-Drp1 and SNO-GAPDH, as these SNO-proteins may contribute to the pathogenesis of multiple neurodegenerative diseases (Hess et al. 2005; Nakamura et al. 2013; Hara et al. 2006).

In neurons, efficient energy production from healthy mitochondria is critical to the maintenance of membrane potential and synaptic transmission. Mitochondria are known to constantly undergo the processes of fission and fusion, collectively termed mitochondrial dynamics. Mitochondrial dynamics regulate the size, shape, number, and intracellular distribution of mitochondria. Moreover, mitochondrial fusion and fission can influence ROS generation, apoptosis, bioenergetics, and mitophagy. Hence, well-balanced mitochondrial dynamics represents a critical cellular process for normal synaptic function and neuronal survival. In a many neurodegenerative diseases, including AD, PD, and Huntington's disease (HD), abnormally fragmented, small-sized mitochondria have been observed, consistent with the notion that abnormal mitochondrial dynamics participate in the pathogenesis of the disease.

As a GTPase, Drp1 functions as a GTP-dependent mitochondrial fission protein. Our group and subsequently others found that oligomeric Aβ peptide or mutant huntingtin (mHtt) induces nitrosative stress, thus causing aberrant S-nitrosylation of Drp1 (forming SNO-Drp1) at Cys644 in both human brain and experimental models of AD and HD (Cho et al. 2009). S-Nitrosylation of Drp1 hyperactivates its GTPase activity, leading to pathologically fragmented mitochondria with damage cristae that are bioenergetically compromised. In contrast, expression of non-nitrosylatable mutant Drp1 prevents excessive mitochondrial fragmentation and synaptic damage in neurons exposed to oligomeric Aβ or mHtt, supporting the notion that SNO-Drp1 plays a causal role in the pathogenesis of AD and HD. Moreover, Drp1 has now been shown to be aberrantly S-nitrosylated in human brains with various neurodegenerative disorders (Cho et al. 2009). These results support our hypothesis that SNO-Drp1-dependent mitochondrial fragmentation mediates a signaling pathway common to several neurodegenerative diseases that leads to compromised mitochondrial bioenergetics, thus contributing to synaptic damage and neuronal loss.

As a second example of aberrant protein S-nitrosylation in neurodegenerative disorders, we next consider SNO-GAPDH. GAPDH is well characterized as a key enzyme in glycolysis, but the protein also plays an important role in transcriptional regulation and apoptosis. S-Nitrosylation of GAPDH mediates a neurotoxic effect of NO not only via inhibition of GAPDH catalytic activity but also by increased binding to the ubiquitin E3 ligase Siah1 (Hara et al. 2006). When S-nitrosylated, GAPDH interacts with Siah1, and the SNO-GAPDH/Siah1 complex translocates to the nucleus because of the nuclear localization signal of Siah1. Once in the nucleus, Siah1 enhances degradation of nuclear proteins, augmenting an apoptotic cascade. In mouse models, this SNO-GAPDH pathway appears to contribute to the neuropathogenesis of PD, HD, stroke, and possibly other neurodegenerative diseases (Hara et al. 2006).

Drugs Affecting Protein S-Nitrosylation

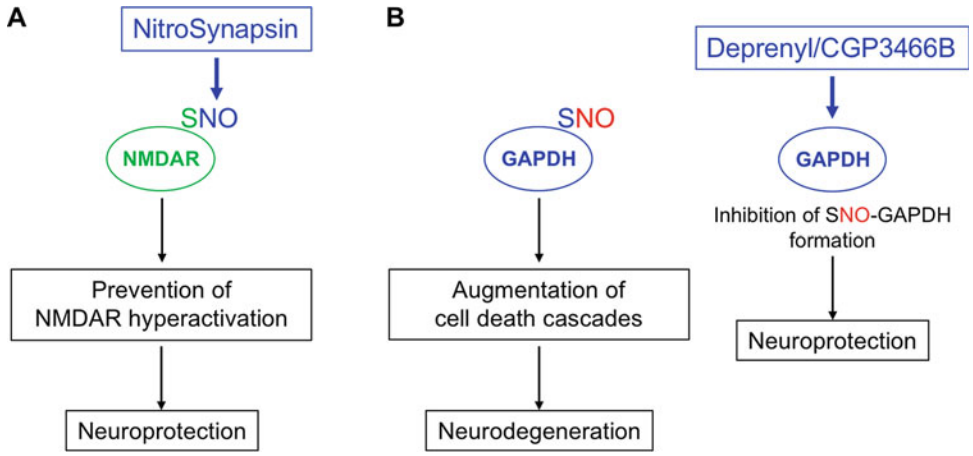
Recent studies with mass spectrometry-based S-nitrosoproteomic techniques have identified several hundreds of S-nitrosylated proteins not only under pathophysiological conditions but also in normal cells (Doulias et al. 2013). Intriguingly,

although many proteins can be aberrantly modified by S-nitrosylation in neurodegenerative brains, in several cases, prevention of S-nitrosylation of just a single protein, such as PDI or Drp1, can mitigate neuropathological features such as protein misfolding or mitochondrial impairment, respectively (Cho et al. 2009). Additionally, pharmacological interventions that affect either physiological or aberrant S-nitrosylation pathways can be harnessed to protect neurons. Two such approaches are highlighted here that selectively regulate SNO-NMDAR and SNO-GAPDH formation, thus potentially protecting neurons in neurodegenerative disorders.

NitroSynapsin

Our group recently developed a neuroprotective small compound, named "NitroSynapsin" that can protect neurons via dual allosteric action on the NMDAR. First, the aminoadamantane moiety of the drug functions as an *u*ncompetitive *f*ast-*o*ff rate antagonist of the NMDAR-associated ion channel (termed "UFO" type of inhibition), similar to our findings with the FDA-approved aminoadamantane drug, memantine. Second, the new drug is a chemical adduct between the aminoadamantane moiety and a nitro group, which functions as a "warhead" on the aminoadamantane that can S-nitrosylate the NMDAR, thus providing additional efficacy for inhibiting excessive receptor activation (Fig. 3a). Critically, the aminoadamantane group serves to target the nitro group to the NMDAR because, like memantine, the aminoadamantane moiety is an "open-channel blocker," meaning that it prefers to bind to excessively open/pathologically-over-activated channels. This mechanism of action also tends to spare physiological/shorter opening of channel during synaptic transmission. Unlike other known NMDAR antagonists that indiscriminately inhibit all NMDARs with high affinity and thus block synaptic activity, the unique features of memantine and NitroSynapsin prevent the drugs from blocking normal synaptic function, thereby manifesting fewer clinical side effects (Lipton 2006, 2007).

Additionally, our group demonstrated that the FDA-approved drug, memantine, as well as NitroSynapsin, preferentially blocks NMDARs at extrasynaptic sites because these ion channels tend



Protein S-Nitrosylation, Fig. 3 NitroSynapsin and deprenyl/CGP3466B show neuroprotective activities via manipulation of protein S-nitrosylation. (**a**) NitroSynapsin contains a nitro group (-NO_2) linked to the memantine moiety. This allows NitroSynapsin to serve as an S-nitrosylating agent specifically targeted to NMDARs. Accordingly, NitroSynapsin can provide increased inhibition of hyperactivated NMDARs via S-nitrosylation of the receptor in addition to memantine-dependent blockage of the ion channel activity. (**b**) CGP3466B (a deprenyl derivative) affords neuroprotection at least in part via inhibition of SNO-GAPDH formation. S-Nitrosylation of GAPDH initiates the formation of a protein complex with Siah1, enhancing its nuclear localization (due to the nuclear localization signal of Siah1) and stimulating cell death pathways. Because CGP3466B (TCH346 or omigapil) directly binds GAPDH and selectively blocks S-nitrosylation of the protein, this drug can serve as a neuroprotective agent

to be excessively/tonically open (i.e., hyperactivated) in neurodegenerative disorders, in contrast to the physiological/phasic activity of synaptic receptors (Lipton 2006, 2007). Since excessive activation of NMDARs can contribute to the pathogenesis of a number of neurodegenerative diseases, this type of drug action affords a degree of neuroprotection. Unfortunately, memantine is positively charged, and as neurons become ill, they depolarize and are relatively more positively charged, thus repelling memantine out of NMDAR-operated ion channels. NitroSynapsin has the ability to compensate for this shortcoming by offering a second site of inhibitory action at the S-nitrosylation sites on the NMDAR. Thus, the dual action of NitroSynapsin at NMDARs affords superior performance to memantine in several models of neurodegenerative and neurodevelopmental disorders (Lipton 2006, 2007). In the future, clinical trials will be needed to see if the potential disease-modifying activity of NitroSynapsin can be realized in humans.

Deprenyl and CGP3466B (TCH346 or Omigapil)

GAPDH has been reported to be a direct target of the putative neuroprotective compound, deprenyl (Selegiline®). Clinically, deprenyl is claimed to delay the progression of symptoms in early PD and AD. The mechanism of action of deprenyl was initially thought to involve selective inhibition of monoamine oxidase-B (MAO-B). However, the deprenyl derivative, CGP3466B (TCH346 or Omigapil), which exhibits virtually no MAO-B inhibition, displayed neuroprotective activity equivalent to or even more potent than deprenyl itself in cell-based and animal models of PD. The findings in these and other studies are consistent with the notion that deprenyl (and related compounds) acts as a protective drug through blockade of GAPDH-dependent cell death pathways; alternatively, deprenyl may exert antioxidant effects or possibly even increase catecholamine content rather than inhibiting MAO-B enzymatic activity. Further along these lines, Solomon Snyder's group more recently found direct binding of deprenyl or CGP3466B to GAPDH that prevents formation of SNO-GAPDH, thereby inhibiting the interaction of GAPDH and Siah1; this effect blocks nuclear translocation of GAPDH (Hara et al. 2006) (Fig. 3b). Based on these encouraging preclinical results, human clinical trials with CGP3466B were then conducted for PD and amyotrophic lateral sclerosis (ALS). Unfortunately, although CGP3466B proved to be nontoxic and nonaddictive in phase I trials, the drug failed to show neuroprotective effects in either disease. In summary, although the neuroprotective action of deprenyl and CGP3466B may in part arise from its ability to block the SNO-GAPDH-Siah pathway, drug efficacy in human clinical trials remains unproven.

Disclosure of Conflicts of Interest

S.A.L. is the inventor on worldwide patents for the use of memantine and NitroSynapsin for neurodegenerative disorders. Per guidelines of Harvard University, his former institution where the work was initially performed, S.A.L. participates in a royalty-sharing agreement with his former institution Boston Children's Hospital/Harvard Medical School, which licensed the drug memantine (Namenda®) to Forest Laboratories, Inc./Allergan. S.A.L. is also a scientific co-founder of Adamas Pharmaceuticals, Inc., which developed or co-developed the FDA-approved drugs NamendaXR®, Namzaric®, and Gocovri®.

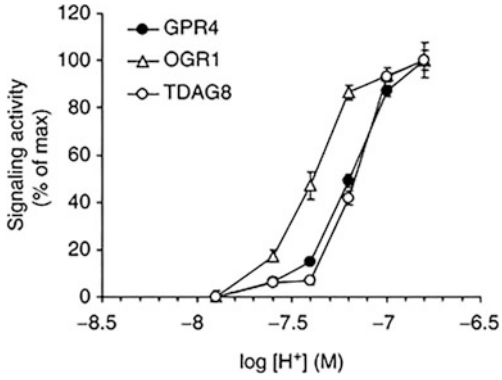
Definition

GPR4, OGR1, and TDAG8 are GPCRs regulated by extracellular pH in the physiological range. These receptors are silent at pH 7.8 and fully activated at pH 6.8.

Basic Characteristics

The receptors GPR4, OGR1, and TDAG8 form a subfamily of GPCRs distantly related to purinergic and angiotensin receptors. These receptors are activated by neutral to slightly acidic extracellular pH (Ludwig et al. 2003; Wang et al. 2004), stimulating second messenger formation as effectively as other receptors activated by, e.g., monoamines, lipids, or peptides, suggesting that protons are the genuine activating ligands (Seuwen et al. 2006). A fourth molecule, the receptor G2A (GPR132), is also related to this group. However, recent data suggest that G2A is a receptor for oxidized fatty acids and N-acyl amino acids (Foster et al. 2019). G2A does not exhibit structural elements required for pH sensing (see below), and activation by acidic pH could not be confirmed (Seuwen et al. 2006; Foster et al. 2019).

The response of GPR4, OGR1, and TDAG8 to extracellular pH in recombinant cell systems is shown in Fig. 1. OGR1 appears slightly more sensitive to extracellular protons than GPR4 and TDAG8. In the experimental setup used,



Proton-Sensing GPCRs, Fig. 1 pH-dependent activation of recombinant receptors expressed in host cells. GPR4 was stably expressed in Hela cells and OGR1 and TDAG8 in CCL39 hamster fibroblasts. For OGR1, formation of inositol phosphates was measured, and for GPR4 and TDAG8, cAMP formation was determined. Data were normalized to maximal stimulation (100%). Untransfected host cells show no pH-dependent activation of second messenger formation. Experimental details are as described in (Ludwig et al. 2003)

half-maximal activation of receptors was observed at pH 7.45 ± 0.04 for OGR1 ($n = 14$), pH 7.18 ± 0.02 for GPR4 ($n = 3$), and pH 7.15 ± 0.02 for TDAG8 ($n = 6$). As described in (Ludwig et al. 2003), the pH values refer to buffers adjusted at room temperature. To obtain pH at 37 °C, 0.15 pH units should be subtracted.

To date, we could not identify other GPCRs showing a similar pH-dependent response. Without exception, all receptors studied so far in our hands show a rather stable signal output over the extracellular pH range of 6.5–7.8 following activation by their cognate ligand (Seuwen et al. 2006). However, the existence of other pH-sensing GPCRs is not excluded.

Structure-Function

OGR1 and GPR4 exhibit a cluster of histidines exposed to the extracellular space, and these amino acids are conserved across mammalian species. Site-directed mutagenesis experiments confirmed the importance of five histidine residues for normal pH sensing of the receptor OGR1 (Ludwig et al. 2003). A similar study confirmed the importance of the histidine cluster for pH sensing in GPR4 (Liu et al. 2010).

No detailed studies are yet available for TDAG8. In the latter receptor, three of the histidine residues shown to be relevant in OGR1 are replaced by basic amino acids. It is possible that these Arg and Lys residues, in the context of other surrounding amino acids in TDAG8, can function in pH sensing (Seuwen et al. 2006).

Crystal structures for the pH-sensing GPCRs are not yet available.

Potential Physiological Roles of pH-Sensing Receptors

The three pH-sensing receptors are found in vertebrates – orthologues for OGR1 and GPR4 are detected in zebrafish, chicken, and in all sequenced mammalian species, but not in *Drosophila*, *C. elegans*, or *Plasmodium*. TDAG8 is not found in zebrafish, but in the mammalian species analyzed to date. The receptors thus appear to be relevant for physiological processes developed relatively late in evolution.

Surprisingly little is known today about the molecular mechanisms governing pH homeostasis of higher organisms. Overall control is achieved through regulation of respiration and renal handling of bicarbonate and protons. The bone plays an important role as a reserve for hydroxyl ions, bicarbonate, and phosphate. Cardiovascular function and immune responses are influenced by acidosis.

Indeed, since the discovery of the pH-sensing properties of GPR4, OGR1, and TDAG8, the receptors have been linked to regulation of pH homeostasis in specific ways. A short summary of pertinent information is given in the following (see also Table 1).

The first data on mice deficient in GPR4, OGR1, and TDAG8 demonstrated that animals were viable and fertile, showing no overt phenotypes. Yang et al. (Yang et al. 2007) reported that adult $GPR4^{-/-}$ mice appear normal; however, increased perinatal lethality was observed which was associated with vascular abnormalities. Indeed, GPR4 is expressed in endothelial cells, and experiments on aortic rings ex vivo showed that microvessel outgrowth was less sensitive to acidic pH in preparations obtained from $GPR4^{-/-}$ mice compared to control. A later study by Wyder

Proton-Sensing GPCRs, Table 1 GPR4 and TDAG8 are Gs-coupled GPCRs; they stimulate cAMP formation inside cells. OGR1 is Gq-coupled, leading to activation of phosphoinositide turnover and release of calcium from intracellular stores (Ludwig et al. 2003; Wang et al. 2004). All receptors were also shown to activate signal transduction through G_{13}/rho activation. Prominent sites of expression, examples for suggested physiological roles (not comprehensive), and currently available pharmacological tools are indicated

Name	Chromosomal location	Signal transduction	Expression and physiological roles	Pharmacological tools
GPR4	19q13.2–q13.3	cAMP ↑ (G_s)	Endothelial cells Angiogensis (Yang et al. 2007; Wyder et al. 2011) Kidney function (Sun et al. 2010) Respiration (Kumar et al. 2015)	Antagonists cpd **3b** (Fukuda et al. 2016) cpd **13** (Velcicky et al. 2017; Sanderlin et al. 2019)
OGR1 (GPR68)	14q31	IP_3/Ca^{2+} ($G_{q/11}$)	Osteoblasts, osteoclasts, smooth muscle cells Bone metabolism (Krieger et al. 2016; Parry et al. 2016) Vascular function (Tomura et al. 2005; Xu et al. 2018) Mechanosensing (Xu et al. 2018; Wei et al. 2018)	Agonist Ogerin (Huang et al. 2015)
TDAG8 (GPR65)	14q31–q32.1	cAMP ↑ (G_s)	Immune system Inflammation (Okajima 2013; Jostins et al. 2012; Lassen et al. 2016; Tcymbarevich et al. 2019; Ma et al. 2017)	Agonist BTB09089 (Onozawa et al. 2012; Ma et al. 2017)

et al. (Wyder et al. 2011) showed a significantly reduced angiogenic response to VEGF-A (vascular endothelial growth factor A), but not to bFGF (basic fibroblast growth factor), in $GPR4^{-/-}$ animals.

Interestingly, GPR4 was also linked to renal acid handling (Sun et al. 2010) and to control of respiration in response to elevated CO_2 (Kumar et al. 2015), two important mechanisms controlling pH homeostasis.

OGR1 is expressed at low but relevant levels in many tissues including notably kidney, bone, and the nervous system (Ludwig et al. 2003 and references cited therein). We and others demonstrated pH-dependent signaling of the receptor in bone-forming osteoblasts as well as in bone-resorbing osteoclasts (Ludwig et al. 2003; Krieger et al. 2016). OGR1-deficient mice show a normally developed skeleton; however, there is a slight increase in bone volume detectable in growing animals, indicating a shift in the bone formation / resorption ratio (Krieger et al. 2016). Additional work is required to assess the response of the skeleton of $OGR1^{-/-}$ mice to chronic acidosis and hormonal changes. Further supporting an involvement of OGR1 in bone metabolism is the observation in humans of loss of function mutations in the OGR1 gene that lead to amelogenesis imperfecta, a disease of teeth characterized by abnormal enamel formation (Parry et al. 2016).

Expression and function of OGR1 were also described in human aortic smooth muscle cells, and the receptor was reported to control acid-induced PGI2 production (Tomura et al. 2005). PGI2 is a vasodilating mediator and may contribute to acidosis-induced vasorelaxation. Recent publications also described machanosensing properties for OGR1, and the receptor may directly transduce effects of shear stress in the peripheral vascular system (Xu et al. 2018; Wei et al. 2018). Importantly, mechanosensing through OGR1 works only at acidic pH, and the concept of co-incidence detection of shear stress and acidic pH was therefore suggested (Xu et al. 2018; Wei et al. 2018). Tissue acidosis and mechanical signals may explain how OGR1 stimulates TGFbeta secretion and fibrosis in mouse models of intestinal bowel disease (Hutter et al. 2018).

TDAG8 appears restricted to the immune system. As tissue inflammation is usually followed

by local hypoxia and acidosis, the pH-sensing property of TDAG8 appeared of particular interest in this context. While initial exploration of mice deficient in TDAG8 failed to unravel a prominent immune-related phenotype, later studies applying specific challenges suggested that TDAG8 inhibits inflammation, which is in line with the coupling of the receptor to cAMP production (Okajima 2013). TDAG8 attracted more attention when GWAS studies in humans linked the gene with high scores to inflammatory bowel disease and other immune disorders (Jostins et al. 2012). The receptor was thereafter shown to be required for normal lysosomal function and clearance of bacteria by macrophages (Lassen et al. 2016). In a DSS colitis model, TDAG8 deficiency enhanced macrophage and neutrophil infiltration into the colon and expression of pro-inflammatory mediators (Tcymbarevich et al. 2019).

In addition to their physiological roles in pH homeostasis, the proton-sensing receptors likely play an important role in cancer. Solid tumors are typically characterized by hypoxia and acidosis, and OGR1, GPR4, and TDAG8 sense low extracellular pH and appear to exert effects on tumor cell survival, proliferation, and motility, but also regulating angiogenesis and immune cell infiltration (Justus et al. 2013; Damaghi et al. 2013; Wiley et al. 2019).

Drugs

Despite the fact that the pH-sensing GPCRs represent attractive targets for drug development, limited information is available to date on modulators of receptor function. A first publication describing BTB09089, an agonist of TDAG8, appeared in 2012 (Onozawa et al. 2012). BTB09089 is able to activate cAMP formation dependent on TDAG8 in the slightly alkaline pH range, where the receptor is normally silent or only weakly active. Potency and efficacy of the molecule is modest, reaching $<30\%$ of the effect of low pH stimulation at a concentration of >10 microM. However, BTB09089 is specific against GPR4 and OGR1 as well as other GPCRs and was shown to inhibit cytokine production in primary murine T cells and macrophages. The molecule is today used to probe the function of TDAG8 in in vitro and in vivo studies (Ma et al. 2017).

Using screening of receptor activity in recombinant yeast, Huang et al. (Huang et al. 2015) identified agonist activity of some benzodiazepine molecules on OGR1. Receptor homology modeling and ligand docking led to the identification of ogerin, a positive allosteric modulator of OGR1, active in the micromolar range. Ogerin is specific against other GPCRs, and importantly, it could be shown to work in a murine in vivo model of fear conditioning (Huang et al. 2015).

For GPR4, potent and specific inhibitors were identified. First, Fukuda et al. described a potent ($IC_{50} = 67$ nanoM) and fully efficacious blocker of GPR4-dependent signaling and demonstrated that the molecule had impressive effects reducing mortality in a murine myocardial infarct model (Fukuda et al. 2016). Velcicki et al. later reported potent and highly selective GPR4 inhibitors with effects on nociception, inflammation, and angiogenesis (Velcicky et al. 2017; Sanderlin et al. 2019).

Conclusions

The data available to date identify GPR4, OGR1, and TDAG8, but not G2A, as genuine pH-sensing receptors. The receptors have been shown to influence processes linked to regulation of pH homeostasis and response to acidosis, such as bone metabolism, kidney function, respiration, and inflammation.

Psychedelic Drugs

David E. Nichols[1] and Charles D. Nichols[2]
[1]Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, NC, USA
[2]Department of Pharmacology and Experimental Therapeutics, LSU Health Sciences Center, New Orleans, LA, USA

Synonyms

Classic hallucinogen; Hallucinogen; Psychotomimetic; Serotonergic hallucinogen

Definition

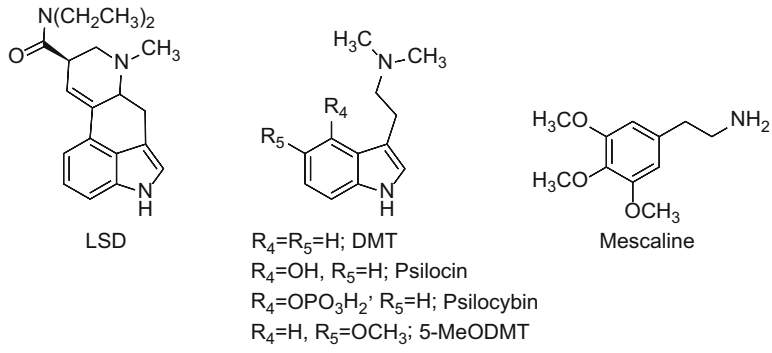
Psychedelic drugs are substances that can produce changes in thoughts, feelings, mood, and alterations in sensory perception that are not experienced otherwise except during dreaming or at times of religious exultation. They do not have reinforcing properties and do not lead to addiction or dependence. At high doses they lead to a breakdown in the perception of time, space, and selfhood. Although "hallucinogen" has been used to refer to any exogenous substance that produces sensory distortions (e.g., cannabis, PCP, MDMA), the term "psychedelic" is reserved for a subclass of hallucinogenic agents that primarily mediate their effects through activation of the serotonin 5-HT_{2A} receptor. There are three different main families of psychedelics based upon structure (Fig. 1).

Background

These substances have been used by humans back through antiquity. References to *Soma* in the Rigveda, the holy literature of India, indicate it was an important ritual drink in ancient India. Its identity is lost today, but descriptions of its effects suggest it was probably some kind of psychedelic drink. Similarly, the Eleusinian mysteries of ancient Greece employed a drink known as κψκεον (*kykeon*) that was a central component in an annual ritual held in the village of Eleusis (Wasson et al. 1978). The ceremony was held each year in the fall for about 2,000 years! Although the composition of *kykeon* remains unknown today, what little was written about the ceremony indicates it was very powerful and suggests that *kykeon* also was some sort of hallucinogenic concoction.

In Mesoamerica, certain mushrooms were used in ritual and healing contexts and were known by the Aztecs as *teonanacatl*, or flesh of the gods. Although Spanish missionaries attempted to destroy all records of the use of these mushrooms, a great number of "mushroom stones" were ultimately recovered, although their significance remained unknown for many years. In 1956 New York banker and amateur mycologist R. Gordon Wasson traveled to Mexico and participated in a mushroom ceremony presided over by Mazatec Curandera Maria Sabina, who taught them about the uses and effects of the mushroom. The description of this trip and ceremony was published in *Life Magazine* in 1957 and ultimately led to the popularization of psychedelic mushrooms in Western society. Psilocybin was subsequently isolated and identified as the active component of these mushrooms by Albert Hofmann in 1959 (Hofmann et al. 1959). Psilocybin is orally active, with a typical dose of 10–30 mg and a duration of effect of 4–6 h.

Mescaline is a naturally occurring psychedelic produced by the peyote cactus *Lophophora*



Psychedelic Drugs, Fig. 1 Structures of commonly used psychedelic drugs. Ergolines are represented by LSD. Tryptamines are represented by psilocybin and DMT. Phenethylamines are represented by mescaline. Whereas ergolines have broad affinity for several monoamine receptor systems, receptor effects of tryptamines are largely restricted to serotonin receptors, and phenethylamines are mainly agonists of 5-HT_2 receptors

williamsii that is native to Mexico and Southwestern Texas. It occurs to the extent of about 0.4% in the fresh cactus. There is archeological evidence that peyote has been used for more than 5,000 years. Today, peyote is the sacrament for the Native American Church (NAC), where the tops (buttons) of the cactus are generally chewed or boiled in water to produce a psychoactive tea. Typically, NAC ceremonies are directed by a Roadman, last all night sitting around a fire with singing and chanting, with the effects of the peyote lasting between 8 and 12 h. The principal psychoactive alkaloid in the peyote cactus, mescaline, was identified by Arthur Heffter in 1898 (Heffter 1898), and its total synthesis reported by Späth in 1919 (Späth 1919). Mescaline is orally active, with a typical dose of 200–400 mg and a duration of effect of 8–12 h.

Another naturally occurring psychedelic is *N,N*-dimethyltryptamine (DMT), which is found in a number of plants including the Amazonian plant *Psychotria viridis*. Prolonged boiling of leaves from *Psychotria* together with the pounded stems of the vine *Banisteriopsis caapi* results in a tisane called ayahuasca. Ayahuasca (hoasca tea) has been used by natives in Amazonia as a religious sacrament whose use may stretch back to the beginnings of the Inca civilization of Peru. Ayahuasca serves as the focus of two syncretic churches, the Santo Daime, founded in the 1930s, and the União do Vegetal, founded in 1961. Although both religions had their origins in the Amazon, there are numerous adherents throughout the world, and the use of ayahuasca by these religions is recognized in Brazil and is protected in the United States under the Religious Freedom Restoration Act (RFRA). Although DMT is a powerful psychedelic, it is not orally active as a result of its first-pass degradation by monoamine oxidase A (MAO-A) in the liver. *Banisteriopsis* vines contain beta-carboline alkaloids such as harmaline, harmine, and tetrahydroharmine, which are reversible MAO inhibitors. Thus, ingestion of the mixture leads to inhibition of MAO-A, preventing degradation of DMT in the liver, and allowing it to produce biological effects, with a duration of action of 4–6 h.

The most potent and perhaps most well-known psychedelic is lysergic acid *N,N*-diethylamide (LSD, LSD-25). It is a semisynthetic molecule first synthesized by Sandoz natural product chemist Albert Hofmann in 1938 (Nichols 2018). Pharmacological studies failed to reveal anything of interest, but 5 years later, in 1943, Dr. Hofmann decided to prepare another sample of LSD, believing that the pharmacology department must have missed something important in their first screening of the molecule. Hofmann was motivated by what he referred to as a "peculiar presentiment." On Friday April 16, 1943, he somehow accidentally ingested a small amount of LSD, which produced remarkable psychic effects. The following Monday, in a self-experiment, he deliberately ingested a solution containing 0.25 mg of LSD tartrate, realizing that no compound then known would produce significant effects at that small dose. Surprisingly, the effects of this dose were very profound. Communicating the results of his self-experiment, his research director found the report somewhat incredulous. Nevertheless, several colleagues at Sandoz ingested doses of 0.08 mg of LSD, which confirmed the remarkable potency and unusual psychological properties of LSD. A typical research dose of LSD was 0.1 mg of the tartrate salt, with a duration of effect of 8–10 h.

Mechanism of Action

There is overwhelming evidence that an agonist or partial agonist action at 5-HT_{2A} receptors expressed in certain cortical regions of the brain is the key mechanism of action for psychedelics (Nichols 2016). Although this conclusion was initially based on in vitro and animal models, the ability of selective 5-HT_{2A} receptor antagonists to block the psychoactive effects of psilocybin and LSD in humans has validated this receptor as the primary target for mediating psychoactive behaviors in humans (e.g., see Vollenweider et al. 1998). Rapid tolerance, called tachyphylaxis, develops to repeated use of most psychedelics such that ingestion of LSD on a daily basis results essentially in a complete lack

of effect by the third or fourth day. Cross tolerance occurs between several of these drugs, emphasizing that they have a similar or identical mechanism of action.

Early mechanistic studies showed that iontophoretic application of LSD to slices of rat brain cortex led to production of excitatory postsynaptic currents (EPSCs) in cortical pyramidal cells (Aghajanian and Marek 1997). Following these EPSCs, there was a slowly developing series of asynchronous depolarizations that appeared to be a result of glutamate diffusion from other cells (Aghajanian and Marek 1998). Beique et al. (2007) then described a population of cells in deeper layers of the cortex that responded to direct application of a psychedelic by generation of action potentials, which released glutamate from their projection fields.

Subsequently, Martin and Nichols (2016) developed a novel method for cell sorting of whole neurons and identified a small population of neurons in deeper layers of the cortex that had higher expression of 5-HT_{2A} receptor mRNA and which became transcriptionally active following systemic administration of a psychedelic in comparison to the bulk of pyramidal neurons that did not. Transcriptional activity and the rapid expression of Immediate Early Genes, as was found in this neuronal population, is generally accepted as a marker for neuronal depolarization. Further, they found that psychedelics also lead to rapid transcriptional activation within small subsets of inhibitory GABA interneurons and astrocytes. The patterns of gene response in a given cell type differed between distinct brain regions. An important brain area that included these cells, which Martin and Nichols named the trigger population, was the claustrum, the most highly connected brain area. Immunohistochemical studies have shown that whereas 5-HT_{2A} receptors are densely expressed on apical dendrites of pyramidal cells in layer 5 of the cortex, the highest expression of 5-HT_{2A} receptors is reported to be in the claustrum (Pazos et al. 1985). Therefore, the acute effects of psychedelics in the brain are rapidly to activate subpopulations of excitatory, inhibitory, and glial cells in differential patterns depending on brain region. These complex cellular responses likely underlie the observed brain network connectivity changes as described below.

Recently, a 2.9 Å resolution x-ray crystal structure was published showing LSD bound within the human serotonin 5-HT_{2B} receptor, which is a close homolog of the 5-HT_{2A} receptor (Wacker et al. 2017). Their results further underscored that LSD is a functionally selective ligand, with the ability to activate not only canonical G protein intracellular signaling pathways but also to promote the recruitment of β-arrestin2. They discovered through receptor kinetics measurements that LSD has a very slow association with the receptor and an even slower dissociation rate. These unusual receptor kinetics were traced to a distinct structural element within both the 5-HT_{2A} and 5-HT_{2B} receptors, extracellular loop 2 (EL2), which connects the top of receptor helix 4 with the top of helix 5. A crucial residue in EL2 L209 (in 5-HT_{2B}) or L229 (in 5-HT_{2A}) "wedges" itself into the orthosteric binding pocket to essentially trap LSD within the receptor. When this leucine was mutated to the much smaller alanine, LSD readily associated and dissociated with the receptor. Molecular dynamics simulations were used to illustrate the effect of this mutation on the relative flexibility of EL2 in the unbound and LSD-bound state of the receptor.

Importantly, they showed that the residence time of LSD in the receptor greatly influenced the ability of the receptor to recruit β-arrestin2. That is, the longer LSD remained bound in the receptor, the greater were the potency and efficacy of the receptor to recruit β-arrestin2. Thus, under in vivo conditions, it would be expected that signaling through the 5-HT_{2A} receptor by LSD would be highly arrestin biased, relative to G protein signaling. The ability of the wild-type receptor to sequester LSD for a long period of time also could be relevant to the long duration of action for this drug.

Based on the crystal structure of LSD within the 5-HT_{2B} receptor, as well as structures of several related ergolines, McCorvy et al. (2018) have given detailed rationales to explain agonist and antagonist activity, as well as potential explanations for ligand bias (G protein vs arrestin

signaling) for the ergoline class of psychedelic. In particular, residues Thr3.37 in helix 3, ala/ser5.46 in helix 5, and Leu7.35 in helix 7 appear to be particularly important. At the present time, there are no crystal structures of other psychedelics bound in the 5-HT_{2A} receptor, and the overall signaling characteristics of ligand-receptor ensembles have not yet been well characterized.

Anti-inflammatory Properties

Yu and colleagues in 2008 made the surprising discovery that psychedelics had potent anti-inflammatory effects (Yu et al. 2008). Their first report examined the ability of several psychedelics in a cell-culture model of vascular cells to prevent inflammation initiated by TNF-α. They found that although several psychedelics were anti-inflammatory, a particular drug related in structure to mescaline, (*R*)-2,5-dimethoxy-4-iodoamphetamine, (*R*)-DOI, had super-potent effects about 100-fold greater than a typical steroidal anti-inflammatory in vascular cells. These effects were blocked by a specific antagonist for the 5-HT_{2A} receptor, indicating that they were being mediated by the same receptor that is the target for its behavioral actions in the brain.

A subsequent study translated this discovery to the whole animal, where (*R*)-DOI was found to block potently the systemic effects of TNF-α (Nau et al. 2013). Since then, (*R*)-DOI has been shown to have therapeutic efficacy to treat inflammation in several models of human diseases including cardiovascular and metabolic disease, and asthma, at sub-behavioral doses of drug (Nau et al. 2015; Flanagan et al. 2019a, b). Although precise mechanisms remain largely unknown, it is believed that activation of the 5-HT_{2A} receptor by psychedelics recruits specific anti-inflammatory pathways to the receptor that serotonin does not. These serve not only to block TNF-α-related pathways, but to also prevent innate immune cells like macrophages and adaptive immune cells like T-helper cells from activating and secreting pro-inflammatory molecules, in addition to preventing recruitment of key immune cells like eosinophils and Th2 cells to sites of inflammation (Flanagan and Nichols 2018). The full therapeutic potential of psychedelics to treat inflammatory-related diseases remains to be determined in human clinical testing.

Clinical Uses

Shortly after its discovery, LSD was hailed as a new breakthrough for psychiatry. From 1950 to the early 1960s, there were approximately 1,000 publications, describing treatment of more than 40,000 patients for a variety of different conditions (Grinspoon and Bakalar 1979). The most promising were the use of LSD to treat alcohol use disorder and treatment of terminal cancer patients. The latter indication was perhaps the most well documented as efficacious. The Controlled Substances Act of 1970 (CSA) placed all psychedelics into the most restrictive drug category, Schedule 1, which was a significant deterrent to further research. The last clinical program with LSD ended in 1976, and no further clinical studies were carried out for almost 20 years.

Clinical studies finally resumed, with Dr. Rick Strassman's 1994 and 1996 reports on the effects of intravenous DMT administration in humans. These studies were widely reported and led to both a book and a movie based on the results. Strassman had finally demonstrated that it was possible to obtain FDA approval to administer psychedelic agents to humans.

Then, in 2006 Dr. Roland Griffiths and colleagues reported on a study of 36 hallucinogen-naïve volunteers who were administered an oral dose of 30 mg/70 kg of psilocybin. Thirty-three percent of the volunteers rated the psilocybin experience as being the single most spiritually significant experience of their lives, with an additional 38% rating it to be among the top five most spiritually significant experiences. Neither the Strassman nor the Griffiths study focused on therapeutic efficacy, however.

The first study of therapeutic efficacy was reported by Moreno et al. in 1997 (Moreno and Delgado 1997), where 9 subjects suffering from obsessive-compulsive disorder were administered a total of 29 psilocybin doses. Marked decreases

in OCD symptoms of variable degrees were observed in all subjects during one or more of the testing sessions. These results were tantalizing, but unfortunately not conclusive.

Then, in 2011, Dr. Charles Grob reported results from a clinical study of psilocybin-assisted psychotherapy in 12 adults with advanced-stage cancer and anxiety (Grob et al. 2011). The State-Trait Anxiety Inventory trait anxiety subscale demonstrated a significant reduction in anxiety at 1 and 3 months after treatment. The Beck Depression Inventory revealed an improvement of mood that reached significance at 6 months.

Gasser et al. (2014) studied LSD-assisted psychotherapy in 12 patients with anxiety associated with life-threatening diseases. Patients received 200 μg of LSD free base in a double-blind randomized placebo-controlled study. At the 2-month follow-up, positive trends were found with the State-Trait Anxiety Inventory (STAI) in reductions in trait anxiety ($p = 0.033$) with an effect size of 1.1, and state anxiety was significantly reduced ($p = 0.021$) with an effect size of 1.2, with no acute or chronic adverse effects persisting beyond 1 day after treatment or treatment-related serious adverse events. STAI reductions were sustained for 12 months.

Subsequently, in 2016, two studies were published describing psilocybin-assisted psychotherapy in cancer patients with a terminal diagnosis. One study, by Dr. Steven Ross and his collaborators at New York University, reported on 29 patients with cancer-related anxiety and depression who were randomly assigned and received treatment with single-dose psilocybin (0.3 mg/kg) or niacin placebo along with psychotherapy (Ross et al. 2016). At the 6.5-month follow-up, psilocybin was associated with enduring anxiolytic and antidepressant effects (approximately 60–80% of participants continued with clinically significant reductions in depression or anxiety), sustained benefits in existential distress and quality of life, as well as improved attitudes toward death. Similarly, in the same year, Griffiths and colleagues at Johns Hopkins University reported on the effects of psilocybin in 51 cancer patients with life-threatening diagnoses and symptoms of depression and/or anxiety (Griffiths et al. 2016). High-dose psilocybin (22 or 30 mg/70 kg) produced large decreases in clinician- and self-rated measures of depressed mood and anxiety, along with increases in quality of life, life meaning, and optimism and decreases in death anxiety. At 6-month follow-up, these changes were sustained, with about 80% of participants continuing to show clinically significant decreases in depressed mood and anxiety.

In addition to relieving depression and anxiety in cancer patients, psilocybin-assisted psychotherapy also proved efficacious in treating alcohol use disorder and nicotine addiction. A 2014 study of psilocybin-assisted therapy by Johnson and colleagues found that 12 of 15 participants (80%) showed 7-day point prevalence abstinence at 6-month follow-up, which far exceeds abstinence rates of around 35% with the best therapies available (Johnson et al. 2014). Similarly, Bogenschutz et al. (2015) studied psilocybin coupled with motivational enhancement therapy in ten subjects with AUD and reported that abstinence increased significantly following psilocybin administration ($p < 0.05$). Gains were largely maintained at follow-up to 36 weeks.

The combination of these studies, and particularly the remarkable efficacy of psilocybin-assisted therapy in cancer patients, has led to a rejuvenation of interest in the potential medical value of psychedelics. Media stories and interviews with clinicians have recently increased dramatically in frequency, and numerous books have also recently appeared, all further stimulating the public's interest in psychedelics. Newer studies now underway are examining psilocybin-assisted therapy for obsessive-compulsive disorder, anorexia, and eating disorders, and much larger studies of alcohol use disorder and nicotine as well as cocaine addiction.

As a result of these very promising clinical results, the FDA has granted breakthrough therapy status for psilocybin-assisted therapy in treating major depressive disorder (MDD) and treatment-resistant depression and has also granted breakthrough therapy status to the use of MDMA-assisted therapy for the treatment of post-traumatic stress disorder (PTSD). If Phase 3 clinical studies prove definitive, one might expect

FDA approval for psilocybin and MDMA to occur in a time frame of perhaps 2–4 years (i.e., 2022–2024).

Effects of Psychedelics on Functional Brain Dynamics

Within about the past 10–15 years, powerful brain imaging technologies, including BOLD-fMRI, EEG, and magnetoencephalography (MEG), coupled with improved computational power, have led to important insights into the effects of psychedelics on brain function. Resting-state brain activities are organized into multiple large-scale functional networks, called resting state networks (RSNs). Numerous studies have revealed that acute administration of psychedelics leads to a reorganization of connectivity within and between resting-state networks, generally showing decreased connectivity within resting-state networks and increased connectivity across such networks. Reduced broadband oscillatory power has been observed following the administration of LSD and psilocybin, especially in the alpha (8–12 Hz) band.

Connectivity analysis has identified sets of regions that are essential for enabling efficient communication between key cortical regions. These "brain hubs" are embedded within central anatomical networks and participate in functional roles across a range of cognitive and affective tasks with widespread dynamic coupling within and across functional networks. These brain hubs are crucial for integrating information that serves as the basis for various aspects of complex cognitive function. Psychedelics acutely reduce the stability and integrity of these well-established brain networks and simultaneously reduce the degree of segregation between them. One of the fundamental large-scale networks where psychedelics (LSD, psilocybin, DMT) have been shown to decrease functional integrity is known as the default mode network (DMN). They increase its functional connectivity with other brain systems and reduce frontoparietal connectivity. Psychedelics also disrupt the internal integration of multiple brain hubs that normally do not have strong connections to each other. After the normal RSN organization is disrupted, however, strong, topologically long-range functional connections emerge that are not present in the normal state.

In summary, activation of 5-HT_{2A} receptors occurs in various important brain hubs, including cortical regions, leading primarily to a reduction in the threshold for cortical cell depolarization. However, the molecular nature of how neurons and cells respond to psychedelics beyond simple reductions in membrane potentials is complex and region dependent. A small subset of excitatory trigger neurons in deeper layers of the cortex depolarizes and initiates recurrent activity that spreads throughout specific regions, which then recruit subpopulations of inhibitory and non-neuronal cells to a supercritical state. That leads to generation of amplifying neuronal avalanches and destabilization of local network hubs, with subsequent changes in global connectivity and ultimately profound alterations in perception and cognition. It remains a significant challenge to understand how these changes in both cellular and molecular processes and global connectivity lead to therapeutic improvement of certain psychiatric disorders, but many laboratories are now focused on answering these questions.

Psychomotor stimulant drugs; Stimulant drugs; Stimulants

Definition

Psychostimulants are drugs that substantially influence cognitive and affective functioning and behaviors. Effects are increased motivational desire, agitation, heightened vigilance, euphoria, hyperactivity, and decreased sleepiness as well as appetite. Traditionally, mainly cocaine and amphetamines as well as other drugs (like MDMA or methamphetamine) are considered psychostimulants. However, nicotine, caffeine, and even certain antidepressants and modafinil could be included in this class. Methylphenidate and amphetamine (like dextroamphetamine) are widely used for the treatment of attention deficit/hyperactivity disorder (ADHD). In the recent years, long-acting formulations of methylphenidate (like OROS methylphenidate among others) or prodrugs (like lisdexamfetamine) came into focus and are mainly used in treatment of adult ADHD. Various formulations (like chewable, liquid, or transdermal) are available (Cortese et al. 2017).

Mechanism of Action

General Remarks

The final pathway of psychostimulants on the behavioral level is an increased mobilization of the normal fight/flight/fright reaction that is mediated by the biogene amines epinephrine, norepinephrine, serotonin, and dopamine. The most widespread extraclinically used psychostimulant is ecstasy (3,4-methylenedioxymethamphetamine, MDMA), which also exhibits perceptual distortions due to 5-HT $_{2A}$-receptor agonism like lysergic acid diethylamide (LSD).

The main target of action of methylphenidate, the most widespread clinically used psychostimulant, is the dopamine transporter (DAT); its inhibition increases intrasynaptic dopamine concentrations. The subcortical dopamine system (mesolimbic and nigrostriatal parts) mediates the unconditioned and conditioned responses toward reinforcement.

Within the striatum, dopamine terminals have direct synaptic contacts with the spines of striatal neurons. These synaptic contacts appear to provide the anatomical substrate for both compartmental (synaptic) and volume (extrasynaptic) transmission. The DAT is located intra- or perisynaptically, suggesting that dopamine has a limited ability to escape the striatal synapse. Moreover, dopamine D2 and, to a lesser extent, D1 receptors are located postsynaptically from dopamine terminals, suggesting compartmental transmission. However, there is a significant cohort of D1 and D2 receptors that are not directly opposed to dopamine terminals, suggesting some component of volume transmission within the striatum. Therefore, tonic and phasic changes in dopamine transmission are critical in producing behavioral effects associated with the striatum. In contrast, in the cerebral cortex, volume transmission appears to be more critical in mediating the effects of dopamine. DAT density is reduced in the frontal cortex (FC) relative to the striatum, and it is localized extrasynaptically. Moreover, D1-immunoreactivity within FC is virtually never opposed to tyrosine hydroxylase immunopositive terminals suggesting that the effect of dopamine on D1 receptors is by volume transmission. This hypothesis has direct relevance to the neurochemistry of ADHD because cognitive functions known to be affected in this disorder, namely, working memory and inhibitory control, are sensitive to manipulations of D1

receptor-mediated dopamine transmission (Taylor and Jentsch 2001; Grace 2001). Thus, the tonic component might be more critical for the behavioral functions of the FC.

Several classes of drugs modulate the firing rates or patterns of midbrain dopamine neurons by direct, monosynaptic, or indirect, polysynaptic, inputs to the cell bodies within the ventral mesencephalon (i.e., nicotine and opiates). In contrast, amphetamine, cocaine, and methylphenidate act at the level of the dopamine terminal interfering with normal processes of transmitter packaging, release, reuptake, and metabolism.

Methylphenidate, Amphetamine, and Cocaine

Methylphenidate like cocaine largely acts by blocking reuptake of monoamines into the presynaptic terminal. Methylphenidate administration in therapeutic dose produces an increase in the steady-state (tonic) levels of monoamines within the synaptic cleft. Thus, DAT inhibitors, such as methylphenidate, increase extracellular levels of monoamines. In contrast, they decrease the concentrations of the monoamine metabolites that depend upon monoamine oxidase (MAO), that is, HVA, but not catecholamine-*o*-methyltransferase (COMT), because reuptake by the transporter is required for the formation of these metabolites. By stimulating presynaptic autoreceptors, methylphenidate-induced increase in dopamine transmission can also reduce monoamine synthesis, inhibit monoamine neuron firing, and reduce subsequent phasic dopamine release.

The pharmacology of amphetamine is considerably more complex. It does not only block monoamine reuptake but also directly inhibits the vesicular monoamine transporter, causing an increase in cytosolic but not vesicular dopamine concentration. This may lead to reverse transport of the amines via the membrane-bound transporters. Further mechanisms of amphetamine action are direct MAO inhibition and indirect release of both dopamine and serotonin in the striatum.

Mild increases in tonic dopamine release – as a consequence of the administration of both methylphenidate and amphetamine – could have important impact on subsequent phasic release by feedback mechanisms (lowering the concentration).

As pointed out before, there are some major differences between the striatal and cortical dopamine terminals (Table 1).

Therefore, dopamine transporter inhibitors exhibit less effect in the FC. There, dopamine seems to be reuptaken by the norepinephrine transporter, which dopamine actually has a higher affinity for than norepinephrine itself.

Amphetamine administration produces a marked increase in cortical dopamine, norepinephrine, and serotonin release that is impulse independent. Methylphenidate can produce significant increases in dopamine and norepinephrine release (Table 2).

Dopaminergic mechanisms within the ventral striatum (i.e., nucleus accumbens) subserve the ability of amphetamine and methylphenidate in low to moderate doses to increase locomotor activity. In contrast, very low dosages in animals seem to cause hypoactivity presumably by stimulation of autoreceptors, a finding that would be compatible with the clinical impression that methylphenidate might be useful in some patients with mania.

At low doses, both psychostimulants could theoretically stimulate tonic, extracellular levels of monoamines, and the small increase in steady-state levels would produce feedback inhibition of further release by stimulating presynaptic autoreceptors. While this mechanism is clearly an important one for the normal regulation of monoamine neurotransmission, there is no direct evidence to support the notion that the doses used clinically to treat ADHD are low enough to have primarily presynaptic effects. However, alterations in phasic dopamine release could produce net reductions in dopamine release under putatively

Psychostimulants, Table 1 Properties of cortical versus striatal dopamine system

	Cortical	Striatal

Norepinephrine	++	++	+
Serotonin	+	++	(+)

altered tonic dopaminergic conditions that might occur in ADHD and that might explain the beneficial effects of methylphenidate in ADHD.

Repeated intermittent exposure to stimulants can produce sensitization, where subsequent drug exposures produce increased behavioral and neurochemical responses. The ability of the drug and ultimately of related stimuli to elicit behavior may be increased with repeated administration or intake of the drug. Dopaminergic sensitization within the amygdala has also been found after repeated exposure to amphetamine, and this can enhance appetitive and aversive learning even after drug cessation.

Cocaine- and amphetamine-regulated transcript (CART) peptides are putative neurotransmitters that are found in those dopaminergic brain regions. Stimulants seem to alter CART mRNA and peptide levels (Jaworski and Jones 2006).

Besides the dopaminergic system, the noradrenergic nucleus, locus coeruleus (LC), may be another structure involved in the mode of action of psychostimulants. Electrophysiological recordings from this area demonstrate a relationship between behavior and response of the LC to targets versus distractors in an attention task. Baseline firing shows a constant increase paralleling the conditions from drowsiness to hyperarousal. In contrast, phasic responses are maximal in an optimal alert attentive state and minimal in drowsiness as well as hyperarousal that may be associated with poor cognitive performance due to high distractibility. Methylphenidate and also amphetamine (although relatively lower in affinity) are also shown to exert direct effects on the noradrenaline (norepinephrine) transporter (NET).

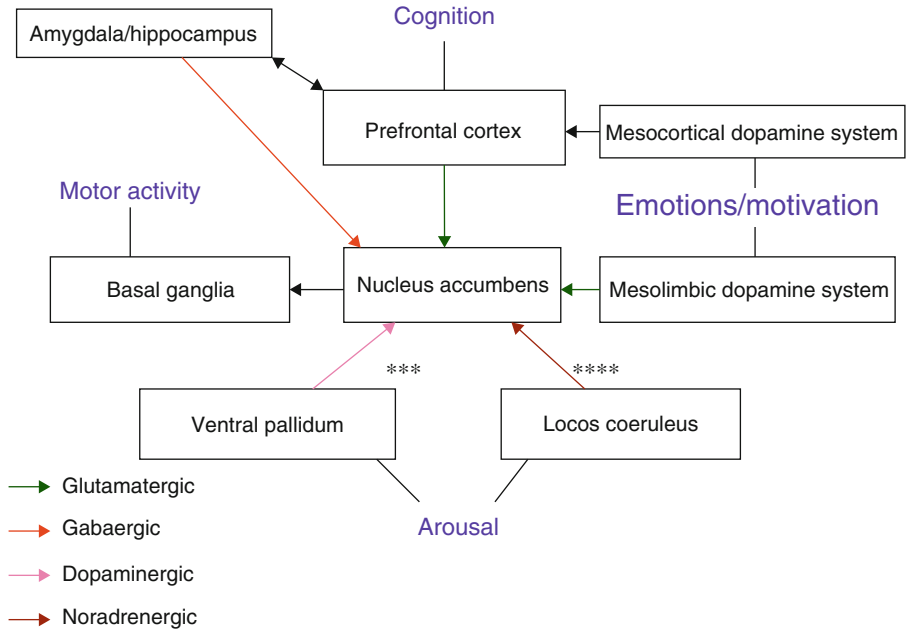
Dose-dependent glutamate effects of methylphenidate linked to behavioral improvement of attention (low dose) and aggression and elevated locomotor activity (high dose) via adrenergic modulation of N-methyl-D-aspartate receptors (NMDAR) and alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPAR) in the prefrontal cortex are also suggested following initial animal data.

Also, immunogenetic effects of psychostimulant administration are researched. First evidence hints at a DAT-genotype-associated effect of methylphenidate on DAT-antibody levels in children with ADHD. Regulatory effects in basal ganglia genes are also reported after psychostimulant use.

Cerebellum alterations have also been linked to ADHD pathology. The cerebellum is a further possible target for psychostimulants since it is not only important for motor coordination but also for processing cognitive situations. Dopamine levels within the dense dopamine projections to the cerebellum could be increased by psychostimulants accounting for registered cerebellar volume changes associated with stimulant treatment in youth with ADHD.

Several mechanisms, postulated in excessive use of especially (meth)amphetamines, are discussed to bring out neurotoxic effects of psychostimulants. Mitochondrial dysfunction, oxidative stress, and excitotoxicity have been laid out, and in the recent years, effects on neuroinflammation, blood-brain barrier (BBB) dysfunction, and impaired neurogenesis are being suggested (Goncalves et al. 2014).

In summary, main structures involved in the action of psychostimulants can be divided into cortical (mainly prefrontal cortex) and subcortical (basal ganglia and related structures, LC and cerebellum) ones. Figure 1 gives a schematic overview of the connections between these structures, omitting the cerebellum due to lack of precise information.



Psychostimulants, Fig. 1 The nucleus accumbens as a major intersection of cognitive, motor, and arousal processes

Modafinil

Modafinil, as its R-enantiomer armodafinil, is a wake-promoting psychostimulant drug. It reduces excessive daytime sleepiness due to narcolepsy, obstructive sleep apnea, and shift workers disorder. It is used off label to treat ADHD or in chronic fatigue. There have been a limited number of clinical trials in ADHD, and results point at modafinil being a reasonable treatment alternative to amphetamine-type stimulants in terms of symptom reduction and tolerability in children and adolescents. Stimulant side effects, including potential addiction, are modest compared to amphetamines. Of note, serious rashes and multi-organ hypersensitivity reactions form very rare, but severe, possible side effects in children and to a lesser degree in adults in post-marketing experience.

Modafinil shows procognitive effects comparable to low-dose amphetamine-type psychostimulants. The exact mechanisms of action of modafinil are not well understood. It inhibits the DAT and lesser so NET with minor affinity to the receptor and therefore enhances tonic rather than phasic dopamine activity. It has been suggested that modafinil increases wakefulness by activating α_1 noradrenergic receptors and via downstream effects that lead to the release of orexin, histamine, 5HT, and glutamate. Also, it may act by modulating the GABAergic tone that might lead to an increased dopamine release in the nucleus accumbens. There is also evidence modafinil elicits anticraving effects via metabotropic glutamate receptor pathways after cocaine administration in rats via increasing extracellular glutamate (Minzenberg and Carter 2008) (Gibson et al. 2006).

Nicotine

Nicotine is the main psychoactive ingredient of tobacco and is responsible for the stimulant effects and abuse/addiction that may result from tobacco use. Cigarette smoking rapidly (in about 3 s!) delivers pulses of nicotine into the bloodstream. Its initial effects are caused by its activation of nicotinic acetylcholine (nACh) receptors. nACh receptors are ligand-gated ion channels and pre- and postsynaptically located. Reinforcement depends on an intact mesolimbic dopamine system (VTA). nACh receptors on VTA dopamine neurons are normally activated by cholinergic innervation from the laterodorsal tegmental nucleus or the pedunculopontine nucleus.

In the last decade, the use of e-cigarettes or vaping became a well-received mode of nicotine consumption. Its clinical use (i.e., for tobacco cessation) is discussed controversially as there is growing evidence of severe side effects (Werner et al. 2020).

Clinical Use

The main indication for certain psychostimulants is ADHD in children, adolescents, and adults (Faraone et al. 2015; Okie 2006). Research shows that the clinical effect and benefit are dramatic even in adults. About 60% of adult patients receiving stimulant medication showed moderate-to-marked improvement, as compared with 10% of those receiving placebo. The core symptoms of hyperactivity, inattention, mood lability, temper, disorganization, stress sensitivity, and impulsivity have been shown to respond to treatment with stimulant medications. Further, there is evidence that severe problems following ADHD (like psychiatric comorbidity and criminality rates) are reduced with stimulant treatment. Patterns of use have changed over the recent years. In the USA methylphenidate (generally considered standard first-line treatment in ADHD) is being outdone by amphetamine in all ages, and psychostimulants are more frequently prescribed to adults than to children. Also more women are prescribed stimulant medication than men.

Other clinical indications include hypersomnia and weight loss. Psychostimulants are also widely discussed to elicit specific neuro-enhancing effects (Spencer et al. 2015).

The characteristic behavioral effects of acute and chronic psychomotor stimulant drugs are locomotor activation, stereotypy, and conditioned reward and stimulus-reward learning. The most important brain regions involved in these effects are summarized in Table 3.

Psychostimulants, Table 3 Acute effects of psychostimulants and the brain regions that are mainly involved in these effects

Acute effects	Mainly involved brain region
Locomotion	Ventral striatum (i.e., nucleus accumbens)
Motor stereotypy	Dorsal striatum (i.e., caudate putamen)
Reinforcement	Ventral striatum
Conditioned reward	Ventral striatum/amygdala
Stimulus-reward learning	Amygdala

Each of these processes depends upon increases in dopaminergic transmission within the striatum and, possibly, amygdala. Moreover, neurochemical actions within the FC may contribute to the ability to modulate some of these basic motivational processes. This data is based primarily on studies in rodents given systemic injections of moderate-to-high doses of stimulants, and it is not known whether lower doses applied orally would produce similar behavioral and neurochemical effects. Nevertheless, when given acutely or chronically to animals, stimulants appear to alter the neurochemistry of the striatum in such a way as to augment the control of behavior by conditioned or unconditioned stimuli associated with reinforcement processes. These effects may be consistent with the suggestion that amphetamine or methylphenidate may exert some of their beneficial clinical effects by augmenting conditioned reinforcement and stimulus-reward associations that could enhance aspects of task performance.

A simple decrease in striatal dopamine transmission produced by even low clinical doses of the drugs according to current data seems an untenable hypothesis. However, if the tonic control of phasic release by dopamine is abnormally low in ADHD, then a high phasic dopamine response may be associated with ADHD and treatment efficacy. Moreover, alterations in corticolimbic tonic/phasic balance may also provide an explanation of why chronically administered psychostimulants in ADHD produce a behavioral profile and response associated with subcortical dopamine neuronal hyperactivity and cortical hypoactivity, though issues of dose and route of administration should be considered in this context.

Another theory for the action of stimulant drugs in ADHD involves effects on nonstriatal monoamine systems. Frontal cortical dopamine,

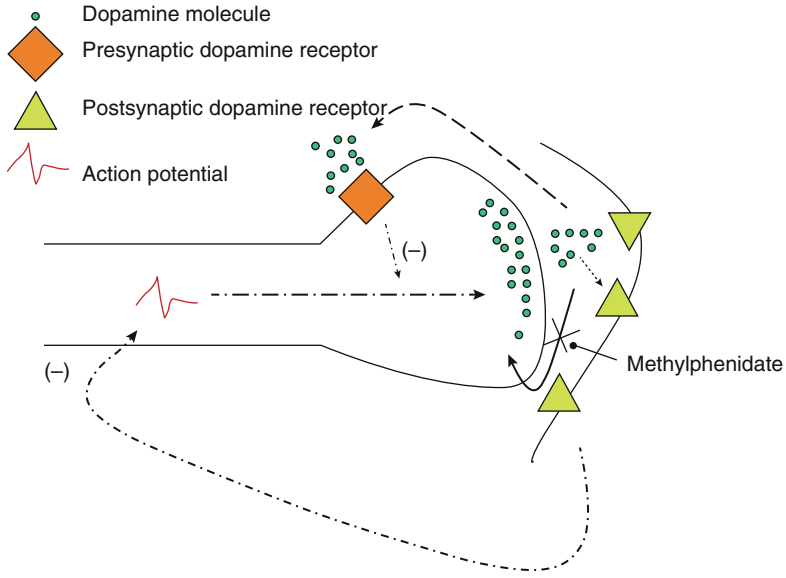
norepinephrine, and serotonin are clearly important in cognitive functioning and impulse control. These neurotransmitters directly modulate reward-related behaviors associated with the striatal dopamine system. Moreover, the amygdala may be pharmacologically influenced leading to enhanced associative learning and recall. Thus, the net behavioral effects of stimulant drugs may promote changes in reward-motivated behaviors and impulsivity, as well as neuromodulation of inhibitory control (FC), working memory, and incentive learning (amygdala).

Dysfunction of cortical-subcortical dopamine systems is associated with an impaired inhibitory control after chronic drug administration.

Since there is some evidence that the dopaminergic system might also play an important role in the pathophysiology of depression, methylphenidate has also been successfully used as an augmentation strategy in the treatment of depressive disorders and reduces risk of comorbid depressive episodes in ADHD. Effects here seem to be rather symptom specific (i.e., to counter lack of drive and in cognitive emotional processing) than genuinely antidepressant as recently underlined by meta-analytic data (Mcintyre et al. 2017). In ADHD patients research goes into whether depressiveness might be a rare stimulant-induced side effect.

Figure 2 (Jaworski and Jones 2006) illustrates the acute and chronic actions of methylphenidate. By blocking DAT, methylphenidate causes an accumulation of dopamine in the synaptic cleft. Although this may initially increase the stimulation of postsynaptic DA receptors, in the long term, the consequence is rather a downregulation of dopamine release. First, there is feedback inhibition of dopamine neuron firing to decreased spike-dependent dopamine release. Second, much larger quantities of dopamine are enabled to escape from the cleft and accumulate in the extrasynaptic space. Presynaptic receptors are stimulated and thus firing rate is reduced. The amount of phasic dopamine that can be released is subsequently diminished.

Moreover, no significant differences could be found between the efficacy of methylphenidate and amphetamine. Methylphenidate is faster

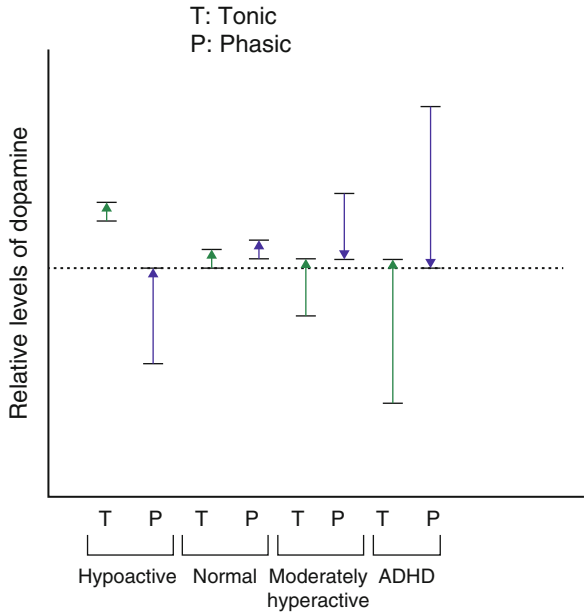


Psychostimulants, Fig. 2 Dopamine molecules have two different possible targets. Both ways are initially increased by DAT inhibition caused by methylphenidate: pre- and postsynaptic dopamine receptors. Stimulation of postsynaptic receptors results in inhibition of presynaptic action potential generation. On the other hand, presynaptic receptor stimulation leads to a transmission inhibition of action potentials. Therefore, both mechanisms are responsible for a decrease in vesicular depletion of dopamine into the synaptic cleft (adapted from Jaworski and Jones 2006)

metabolized and seems to be associated with fewer side effects regarding appetite loss and insomnia. From a clinical point of view, dosage and route of administration are the most important features influencing the spectrum of effects and side effects. ADHD drugs and cardiovascular risk (especially via increased heart rate, blood pressure, and to a lesser degree QTc elongation) has recently become a major issue with regard to sudden death. Although risk of severe cardiovascular events is considered very low (Martinez-Raga et al. 2013), selective and restricted use to clear-cut diagnoses are advocated, and side effects are regularly to be monitored.

An important clinical clue connected with the difference between tonic and phasic dopamine release is the so-called rate dependence of psychostimulant action. That means it depends on the actual dopaminergic state (tonic and phasic) how an individual will react to psychostimulants. Figure 3 illustrates this rule by some examples (Jaworski and Jones 2006). The arrows represent the response of each component to methylphenidate for each of the classes of subjects tested, with the horizontal dashed line representing the baseline tonic and phasic levels present in control individuals. Summarizing, methylphenidate tends to normalize dopamine transmission regardless what the baseline rate is.

Despite their clinical use, psychostimulants are strongly reinforcing, and their long-term use is linked to potential abuse and addiction, especially when they are rapidly administered. Nevertheless, long-term use is rather associated with emotional and motivational than with physical dependence. This is also true for cocaine and (meth)amphetamine. Methylphenidate might also be abused, although it is far less potent, possibly due to its specific mode of action (see above). Two drugs with low, if at all, abuse potential that are used in ADHD are atomoxetine (Gibson et al. 2006), a noradrenaline reuptake inhibitor, and bupropion, a dopamine and noradrenaline reuptake inhibitor. By their mode of action, they would rather fit into the group of antidepressants than psychostimulants.



Psychostimulants, Fig. 3 Effect of methylphenidate depending on baseline tonic (T) and phasic (P) dopamine levels. In a "normal" state, only minimal changes are noted (which points to a rather low abuse potential). From a "hypoactive" state, methylphenidate increases both T and P levels. However, this is much more true for the strongly lowered P tone. In contrast, in moderately hyperactive states and ADHD, T levels are increased, and P levels are decreased, respectively, correlating with the baseline levels (adapted from Jaworski and Jones 2006)

Nicotine differs from cocaine in that it is powerfully reinforcing in the absence of subjective euphoria. The high incidence of cancerogenicity associated with long-term tobacco use is associated with compounds other than nicotine that are also contained in tobacco. Main short-term effects of nicotine are increased alertness, muscle relaxation, nausea, and increased psychomotor activation. Typical withdrawal symptoms include dysphoria, increased appetite, hyperventilation, and concentration difficulties. If the α4β2 nicotinic partial agonist varenicline that is used for smoking cessation is also to be regarded as a stimulant drug still remains to be elucidated.

Pulmonary Arterial Hypertension

Mario Boehm and Ralph T. Schermuly
Department of Internal Medicine, Justus-Liebig-University Giessen, German Center for Lung Research, Giessen, Germany

Synonyms

Pulmonary vascular disease; Pulmonary vascular remodeling

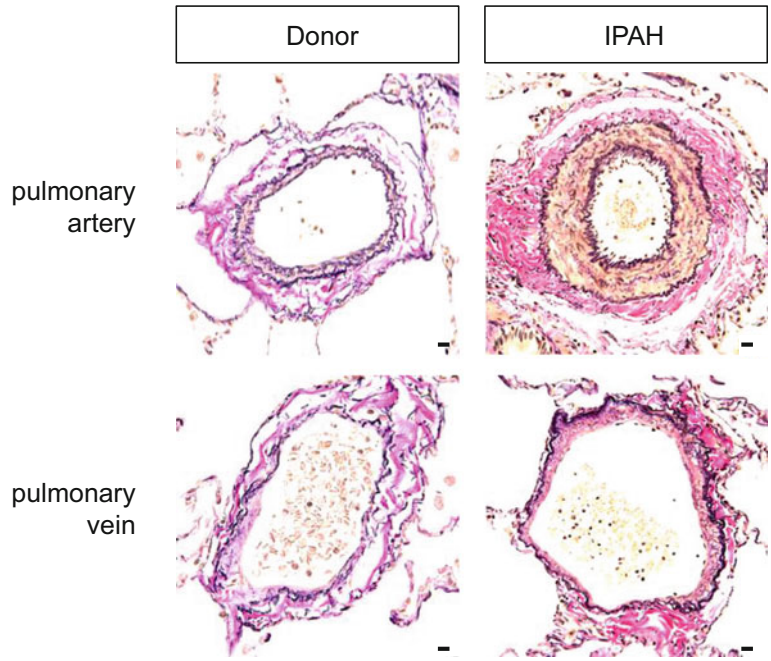
Definition

Pulmonary arterial hypertension (PAH) is a life-threatening lung disease clinically defined by a mean pulmonary artery pressure (mPAP) above 20 mmHg at rest in the presence of a pulmonary capillary wedge pressure equal or below 15 mmHg assessed by right heart catheterization (Galiè et al. 2019). Loss of patency of the lung vasculature through dysbalanced vasoactive mediators and obstructive remodeling of the pulmonary vascular bed account for a rise in pulmonary vascular resistance and mPAP, leading to progressive functional decline over time and, ultimately, right ventricular heart failure and death. The central histopathologic feature underlying PAH disease is a progressive narrowing of the pulmonary vasculature through inward remodeling of small pulmonary arterioles for which there are limited therapies and no cure (Humbert et al. 2019). This occlusive vasculopathy is characterized by changes in all three layers of the vascular wall (Rabinovitch 2012) and is frequently accompanied by loss of pre-capillary arteries. Current therapies target the vasoconstrictive component of the disease with limited long-term success as the underlying remodeling processes remain unchecked (Lau et al. 2017).

Basic Mechanisms

PAH is attributed to excessive pulmonary vasoconstriction and vascular obstruction occurring in distal muscular-type arteries ranging from 500μm down to 70μm in diameter, in addition to stiffening of large elastic main, lobar, and segmental pulmonary arteries (Humbert et al. 2019). Key features are medial hypertrophy/hyperplasia, intimal and adventitial fibrosis, adventitial immune cell infiltration, and plexiform lesions (Schermuly et al. 2011). Affected pulmonary arteries can be differentiated from pulmonary veins through their topography within the lung – since arteries are always neighbored by an airway (bronchiole) – and through their microscopic anatomy, which includes a neatly defined tunica media that is delimited by the *elastic laminae interna* and *externa*. In addition, small pre-capillary pulmonary arteries ranging from 70μm down to 20μm in diameter (arterioles) are involved in all forms of human PAH through processes of loss and obliteration, abnormal muscularization, and perivascular inflammation (Rabinovitch 2012). In contrast to the muscular-type arteries, arterioles can only be indirectly distinguished from small post-capillary venules of the same size by vessel tracing and reconstruction of the vascular tree. The capillary compartment that arises from the arteriolar microvasculature is involved in vessel obliteration, and there is accumulating evidence supporting the involvement of the post-capillary pulmonary venous vasculature in all PAH groups with varying degrees of intensity. Pulmonary veins running within interlobular septa normally comprise a thinner medial layer as compared with similar sized arteries and contain only a single *elastic lamina*, allowing histological distinction. However, remodeled pulmonary veins may histologically appear "arteriolized," mimicking the exact microscopic anatomy of muscular-type pulmonary arteries (Humbert et al. 2019). On a cellular level, unlike the intima and media, which are composed of single, although heterogeneous, cell types, the adventitia contains, in addition to fibroblasts, leukocytes (including macrophages, dendritic cells, and mast cells), progenitor cells, nerves (sympathetic and parasympathetic), lymphatics, as well as an extra blood supply, the vasa vasorum (Rabinovitch 2008) (Fig. 1).

Immunohistological staining of small pulmonary artery and vein cross sections from human donor and idiopathic PAH (IPAH) patients demonstrates a characteristic decrease in arterial vascular luminal diameter through prominent changes in the endothelium of the vessel wall, thickening of the vascular smooth muscle cell layer (brown) that is delimited by the elastic laminae *interna* and *externa* (dark violet), and accumulation of cells in the adventitial cell layer (pink). Pulmonary veins appear with a thickened smooth muscle cell layer and a single elastic lamina. Scale bar: 20μm.



Pulmonary Arterial Hypertension, Fig. 1 Van Gieson staining of human donor and IPAH lung tissue

Vasoreactivity

Patients with PAH present with a reduced capacity to generate vasodilatory mediators, such as prostaglandin, nitric oxide, cyclic guanosine monophosphate, or vasoactive intestinal peptide along with an increased presence of vasoconstrictive molecules, such as endothelin-1, serotonin, or thromboxane. It is conceivable that the beneficial effects of the currently clinically available treatments for PAH patients, such as prostacyclin, NO pathway modulators, and endothelin antagonists, are – at least in part – a result of rebalancing the signaling of these vasoactive mediators.

In addition, abnormalities in K^+ and Ca^{2+} channel expression and gating characteristics have been linked to a pathologic pulmonary vascular tone, particularly in vascular smooth muscle cells; and selective downregulation of voltage-gated K^+ channels causes an altered potassium flux into the cell, membrane depolarization, opening of voltage-gated Ca^{2+} channels, and induction of smooth muscle cell contraction via a Ca^{2+}-calmodulin mechanism that involves myosin light-chain kinase. In addition, Ca^{2+} signaling through transient receptor potential (TRP) ion channels is an important mechanism that contributes to vascular tone as, for example, the acute hypoxic vasoconstrictor response relies on TRPC6 function.

Pulmonary Vascular Remodeling

The pathogenesis of PAH involves complex and multifactorial processes as evidenced by the notion that PAH arises as a consequence of many different etiologies, including heritable mutations, congenital heart disease, systemic inflammatory conditions, viral infection, and drug and toxin exposure (Simonneau et al. 2019). Common to all forms of PAH are histological changes in all three layers of the vessel wall, suggesting that diverse upstream triggers converge on a core arterial remodeling program that may represent a clinically relevant therapeutic target to halt or reverse PAH disease progression.

Genetic Mutations

Genetic mutations in the gene encoding the bone morphogenetic protein type 2 receptor (BMPR2), a receptor of the transforming growth factor-beta

(TGFb) superfamily, account for over 80% of familial PAH and approximately 20% of sporadic cases. However, disease penetrance in patients harboring a BMPR2 mutation is often incomplete (20–30%) (Southgate et al. 2020), implying that other (epi-) genetic and environmental factors equally contribute to PAH disease pathogenesis. Yet, PAH-causing genetic mutations in other components of the TGFb/BMP signaling pathway have been identified (such as ACVRL and ENG), and case reports of rare sequence variation in the BMP signaling components, SMAD1, SMAD4, and SMAD9 provide further evidence for deregulated TGFb/BMP signaling as a causal driver of PAH pathogenesis. However, genetic mutations in other pathways than the TGFb/BMP pathway have been similarly linked to PAH susceptibility, as, for example, deleterious genetic variants in potassium channels (KCNK3 and ABCC8) or transcription factors (TBX4 and SOX17) are causal for PAH disease development (Gräf et al. 2018). A pathologically distinct form of PAH that predominantly affects the pulmonary venous circulation is caused by EIF2AK4 mutations that lead to pulmonary veno-occlusive disease (PVOD) (Eyries et al. 2014).

Signaling Abnormalities

On a cellular level, a deregulation in cell proliferation and survival accounts for the accumulation of vascular cells within the vessel wall. Medial smooth muscle and intimal endothelial cells in the pulmonary vasculature express G-protein-coupled receptors (GPCRs) that – depending on the upstream trigger – mediate complex downstream intercellular signaling events. In this regard, vasoactive mediators such as endothelin, angiotensin II, serotonin, and vasoactive intestinal peptide are extracellular ligands that upon GPCR binding induce a conformational switch in the intracellular docking domain of heterotrimeric G-proteins (composed of Gα and Gβγ subunits). This switch leads to dissociation of the heterotrimeric complex and thereby activation of the respective G-proteins with subsequent downstream signaling. While Gαs signaling can cause an elevation in intracellular cAMP levels, subsequent PKA activation, and reduced intracellular Ca^{2+} concentrations along with vasorelaxation, Gαq activates PLCβ and IP_3 signaling and initiates Ca^{2+} release from internal stores, such as the sarcoplasmatic reticulum, which promotes vasoconstriction through a Ca^{2+}-calmodulin-dependent mechanism that involves myosin light-chain phosphorylation, actin-myosin cross-bridging, and smooth muscle cell contraction (Strassheim et al. 2018). RhoA and Rho-kinase (ROCK), for example, are additional downstream targets of GPCR-mediated Gα12/13 activation in response to vasoactive ligands such as serotonin.

Reduced BMPR2 expression and dysfunctional BMP signaling recapitulate many of the cellular derangements attributed to PAH pathogenesis; and even patients with PAH without a BMPR2 mutation have reduced BMPR2 expression and BMP signaling in lung and blood cells. Given the high attrition rates of PAH studies, substantial development costs, and the slow pace of new drug development, repositioning of "old" drugs is increasingly recognized as an attractive path to identify novel PAH treatment options. Therefore, deregulated signaling pathways in PAH patients are frequently targeted with repurposed drugs such as FK506 (tacrolimus), enzastaurin, or (multi-) kinase inhibitors and show promise in pre-clinical PAH models, with some early encouraging results in selected patients. Many of these drugs are cancer therapeutics, and resident pulmonary vascular cells isolated from PAH patients' lungs share a number of cancer-cell characteristics, such as sustained proliferative capacity, resistance to cell death, de-regulated cellular energetics, and avoidance of immune cell destruction (Cool et al. 2020). Therefore, besides vasoactive mediators and dysbalanced BMP/TGFb signaling, growth factors such as platelet-derived growth factors (PDGFs), fibroblast growth factor (FGFs), or epidermal growth factors (EGFs), all similarly deregulated in cancer pathologies, are critically involved in PAH pathogenesis. These factors act as ligands and signal through their respective receptor kinases to over-activate downstream kinase-dependent phosphorylation cascades, which in turn cause aberrant cell behavior, such as increased proliferation, increased resistance to

apoptosis, or metabolic abnormalities. One critical signaling hub in PAH disease is signaling through PDGFRb in pulmonary artery smooth muscle cells and pericytes, which drives thickening of the medial pulmonary artery layer and hypoxia-dependent distal muscularization of previously non-/partially muscularized pulmonary arterioles (Sheikh et al. 2015). PDGFRb activates a variety of downstream signaling pathways, including Ras/MAPK, PI3K, and PLCγ, that further modulate transcriptional programs and – depending on the upstream trigger and cell type – cause changes in cell behavior. In a clinical phase III trial, pharmacological treatment of PAH patients with imatinib, a multi-kinase inhibitor that inhibits PDGFRb signaling among other pathways, improved pulmonary vascular remodeling, at the cost of serious adverse events, such as peripheral edema and subdural hematoma (Hoeper et al. 2013). Along this line, overactivation of various pro-proliferative signaling pathways has been reported in the context of PAH, and several multi-targeted tyrosine-kinase inhibitors approved as promising cancer therapeutics were subsequently linked to PAH pathogenesis and tested in therapeutic settings. For example, sorafenib, a multi-kinase inhibitor that inhibits PDGFRs, VEGFRs, Flt3, c-Kit, c-RAF, and b-RAF, has been studied in a phase Ib safety trial in PAH patients (Gomberg-Maitland et al. 2010). Based on promising pre-clinical results, a phase II trial to study the effects of nilotinib (Bcr-Abl, c-Kit, PDGFR-α/β inhibitor) was initiated. The latter was terminated due to unwanted side effects; and limited therapeutic use in PAH patients was similarly recognized for nintedanib and dasatinib (Bcr-Abl, c-Kit, PDGFR-α/β, and Src inhibitor).

To narrow down the broad spectrum of kinase signaling pathways that are frequently activated through mitogens and growth factors, more specific targeting of intracellular kinases that mediate the pro-proliferative signaling responses was studied. Dysregulation of p38 MAPK signaling is directly linked to PAH disease development, and inhibition of p38-MAPK signaling has emerged as a potential therapeutic option in PAH. Inhibition of the p38-MAPK pathway improved pulmonary hypertension in pre-clinical models and was linked to blockage of IL-6 induced pro-inflammatory signaling. Along the same line, inhibition of ASK1 – a p38 upstream kinase that is activated in response to oxidative stress – halted disease progression in pre-clinical models. Another mediator pathway is characterized by a JAK/STAT signaling hub that directly links upstream trigger of cell immunity, proliferation, and survival with transcription of specific gene sets under STAT control. JAK/STAT deregulation has been recognized in PAH pathobiology and has more recently been associated with fibrotic disorders such as myelofibrosis. As an example, Jak2 is a major mediator and regulator of growth factor-induced signaling through downstream activation of Stat3 that causes non-canonical PI3K signaling and MAPK activation (Paulin et al. 2012). Ruxolitinib, a small-molecule inhibitor of JAK/STAT signaling, improved pulmonary vascular remodeling in pre-clinical PAH models and in patients with myelofibrosis through inhibition of smooth muscle cell proliferation and rebalancing of vasoreactivity. A similar signaling cascade involves mammalian target of rapamycin (mTOR), a cellular regulator of metabolism, proliferation, and survival, that functions through two distinct multi-protein complexes (mTOR complex 1 (mTORC1) and mTORC2). mTORC1 activates its downstream targets p70 S6 kinase 1 (S6K1) and 4E-binding protein 1 (4E-BP1) through phosphorylation that in turn increases protein synthesis and cell proliferation. mTOR inhibition with rapamycin reduces pulmonary vascular remodeling in pre-clinical PAH models, and in a clinical safety and efficacy trial, everolimus (structurally related to rapamycin) reduced pulmonary vascular resistance without severe side effects in patients.

On a subcellular level, hyper-proliferation of pulmonary artery smooth muscle cells is linked to aberrant cell cycle progression which is tightly controlled through cyclin-dependent kinase (CDK) activity. CDKs are increasingly active in pulmonary artery smooth muscle cells from IPAH patients contributing to their pro-proliferative phenotype. CDKs regulate cell cycle progression in a Rb (retinoblastoma protein)-dependent

manner to control E2F proliferative target genes and cell growth. Thereby, CDKs drive the pro-proliferative phenotype of these cells, and pharmacological targeting of CDK4/CDK6 causes cell cycle arrest, reduces proliferation through modulation of CDK-Rb-E2F signaling, and reduces disease pathogenesis in pre-clinical PAH models. However, whether direct cell cycle inhibition in a long-term treatment approach in PAH patients is effective, well-tolerated, and safe is currently unknown (Weiss et al. 2019).

Metabolism and Hypoxia

In an attempt to meet their increased energetic demand within the diseased environment, pulmonary vascular cells undergo metabolic reprogramming with an energetic shift from oxidative phosphorylation towards glycolysis (Warburg effect). This shift is coupled with multiple abnormalities in mitochondrial function, including suppressed activity of pyruvate dehydrogenase and glucose oxidation, superoxide dismutase 2 deficiency, as well as mitochondrial hyperpolarization and fragmentation (Archer 2016). Increased glutaminolysis and fatty acid oxidation further contribute to energetic adaptation. The change in ATP energy production comes along with an increased resistance towards mitochondria-dependent cell death. This apoptosis resistance is critically regulated by pyruvate dehydrogenase kinase (PDK) which balances mitochondrial enzyme pyruvate dehydrogenase (PDH) function. Therapy with dichloroacetate (DCA), a PDH inhibitor, improved hemodynamics in some PAH patients, while others remained unresponsive. This heterogeneity in treatment responsiveness was *post hoc* linked to single nucleotide polymorphisms in sirtuin 3 (Sirt3) and uncoupling protein 2 (Ucp2), both upstream regulators of PDH. This provides further evidence for significant molecular heterogeneity in PAH patients suffering from a similar clinical and histological pathology. It is worth to mention, that it is unclear, whether the increased energy demand is caused by the vascular remodeling processes or vice versa. Malnutrition and cellular oxygen homeostasis, however, are similarly controlled by a key transcription factor, hypoxia-inducible factor (HIF), a master regulator of oxygen homeostasis that acts as a heterodimeric complex composed of an oxygen-sensitive α-subunit and an oxygen-insensitive β-subunit (Pullamsetti et al. 2020). In oxygenized cells, HIFα is inactivated via hydroxylation by prolyl hydroxylases and HIF-inhibiting factors, leading to HIFα ubiquitination and proteasomal degradation. Cellular hypoxia results in stabilization and nuclear translocation of HIFα, whereas activated HIF acts as a transcriptional regulator of a broad range of genes associated with vascular tone, cellular metabolism, proliferation, survival, and autophagy. In the lung, abnormal HIF-1 and HIF-2 activation due to cellular hypoxia have been linked to PAH disease pathogenesis with cell type-specific roles for both transcription factors. This is important as the mechanisms responsible for endothelial activation likely differ from the mechanisms responsible for smooth muscle cell activation. However, a number of stimuli, including shear stress from increased pulmonary blood flow, viral infection (HIV), and alveolar hypoxia, may potentially activate such a response in (genetically) predisposed individuals. The nature of the initial stimulus that precedes the vasoconstrictive/vasoproliferative events is unknown. However, an attractive hypothesis is that injury to the endothelium leads to apoptosis of the usually quiescent cells; destabilization of the pulmonary vascular intima, preferably at branching points; and uncontrolled proliferation of endothelial cells. Most of the physiological consequences of PH would then emanate from the resultant narrowing of the pulmonary vessels.

Inflammation

The inflammatory processes underlying PAH pathogenesis are complex, vary in their degree and form, and are often spatially confined with a strict underlying temporal sequelae of events. Pre-clinical work suggests that aberrant reparative immunity and loss of self-tolerance result in exuberant inflammation, which seems to perpetuate vascular injury and remodeling. In PAH patients, inflammatory cells localize around remodeled lung vessels, and levels of multiple cytokines are abnormally elevated in peripheral blood. The

levels of circulating cytokine heterogeneity among different PAH populations are unknown up this point; however, first machine learning approaches using unsupervised computer algorithms for inflammatory phenotyping begin to uncover specific cytokine profiles that are more and more linked to clinical phenotypes (Sweatt et al. 2019). Substantial evidence indicates a role for elevated pro-inflammatory circulating cytokines MCP-1, TNFα, IL-1β, and IL-6 in PAH patients. Further, chemokine-dependent mechanisms lead to inflammatory cell recruitment towards PAH lungs. FKN (also known as C-X3-C motif chemokine 1), for example, is a soluble chemotactic protein that is found as a membrane-anchored cell-adhesion molecule on endothelial cells. The actions of FKN are mediated by CX3C chemokine receptor 1 (CX3CR1), a transmembrane receptor expressed by monocytes, microglial cells, neurons, natural killer cells, mast cells, and subpopulations of T lymphocytes. Unlike other chemokines, FKN can mediate the rapid-capture, integrin-independent adhesion, and activation of circulating CX3CR1+ leukocytes under high blood flow (Fong et al. 1998). FKN expression is increased in circulating CD4+ and CD8+ T lymphocytes from patients with PAH, in inflammatory cells surrounding plexiform lesions, and in pulmonary arterial smooth muscle cells of remodeled arteries. Other cytokines overproduced in patients with PAH are RANTES and chemokine ligand 2 (CCL-2). CCL-2 overproduction is a feature of the abnormal pulmonary endothelial cell phenotype in IPAH, and, compared with healthy controls, pulmonary artery SMCs from patients with IPAH exhibited stronger migratory and proliferative responses to CCL-2.

In addition, infectious organisms can affect the lung circulation either directly by obliterating lung vessels or indirectly via release of inflammatory cells, pro-inflammatory mediators, or activation of the immune system (Knafl et al. 2020). Some of these cells include monocytes, macrophages, T lymphocytes, and dendritic cells that are also found in plexiform lesions and other vascular lesions of PAH-affected human lungs.

PAH is directly associated with latent viral infections (e.g., HIV, human herpes virus [HHV], Epstein-Barr virus, and cytomegalovirus) (Cool et al. 2011), whereas the causative role of viruses in PAH induction is not well understood. PAH disease is further associated with schistosomiasis, a parasitic infection that causes substantial inflammation and pulmonary vascular disease. Over 200 million people worldwide are currently infected with schistosomiasis, and up to 20% of those with long-term infection develop PAH. Lung tissue parasitic egg burden induces inflammatory and immune processes and may underlie PAH pathogenesis in infected patients.

Summary

Genetic, signaling, metabolic, and environmental abnormalities that involve various deregulated signaling molecules underlie PAH pathogenesis and lead to intimal changes, including endothelial injury, endothelial cell proliferation, non-endothelial cell invasion, and enhanced matrix deposition; medial changes with abnormal vascular smooth muscle cell behavior (pro-proliferative, pro-migratory, anti-apoptotic); and chronic inflammatory conditions through adventitial immune cell infiltration, elevated circulating cytokines, and recruitment of circulating cell types to the lung. On a molecular level, deregulation of many signaling molecules contribute to an imbalance in vasoactive mediators, increased cell proliferation and resistance to apoptosis, chronic inflammation, and metabolic abnormalities. The ongoing efforts in deciphering cellular heterogeneity and cause-consequence relations will pave the way for precise pharmacological strategies tailored to individuals to tackle the progressive pulmonary vasculopathy seen in PAH patients.

Purinergic System

Geoffrey Burnstock
Department of Pharmacology and Therapeutics, The University of Melbourne, Parkville, VIC, Australia

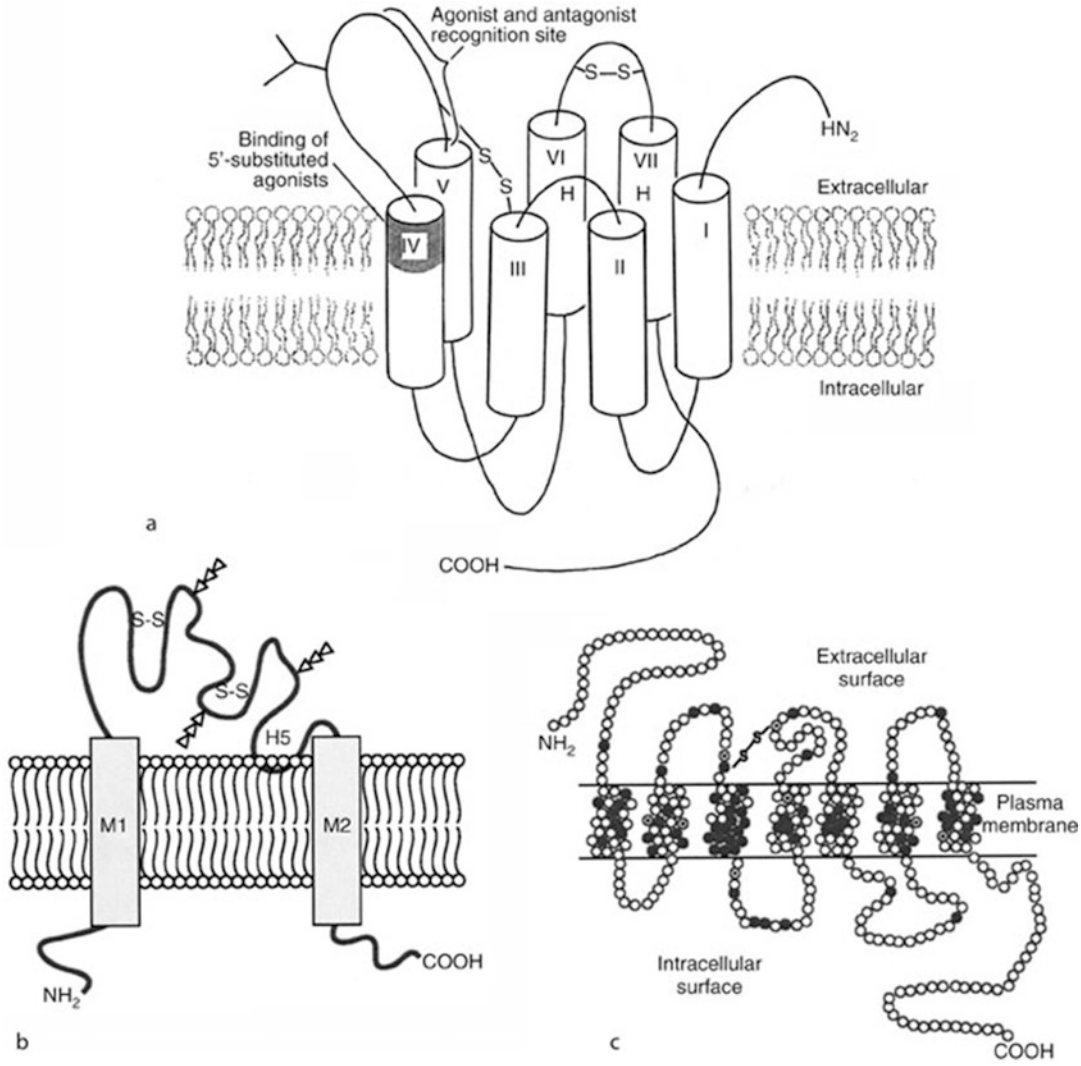
Definition

The purinergic system is a signaling system, where the purine nucleotides, **ATP** and **ADP**, and the nucleoside, **adenosine**, act as extracellular messengers. This concept, which was first proposed over 30 years ago (Burnstock 1997), met with considerable resistance for many years, because ATP had been established as an intracellular energy source involved in various metabolic cycles and it was thought that such a ubiquitous molecule was unlikely to be involved in selective extracellular signaling. However, ATP was one of the first molecules to appear in biological evolution so that it is not really surprising that it should have been utilized early for extracellular, as well as intracellular, purposes. The existence of potent extracellular enzymes that regulate the amount of ATP and adenosine available for signaling also provides support that ATP has extracellular actions.

Basic Characteristics

Purinoceptor Subtypes

Implicit in purinergic signaling is the presence of receptors for ATP (Ralevic and Burnstock 1998). A basis for distinguishing adenosine receptors (P1), from ATP/ADP receptors (P2), was proposed in 1978. This helped resolve some of the earlier ambiguous reports, which were complicated by the breakdown of ATP to adenosine by ectoenzymes, so that some of the actions of ATP were directly on P2 receptors, while others were due to indirect action via P1 receptors. Four subtypes of P1 receptors have been cloned, namely, A_1, A_{2A}, A_{2B}, and A_3 (Fig. 1a). P2 receptors belong to two families based on molecular structure and second messenger systems, namely P2X ionotropic ligand-gated ion channel receptors and P2Y metabotropic G protein-coupled receptors. This framework allows for a logical expansion as new receptors are identified. There are currently seven subtypes of P2X receptors and eight subtypes of P2Y receptors identified and characterized in mammals. P2X receptors are characterized by two transmembrane domains, short intracellular N- and C-termini, and an extensive extracellular loop with conservation of 10 cysteines (Fig. 1b). Broadly, P2X1 receptors are strongly represented in smooth muscle, P2X2, P2X4, and P2X6 receptors in the central nervous system, P2X3 receptors on sensory neurones, P2X5 receptors associated with cell proliferation, and differentiation and P2X7 receptors with cell death. The ion pores appear to consist of three subunits forming homomultimers or heteromultimers, including P2X1/2, P2X1/4, P2X1/5,



Purinergic System, Fig. 1 Membrane receptors for extracellular ATP and adenosine. P1 family of receptors for extracellular adenosine are G protein-coupled receptors signaling by inhibiting or activating adenylate cyclase (**a**). The P2 family of receptors bind extracellular ATP or ADP and are comprised of two types of receptors (P2X and P2Y). The P2X family of receptors are ligand-gated ion channels (**b**), and the P2Y family are G protein-coupled receptors (**c**). (**a,** reproduced from 2 with permission from the American Society for Pharmacology and Experimental Therapeutics; (**b**), from Brake, A. J., Wagenbach, M. J. and Julius, D. (1994). New structural motif for ligand-gated ion channels defined by an ionotropic ATP receptor. *Nature* **371**, 519–523, reproduced with permission from Nature; (**c**) Modified from Barnard, E. A., Burnstock, G. and Webb, T.E. (1994). G protein-coupled receptors for ATP and other nucleotides: a new receptor family. *Trends in Pharmacological Sciences* **15**, 67–70, reproduced with permission from Elsevier)

P2X2/3, P2X2/6, and P2X4/6. P2Y receptors, in common with other protein-coupled receptors, have seven transmembrane domains, an extracellular N, and intracellular C-terminus (Fig. 1c). $P2Y_1$ receptors are ADP-selective in mammals and 2-methylthioADP and MRS 2179 are selective agonists and antagonists, respectively. At $P2Y_2$ and $P2Y_4$ receptors in the rat, ATP and UTP are equipotent, but the two receptors can be distinguished with antagonists. $P2Y_6$ is UDP-selective. $P2Y_{11}$ is unusual in that there are two transduction pathways, adenylate cyclase

as well as inositol trisphosphate, which is the second messenger system used by the majority of the P2Y receptors. The $P2Y_{12}$ receptor is found on platelets. $P2Y_{13}$ is ADP selective and acts via adenylate cyclase, while $P2Y_{14}$ receptors are selective for UDP-glucose and UDP-galactose.

Physiology

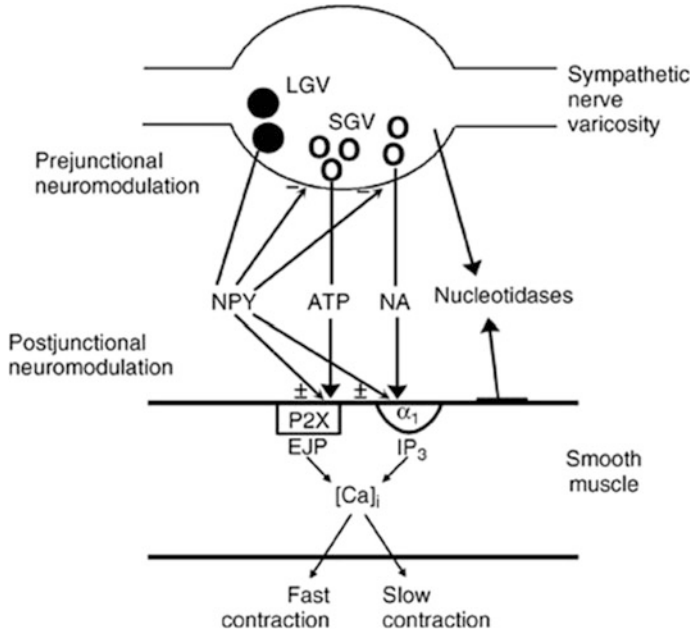
Short-Term Neuronal Signaling

There was early evidence that ATP was a **neurotransmitter** in nonadrenergic, noncholinergic (NANC) nerves supplying the gut and bladder. There is now supporting evidence that ATP is a cotransmitter in many nerve types (Burnstock 1997), probably reflecting the primitive nature of purinergic signaling. Thus, there is now evidence for ATP as a cotransmitter with:

- Noradrenaline (NA) and neuropeptide Y in sympathetic nerves
- ATP with acetylcholine and vasoactive intestinal peptide in some parasympathetic nerves
- ATP with nitric oxide and vasoactive intestinal peptide in enteric NANC inhibitory nerves
- ATP with calcitonin gene-related peptide and substance P in sensory-motor nerves

There is also evidence for ATP as a cotransmitter with γ-aminobutyric acid or with glutamate, serotonin, NA, or dopamine in nerves in the central nervous system.

In sympathetically innervated tissues, such as vas deferens or blood vessels, ATP produces fast responses mediated by P2X receptors followed by a slower component mediated by G protein-coupled α-adrenoceptors (Fig. 2); neuropeptide



Purinergic System, Fig. 2 Schematic of sympathetic cotransmission. ATP and NA released from small granular vesicles (SGV) act on P2X and α_1 receptors on smooth muscle, respectively. ATP acting on inotropic P2X receptors evokes excitatory junction potentials (EJPs) and increases in intracellular calcium ($[Ca^{2+}]_i$) and fast contraction, while occupation of metabotropic α_1 adrenoceptors leads to production of inositol triphosphate (IP_3), increases in $[Ca^{2+}]_i$, and slows contraction. Neuropeptide Y (NPY) stored in large granular vesicles (LGV) acts after release both as a prejunctional inhibitory modulator of release of ATP and NA and as a postjunctional modulatory potentiator of the actions of ATP and NA. Soluble nucleotidases are released from nerve varicosities and are also present as ectonucleotidases. (Reproduced from Burnstock, G. (2007). Neurotransmission, Neuromodulation: Cotransmission. In: *New Encyclopaedia of Neuroscience,* Elsevier, The Netherlands (In Press), with permission from Elsevier)

Y usually acts as a pre- or postjunctional modulator of the release and/or action of noradrenaline and ATP. Similarly, for parasympathetic nerves supplying the urinary bladder, ATP provokes a fast, short-lasting twitch response via P2X receptors, whereas the slower component is mediated by G protein-coupled muscarinic receptors. In the gut, ATP released from NANC inhibitory nerves produces the fastest response, nitric oxide gives a less rapid response, and vasoactive intestinal peptide produces slow tonic relaxations. In all cases of **cotransmission**, there are considerable differences in the proportion of the cotransmitters in nerves supplying different regions of the gut or vasculature, in different developmental or pathophysiological conditions and between species.

The first clear evidence for nerve-nerve purinergic **synaptic transmission** was in 1992, when it was shown that excitatory postsynaptic potentials in the celiac ganglion and in the medial habenula in the brain were reversibly antagonized by suramin, a P2 receptor antagonist. Since then, there have been many articles describing either the distribution of various P2 receptor subtypes in the brain and spinal cord or electrophysiological studies of the effects of purines in brain slices, isolated nerves, and glial cells. Synaptic transmission has also been found in the myenteric plexus and in various sensory, sympathetic, and pelvic ganglia.

Short-Term Nonneuronal Signaling

There are many examples of purinoceptor-mediated responses in nonneuronal cell types (Abbracchio and Williams 2001). **Endothelial cells**, which express $P2Y_1$, $P2Y_2$, and probably $P2Y_6$ and P2X4 receptors, when occupied, release nitric oxide leading to vasodilatation (Fig. 3). The discovery of P2X receptors in endothelial cells suggests a role regulating gap and tight junctions involved in permeability and in cell adhesion. $P2Y_1$ receptors in pancreatic **β**-cells have been shown to be involved in insulin secretion, and $P2Y_2$ receptors are present on hepatocytes. $P2Y_{12}$, P2X1, and $P2Y_1$ receptors are expressed in platelets and $P2Y_1$ and $P2Y_2$ receptors on nonmyelinating and myelinating Schwann cells, respectively. Purinergic receptors are also involved in signaling to endocrine cells, leading to hormone secretion and in neuron-glial cell interactions.

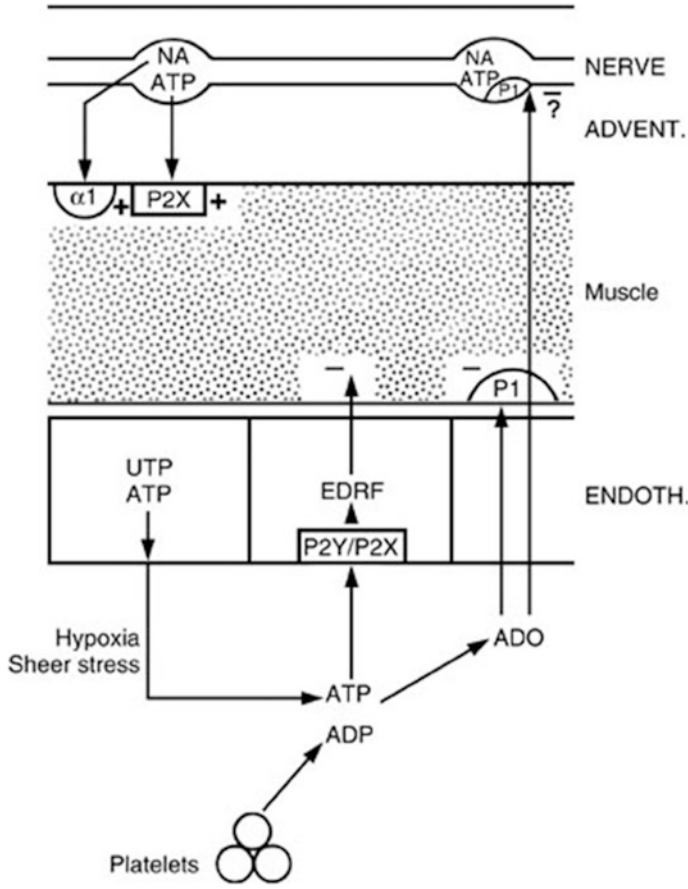
Long-Term (Trophic) Signaling

Purinergic signaling is also concerned with long-term events, such as cell proliferation, migration, differentiation, and death associated with development and regeneration (Burnstock 1997; Abbracchio and Williams 2001; Burnstock 2006). For example, **α**,**β**-methylene ATP produces proliferation of glial cells, whereas adenosine inhibits proliferation. A p2y8 receptor was cloned from the frog embryo, which appears to be involved in the development of the neural plate. $P2Y_1$ receptors seem to have a role in cartilage development in limb buds and in development of the mesonephros. P2X5 and P2X6 receptors have been implicated in the development of chick skeletal muscle. In studies of purinoceptor expression in developing mouse myotubes, there was progressive expression of P2X5, P2X6, and P2X2 receptors. The P2X1 receptor is prominent in contractile smooth muscle phenotype, but is absent in the synthetic smooth muscle phenotype grown in culture, while P2Y receptor expression is substantially increased. There are several reports showing that P2X and P2Y receptors in **osteoclasts** and **osteoblasts** are involved in bone development and remodeling.

Pathophysiology and Therapeutic Potential

There is increasing interest in the therapeutic potential of purinergic compounds in relation to both P1 and P2 receptors (Burnstock 2006). A number of purine-related compounds have been patented.

It is well established that the **autonomic nervous system** shows marked plasticity. The expression of cotransmitters and receptors shows dramatic changes during development and ageing, in nerves that remain after trauma or surgery and in disease conditions. There are now a number of examples where the purinergic component of cotransmission is increased in pathological conditions(Burnstock 2006). Purinergic nerve-



Purinergic System, Fig. 3 A schematic representation of the interactions of ATP released from perivascular nerves and from the endothelium (ENDOTH). ATP and UTP are released from endothelial cells during changes in blood flow (sheer stress) and hypoxia to act on endothelial P2Y and P2X receptors leading to production of EDRF (nitric oxide) and subsequent vasodilatation (−). In contrast, ATP released as a cotransmitter with noradrenaline (NA) from perivascular sympathetic nerves at the adventitia (ADVENT)/muscle border produces vasoconstriction (+) via P2X receptors on the muscle cells. Adenosine (ADO), resulting from rapid breakdown of ATP by ecto-enzymes, produces vasodilatation by direct action on the muscle via P1 receptors and acts on the perivascular nerve terminal varicosities to inhibit transmitter release. (Modified from Burnstock G, (1987). Local control of blood pressure by purines. *Blood Vessels* **24**, 156–160, reproduced with permission from Karger AG)

mediated contractions of the human bladder are increased up to 40% in pathophysiological conditions such as interstitial cystitis, outflow obstruction, and probably also neurogenic bladder. ATP plays a significantly greater cotransmitter role in sympathetic nerves supplying hypertensive blood vessels. Upregulation of P2X1 and $P2Y_2$ receptor mRNA in hearts of rats with congestive heart failure has been reported. Adenosine modulates long-term synaptic plasticity in the hippocampus; it attenuates long-term potentiation (LTP); P1 receptor antagonists facilitate LTP. It is suggested that adenosine-related compounds might prove helpful in the treatment of memory disorders and intellectual performance related to caffeine intake.

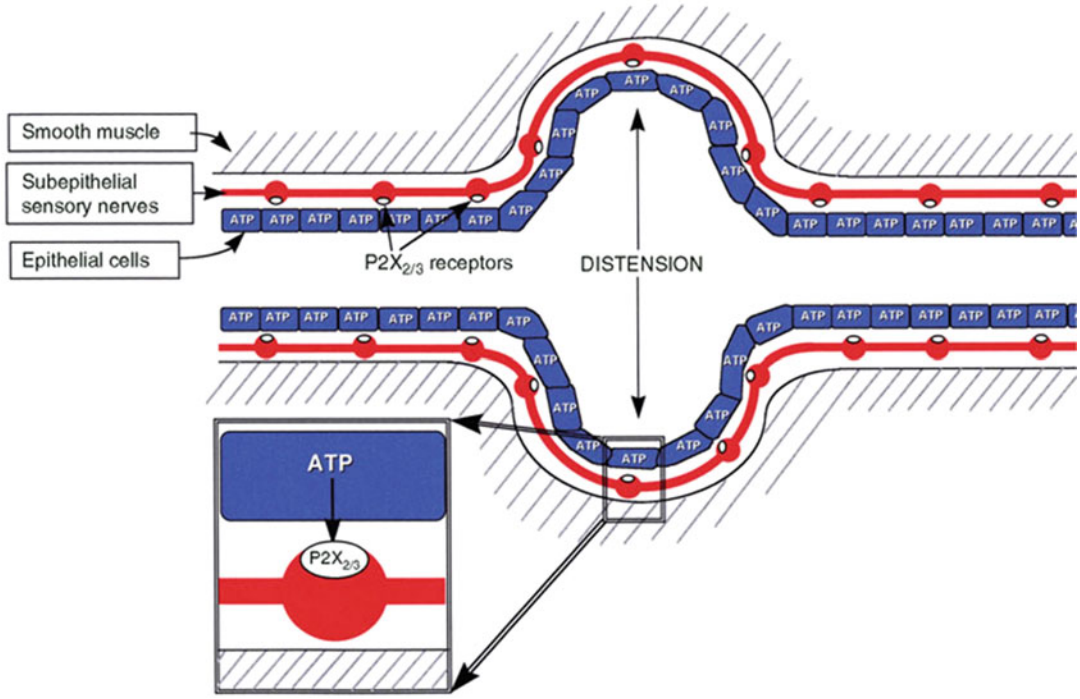
A new hypothesis for purinergic **mechanosensory transduction** in visceral organs involved in the initiation of pain has been proposed. It is suggested that distension of tubes (such as the ureter, salivary duct, and gut), and sacs (such as urinary and gall bladder), leads to the release of ATP from the lining epithelial cells that diffuses to subepithelial sensory nerves expressing P2X3 and/or P2X2/3 nociceptive receptors, which

mediate messages to pain centers in the central nervous system (Burnstock 2001) (Fig. 4). Recording in P2X3 knockout mice has shown that the micturition reflex is impaired and that responses of sensory fibers to P2X3 agonists are gone, suggesting that P2X3 receptors on sensory nerves in the bladder have a physiological as well as a nociceptive role.

P1 (adenosine) receptors were explored as therapeutic targets before P2 receptors. Adenosine was identified early and is in current use to treat **supraventricular tachycardia**. A_{2A} receptor antagonists are being investigated for the treatment of **Parkinson's disease** and patents have been lodged for the application of P1 receptor subtype agonists and antagonists for myocardial ischemia and reperfusion injury, cerebral ischemia, stroke, intermittent claudication, and renal insufficiency.

Purinergic receptors have a strong presence in bone cells. P2X and P2Y receptors are present on osteoclasts, with P2Y receptors only being present on osteoblasts. ATP, but not adenosine, stimulates the formation of osteoclasts and their resorptive actions *in vitro* and can inhibit osteoblast-dependent bone formation. A study has shown that very low (nM) concentrations of ADP acting through $P2Y_1$ receptors turn on osteoclast activity. Modulation of P2 receptor function may have potential in the treatment of osteoporosis. The anticancer activity of adenine nucleotides was first described in 1983 and since then, intraperitoneal injection of ATP into tumor-bearing mice has resulted in significant anticancer activity against several fast-growing aggressive carcinomas.

Purinergic signaling is important in the special senses. For example, $P2Y_2$ receptor activation increases salt, water, and mucus secretion in the



Purinergic System, Fig. 4 Schematic representation of the hypothesis for purinergic mechanosensory transduction in tubes (e.g., ureter, vagina, salivary and bile duct and gut) and sacs (e.g., urinary and gall bladders, and lung). It is proposed that distension leads to release of ATP from the epithelium lining the tube or sac, which then acts on $P2X_{2/3}$ receptors on subepithelial sensory nerves to convey sensory (nociceptive) information to the CNS. (From Burnstock, G. (1999) Release of vasoactive substances from endothelial cells by shear stress and purinergic mechanosensory transduction. *Journal of Anatomy*, **194**, 335–342, with permission from Blackwell Publishing)

eye and thus represents a potential treatment for dry eye disease. P2 receptor agonists have greater efficacy in reducing intraocular pressure than cholinergic and adrenergic agents, raising possibilities for novel treatment of glaucoma. It has been suggested that ATP may regulate fluid homeostasis, cochlear blood flow, hearing sensitivity and development, and thus may be useful in the treatment of Ménières disease, tinnitus, and sensorineural deafness.

There have been very promising developments concerning purinergic drugs aimed at treating **thrombosis**. Clopidogrel and ticlopidine are antagonists to the $P2Y_{12}$ receptor and appear to reduce the risks of recurrent strokes and heart attacks, especially when combined with aspirin. Further therapeutic targets include: chronic renal failure, congestive heart failure, hypertension, stroke, angina, asthma, chronic obstructive pulmonary disease, epilepsy, sleep apnea, diabetes, inflammation, erectile function, and wound healing.

Recent advances have been made about the pathophysiology and therapeutic potential of purinergic signalling (Burnstock 2017).

GPCR135); RXFP4 (relaxin family peptide receptor 4; RLN3R2; RXFPR4; GPCR142; GPR100) (Alexander et al. 2019).

Definition

The relaxin family peptides relaxin, insulin-like peptide (INSL)3, relaxin-3, and INSL5 mediate hormonal and neuropeptide actions by acting on a group of four relaxin family peptide (RXFP) receptors (Bathgate et al. 2013; Halls et al. 2015; Alexander et al. 2019; Valkovic et al. 2019). The receptor systems have roles in the cardiovascular system, formation of connective tissue and bone, and reproduction and act in the brain as neuropeptides to modulate stress, anxiety and mood, arousal, and behaviors such as feeding and drug seeking. The antifibrotic effects of relaxin at RXFP1 have therapeutic potential given the role of fibrosis in progressive cardiovascular and renal disease and asthma.

Basic Characteristics

The relaxin family peptides are two-chain peptides closely resembling insulin in structure. All have an A-chain linked to a B-chain by two interchain disulfide bonds and an intrachain disulfide bond in the A-chain. Relaxin, INSL3, relaxin-3, and INSL5 are the cognate ligands for the relaxin family peptide receptors RXFP1–4, respectively (Bathgate et al. 2013; Halls et al. 2015). Relaxin was discovered as a factor in pregnant guinea-pig serum that relaxed the birth canal, and the study of its biological actions, structure, and molecular biology led to the identification of the genes encoding the related INSL3, relaxin-3, and INSL5 (Bathgate et al. 2013; Halls et al. 2015). While there is evidence that relaxin acting at RXFP1 has widespread functions in the reproductive system, brain, and cardiovascular system as well as general metabolic and antifibrotic actions, INSL3 activation of RXFP2 has specific and limited actions mainly in the reproductive system. INSL3 is found in the Leydig cells of the testis and plays a critical role in gubernaculum development and testis descent and in females has a role in maintaining ovarian function. In contrast to the other relaxins, relaxin-3 acting at RXFP3 is well conserved across species and is believed to be the ancestral peptide that has well-defined roles as a neuropeptide in mammals. The cognate ligand for RXFP4, INSL5, is more widely distributed with particularly high concentrations found in the L-cells of the gastrointestinal tract where it likely has metabolic functions (Bathgate et al. 2013; Halls et al. 2015).

While the relaxin family peptide receptors are all GPCRs with the typical seven transmembrane-spanning regions, RXFP1 and RXFP2 differ structurally quite markedly from RXFP3 and RXFP4. RXFP1 and 2 have a large extracellular domain comprising ten leucine-rich repeats (LRR) and an N-terminal low-density lipoprotein receptor type A module (LDLa). Binding of relaxin to RXFP1 involves a high-affinity component between the B-chain of the peptide and the LRR and lower-affinity binding to receptor ECLs followed by an essential interaction involving the LDLa module. Receptor activation increases cellular cAMP levels and activates ERK1/2, tyrosine kinases, NO signaling, as well as changing gene transcription and glucocorticoid receptor signaling. RXFP2 signaling is simpler and usually but not always involves increases in cAMP generation. In contrast to RXFP1 and 2, RXFP3 and 4 are classical family A GPCRs with small N-terminal domains, and activation leads to a decrease in intracellular cAMP levels (Bathgate et al. 2013; Halls et al. 2015; Valkovic et al. 2019).

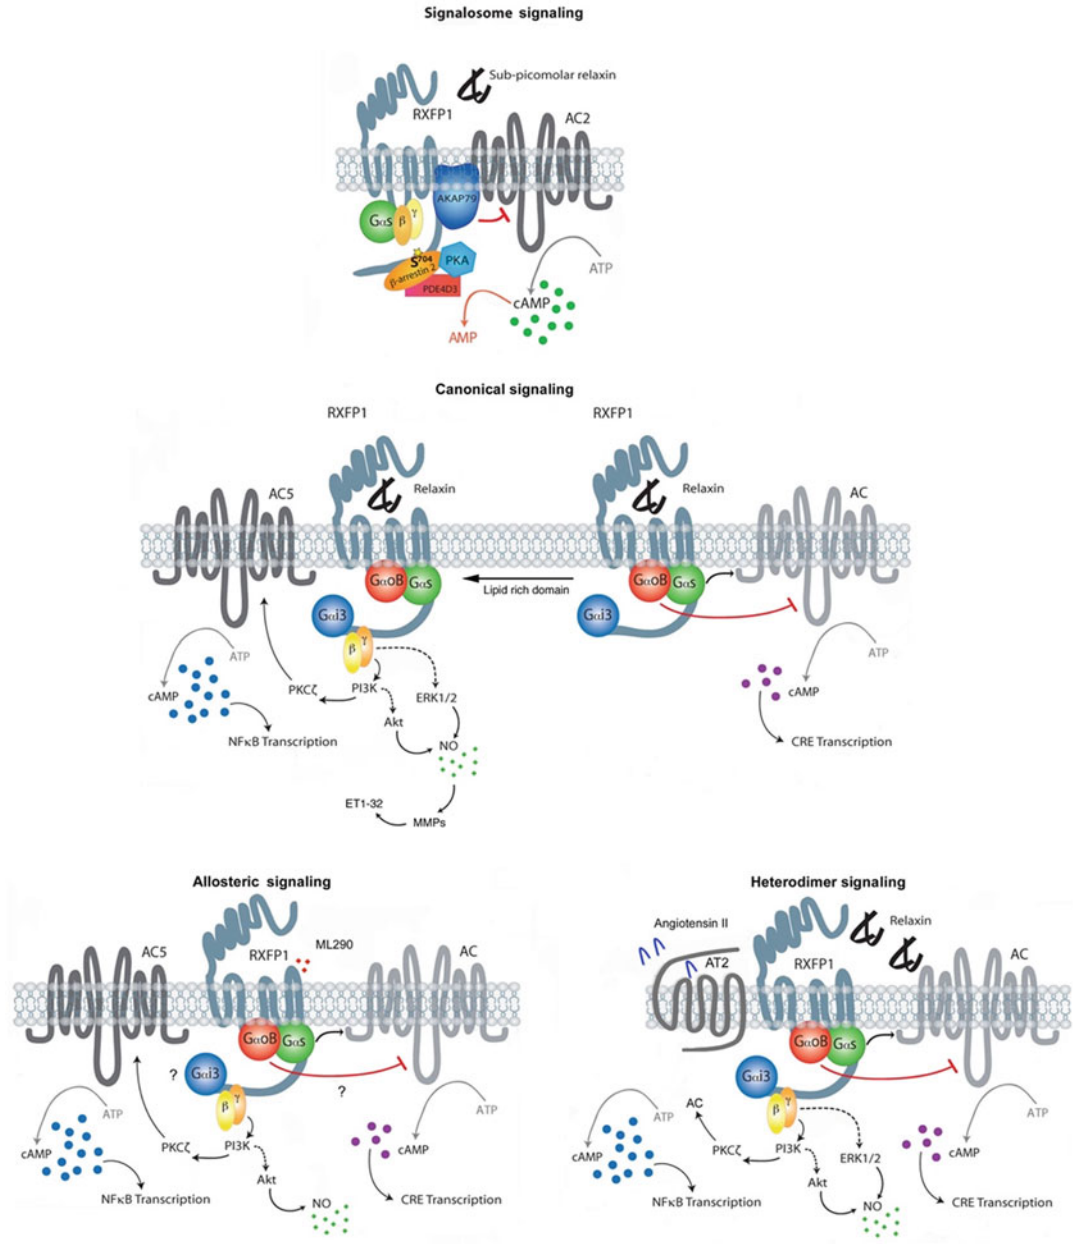
RXFP1 and 2 share 60% amino acid identity and 80% homology. Many splice variants of the receptors have been identified with many being nonfunctional. A secreted variant RXFP1-truncate is increased in pregnancy and appears to act as a functional antagonist of RXFP1 (Alexander et al. 2019). RXFP3 and 4 are encoded by a single exon in human, but RXFP4 is a pseudogene in rat that does not encode a functional protein.

RXFP1 and 2 are unique among GPCRs in containing the LDLa module at the N-terminus that is believed to act as a tethered ligand. Receptor variants that lack the LDLa module bind their cognate ligands normally but cannot signal.

Studies with chimeric receptors suggest that interaction between the LDLa module and TM regions is important for producing a receptor conformation necessary for signaling. The LRR region contains glycosylation sites that are important for receptor translocation and efficacy of signaling but not binding. The key residues whereby relaxin interacts with RXFP1 form the RxxxRxxI motif in the B-chain with the arginines interacting with acidic residues in LRR8 and LRR6 and the isoleucine interacting hydrophobically with LRR4 and LRR5 (Halls et al. 2015). The activation of RXFP2 by INSL3 utilizes different residues in the B-chain and also different interactions with the receptor TM region. Although relaxin can bind to RXFP2 as well as RXFP1, it does so in a different manner that also differs from the binding of INSL3 at RXFP2. For both RXFP1 and 2, the primary high-affinity binding site is located in the LRR, but there is also evidence for a lower-affinity binding site in the TM region (Valkovic et al. 2019). It has been suggested that this interaction directs the LDLa to bind to the TM region of a homodimer partner to drive receptor activation. As in many GPCRs, the ICL3 region of RXFP1 and 2 is important for interaction with the G proteins Gαs and GαoB. For RXFP1 but not RXFP2, the C-terminal tail is essential for cAMP generation mediated by an unusual mechanism involving Gαi3 (Halls et al. 2015). The C-terminal tail of RXFP1 also contains other consensus sequences for phosphorylation and protein interactions not shared by RXFP2 perhaps reflecting the more complex signaling and wider physiological role of the relaxin RXFP1 system. In contrast, activation of RXFP3 and 4 does not appear to involve the N-terminus of the receptors. Arginines in relaxin-3 interact with acidic residues in ECL1 and 2 of RXFP3 and allow the C-terminus of the peptide to insert into a classical GPCR-binding pocket and activate the receptor. Studies using RXFP3/4 chimeras suggest that for both receptors TM2, 3, and 5 and ECL2 are involved in binding and activation (Halls et al. 2015).

RXFP1 signaling is complex and involves cAMP, ERK1/2, tyrosine kinases, and NO (Fig. 1). RXFP1 couples to Gαs to increase cAMP levels, modulated by GαoB, but it also couples to Gαi3 to produce a delayed surge in cAMP via a Gβγ-PI3K-PKCζ pathway that activates AC5 (Bathgate et al. 2013; Halls et al. 2015; Valkovic et al. 2019). The latter mechanism is responsible for the pertussis toxin-sensitive positive inotropic and chronotropic effects of relaxin in the heart (Bathgate et al. 2013). cAMP accumulation in response to relaxin may also occur by G protein-independent mechanisms such as activation of tyrosine kinases, but these responses are very cell-type dependent. Many cardiovascular responses involve NO, and relaxin acting via RXFP1 has been shown to activate eNOS and nNOS and increase iNOS expression. Many cell types respond to relaxin by transient activation of ERK1/2, including human endometrial, coronary artery, and pulmonary arterial cells. A more sustained response is observed in HeLa and HUVECs. The antifibrotic actions of relaxin are associated with inhibition of TGF-β_1 signaling involving PI3K and NOS-NO-cGMP. Relaxin also activates a number of noncanonical signaling pathways such as the glucocorticoid receptor (GR). Relaxin coprecipitates with the GR and can compete for glucocorticoid binding (Halls et al. 2015). Many of the inhibitory actions of TNF-α on vasodilatation can be reversed by relaxin acting at GR. The actions of relaxin on gene transcription likely involve in part its actions at the GR. Another unusual aspect of RXFP1 signaling is the relaxin signalosome (Summers et al. 2018). While relaxin in the nM range activates RXFP1, the circulating peptide concentrations are usually lower. However, studies using highly sensitive FRET-based biosensors illustrate that a RXFP1-dependent cAMP response can be produced by attomolar concentrations of relaxin acting at signalosomes (Fig. 1). The signalosome comprises RXFP1 in a protein complex with AC2 and AKAP79, thus facilitating interaction with Gαs and Gβγ subunits and regulated by PDE4D3 that is scaffolded to the receptor C-terminus by β-arrestin. cAMP produced by the signalosome is also compartmentalized suggesting specialized physiological roles (Summers et al. 2018).

There is evidence that RXFP1 receptors form homo- and heterodimers and that these are responsible for signal transduction and some of the



Relaxin Family Peptides and Their Receptors, Fig. 1 Major signaling pathways for relaxin acting at RXFP1. Signalosomes are signaling complexes activated by sub-pM relaxin that respond to the amounts of relaxin in the circulation. Canonical signaling in many cell types involves interaction of RXFP1 with at least 3 G proteins and the generation of cAMP and cGMP. Signaling is compartmentalized with RXFP1-Gα_{i3} interactions occurring in lipid domains in the cell membrane. The agonist ML290 interacts at an allosteric site on RXFP1 to produce a biased signaling profile that preferentially activates cGMP over cAMP. There is also evidence that suggests that the anti-fibrotic effects of relaxin involve the formation of heterodimers between RXFP1 and the angiotensin AT2 receptor

therapeutically relevant actions of relaxin. Although it has been suggested that RXFP1 signaling involves binding to one homodimer partner and interaction of the LDLa module with the other partner receptor, there is no convincing evidence currently available to support this concept (Halls

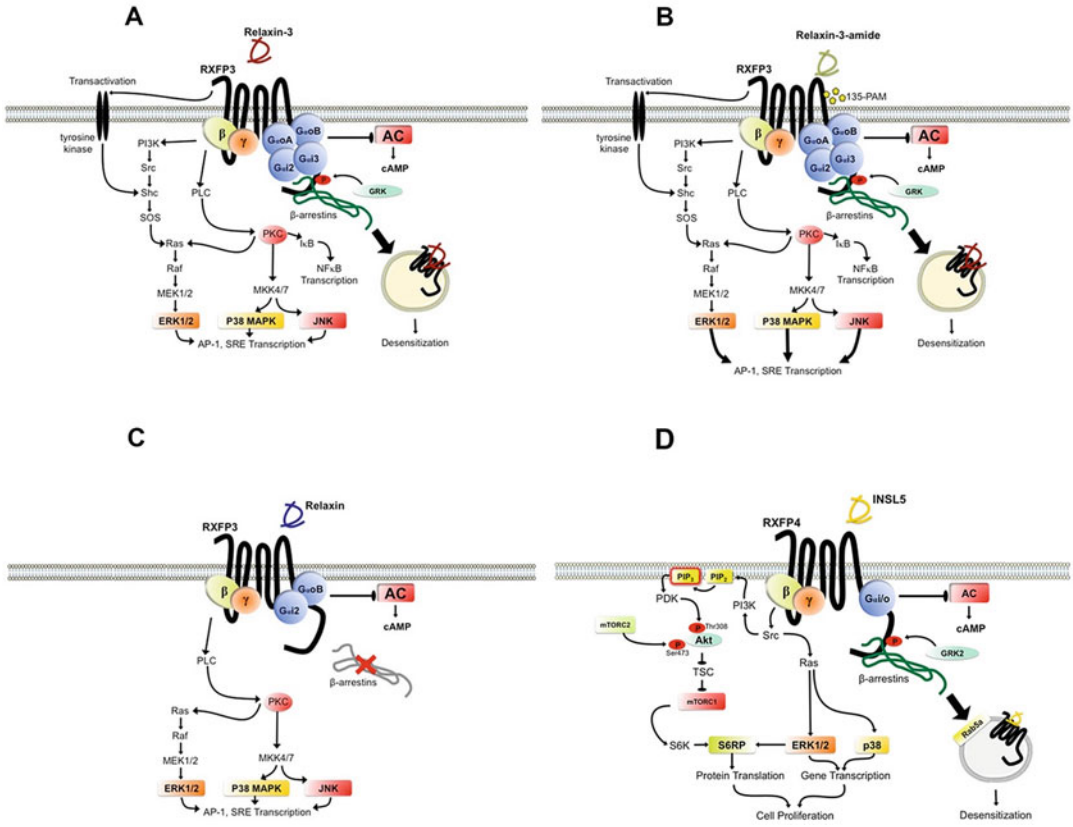
et al. 2015; Summers et al. 2018). Bell-shaped concentration-response curves are also a feature of many studies of relaxin-RXFP1 pharmacology and have been reported for in vitro and in vivo assays and in clinical trials. In vitro studies suggest that the bell-shaped curves are the result of sequential coupling of RXFP1 to Gαs and GαoB at different levels of receptor occupation (Sarwar et al. 2015). Bell-shaped curves become sigmoid after treatment of cells with a selective Gi/o inhibitor (Sarwar et al. 2015; Summers et al. 2018; Valkovic et al. 2019). Some actions of relaxin such as its antifibrotic actions are dependent on the formation of heterodimers between RXFP1 and other GPCRs (Fig. 1). Thus the antifibrotic actions of relaxin are absent in angiotensin AT_2 receptor knockout mice or in animals treated with the AT_2R antagonist PD123319. Likewise, recent studies have shown that the antifibrotic actions of relaxin are also blocked by the AT_1R antagonists irbesartan or candesartan (Halls et al. 2015; Summers et al. 2018; Chow et al. 2019). BRET studies demonstrate a constitutive interaction between RXFP1 and the AT_2 and AT_1R. Although AT_1 or AT_2R antagonists do not directly interact with relaxin binding to RXFP1, blockade of either receptor abolishes the antifibrotic effects of relaxin (Summers et al. 2018; Chow et al. 2019). These studies may provide an explanation for the observation that the antifibrotic actions of relaxin are only seen in pathological states where AT receptor expression is increased and why relaxin has failed in clinical trials for conditions where a proportion of patients were undergoing treatment with drugs acting on the renin-angiotensin system.

The small-molecule allosteric-biased agonist ML290 does not require the LDLa module to interact with RXFP1 and stimulate signal transduction. In addition, it does not utilize the binding sites used by relaxin and does not compete for relaxin binding (Kocan et al. 2017). The pattern of G protein activation by ML290 differs from that of relaxin, and while ML290 resembles relaxin in producing cAMP and cGMP accumulation and p38MAPK activation, although with lower potency, it differs from relaxin in that it does not acutely activate ERK1/2 in any system studied (Fig. 1) (Kocan et al. 2017). Like relaxin, ML290 promotes MMP2 expression and inhibits TGF-β_1-induced Smad2 and 3 phosphorylation suggesting that it has antifibrotic properties (Valkovic et al. 2019).

RXFP2 signaling pathways are a subset of those activated by RXFP1. INSL3 activation increases cAMP involving Gαs and GαoB, but there is no subsequent involvement of Gαi3 or a high-sensitivity signalosome response. In some cell types such as testicular germ cells or oocytes, INSL3 causes RXFP2-mediated inhibition of cAMP accumulation (Halls et al. 2015; Summers et al. 2018).

RXFP3 signaling follows a classical pattern of a Gi/o-coupled GPCR with inhibition of cAMP accumulation and activation of ERK1/2 and other MAP kinases (Fig. 2a). The particular Gi/o subtypes involved may vary with cell type, but the response pattern tends to be consistent. Ligand-directed signaling bias has been observed for relaxin-3, relaxin, and the RXFP3 antagonist R3(BΔ23-27)R/I5 (Fig. 2c). RXFP3 signaling was first observed for relaxin using microphysiometry but followed up by weak inhibition of cAMP generation by relaxin and INSL3 and AP-1 reporter gene activation by relaxin. The RXFP3 antagonist R3(BΔ23-27) R/I5 effectively blocked relaxin-3 but not relaxin-mediated AP-1 activation or relaxin-3 NFκB activation. BRET studies revealed a different pattern of G protein activation by relaxin-3 and relaxin. RXFP3 can also be allosterically modulated by 135PAM1, but the actions are limited by probe dependence (Fig. 2b) (Kocan et al. 2018).

RXFP4 like RXFP3 is a Gi/o-coupled receptor that when activated increases GTPγs binding and inhibits forskolin-stimulated cAMP accumulation but also increases phosphorylation of ERK1/2, p38MAPK, Akt-Ser473, Akt-Thr308, and S6 ribosomal protein (S6RP) (Ang et al. 2017) (Fig. 2d). Rescue studies with PTX-resistant G proteins suggest that $G\alpha_{oA}$, $G\alpha_{oB}$, and $G\alpha_{i2}$ and to a lesser extent $G\alpha_{i1}$ and $G\alpha_{i3}$ are involved. INSL5 exposure results in interaction with β-arrestins, internalization, and desensitization (Kocan et al. 2018).



Relaxin Family Peptides and Their Receptors, Fig. 2 Signaling pathways activated by RXFP3 and RXFP4 following activation. (**a**) RXFP3 canonical signaling following activation by relaxin-3; (**b**) allosteric modulation of relaxin-3 amide signaling by 135PAM1; (**c**) biased signaling by relaxin; (**d**) RXFP4 canonical signaling in response to INSL5. RXFP3 and RXFP4 inhibit cAMP production by coupling to Gi/o proteins and activate extracellular signal-regulated kinase (ERK)1/2 and phosphatidylinositol 3-kinase (PI3K). Both receptors undergo phosphorylation by GRK2 leading to recruitment of β-arrestins, desensitization, and internalization

RXFP1 is widely distributed in female reproductive tissues including the pubic symphysis, cervix, uterus, nipples, and mammary glands, and there is also evidence that relaxin has important roles in the cardiovascular adaptive changes associated with pregnancy including increases in plasma volume, cardiac output, and heart rate, together with decreased blood pressure and vascular resistance. In male and female brain, RXFP1 is localized to discrete regions of the olfactory system, neocortex, hypothalamus, hippocampus, thalamus, amygdala, midbrain, and medulla (Bathgate et al. 2013; Halls et al. 2015; Summers et al. 2018). Relaxin inhibits collagen biosynthesis and promotes collagen breakdown in many tissues as well as reproductive tissues, which has led to an interest in its use as an antifibrotic agent. However, the antifibrotic actions of relaxin are dependent on the presence not only of RXFP1 but also the angiotensin AT_2 receptor and likely also the AT_1 receptor, since the actions are blocked by either AT_1 or AT_2 receptor antagonists (Chow et al. 2019). RXFP2 has a much more restricted distribution being found in the uterus and in testis in Leydig cells, spermatocytes, spermatids, and the epididymal epithelium. Deficits in INSL3/RXFP2 signaling are correlated with reduced bone mass, and RXFP2 mutations may be linked with osteoporosis in men. RXFP3 is predominantly expressed in the brain with high RNA levels in olfactory bulb, paraventricular and supraoptic nuclei, and preoptic and posterior areas

of the hypothalamus, hippocampus, septum, and amygdala with lower levels in the cortex, periaqueductal gray, nucleus incertus, and areas of brainstem. There is low expression of RXFP3 in the adrenal gland, testis, salivary gland, and pancreas but little evidence of physiological function. Early studies of RXFP4 distribution showed protein expression in the heart, skeletal muscle, salivary gland, bladder, kidney, liver, placenta, stomach, jejunum, thyroid, ovary, and bone marrow with the highest expression in the pancreas. Subsequent RNA expression studies show expression in human colon but also in the placenta, testis, thymus, prostate, kidney, and brain with expression in the colon closely matching expression of INSL5 (Bathgate et al. 2013; Halls et al. 2015; Kocan et al. 2018; Summers et al. 2018).

The role of the relaxin/RXFP1 system in reproduction varies enormously across species. In humans, relaxin plasma levels are greatest in the first semester of pregnancy suggesting a role in implantation, but it may also be involved in the cardiovascular adaptations later in pregnancy and in the growth and development of mammary glands. Relaxin is found in seminal plasma and may have a role in preparing the uterine endometrium for implantation. In the brain, RXFP1 is found in the SFO and OVLT where it acts to reduce plasma osmolality. Relaxin increases cardiac output and heart rate and decreases vascular resistance – all adaptive changes to pregnancy but also present in nonpregnant animals. These effects contribute to increases in renal plasma flow and GFR that are clear in animals but require confirmation in humans (Bathgate et al. 2013; Halls et al. 2015). The vasodilator actions of relaxin are complex and involve NOS activation, cAMP generation, VEGF, placental growth factor, MMPs, ET_B receptors, and antifibrotic effects in blood vessel walls (Sarwar et al. 2017). NOS activation and cAMP generation are acute responses, whereas the other mechanisms are longer term. Relaxin acting at RXFP1 is a potent inotropic and chronotropic agent in atria, and the effects are preserved in failing hearts. The peptide has cardioprotective actions in rat models of ischemia and reperfusion and has anti-arrhythmic properties. In chronic heart failure, circulating levels of relaxin increase and are correlated with the degree of failure. This led to clinical trials to treat acute heart failure that although successful up to Phase III in limited trials eventually failed in a large-scale extended Phase III trial. It is possible that concurrent treatment with drugs acting on the renin-angiotensin system may have affected the outcome of these trials (see above). Attempts have also been made to harness the antifibrotic actions of relaxin that have been demonstrated in numerous animal models. Relaxin failed Phase III clinical trials for the treatment of scleroderma possibly due to an incomplete understanding of the disease (Bathgate et al. 2013; Halls et al. 2015). Dermal fibrosis in the relaxin knockout mouse can be reversed by relaxin treatment in the early but not the late stages of the condition. The expression of relaxin is increased in a variety of tumors, and high levels are associated with a poor prognosis and increased tumor growth, metastasis, and angiogenesis. The INSL3 RXFP2 system has specialized roles in reproductive function such as the development of the gubernaculum and in Leydig cell function and in females in the maturation of ovarian follicles. There is also evidence that it may be involved in the CNS, in tumor metastasis, in bone function, and in the kidney (Bathgate et al. 2013; Halls et al. 2015).

The relaxin-3 RXFP3 system is almost exclusively confined to the brain, and although relaxin-3 has been shown to be active at RXFP1 and RXFP4, the localization patterns of peptide and receptor suggest that this has no physiological importance. The colocalization of relaxin-3 and RXFP3 in the hypothalamus, stria terminalis, lateral septum, periaqueductal gray, and dorsal raphe suggests roles in stress and in feeding and metabolism. There is also evidence for roles in behavioral activation and arousal and that modulation of the system could be useful in the treatment of addiction. The evidence that the INSL4 RXFP4 system has important metabolic roles is becoming more compelling. INSL5 is synthesized and released from enteroendocrine L cells and circulates to act on RXFP4 receptors located in the hypothalamus, pituitary, testis, epididymis, ovary, uterus, pancreas, and liver. INSL5

knockout mice have impaired glucose homeostasis, and humans with RXFP4 polymorphisms have a high BMI and a tendency to obesity. Although INSL5 plasma levels are associated with feeding, the precise mechanisms involved have yet to be identified.

Drugs

Although the cognate relaxin family peptide ligands for the relaxin receptors RXFP1–4 have been defined, some interactions have been identified in in vitro systems. Human relaxin activates RXFP2 in addition to RXFP1 and acts as a biased agonist at RXFP3. Relaxin-3 is active at RXFP1 and RXFP4 as well as at its cognate receptor RXFP3. INSL5 is a weak antagonist at RXFP3 and is the cognate agonist for RXFP4.

Relaxin peptides show considerable variation across species, but all have the cysteines necessary for formation of disulfide bonds between the A- and B-chains and the conserved RxxxRxxI/V motif in the B-chain. Replacement of arginine, isoleucine, or valine in the conserved region leads to loss of activity. In the A-chain, G14 is necessary for chain flexibility and structure. Variants of relaxin such as H2:A(4-24)(F23A) retain potency at RXFP1 but have no activity at RXFP2. Others such as H2:(B7-24) or H2:(A4-24)(B7-24) have reduced binding and potency for cAMP generation but retain antifibrotic activity (Halls et al. 2015; Valkovic et al. 2019). C1q-tumor necrosis factor-related protein 8 and similar short linear peptides appear to activate many of the RXFP1 signaling pathways associated with the antifibrotic effect. Although studies indicate an interaction between CTRP8 and RXFP1, it is not clear if this reflects a physiological or pathological process (Halls et al. 2015; Summers et al. 2018; Valkovic et al. 2019). An HTS strategy designed to identify small molecular weight compounds active at RXFP1 identified ML290 that acts as an allosteric-biased agonist at RXFP1. Unlike relaxin, ML290 activates RXFP1 by interacting with TM7 and ECL3 (Kocan et al. 2017). ML290 activates human, macaque, and pig but not mouse RXFP1 leading to the development of a "humanized" mouse to enable studies in cellular and animal disease models (Summers et al. 2018). In contrast to relaxin, INSL3 is quite selective for RXFP2. Truncation of the A-chain of relaxin peptides improves selectivity for RXFP1, whereas similar modifications to INSL3 abolish activation of RXFP2 but not binding emphasizing the different modes of interaction. Unlike RXFP1, it has proved relatively easy to produce antagonists of RXFP2. Deletion of residues from the N-terminus of the A- or the B-chain or disruption of an intrachain disulfide bond of INSL3 produces competitive peptide antagonists of RXFP2. B-chain variants can be produced that are antagonists with relatively high affinity (Halls et al. 2015; Valkovic et al. 2019).

Relaxin-3 although similar in structure to other relaxin peptides interacts with RXFP3 and 4 in a different manner than it interacts with RXFP1. Alterations to the A-chain have little effect on RXFP3 binding but reduce activity at RXFP1. In the B-chain, R8, R16, I5, and F20 are required for relaxin-3 binding to RXFP3 and 4 with R12 also required for RXFP3 (Halls et al. 2015; Valkovic et al. 2019). Antagonists have been developed by modification of the B-chain combined with the INSL5 A-chain (R3(BΔ23-27)R/I5) or (H3: B1-22R). Relaxin activates RXFP3 with a signaling profile different from that of relaxin-3. A positive allosteric modulator 135PAM1 has been described that displays probe selectivity with C-terminal amidated relaxin-3 or R3/I5 (Halls et al. 2015; Kocan et al. 2018). INSL5 differs from relaxin-3 that activates both RXFP3 and 4, in that it activates RXFP4 but acts as a weak antagonist at RXFP3. INSL5 A- and B-chains are also inactive at RXFP4. F20 is necessary for affinity and the B-chain C-terminus for activity without affecting affinity. Synthesis of human INSL5 is challenging leading to the development of simpler analogues that retain the C-terminus of the B-chain and interchain disulfide bonds necessary for activity. Some antagonists have been synthesized including minimized relaxin-3 analogue 3 and R3(BΔ23-27)R/I5 (Kocan et al. 2018). Small-molecule agonists active at RXFP3 and 4 are now starting to emerge that have many of the properties of the endogenous peptides (DeChristopher et al. 2019).

RAAS; Renin–angiotensin system (RAS)

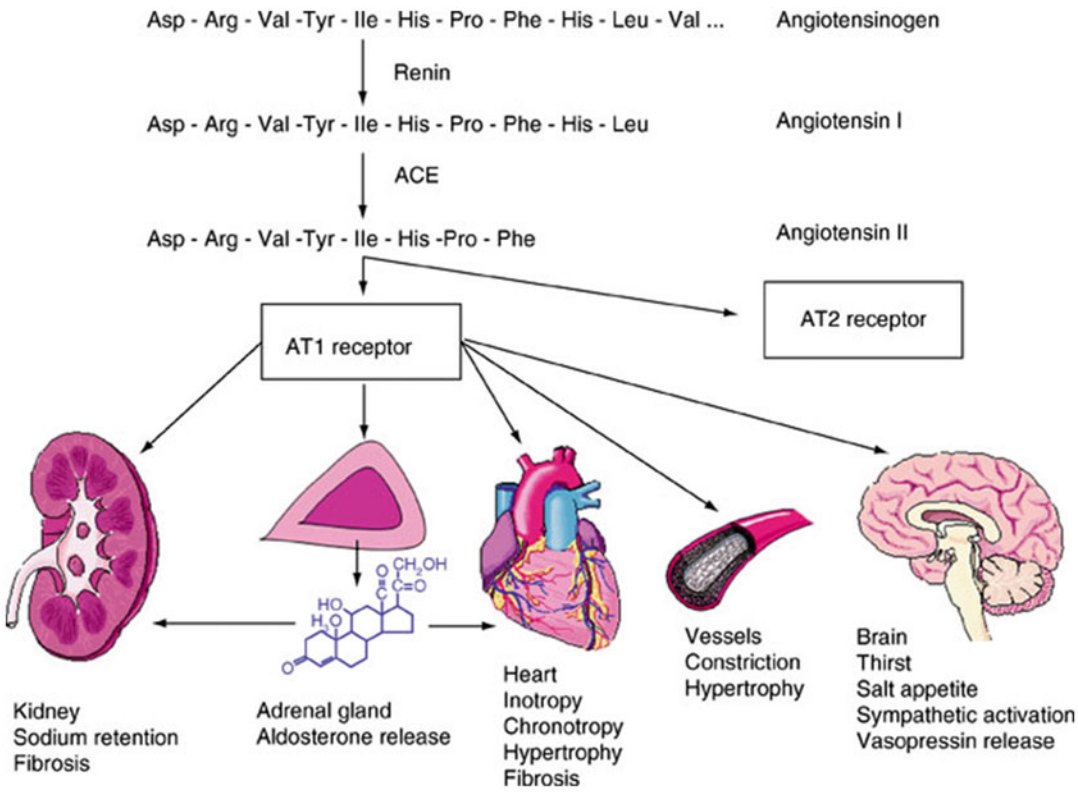
Definition

The renin–angiotensin–aldosterone system (RAAS) generates the peptide hormone angiotensin II and subsequently the mineralocorticoid aldosterone, which both exert considerable impact on blood pressure (blood pressure control) and fluid homeostasis and have prime etiologic and therapeutic significance for cardiovascular diseases.

Basic Characteristics

General

Renin is a circulating enzyme formed in specialized smooth muscle cells in the kidney that cleaves its only, liver-born substrate, angiotensinogen, in the plasma to form the inactive decapeptide angiotensin I (Bader 2010). Angiotensin I is then metabolized further into the octapeptide angiotensin II via the endothelium-bound angiotensin converting enzyme (ACE). Angiotensin II elicits an increase in blood volume and blood pressure by stimulating vasoconstriction, sodium retention, thirst, the sympathetic nervous system, and aldosterone secretion from the adrenal gland (Fig. 1). Aldosterone is a steroid hormone that binds to the mineralocorticoid receptor and amplifies the sodium-retaining effect. Physiologically this makes sense, since the RAAS is activated under conditions of acute volume loss by the induction of the rate-limiting enzyme renin. Major renin-inducing stimuli include a fall in renal perfusion pressure, a decrease in salt content in the distal tubule sensed and transmitted via the macula



Renin–Angiotensin–Aldosterone System, Fig. 1 Renin–Angiotensin–Aldosterone System

densa, an increase in the renal sympathetic tone, and a reduction in angiotensin II concentration employing a negative feedback mechanism. In addition to their hemodynamic actions, angiotensin II and aldosterone also induce growth- and fibrosis-related processes in several organs, such as vessels, heart, and kidney.

The renin–angiotensin–aldosterone system. Angiotensin II is generated in a two-step enzymatic process from the liver-borne protein angiotensinogen by the kidney-derived enzyme renin and the endothelium-bound angiotensin converting enzyme (ACE). The octapeptide interacts with two receptors, AT1 and AT2. The AT1 receptor confers most of the known actions of angiotensin II such as the liberation of aldosterone from the adrenal gland. Aldosterone via the mineralocorticoid receptor (MR) and angiotensin II together induce sodium retention in the kidney and fibrotic processes in kidney and heart. Moreover, angiotensin II elicits constriction of vessels, has positive inotropic and chronotropic actions on the heart, promotes growth in vessels and heart, and induces thirst, salt appetite, vasopressin release, and the activation of the sympathetic nervous system in the brain. Some of these effects are also mediated by locally produced angiotensin II in the respective tissues.

To elicit these effects, angiotensin II binds to two main receptors, AT1 and AT2, which both belong to the ▶ G-protein-coupled receptor family. Most of the abovementioned effects of angiotensin II are, however, mediated by the AT1 receptor, while the physiological function of the AT2 receptor is enigmatic. In most studied cases, the AT2 receptor counteracts the AT1 effects by exerting growth-inhibiting and vasodilatating actions partly by the stimulation of kinin generation. Therefore, AT2 agonists are developed for the therapy of multiple diseases.

Angiotensin II binding to the AT1 receptor stimulates via the G-protein, G_q, the activity of phospholipase C to generate the second messengers inositol phosphate (IP3) and diacylglycerol, and inhibits via G_i the activity of adenylyl cyclase to reduce the synthesis of cyclic AMP. Diacylglycerol activates protein kinase C and can be converted to arachidonic acid and Eicosanoids. Furthermore, angiotensin II induces the generation of reactive oxygen species by the stimulation of membrane-bound NAD(P)H oxidase. One of the immediate consequences of these early signals is activation of tyrosine kinases that include PYK2, c-Src, JAK2, platelet-derived growth factor (PDGF) receptor, and the epidermal growth factor (EGF) receptor, as well as of the serine/threonine kinases, ERK, Akt/protein kinase B and S6 kinase, and subsequent induction of immediate early genes and protein synthesis.

Besides the plasma renin–angiotensin system (RAS), intrinsic tissue RAS exist (Bader 2010). Angiotensin II is generated not only in the circulation but also locally in organs from precursors and enzymes either locally synthesized or imported from the plasma. These systems are autonomously regulated and have physiological functions inside the respective organs. Local RAS have been described for organs involved in cardiovascular control such as kidney, vessels, heart, adrenal gland, and brain.

Adrenal Gland

In the zona glomerulosa of the adrenal gland, renin is locally synthesized, and together with angiotensinogen and ACE generates angiotensin II, which acts as paracrine or intracrine hormone on adrenocortical cells. Circulating as well as this locally produced angiotensin II stimulates aldosterone release by increasing the expression of aldosterone synthase, the rate-limiting enzyme of aldosterone synthesis.

Kidney

The kidney contains the major site of renin synthesis, the juxtaglomerular cells in the wall of the afferent arteriole. From these cells, renin is secreted not only into the circulation but also into the renal interstitium. Proximal tubular cells synthesize angiotensinogen and ACE. The RAS proteins interact in the renal interstitium and in the proximal tubular lumen to synthesize angiotensin II. In the proximal tubule, angiotensin II activates the sodium/hydrogen exchanger (NHE) that increases sodium reabsorption. Aldosterone elicits the same effect in the distal tubule by activating epithelial sodium channels (ENaC) and the sodium-potassium-ATPase. Thereby, it also induces water reabsorption and potassium secretion.

In the interstitium, angiotensin II induces proliferation of mesangial cells and fibroblasts and the synthesis of collagen and other matrix molecules by these cells via the AT1 receptor. Moreover, by the concomitant stimulation of chemoattractant cytokines, inflammation is induced. These processes are mediated by endothelin, transforming growth factor β, and reactive oxygen species and finally lead to interstitial fibrosis and glomerulosclerosis observed in hypertension and diabetes.

Heart and Vessels

In heart and vessels, angiotensin II is generated mostly by renin and angiotensinogen imported from the plasma and locally synthesized ACE. Additionally in the human heart, mast cells contain the enzyme chymase that also metabolizes angiotensin I to angiotensin II. The physiological relevance of this enzyme is controversial. Circulating as well as locally generated angiotensin II induces vasoconstriction and exerts direct inotropic and chronotropic actions on the heart. These effects are enhanced by a facilitation of noradrenaline release from sympathetic nerve endings.

Alike in the kidney, angiotensin II also in the heart induces inflammation and fibrosis by increasing endothelin, transforming growth factor β, reactive oxygen species, and proinflammatory cytokines. Furthermore, angiotensin II induces hypertrophy of cardiomyocytes and smooth muscle cells in the heart and vessels, respectively, partially employing the same mediators. This is aggravated by increased circulating aldosterone levels that also elicit fibrotic processes in the heart by a yet unresolved mechanism.

Brain

Circulating angiotensin II can only reach the circumventricular organs of the brain, which express AT1 receptors and lack a blood-brain barrier normally limiting the access of peptides to brain receptor sites. However, areas beyond the blood-brain barrier have been shown to be responsive to angiotensin II and to express AT1 receptors. These sites are affected by locally synthesized RAS components. Possibly, other enzymes than renin may also be involved in angiotensin II generation in the brain, for example, cathepsins. Circulating and locally synthesized angiotensin II induces thirst, salt appetite, and vasopressin release, stimulates the sympathetic nervous system and moderates the baroreceptor reflex, and thereby increases blood volume and blood pressure.

Alternative RAS

Angiotensins can be further metabolized by ACE2 or neutral endopeptidase 24.11 (neprilysin, NEP) to angiotensin-(1–7) lacking the C-terminal Phe residue (Santos et al. 2018). This peptide interacts with its receptor Mas and has been shown to exert protective effects in cardiovascular tissues mostly opposing the actions of angiotensin II. Strategies to pharmacologically activate this system are pursued and may lead to novel drugs in the future.

Drugs

ACE Inhibitors

Pharmacological intervention in RAS began in the late 1960s with the discovery that the venome of the Brazilian snake *Bothrops jararaca* contains a substance that inhibits ACE. In first clinical trials, this substance proved to be a potent antihypertensive agent but it had the disadvantage that it could only be taken by injection. By modeling the active site of ACE and designing drugs potentially binding to this site, the first orally available ACE inhibitor, captopril, was discovered. In the meantime, at least a dozen compounds have been developed and marketed: captopril, enalapril, lisinopril, perindopril, cilazapril, benazepril, quinapril, fosinopril, ramipril, moexipril, and trandolapril. ACE inhibitors are first choice antihypertensive drugs. Furthermore, a multitude of large-scale clinical studies have proven a strong beneficial effect of these drugs on morbidity and mortality in congestive heart failure, for example, after myocardial infarction, and chronic renal diseases, for example, caused by diabetes or hypertension. In the heart, ACE inhibitors exert their beneficial actions by reducing preload and afterload and inhibiting myocardial fibrosis and remodeling processes. In the kidney, a reduction in glomerular pressure as well as antifibrotic and anti-inflammatory actions contribute to the efficiency of the drugs.

ACE not only activates angiotensin but is also involved in the metabolism of other peptides, for example, it is a major kinin-degrading enzyme. Therefore, ACE inhibitors also increase kinin concentrations. Furthermore, it has recently been shown that these drugs potentiate kinin effects by modulating a direct interaction between the ACE protein and the kinin B2 receptor, which is independent from the enzymatic activity of ACE. Kinin potentiation may be involved in the beneficial action of ACE inhibition since kinins are known to exert cardio- and renoprotective actions. However, it is also the major reason for the adverse side effects of ACE inhibitors, namely cough and angioedema. Another observed side effect, first-dose orthostatic hypotension, is probably due to both angiotensin inhibition and kinin potentiation.

Since angiotensin II is important for kidney development in mammals, ACE inhibitors and other drugs interfering with RAS should not be given during pregnancy.

AT1 Antagonists

A second group of drugs interfering with RAS are specific antagonists for the AT1 receptor. The first example of this class was losartan which was followed by at least seven other sartans (telmisartan, candesartan, valsartan, eprosartan, irbesartan, olmesartan, azilsartan). These drugs exert a more complete angiotensin blockade, since alternative pathways of angiotensin generation not affected by ACE inhibitors and employing cathepsins or chymase become ineffective by AT1 antagonism. They are also more

specific for the RAS than ACE inhibitors, since other peptide systems should not be affected. However, the compensatory increase in renin concentration after AT1 blockade leads to an accumulation of angiotensin II, which activates the AT2 receptor. It is yet unknown whether this AT2 stimulation often followed by kinin generation is involved in the action of AT1 antagonists.

In clinical trials, AT1 antagonists have proven to be as effective as ACE inhibitors in hypertension, congestive heart failure, and renal failure, with a more favorable side effect profile.

Renin Inhibitors

The most logical point to interfere pharmacologically with the RAS is the rate-limiting enzyme renin. Intervention at this step is more specific than ACE inhibition and AT1 antagonism, since hardly any angiotensin peptide can be generated and no other peptide system is directly affected. Therefore, fewer compensatory and unwanted effects are expected, and thus, renin inhibitors should be safe drugs. However, the development of such drugs faced several problems: First, since the human renin protein is different from the rodent enzymes and only interacts with primate or human angiotensinogen, the testing of such drugs cannot be performed in classical animal models. Second, the first renin inhibitors were difficult to synthesize and exhibited a low bioavailability. However, with the availability of a transgenic rat model expressing the human renin and angiotensinogen genes as test system novel substances could be developed. A first renin inhibitor, aliskiren, has been approved for clinical use after clinical trials which have proven its safety and efficacy (Musini et al. 2017).

Vasopeptidase Inhibitors

(Vasopeptidase inhibitors) Two new classes of drugs have been developed that inhibit NEP and one RAS component, either ACE or AT1. Besides generating angiotensin-(1–7) (see above), NEP also degrades vasodilatory peptides such as kinins, natriuretic peptides, and adrenomedullin, and therefore, its inhibition should complement the vasodilatory action of ACE or AT1 inhibition. Dual inhibitors for ACE and NEP, such as omapatrilat, sampatrilat, and gemopatrilat, were more effective than ACE inhibitors in blood pressure reduction in clinical trials, but also caused more side effects and therefore these drugs have been withdrawn. The most important side effects were partially life-threatening angioedema probably elicited by an overproduction of kinins which are degraded by ACE and NEP. Recently a combination drug, LCZ696, containing the NEP inhibitor sacubitril and the AT1 antagonist valsartan was approved for the treatment of heart failure after a successful clinical trial (McMurray et al. 2014). The side effect profile of this drug seems to be acceptable.

Aldosterone Antagonists

ACE inhibitors do not completely block aldosterone synthesis. Since this steroid hormone is a potent inducer of fibrosis in the heart, specific antagonists, such as spironolactone and eplerenone, have recently been very successfully used in clinical trials in addition to ACE inhibitors to treat congestive heart failure (Kapelios et al. 2019). Formerly, these drugs have only been applied as potassium-saving diuretics in edematous diseases, hypertension, and hypokalemia as well as in primary hyperaldosteronism. Possible side effects of aldosterone antagonists include hyperkalemia and, in case of spironolactone, which is less specific for the mineralocorticoid receptor than eplerenone, also antiandrogenic and progestational actions.

Retinoids

Pierre Germain, Albane le Maire and William Bourguet
Centre de Biologie Structurale (CBS), INSERM, CNRS, Université Montpellier, Montpellier, France

Synonyms

Retinoic acid; Vitamin A metabolites

Definition

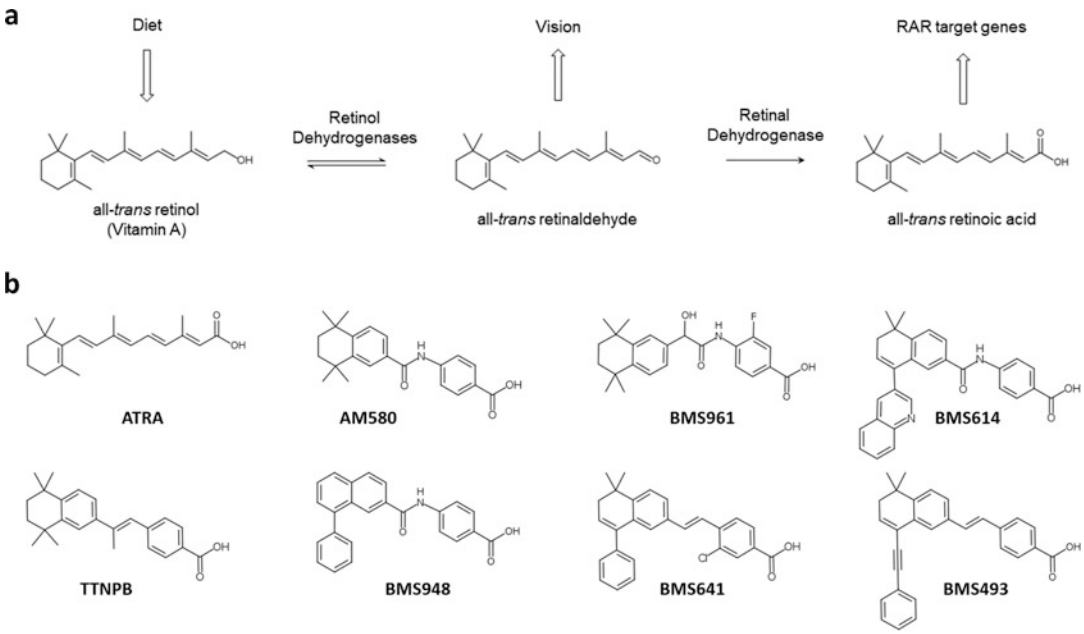
Retinoid is a generic term covering compounds that include both vitamin A (all-*trans* retinol) and its naturally occurring metabolites and synthetic analogs. These molecules are critical agents in a wide variety of essential biological processes, such as embryogenesis and organogenesis, apoptosis, reproduction, vision, and regulation of growth and differentiation of normal and neoplastic cells in vertebrates. The ability of these molecules to regulate expression of several hundred genes through binding to nuclear transcription factors (all-*trans* retinoic acid receptors (RARs)) is considered to mediate most of these functions (Chambon 1996; Mark et al. 2006).

Humans are unable to synthesize vitamin A *de novo* and must get it from the diet. Major sources of natural retinoids (retinol, retinyl ester, or beta-carotene) are animal fats, fish liver oil, and vegetables. All-*trans* retinoic acid (ATRA) is considered to be the main and the most potent biologically active metabolite of vitamin A (Blomhoff and Blomhoff 2006). The large group of synthetic retinoids covers a panel of modulators with activities ranging from agonists to inverse agonists. All these compounds are fat-soluble unsaturated isoprenoids, hydrophobic, and of small size, so that they can easily cross the lipid bi-layer of cell membranes. The basic structure of a retinoid is composed of three parts: a trimethylated cyclohexene ring that is a bulky hydrophobic group, a conjugated tetraene side chain that serves as a linker unit, and a polar carbon–oxygen functional group (Fig. 1). For instance, ATRA is composed of 20 carbon atoms arranged as a beta-ionone ring with a conjugated isoprene tail that terminates with a carboxylate functional group.

Basic Mechanisms

Transport, Biosynthesis, Metabolism

Vitamin A serves as a parent compound for active derivatives that impart two very different physiologic effects (Fig. 1a). All-*trans* retinaldehyde, an aldehyde derivative, is the active chromophore of



Retinoids, Fig. 1 Metabolic flow from vitamin A (all-*trans* retinol) to all-*trans* retinoic acid (ATRA). (**a**) In the cytosol, vitamin A is reversibly oxidized to all-*trans* retinaldehyde by members of the retinol dehydrogenase family. All-*trans* retinaldehyde, the active chromophore of vision, is irreversibly oxidized to the transcriptionally active ATRA by the retinal dehydrogenase (RALDH). (**b**) Chemical structures of a number of synthetic retinoids ranging from pan and subtype-selective RAR agonists (ATRA, TTNPB, AM580 (RARα), BMS948 (RARβ), BMS641 (RARβ), BMS961 (RARγ)) to the selective RARα antagonist (BMS614) and the pan RAR inverse agonist (BMS493)

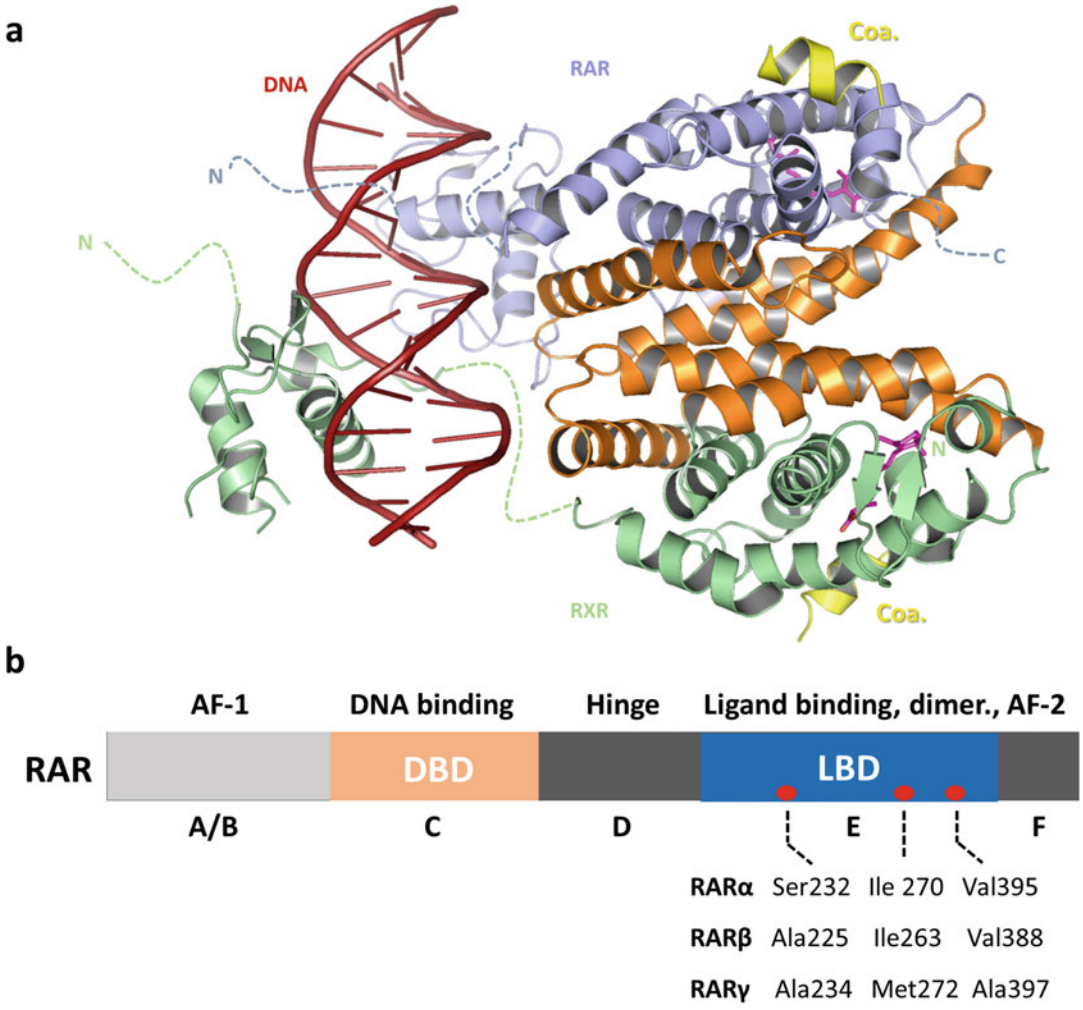
vision while ATRA plays a key role in genomic regulation and has the ability to reverse developmental defects in vitamin A-deficient (VAD) animals. In the body, retinoids need to be solubilized, protected, and detoxified (Blomhoff and Blomhoff 2006). To this end, various specific and aspecific binding proteins carry retinoids in both extracellular and intracellular environments. In the extracellular compartments, retinol-binding protein (RBP) is the most relevant retinoid binding protein and binds preferentially vitamin A. Other extracellular binding proteins show different binding preferences. Inside the cells, the two isoforms of the cellular retinoid acid-binding protein (CRBP1 and CRBP2) bind only ATRA, both CRBP3 and CRBP4 preferentially bind vitamin A, while the cellular retinal-binding protein (CRALBP) displays a marked preference for all-*trans* retinal. These CRBPs are not absolutely essential under circumstances of high dietary vitamin A supply. However, their importance becomes more evident when the dietary retinoid uptake is low and insufficient.

Active retinoids are produced *in vivo* from the oxidation of vitamin A (Fig. 1a). Synthesis of ATRA is a two-step enzymatic process in which the cytosolic alcohol dehydrogenase performs the oxidation of all-*trans* retinol to all-*trans* retinaldehyde, followed by the irreversible oxidation of the latter into ATRA by the retinaldehyde dehydrogenase (Blomhoff and Blomhoff 2006). This subsequent oxidation of all-*trans* retinaldehyde is the rate-limiting step in the ATRA production. On the other hand, to keep the level of ATRA within a narrow range, its concentration is maintained by its degradation into hydroxylated metabolites carried out by the cytochrome P450 CYP26 enzyme.

Nuclear and Nongenomic Signaling Pathways of RARs

Retinoids exert their pleiotropic effects through the three RAR paralogs RARα (NR1B1), RARβ

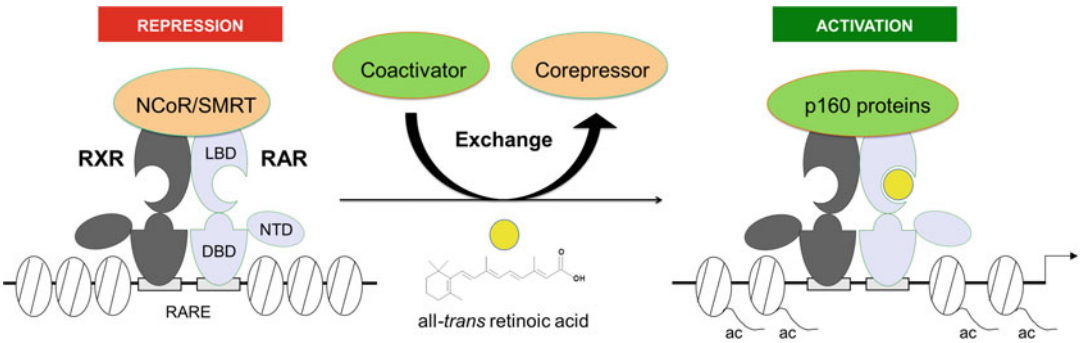
(NR1B2), and RARγ (NR1B3) that originate from three distinct genes and belong to the nuclear hormone receptor superfamily (Germain et al. 2006a, b; Khorasanizadeh and Rastinejad 2016). For each RAR subtype, several isoforms exist. RARs are modular proteins composed of six regions of homology (designated from A to F, from the N- to the C-terminal end) harboring specific functions (Fig. 2) (Chandra et al. 2017; Germain et al. 2006a, b). Regions C and E, which encompass the DNA binding domain (DBD) and the ligand binding domain (LBD), respectively,



Retinoids, Fig. 2 Structural and functional organization of RARs. (**a**) Crystal structure of RARβ/RXRα heterodimer bound to DNA (Chandra et al. 2017). LBDs (dark and light blue) and DBDs (dark and light green) are represented as ribbons. Helix H12 (AF-2) of each monomer is highlighted in purple. The coactivator peptides (Coa.) interacting with the heterodimer are drawn in yellow and the agonist ligand (9-*cis*-RA) in each subunit are drawn as pink sticks. Dotted lines denote regions with unresolved structures. (**b**) Functional organization of RARs. RARs consist of six functional domains (A–F) based on regions of conserved sequence and function. The DBD (C) mediates sequence-specific DNA recognition. The LBD (E) mediates ligand binding, dimerization, and a ligand-dependent transactivation function (AF-2). The N-terminal A/B region contains a ligand-independent activation function (AF-1). The region D corresponds to a linker allowing the proper orientation of DBD and LBD within DNA-bound dimers. The function of the F region is poorly understood. Residues of the ligand binding pocket specific of each RAR subtype are indicated

are the most conserved and important domains that govern the classical model of RAR transcriptional activity. In contrast, the A/B, D, and F regions are poorly conserved. The D region is considered to serve as a hinge between the DBD and the LBD, allowing different positions of the two domains. It might allow the DBD and the LBD to adopt different conformations without creating steric hindrance problems. D region also contains nuclear localization signals. The A and B regions correspond to the N-terminal domain (NTD) and includes the activation function AF-1 which plays a role in the control of transcription of retinoid target genes. It is interesting to note that within the NTD, the A region differs between the different subtypes and between isoforms. In contrast, the B region is rather conserved and depicts a proline-rich motif, which contains phosphorylation sites. Finally, not much information has been provided on the function of the C-terminal F domain.

In vitro studies demonstrated that RARs function essentially as heterodimers with the retinoid X receptors (RXRs) which are the functional entities and act as ligand-dependent transcriptional regulators by binding to the specific retinoic acid response element (RARE) DNA sequences found into the promoter region of retinoid target genes (Piskunov et al. 2014). RXR-RAR heterodimers control transcription *via* several distinct mechanisms, including both repression and activation (Fig. 3). In the absence of RAR agonist, the RXR-RAR heterodimer recruits the corepressor proteins NCOR1 (former N-CoR) or NCOR2 (former SMRT). These two major corepressors have been shown to mediate the active repression associated with unliganded (apo-) RARs and with many other transcription factors. Note in this respect that the three RAR subtypes display graded repression function, with RARα having the highest affinity for corepressors and RARβ exhibiting the weakest. Corepressors do not appear to possess intrinsic repressive properties but are rather large multidomain proteins that can be considered as docking platforms to tether the repression machinery to transcription factors. Indeed, NCOR1 and NCOR2, which share similar domain organizations, interact directly with DNA-bound unliganded RXR-RAR heterodimers through their nuclear receptor interaction domain (NRID) and allow the recruitment of various silencing factors such as histone deacetylases (HDACs) or DNA-methyl transferases (DNMTs) that may lead to an inactive condensed chromatin



Retinoids, Fig. 3 ATRA facilitates the exchange between corepressor and coactivator complexes that are central to the control of target gene transcription. RXR-RAR heterodimers bind to the specific retinoic acid response element (RARE) DNA sequences found in the promoter region of retinoid target genes. In the absence of ATRA, the RXR-RAR heterodimer recruits the corepressor proteins NCoR or SMRT and associated enzymatic factors that may lead to an inactive condensed chromatin structure, preventing transcription. Upon ATRA binding to the RAR ligand binding domain (LBD), corepressors are released, and coactivators (p160 proteins) are recruited. The subsequent recruitment of epigenetically active and/or chromatin-modifying complexes such as histone acetyltransferases or histone arginine methyltransferases leads to chromatin alterations that facilitate activation of target gene expression by the basal transcriptional machinery. *NTD* N-terminal domain, *DBD* DNA binding domain, *ac* acetyl

structure over the target promoter preventing transcription. Identification of HDAC3 as the catalytic component of corepressor complexes has provided a mechanistic link between transcriptional repression by RARs and histone deacetylation. Upon ATRA binding, RAR LBDs undergo a conformational change inducing the release of corepressor complexes and allowing the recruitment of a series of coactivator complexes. The p160 coactivator family includes SRC-1 (also known as NCoA1), TIF-2 (SRC-2 and GRIP1), and RAC3 (SCR-3, ACTR, TRAM-1, pCIP) that serve as adaptors recruiting other complexes with different enzymatic activities such as the histone acetyltransferases (HATs), CBP/p300 (CREB binding protein) and p/CAF (p300/CBP-associated factor), the histone methyl transferases (HMTs) CARM1 (coactivator-associated arginine methyltransferase 1) and PRMT1 (protein arginine methyl transferase 1), ubiquitinases/deubiquitinases or nucleosome remodeling complexes such as SWI/SNF (switch/sucrose nonfermenting). All these complexes alter the chromatin structure surrounding the promoter of target genes to allow their activation.

Beside their pivotal role in the genomic pathways of RARs, retinoids have also been shown to interact with a membrane-associated fraction of these receptors (Piskunov et al. 2014). Indeed, it is now well accepted that a few percent of RARs are associated with membrane lipid rafts in a number of cell types. Retinoid binding to membrane RARs rapidly (within minutes) induces cascades of transient interaction and activation of several types of kinases, thereby spreading signals to downstream cytosolic or nuclear machineries. These ATRA-activated kinases are able to phosphorylate several nuclear proteins involved in the transcription of retinoid target genes such as histones, RAR coregulators, and RARs themselves, thus indicating crosstalk between the genomic and nongenomic RAR signaling. Accordingly, RAR LBDs contain phosphorylation sites that serve as substrate for kinases including the cyclic AMP-dependent protein kinase (PKA) and stress-activated protein kinase (MSK1), while the NTD contains a proline-rich motif used by cyclin-dependent kinases (CDKs) and mitogen-activated protein kinases (MAPKs).

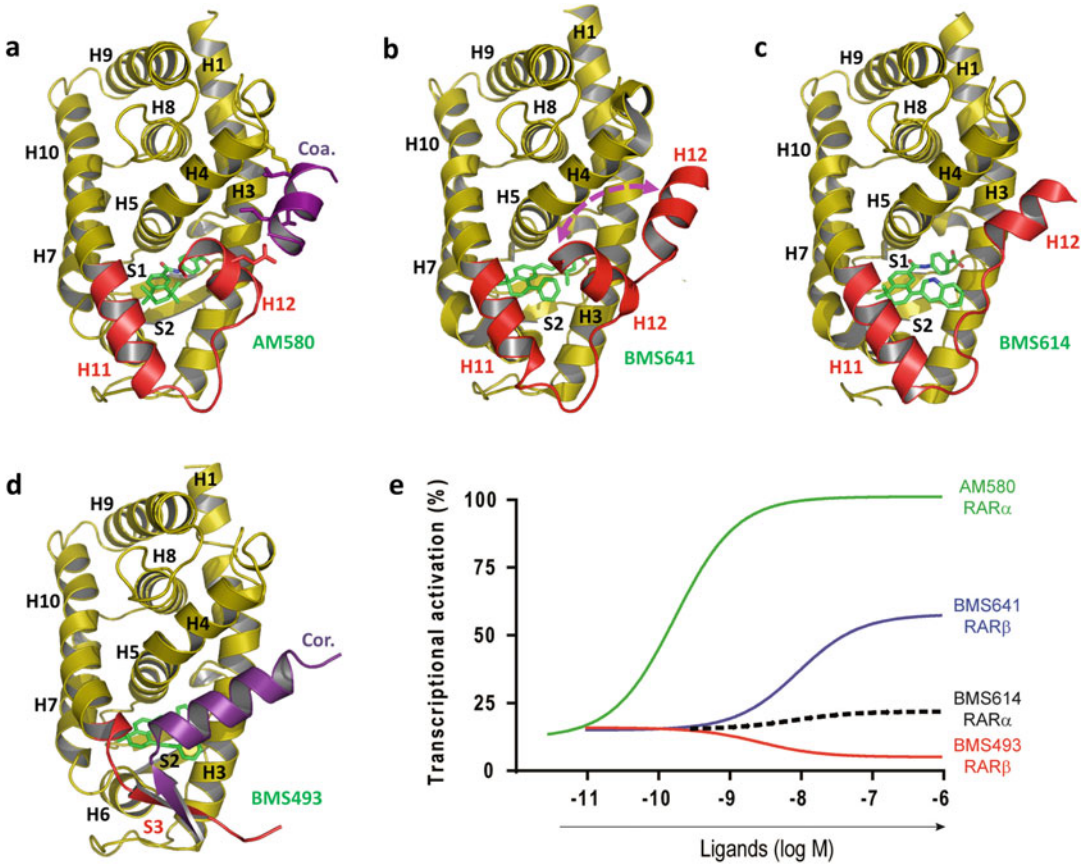
Various Classes of RAR Modulators

Whereas natural retinoids such as ATRA act as RARs activators and are therefore classified as "agonists," a plethora of synthetic ligands with a wide range of activities have been developed for potential therapeutic use (Fig. 1b) (Altucci et al. 2007). These derivatives have been shown to modulate the transcriptional activity of RARs in a positive or negative fashion and in a cell-specific manner. The spectrum of RAR modulators ranges from full agonists to pure antagonists through partial- and inverse agonists. As aforementioned, agonist ligands allow the recruitment of coactivators by RARs and the subsequent transcription of RAR-dependent genes. In contrast, by a mechanism described below, full or "neutral" antagonists prevent the association of RARs with any type of coregulatory proteins thus generating "necked" receptors characterized by very weak transcriptional activation or repression levels. Partial agonists lie between these two types of ligands so that they can act as cell-selective modulators with agonist or antagonist properties depending on the cellular context, in particular the ratio between coactivators and corepressor levels. The fourth pharmacological class of RAR ligands corresponds to that of inverse agonists which strengthen the interaction of the receptor with corepressors, thereby further increasing the basal repression function of RARs.

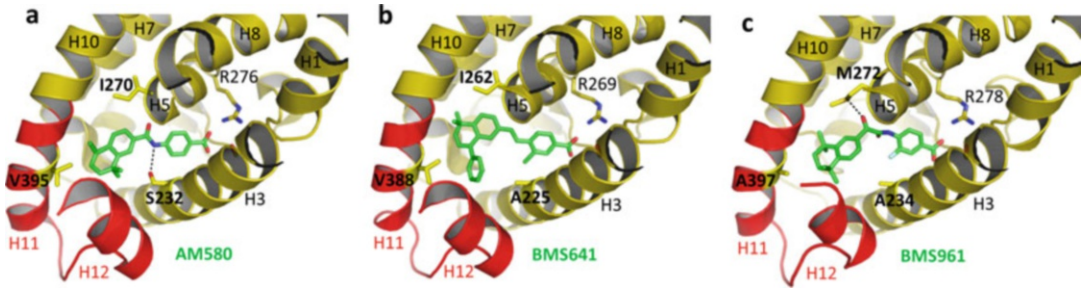
Structural Basis of Ligand Activity

Crystallographic studies of RAR LBDs in complex with all types of ligands have provided a deep insight into the molecular basis of ligand action, revealing how different pharmacological classes of ligands remodel the receptor surface to increase or reduce interaction with a given type of coregulator (le Maire and Bourguet 2014). The LBD of RARs is organized as an antiparallel α-helical sandwich with 12 conserved helices arranged in three layers with a β-turn (S1 and S2) located between helices H5 and H6. Helices H4, H5, H8, H9, and H11 are sandwiched between H1,

H2, and H3 on one side and H6, H7, and H10 on the other side (Fig. 4). In contrast, the C-terminal helix H12 (also termed activation or AF-2 helix) is flexible and can adopt various conformations depending on the type of bound ligand. This LBD architecture generates a ligand-binding pocket (LBP) primarily made of hydrophobic residues from helices H3, H5, H7, H11, and the β-sheet segment. Structural studies have revealed that ligands are stabilized in the RAR LBPs through extensive van der Waals contacts and a network of ionic and hydrogen bonds between their carboxylate moieties, a conserved arginine in H5, and water molecules (Fig. 5).



Retinoids, Fig. 4 Structural basis of retinoid receptor modulation by different classes of ligands. (**a**) Overall structure of the agonist (AM580, green sticks)-bound RARα LBD in complex with a coactivator fragment (Coa., purple). The C-terminal portion of the LBD that is subjected to important conformational changes is highlighted in red. (**b**) Overall structure of the partial agonist (BMS641, green sticks)-bound RARβ LBD. The pink harrows indicate that the activation helix remains dynamics in the presence of this type of ligand. (**c**) Overall structure of the antagonist (BMS614, green sticks)-bound RARα LBD. The antagonist extension of BMS614 prevents H12 from adopting the active conformation. (**d**) Overall structure of the inverse agonist (BMS493, green sticks)-bound RARα LBD in complex with a corepressor fragment. The CoRNR1 peptide (Cor., purple) is composed of a short β-strand and of a four-turn α-helix. Residues that belong to H11 in the other structures adopt a β-sheet (S3) conformation in this structure. H1-H12: α-helices 1 to 12, S1-S3: β-strand 1 to 3. (**e**) Functional classification of retinoids. Upon binding to RARs, retinoids control the expression of RAR target genes. AM580 fully activates transcription through RARα (green line) and is classified as full agonist. BMS641 exhibits a weaker efficacy than full agonists and is considered as a so-called partial agonist to RARβ (blue line). By preventing the interaction with both corepressors and coactivators, BMS614 is defined as neutral antagonist to RARα (dotted line). The so-called inverse agonist BMS493 increases the repression function of RARβ in keeping with its ability to strengthen the interaction of RARs with corepressors (red line)



Retinoids, Fig. 5 Structural basis for RAR-subtype selectivity. The ligand-binding pockets of RARα (**a**), RARβ (**b**), and RARγ (**c**) bound to their selective agonist AM580, BMS641, and BMS961, respectively, are shown. Amino acid side chains that differ between the different isotypes are depicted (yellow), together with the conserved arginine (H5) and serine (H3) (olive) that serve as anchoring points for the ligands. Dotted lines indicate key hydrogen bonds for ligand selectivity. H1-H12: α-helices 1 to 12

Agonist (*e.g.,* AM580, Fig. 1b) binding stabilizes a LBD conformation where the AF-2 helix seals the LBP (Fig. 4a). This particular position defines a hydrophobic surface comprising the C-terminal part of helix H3, helix H4, the L3–4 loop linking H3 and H4, and H12. This recognition surface accommodates the short LXXLL-containing helical motif of coactivator proteins. The coactivator helix is held in place by interactions of the leucine residues with the hydrophobic groove and by hydrogen bonds with a lysine at the C-terminus of H3 and a glutamate in H12 which together form a "charge clamp." It is noteworthy that this conformation is not specific to RAR as it can be observed in all agonist-bound NRs and thus, corresponds to the canonical transcriptionally active form of nuclear receptors (Fig. 4e).

In contrast to full agonists, partial agonists (*e.g.,* BMS641, Fig. 1b) are able to bind to RARs with high affinity, but even so, they incompletely stabilize the active form (Fig. 4b). The partial antagonist activity of these ligands is a consequence of the low interaction strength between H12 in the active position and the H3/H11 surface that renders the activation helix more dynamic. In this case, the association with coactivators is weaker than in the full agonist-bound situation. Nevertheless, the presence of coactivators helps stabilize the active conformation so the transcriptional outcome of partial agonist binding greatly depends on the intracellular concentration of coregulators (Fig. 4e).

The crystal structures of RAR LBD in complex with the antagonist BMS614 (Figs. 1b and 4c) or the inverse agonist BMS493 (Figs. 1b and 4d) show that these compounds encompass bulky extensions protruding between helices H3 and H11 which are too long to be accommodated within the LBP with H12 in the active conformation. A consequence of this steric clash is that the AF-2 helix either adopts an alternative conformation by docking to the coregulator binding groove, as seen in the BMS614 complex, or has no defined position and appears highly mobile, as in the presence of BMS493. By relocating the AF-2 helix to the coregulator groove, the antagonist BMS614 prevents any interaction with both coregulator types and renders the receptor transcriptionally silent (Fig. 4e). In contrast, the inverse agonist BMS493 favors the recruitment of corepressors by generating an interaction surface for the CoRNR1 motif present in NCOR1/2 and therefore increases the repression function of RARs (Fig. 4e). Unlike the AM580, BMS641, and BMS614 complexes in which residues C-terminal of helix H10 adopt a helical structure (H11), these residues assume an extended β-strand (S3) conformation in the BMS493 complex, allowing for the formation of an antiparallel β-sheet with N-terminal residues of CoRNR1 (compare Fig. 4a–d). The remainder of CoRNR1 folds as a four-turn α-helix that docks into the coregulator groove of RAR through the conserved LXXXIXX(I/V)IXXX(Y/F) motif reminiscent of

the short LXXLL sequence of coactivators (le Maire et al. 2010).

RAR-Subtype Selective Retinoids

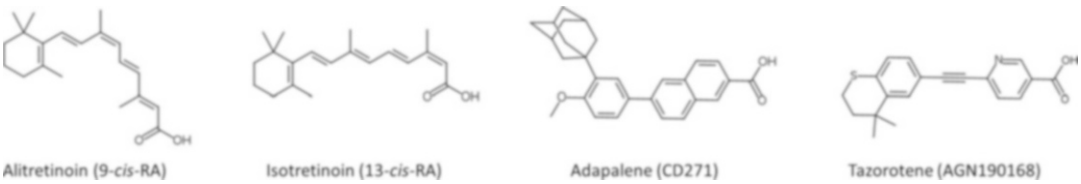
While topologically very similar, the LBPs of RARα, β, and γ differ by three residues located in helices H3, H5, and H11, and these amino acid divergences have been exploited for the design of synthetic retinoids with RAR-subtype selectivity that represent unique pharmacological tools for the study of RARs-specific functions (le Maire et al. 2012, 2019). In their LBPs, RARα (Ser232, Ile270, Val395) and RARβ (Ala225, Ile262, Val388) differ just by one amino acid in helix H3, whereas RARβ and RARγ (Ala234, Met272, Ala397) differ by two residues located in helices H5 and H11 (Fig. 2). RARα selectivity is favored by the formation of a specific hydrogen bond between serine residue S232 in H3 and a nitrogen atom of an amide bond as observed with AM580 (Fig. 5a), whereas the presence of an hydrogen bond between methionine M272 in helix H5 and an hydroxyl moiety present in the central region of the ligand is a characteristic feature of selective RARγ ligands, as exemplified by BMS961 (Fig. 5c). Finally, RARβ selectivity exploits the presence of a somewhat larger LBP subpocket that is able to accommodate bulkier groups attached to the ligand as, for example, in the case of BMS641 (Fig. 5b).

Pharmacological Relevance

Retinoids in Medical Use

RARs have been associated with several diseases such as cancer or skin disorders. Accordingly retinoids are used in a variety of chemopreventive and chemotherapeutic settings (di Masi et al. 2015; Uray et al. 2016). Three generations of retinoid acid analogs have been generated for systemic and topical treatment of various skin disorders (Fig. 6). The first generation includes nonaromatic retinoids such as vitamin A, ATRA (tretinoin), 13-*cis*-RA (isotretinoin), and 9-*cis*-RA (alitretinoin). The second generation of molecules includes monoaromatic retinoid analogs and the third generation of compounds corresponds to polyaromatic derivatives such as adapalene (CD271) and tazorotene (AGN190168). It is noteworthy that thousands of synthetic retinoids have been developed up to now. The recognized potential of retinoids in skin disorders was demonstrated by the clinical efficacy of ATRA in keratinizing disorders. However, ATRA was considered too toxic and minor structural changes of this molecule yielding *cis*-isomers resulted in oral retinoids with improved pharmacological properties. In particular, 9-*cis*-RA and 13-*cis*-RA are used for dermatological indications including acne, psoriasis, antiaging, or photo-damage. In addition to these ATRA isomers, the two synthetic retinoids adapalene and tazarotene are also efficient for the treatment of acne and stable plaque psoriasis, respectively.

Retinoids are mostly involved in the regulation of processes like differentiation and cell death which play critical roles in the outcome of malignant transformation of tissues. The most direct implication of RAR in human cancer is given by acute promyelocytic leukemia (APL), which is caused by a somatic translocation between chromosomes 15 and 17 that fuses RARα and promyelocyte leukemia protein (PML) human genes, leading to the alteration of the signaling of both RARα and PML proteins (de The et al. 2017). The resulting fusion protein PML-RARα contains large parts of both proteins, including the LBD



Retinoids, Fig. 6 Retinoids in clinical use. For each molecule, the name of the commercial drug is given as well as the chemical name in brackets

and the DBD of RARα, and displays increased binding efficiency to transcriptional corepressors which do not dissociate in the presence of physiological concentrations of ATRA. The subsequent silencing of RAR target genes arrests myelopoiesis at the promyelocyte stage and prevents the differentiation of APL cells. However, the use of supraphysiological doses of ATRA induces dissociation of the silencing complex, postmaturation apoptosis, and remission in patients with APL. Therefore, ATRA-based differentiation therapy of APL restores normality by guiding the cancer cell back into the regular cycle of a differentiated cell and forces it into death. In addition to this successful retinoid-based differentiation therapy, retinoids are used as chemopreventive agents and to treat various cancers such as refractory cutaneous Kaposi's sarcoma (9-*cis*-RA), cutaneous T-cell lymphoma (CTCL) (tazarotene), and neuroblastoma (13-*cis*-RA).

Retinoids as Pharmacological Tools

RARs are attractive drug targets because they are master regulators of a large variety of major (patho)physiological processes and their cognate ligands are small molecules that are convenient for chemical synthesis. Moreover, the success of the cancer differentiation therapy in the ATRA-treated APL has stimulated considerable interest in fields of retinoid research. However, despite their chemotherapeutical potential, retinoic acids can be both beneficial and detrimental, and their pharmacological use has been restricted because of their pleiotropic activities and their teratogenic effects. Accordingly, a major goal of drug development is the generation of RAR modulators that display increased target selectivity and/or functional specificity in order to overcome the limitations of current drugs. In addition, even if a great number of gene ablation studies have partially revealed the global impact of RARs in physiological processes, there is still a need for pharmacological agents to address the specific function of RAR subtypes *in vitro* and in animal models. Overall, the challenge is to integrate the structural and molecular biological information accumulated over the years into studies on the (patho) physiological relevance of RAR signaling, to provide novel tools for research and therapy. Then major synthetic chemistry efforts have been directed to the identification of potent compounds leading to the generation of thousands of configurationally and/or conformationally restricted analogs of ATRA. Importantly, subtle changes in the chemical structure of these synthetic retinoids can direct the activity toward various types of functional specifications, such as agonism/antagonism/inverse agonism, subtype selectivity, or cell/pathway selectivity, and translate into very selective effects on the transcriptional potential of the receptor. Of note, it is of utmost importance to accurately characterize these modulators for an appropriate use avoiding data misinterpretations. Accordingly, the molecular details by which synthetic retinoids direct specificity and functionality of RARs have to be precisely uncovered (le Maire et al. 2019). It has been possible to generate entirely RAR subtype-selective agonists, such as AM580 (RARα), BMS948 (RARβ), and BMS961 (RARγ) (Fig. 1b). Note that to be considered as selective a given ligand (agonist and antagonist) has to exhibit an affinity difference greater than 100-fold between its primary target and other receptors (see International Committee of Pharmacology Committee on Receptor Nomenclature and Classification). Under 100-fold difference, the ligand may be defined as a compound that shows a preference for a given receptor. Hence, the potency (amount of a drug that is needed to produce a defined effect) of the compound has to be considered. Another property to consider is the transcriptional efficacy of the compound, namely maximum effect that a drug can produce regardless of dose, and consequently independent of its binding affinity. The differential interaction with coregulators is the basis of the diverse functionality of retinoids and allows their functional classification as agonists (*e.g.,* AM580), partial agonists (*e.g.,* BMS641), neutral antagonists (*e.g.,* BMS614), and inverse agonists (*e.g.,* BMS493), as described above. As coregulators are platforms for complexes with epigenetic activities, such as histone methylation/acetylation and deacetylation, such different classes of ligands can be used to regulate RAR-mediated gene programs in very different directions.

Definition

Rheumatoid arthritis (RA) is best thought of as an inflammatory syndrome with autoimmune features with its predominant expression in synovial joints. It is the most common form of inflammatory polyarthritis. Current thinking favors the hypothesis that interplay between genetic factors, sex hormones, and possibly an infectious agent or another immune-activating agent initiates an autoimmune pathogenic mechanism that culminates in a disease with inflammatory and destructive features.

To date there are no laboratory tests that are pathognomonic for RA, but the presence of anti-cyclic citrullinated protein antibody (ACPA) and/or IgM rheumatoid factor is relatively specific for this condition. However, neither of these tests are sufficiently specific to establish the classification of RA, and prognosis varies widely within seropositive and seronegative patient populations, respectively. Because of the heterogeneity in presentation and disease course, in order to recruit relatively homogeneous populations into clinical trials, the American College of Rheumatology formulated the 1987 revised classification criteria for the diagnosis of RA (Arnett et al. 1988) based on a hospital population of patients with established, active disease. These criteria combined a constellation of clinical, serological, and

radiological features that help to differentiate RA from other forms of inflammatory arthritis with a diagnostic sensitivity and specificity of about 90% for active disease. However, these requirements have a much poorer sensitivity for a diagnosis of RA in the early stages of presentation at which time there may be an insufficient number of features required to satisfy the classification criteria. Recognizing that best outcomes are achievable when treatment intervention is as early as feasible in the evolution of the illness, updated classification criteria were published in 2010 by the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) and designed to identify patients with unexplained synovitis in at least one peripheral joint and a short duration of symptoms who would benefit from early therapeutic intervention (Aletaha et al. 2010). In this system, a score-based algorithm is employed for the classification of RA based on four domains: joint involvement; serological test results; acute-phase reactant test results; and patient self-reporting of the duration of signs and symptoms. The maximum number of possible points is 10, and classification of definitive RA requires a score of 6/10 or higher. Patients with a score lower than 6/10 should be reassessed over time. If patients already have erosive changes characteristic of RA, they meet the definition of RA, and application of this diagnostic algorithm is unnecessary. The score is calculated as shown in Table 1.

Rheumatoid Arthritis, Table 1 The 2010 ACR/EULAR classification criteria for RA

Joints Distribution (0–5)	
1 Large joint	0
2–10 Large joints	1
1–3 Small joints (large joints not counted)	2
4–10 Small joints (large joints not counted)	3
>10 joints (at least one small joint)	5
Serology (0–3)	
Negative RF *and* negative ACPA	0
Low-positive RF *or* low-positive ACPA	2
High-positive RF *or* high-positive ACPA	3
Symptom Duration (0–1)	
<6 weeks	0
≥6 weeks	1
Acute Phase Reactants (0–1)	
Normal CRP *and* normal ESR	0
Abnormal CRP *or* abnormal ESR	1

Basic Mechanisms

Characteristics

Once established, RA is characterized by deforming symmetrical polyarthritis associated with synovitis of joint and tendon sheaths, articular cartilage loss, and erosion of juxta-articular bone of varying extent and severity (Taylor 2006). IgM rheumatoid factor is detectable in the blood in a majority of patients. It is an autoantibody whose autoantigen is the Fc portion of IgG. The prevalence of rheumatoid factor increases with duration of disease in rheumatoid arthritis: at 3 months the prevalence is 33%, while at 1 year it is 75%. Up to 20% of RA patients remain negative for rheumatoid factor (also known as "seronegative rheumatoid arthritis") throughout the course of their disease. Antibodies to cyclic-citrullinated peptides (anti-CCP) have a similar sensitivity to rheumatoid factor, but higher specificity (Taylor 2019b). As in the case of high-titer rheumatoid factor, anti-CCP antibodies are associated with persistence and destructiveness of rheumatoid arthritis and may precede the onset of clinical disease.

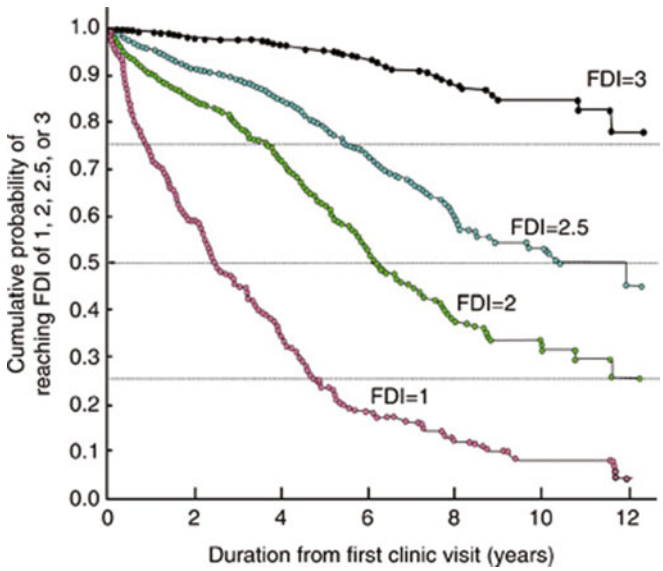
In a proportion of patients, systemic and extra-articular features may be observed during the course of the disease (and rarely prior to joint disease). These include anemia; weight loss; vasculitis; serositis; nodules in subcutaneous, pulmonary, and sclera tissues; mono-neuritis multiplex; and interstitial inflammation in lungs as well as in exocrine salivary and lacrimal tissue. However, these systemic manifestations occur relatively late in the disease progression.

The clinical presentation of RA is heterogeneous with a wide spectrum of age of onset, degree of joint involvement, and severity. Similarly, the disease course of RA is variable. This ranges from a brief, mild, self-limiting oligoarticular illness with minimal joint damage to a sustained polyarticular, synovial inflammation resulting in relentlessly

progressive cartilage destruction, erosion of bone, and ultimately changes in joint integrity with corresponding functional impairment. Up to 90% of patients with marked synovitis have radiographic evidence of bone erosion within 2 years of diagnosis, despite treatment with conventional synthetic disease-modifying anti-rheumatic drugs, the most commonly prescribed being MTX, leflunomide, sulfasalazine, and hydroxychloroquine. If disease remains uncontrolled, without successful intervention with a targeted therapy, the majority of patients with a more aggressive disease evolution become clinically disabled within 20 years (Fig. 1). For those with severe disease or extra-articular features, the mortality is equivalent to that of patients with three vessel coronary artery disease or stage IV Hodgkin's lymphoma.

Cellular Pathology

RA is characterized by chronic inflammation of synovial joints with synovial proliferation and infiltration by blood derived cells, in particular, memory T cells, macrophages, and plasma cells, all of which show signs of activation. Prominent vasculature is a feature of RA synovitis that is observed as a fine network of vessels over the rheumatoid synovium at arthroscopic inspection of RA joints. Angiogenesis is evident on microscopic examination of synovial biopsies from the earliest stages of disease development. Formation of new blood vessels permits a supply of nutrients and oxygen to the augmented inflammatory cell mass and so contributes to the perpetuation of synovitis. In the chronic phase of disease, capillaries and post-capillary venules are particularly evident in the synovial sublining region. In histological sections mononuclear and polymorphonuclear leukocytes can sometimes be found in close apposition to vascular endothelium, probably in the process of margination and adhesion prior to migration into the inflamed tissue. The synovial tissue becomes markedly hyperplastic and locally invasive at the interface of cartilage and bone with progressive destruction of these tissues in the majority of cases. This invasive tissue is referred to as "pannus," comprising mainly lining cells with the appearance of proliferating mesenchymal cells with very little sublining lymphocytic infiltration. The accompanying destruction of bone and cartilage is thought to be mediated by cytokine-induced degradative enzymes, notably the matrix metalloproteinases. Although RA has its principal manifestation in joints, there is also evidence of systemic involvement, for example, the upregulation of acute phase proteins, and a wide variety of extra-articular features may develop. These occur predominantly in patients who are rheumatoid factor positive and carry the HLA-DR4 gene.



Rheumatoid Arthritis, Fig. 1 The development of disability over time in a group of RA patients studied prior to the era of targeted therapies. *FDI* functional disease index where 1 = moderate disability, 2 = more marked disability, 3 = severe disability, and 4 = very severe disability. (From Wolfe and Cathey 1991)

Genetic Factors

Genetic factors were originally implicated in the etiopathogenesis of RA following the discovery that in population studies, there is a slight increase in the frequency of RA in first-degree relatives of patients with this disease, especially if seropositive for rheumatoid factor. In hospital-based population studies of identical twins, concordance rates of disease are around 30%, compared with 5% in nonidentical twins. The figures are lower in community-based studies and, although still supportive of the concept of a genetic contribution, argue against the proposition that RA is the result of a dominant single-gene disorder. These and other epidemiological studies have led to the conclusion that RA is a polygenic disease and that non-inherited factors are also of great importance (Kurkó et al. 2013).

Genes encoding particular class II human leukocyte antigens (HLA) are among candidates for involvement in predisposition to RA. This discovery came about with the observation that 60–70% of Caucasian patients with RA are HLA-DR4 positive by cellular or serological techniques compared with 20–25% of control populations. Furthermore, patients with more severe RA, especially those with extra-articular complications such as vasculitis and Felty's syndrome, are even more likely to be HLA-DR4 positive than patients with less severe disease confined to joints.

Class II HLA molecules are expressed on the surface of antigen-presenting cells. They play a key role in presentation of processed linear peptide antigens of at least nine amino acids to T cells. Antigen is bound to the HLA-binding cleft formed by the α and β chains of the HLA class II molecule. This trimolecular HLA–antigen complex binds in turn to the variable portion of the T-cell receptor.

Nucleotide sequencing of HLA-DR β *1* exons coding amino acid residues 70–74 has revealed that HLA-DR4 subtypes Dw4, Dw14, and Dw15 share similarities with each other (with a conservative substitution of glutamine with lysine at position 71 in Dw4) and with HLA-DR1. The sequence predicts susceptibility to RA and is associated with RA in 83% of Caucasian patients in the United Kingdom. In contrast, negative associations are observed in individuals who are DR4w10, in whom the charged basic amino acids glutamine and arginine in positions 70 and 71 are replaced by the acidic amino acids aspartic and glutamic acid. In Dw13 individuals, in whom a negative association is also observed, arginine is substituted for glutamic acid in position 74. Molecular modelling studies suggest that amino acid residues 70–74 are located in the α-helix forming the wall of the peptide-binding groove and thus likely to be involved in antigen binding and subsequent interaction with T-cell receptors (Kurkó et al. 2013). Acidic substitutions could profoundly alter protein structures and thereby alter affinity for peptide antigens. However, molecular mechanisms accounting for susceptibility to RA remain to be elucidated. Possibilities include permissive binding of specific peptides such as those on autoantigens or on environmental antigens, initiation of disease by specific binding of superantigens to HLA molecules, or modulation of the T-cell repertoire by selection or tolerance. HLA and some non-HLA genes have been linked to autoimmunity to citrullinated proteins (anti-CCP) as well as smoking. Smoking, oral microbiota, and possibly other environmental and lifestyle-related factors may trigger the development of anti-CCP in some patients. It has been hypothesized that the severity of disease and extra-articular complications are related to homozygosity and the density of disease-associated MHC molecules that critically influence the selection of the T-cell repertoire and tolerance to antigens.

Cytokines

Cytokines are small, short-lived proteins and important mediators of local intercellular communication. Cytokines mediate both innate and adaptive immune cellular responses and play a key role in integrating responses to a variety of stimuli that contribute to inflammation and joint injury that characterize RA pathology. Much of the activity of key cytokines in RA pathology is paracrine in nature. By binding their cognate receptors on target cells in their immediate vicinity, these molecules participate in many important biological

activities including cell proliferation, activation, death, and differentiation. In experimental systems, some cytokines are proinflammatory, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF); others, such as interleukin-10 (IL-10) and transforming growth factor β (TGFβ), exert predominantly anti-inflammatory effects. However, it is now known that many cytokines, for example, interferon γ (IFNγ), with chiefly proinflammatory activity can also in some instances have anti-inflammatory properties. Similarly, IL-10 and TGFβ may also exhibit proinflammatory properties under certain experimental conditions. Interleukin-6 (IL-6) does not have a classical pro-inflammatory action but has been implicated in the process of erosion of bone in inflammatory arthritis. Paracrine or autocrine pathways involving cytokines with either pro- or anti-inflammatory activity form complex networks determining whether chronic inflammation results. Following engagement with receptors on the surface of responder cells, cellular responses are mediated by an intracellular cascade of phosphorylation steps through a number of distinct signaling pathways. As understanding of cytokine signaling has advanced, various intracellular signaling molecules have been proposed as potential therapeutic targets. The Type I/II cytokines, which include IL-6, signal through the Janus kinase (JAK) enzymes comprising a family of four intracellular tyrosine kinases. The only targeted small molecule therapies to be approved for RA to date are JAK inhibitors.

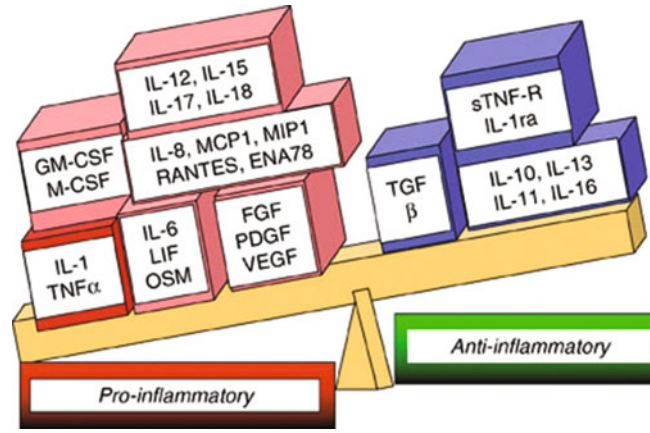
Role of Cytokines in the Pathogenesis of RA

Cytokines derived from macrophages and fibroblasts are abundant in the rheumatoid synovium. These include IL-1, TNF, granulocyte macrophage colony-stimulating factor (GM-CSF), IL-6, and numerous chemo-attractant cytokines known as chemokines. Many of these factors are of importance in regulating inflammatory cell migration and activation. By contrast, given the extent of synovial inflammation and lymphocytic infiltration, factors produced by T cells, for example, IFNγ, interleukin-2 (IL-2), and interleukin-4 (IL-4), are surprisingly sparsely expressed. However, there are a number of cytokines that cause co-stimulation of T helper cells including interleukin (IL)-7, IL-12, IL-15, and IL-18. There is a predominance of Th1 cell activity, as defined by IFNγ production, and low Th2 cell activity as defined by IL-4 production (Firestein and McInness 2017).

An extensive range of proinflammatory cytokines can be detected in RA synovial samples, regardless of differences in donor disease duration, severity, or even conventional (non-biologic) drug therapy. Proinflammatory cytokines are spontaneously produced over several days in dissociated RA synovial membrane cell cultures comprising a heterogeneous population of cells. This occurs in the absence of extrinsic stimulation, suggesting that the cultures produce one or more soluble factors regulating prolonged cytokine synthesis. Addition of anti-TNF antibodies to these cell cultures was observed to strikingly reduce the production of other proinflammatory cytokines, including IL-1, GM-CSF, IL-6, and IL-8. In contrast, blockade of IL-1 by means of the IL-1 receptor antagonist results in reduced production of IL-6 and IL-8 but not that of TNF. These observations led to the concept that TNF occupies a dominant position at the apex of a proinflammatory cytokine network.

In support of the concept of a cytokine disequilibrium within the chronic inflammatory situation in rheumatoid synovium is the observation that multiple anti-inflammatory mediators are also upregulated, but at a level insufficient to suppress synovitis. Examples include the abundant expression of IL-10, IL-13, and TGFβ both in latent and active form. Naturally occurring cytokine inhibitors, such as interleukin-1 receptor antagonists (IL-1ra) and soluble TNF receptors, the specific inhibitors of IL-1 and TNF, respectively, are also upregulated in the rheumatoid joint (Fig. 2).

TNF is a pleiotropic cytokine with biological properties that include enhanced synovial proliferation, production of prostaglandins and metalloproteinases, as well as regulation of other proinflammatory cytokines. The predicted clinical success of anti-TNF therapy in RA was based on the demonstration of RA synovial tissue expression of TNF and its receptors, in vitro experiments employing dissociated synovial cell cultures, and



Rheumatoid Arthritis, Fig. 2 The concept of a cytokine disequilibrium. Many cytokines are detectable in rheumatoid synovial tissues, including those with predominantly anti-inflammatory properties. But the net effect is a dominance of proinflammatory activity

preclinical in vivo studies. A number of independent in vivo studies demonstrated that antibody therapies blocking bioactivity of TNF, administered either during the induction phase of murine collagen-induced arthritis or, more importantly, after the onset of disease, were able to ameliorate clinical symptoms and prevent joint destruction. Furthermore, in a murine model, the overexpression of a human TNF transgene modified at its 3′ end to prevent degradation of its mRNA was associated with the development of a destructive form of polyarthritis 4–6 weeks after birth. This could be prevented by administration of a human TNF-specific mAb.

Pharmacological Intervention

A major emphasis in the management of RA over recent years has been on early diagnosis and treatment, before the onset of erosions, in order to best realize opportunities to achieve and sustain the ideal goal of remission and to prevent joint damage and disability. The heterogeneity of presentation of RA and subsequent disease course is such that pharmacological treatment will need to be adapted to the needs of the individual. Optimum suppression of inflammation is considered the most effective means to achieve optimal outcomes. In early RA, treatment is initiated with a csDMARD, most commonly methotrexate, unless contraindicated. Methotrexate can be administered either orally or parenterally and has a large dose-titratable range. Because of these features, as well as its efficacy, safety, and cost-effectiveness, methotrexate holds a unique place in the management of RA (Taylor et al. 2019). Methotrexate monotherapy is recommended as an initial pharmacological strategy, but it can also be used as an "anchor drug" in combination with another csDMARDs or targeted therapies. Symptomatic benefit following initiation of csDMARDs tends to be relatively slow in onset, often taking many weeks. Short-term glucocorticoids are often used as a "bridging" therapy when a more slowly acting oral csDMARD is initiated so that rapid suppression of synovitis can be achieved before the slower benefits of the csDMARD are expressed. Corticosteroids can be used effectively in a range of dose regimens and routes of administration but should be tapered as rapidly as clinically feasible.

There have been unprecedented advances in our understanding of the pathophysiology of RA over the last few decades which have been translated into a broad range of efficacious, so-called targeted, therapies directed against relevant cells and molecules contributing to disease pathogenesis. These include parenterally administered biologic DMARDs (bDMARDs) and orally available targeted synthetic DMARDs (tsDMARDs). bDMARDs are protein-based drugs derived from living organisms that are designed to either inhibit or augment specific component of the immune system.

The first bDMARDs to be approved were TNF inhibitors. The first generation of bDMARDs, referred to as bio-originators, was approved with finite patent life. Following patent expiry of the

earliest bio-originator bDMARDs, biosimilars have emerged. A biosimilar is a biological medicinal product that is highly similar to an already authorized original biological medicinal product (reference medicinal product or bio-originator) in terms of quality, safety, and efficacy, based on a comprehensive comparability exercise. Following their introduction to the clinic, in many healthcare economies high procurement costs of bio-originator bDMARDs limited their access to patients meeting eligibility criteria. In the case of the class of anti-TNF bDMARDs, bio-originators included three monoclonal antibodies (infliximab, adalimumab, and golimumab), a TNF receptor fusion protein (etanercept), and a pegylated antibody-binding fragment (certolizumab). There are now several biosimilars of infliximab, etanercept, and adalimumab which are introducing cost competition and may potentially widen patient access to the anti-TNF bDMARD class. Another class of bDMARDs directed against cytokines comprise antibodies directed against interleukin-6 receptor (IL6R). Two bio-originator anti-IL6R mAbs have been approved, tocilizumab and sarilumab.

An entirely different treatment approach to the blockade of pro-inflammatory cytokines is the targeting of cells implicated in the persistence of RA. At present there are two other classes of bDMARD with specificity for cellular targets, namely, cell surface molecules associated with B cell subsets, most notably CD20, and co-stimulation molecules expressed on antigen-presenting cells that recognize cognate ligands on T cells. There is one approved bio-originators directed against the CD20 antigen expressed on a B cell subset, rituximab, and there are now approved biosimilars. The bio-originator abatacept is the only representative of the final class of currently approved bDMARD. It is an inhibitor of the CD28-CD80/86 co-stimulatory signal necessary for T cell activation comprising a fusion protein composed of the Fc region of the human IgG1 fused to the extracellular domain of cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4).

In contrast to bDMARDs, which are large molecular weight proteins that must be injected and are incapable of penetrating the lipid bilayer of cell membranes, tsDMARDs are low molecular weight, orally available, "small molecules." The only tsDMARDs currently available for the treatment of RA are JAK inhibitors or "jakinibs," multi-cytokine inhibitors that can cross the cell membrane to block activity of one or more cytoplasmic JAKs. Tofacitinib selectively inhibits JAK1 and JAK3 and was the first JAK inhibitor to be approved, initially with twice daily dosing. A modified release formulation for once daily use has since been developed. Baricitinib selectively inhibits JAK1 and JAK2 and is dosed once daily. Both drugs have undergone extensive clinical trials and demonstrated rapid improvements in symptoms and signs when used in combination with concomitant MTX, other conventional disease-modifying anti-rheumatic drugs (cDMARDs), or as monotherapy (Taylor 2019a) with benefits reported as early as 2 weeks. Both agents inhibit structural damage progression. Remarkably, in MTX inadequate responders, the combination of MTX and baricitinib 4 mg od demonstrated superiority for ACR20 responders and DAS28-CRP reduction over the standard of care biologic adalimumab used with background MTX. Other JAK inhibitors in development include upadacitinib and filgotinib, both with selectivity for JAK1. Both drugs have demonstrated efficacy in combination with MTX and as monotherapy in phase III trials.

In summary, the introduction to the clinic in the late 1990s of bDMARDs directed against TNF heralded the beginning of the era of targeted therapies. Other bio-originator bDMARDs with distinct mechanisms of action followed, and most recently, JAKs have been validated as a therapeutic target with the introduction of orally available small molecular therapies. This expansion of therapeutic options has contributed to a greatly improved outlook for people living with RA and set a high standard for symptom control and prevention of joint destruction.

Ca^{2+}-induced Ca^{2+} release (CICR) channel; Foot

Definition

Ryanodine receptor (RyR) is an intracellular Ca^{2+} release channel in the **sarcoplasmic reticulum** (SR) or the endoplasmic reticulum (ER). RyR binds ryanodine (a plant alkaloid, see Drugs) with a high affinity, after which it is named.

Basic Characteristics

Occurrence and Role

There are three genetically distinct isoforms of RyR in mammals: RyR1, RyR2, and RyR3

(Table 1). RyR1 is predominantly expressed in the skeletal muscles, and RyR2 is the major isoform in the heart (Ogawa 1994; Sutko and Airey 1996). RyR3 is ubiquitously expressed in a minute amount over the various tissues. All the three isoforms are expressed in the central nervous system (CNS), but their localizations are different (Sutko and Airey 1996). RyR1 and RyR2 play a pivotal role in **excitation-contraction coupling** (E-C coupling) of skeletal and cardiac muscles, respectively.

Structure

RyR forms a large homotetrameric channel composed of four identical monomers of ~5,000 amino acid residues. Three-dimensional architectures obtained by cryo-electron microscopy at near-atomic resolution demonstrate a large, four-fold symmetric cytoplasmic assembly and a small transmembrane assembly forming an ion channel (Ogawa et al. 2020; Zalk and Marks 2017) (Fig. 1). A cytoplasmic assembly consists of 12 domains, including 10 N-terminal domains (NTD, SPRY1, P1, SPRY2, SPRY3, HANDLE, HD1, P2, HD2, and CENTRAL), the S2S3 domain in the channel region, and the C-terminal domain (CTD) (Fig. 1a–c). The cytoplasmic assembly has been identified as "foot" in the electron microscopic observation of the skeletal muscle triads (Franzini-Armstrong and Protasi 1997) (Fig. 2). All the three isoforms show very similar structures and 65% amino acid residues are identical between any two of the RyR isoforms (Ogawa 1994; Sutko and Airey 1996). However, there are three major regions of diversity, designated DR1, DR2, and DR3 (Fig. 1a). DR2 is characteristically missing in RyR3. These divergent regions could account for functional difference between these isoforms. RyR forms multiprotein complex with several associated proteins, such as calmodulin (CaM) and 12 kDa FK506-binding protein (**FKBP12**) (Fill and Copello 2002; Meissner 2017) (Fig. 1a–c).

A C-terminal ~1/10 part constitutes the ion channel formed by six transmembrane segments (Fig. 1a, c). Like many other ion channels, the two most C-terminal transmembrane segments constitute the ion-conducting pore, and a loop between them forms a "P-loop" containing a short pore helix and the selective filter (Ogawa et al. 2020; Zalk and Marks 2017). The RyR forms the cation channel characteristic of a large conductance (~700 pS with Na^+ or K^+ and ~100 pS with Ca^{2+}) (Fill and Copello 2002). The RyR channel is selective for Ca^{2+} over monovalent cations (pCa/pNa = 6-7). The selectivity, however, is

Ryanodine Receptor, Table 1 Three mammalian RyR isoforms

	RyR1	RyR2	RyR3
Gene locus (human)	19q13.1	1q42.1-43	15q14-15

Related diseases	MH, CCD, MmD	CPVT, ARVC2, IVF, LQTS, LVNC	Schizophrenia
			Hyperinsulinism

[a]RyR3 is temporarily expressed in mammalian skeletal muscle during development and downregulated to a negligible amount in adult except for diaphragm and soleus muscles. In some nonmammalian vertebrates (e.g., fish, frogs, and birds), nearly equivalent amounts of RyR1 and RyR3 are expressed in adult skeletal muscles (Ogawa 1994; Sutko and Airey 1996)

[b]Some alterations in CNS function (e.g., enhanced locomotor activity or alterations in synaptic plasticity) are reported (Fill and Copello 2002; Kushnir and Marks 2010)

Ca^{2+} is shown as a cyan ball; ATP and caffeine are shown in sphere representation. B, top view (from the T-tubule); C, side view (parallel to the SR membrane), two of the four protomers facing each other are shown; D, magnified view of the red dotted square shown in C

less than that of the voltage-dependent Ca^{2+} channel (VDCC) showing pCa/pNa > 1,000.

Ca^{2+} Release Mechanisms

All the RyR channels are gated by cytoplasmic Ca^{2+}, known as Ca^{2+}-induced Ca^{2+} release (CICR) (Endo 2009; Fabiato 1983; Rios 2018) (Table 1). CICR functions as an amplifier of small Ca^{2+} signals in various excitable and nonexcitable tissues and well documented in E-C coupling in the heart. In addition, RyR1 also mediates depolarization-induced Ca^{2+} release (DICR), which is gated through some protein-protein interactions. DICR is the principal Ca^{2+} release mode in E-C coupling in vertebrate skeletal muscle.

CICR and Its Endogenous Modulators

In CICR, the RyR channel is activated by μM Ca^{2+} and inhibited by sub-mM or higher Ca^{2+} (Endo 2009; Meissner 2017; Murayama and Kurebayashi 2011; Rios 2018). This biphasic Ca^{2+} dependence can be explained by two distinct Ca^{2+} binding sites: high-affinity Ca^{2+} site for activation (A-site) and low-affinity Ca^{2+} site for inactivation (I-site). The A-site is located at the interface between Central and CTD (Ogawa et al. 2020; Zalk and Marks 2017) (Fig. 1c, d). The I-site remains to be unidentified. In addition to the occupation with Ca^{2+} of the A- and I-sites, the CICR activity of RyR is also determined by a third parameter independent of Ca^{2+} which sets the maximal attainable level.

CICR is modulated by several endogenous ligands. Mg^{2+} inhibits CICR by acting as a competitive antagonist in the A-site and as an agonist in the I-site (Meissner 2017; Murayama and Kurebayashi 2011). Adenine nucleotides such as ATP greatly stimulate CICR by increasing the maximal attainable level without changing Ca^{2+} dependence (Endo 2009). The binding site for ATP is located at the interface between central domain, S6, and CTD (Ogawa et al. 2020; Zalk and Marks 2017) (Fig. 1c, d). Posttranslational modifications of specific residues (phosphorylation, oxidation, or S-nitrosylation) modulate the CICR activity (Fill and Copello 2002; Meissner 2017).

CICR is modulated by a large number of associated proteins (Fill and Copello 2002; Kushnir and Marks 2010; Meissner 2017). Among them, CaM and FKBP12/12.6 tightly bind to RyR and are well investigated. Calmodulin binding site is an elongated cleft formed by Handle, HD1, HD2, and Central domains (Ogawa et al. 2020) (Fig. 1b, c). The action of CaM is isoform-dependent: it activates RyR1 and RyR3 at a low (submicromolar) Ca^{2+} and inhibits at a higher Ca^{2+}, whereas it inhibits RyR2 irrespective of Ca^{2+} concentrations (Meissner 2017). FKBP12 and FKBP12.6 bind to RyR1 and RyR2, respectively (Fill and Copello 2002). They bind to the cytoplasmic region surrounded by the NTD-C, SPRY1, SPRY3, and Handle domains (Ogawa et al. 2020; Zalk and Marks 2017) (Fig. 1b, c). FKBP12 stabilizes the RyR1 channel activity, whereas effect of FKBP12/12.6 on RyR2 is controversial. RyR3 could bind FKBP12 with unchanged activity.

The RyR channels seem to be regulated by luminal Ca^{2+}. Luminal Ca^{2+} may activate the RyR2 channels in the heart (Bers 2008; Priori and Chen 2011). The association of **calsequestrin** with RyR2 via triadin or junctin is proposed as a possible regulatory mechanism (Beard et al. 2004; Fill and Copello 2002). Such activation by luminal Ca^{2+} remains controversial in the skeletal muscle.

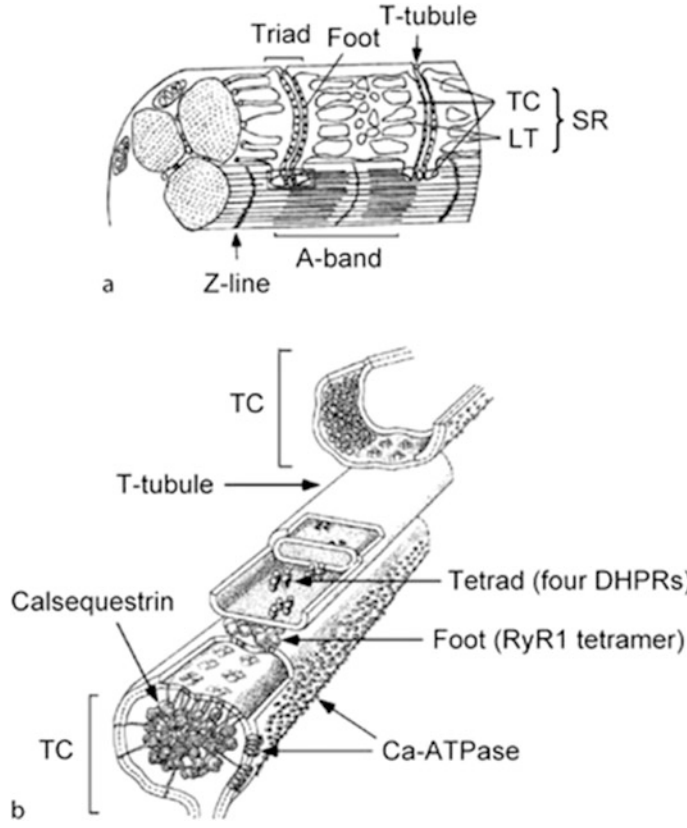
E-C Coupling in Skeletal Muscle

In E-C coupling in vertebrate skeletal muscle, the RyR1 channel releases Ca^{2+} from the SR on depolarization of the T-tubules. The process is known as depolarization-induced Ca^{2+} release (DICR) (Schneider 1994). In skeletal muscle, T-tubule invaginates at the specific sites to form "triad" structure with the terminal cisternae (TC) of the SR on the both sides (Franzini-Armstrong and Protasi 1997) (Fig. 2a). At the triad, four skeletal muscle-type DHPRs (containing $Ca_v1.1$ as the pore-forming subunit) assemble into "tetrad" and are closely apposed in precise register to the alternate RyR1 tetramers (feet) which are aligned in two rows on each junctional face of the TC (Fig. 2b). The current view of DICR is that depolarization of T-tubule induces the conformation change in the **dihydropyridine receptor** (DHPR) containing $Ca_v1.1$, which, in turn, activates the coupled RyR1 channels through the protein-protein interaction (Tanabe et al. 1990). Ca^{2+} influx through DHPR is not necessary in DICR. Thus, DHPR serves as the voltage sensor instead of the Ca^{2+} channel. The RyR1-$Ca_v1.1$ interaction cannot be replaced by any other isoforms of RyR or DHPR and are supported at least three proteins: DHPR β1a, stac3, and junctophillin2 (Perni et al. 2017). Studies with chimeric RyRs have proposed that multiple regions within the cytoplasmic assembly may be involved in this interaction.

In the skeletal muscle, RyR1 can also mediate CICR. Therefore, it may reasonably be hypothesized that Ca^{2+} released from the RyR1 coupled with DHPR might induce CICR via the uncoupled RyR1 in physiological **twitch** or **tetanus**. The rate of CICR estimated under physiological condition, however, is much slower than the rate of DICR, suggesting only minor contribution of CICR to the physiological muscle **contraction** (Murayama and Kurebayashi 2011). Enhanced CICR is the pathogenesis of some muscle diseases (see Disease).

E-C Coupling in Heart

In E-C coupling in the heart, the RyR2 channel releases Ca^{2+} from the SR on depolarization of the plasma membrane or T-tubules by CICR mechanisms (Bers 2008). The cardiac junctional SR forms dyad structure (similar to triad structure in the skeletal muscle) with the plasma membrane or T-tubule, where a cluster of L-type voltage-dependent Ca^{2+} channel (cardiac **dihydropyridine**



Ryanodine Receptor, Fig. 2 Schematic drawings of mammalian skeletal muscle (a) and characteristic configuration of the components essential for E-C coupling in the triad (b). A, the T-tubule invaginates at the A-I junction to form triad structure with terminal cisternae (TC) of the SR. LT, longitudinal tubule of the SR. Modified from Fawcett (1994) Bloom and Fawcett a "Textbook of Histology" (12th ed., Chapman & Hall, New York and London), p. 278. B, at the triad, two rows of feet (RyR1 tetramers) are aligned in the junctional face of the TC, and tetrads (four DHPRs) in T-tubules are located in precise register with opposite alternate feet. Modified from Block et al. (1988) J Cell Biol 107: 2587–2600

receptor (DHPR) containing $Ca_v1.2$) is closely apposed to a cluster of RyR2 in the SR, although there is no direct association between individual RyR2 and DHPR molecules (Franzini-Armstrong and Protasi 1997). RyR2 is activated by Ca^{2+} which enters via the Ca^{2+} channel on depolarization. "**Ca^{2+} sparks**" are thought to be an elementary event of the Ca^{2+} release in which multiple RyR2 channels in a cluster open synchronously (Lederer et al. 2004). In the Ca^{2+} overloaded muscles, Ca^{2+} release via RyR2 may occur spontaneously without Ca^{2+} influx and propagate in the cell as **Ca^{2+} waves** (Bers 2008).

Similar Ca^{2+} release mechanism operates also in smooth muscles, neurons, and some peripheral tissues.

Diseases

Genetic mutations in RyR1 are linked to some cases of **malignant hyperthermia** (MH), **central core disease** (CCD), and multiminicore disease (MmD) (Dirksen and Avila 2002; Riazi et al. 2018), whereas mutations in RyR2 are associated with arrhythmogenic diseases such as **catecholaminergic polymorphic ventricular tachycardia** (CPVT1), arrhythmogenic right ventricular cardiomyopathy (ARVC2), left ventricular noncompaction (LVNC), long QT syndrome (LQTS), and idiopathic ventricular fibrillation (IVF) (Priori and Chen 2011). More than 300 mutations have been identified for each of RyR1 and RyR2. Several mutations in RyR3 are reported to be linked with schizophrenia and hyperinsulinism.

These mutations may alter the Ca^{2+} release channel functions. MH and some CCD mutations in RyR1 cause gain-of-function effect, that is, increased CICR activity, whereas most CCD mutations lead to loss-of-function of the channel (referred to as E-C uncoupling) (Dirksen and Avila 2002). CPVT and LVNC mutations in RyR2 cause gain-of-function effects, whereas

RyR2 mutations linked to LQTS and IVF include both gain-of-function and loss-of-function mutations (Priori and Chen 2011).

In addition to genetic mutations, post-tlanslational modifications of RyRs such as phosphorylation or redox modifications have been reported to destabilize the channel and result in a pathological Ca^{2+} leak from the SR in skeletal and cardiac muscles (Bers 2014; Denniss et al. 2018; Kushnir and Marks 2010).

Drugs

Ryanodine

Ryanodine is a neutral plant alkaloid from *Ryania speciosa*. Ryanodine binds specifically to the pore of open RyR channel with a high affinity (K_D ~nM) and locks the channel to a subconductance open state (Meissner 2017; Ogawa 1994). The binding of [^{3}H]ryanodine is used as a quantitative measure for the RyR channel activity (Murayama and Kurebayashi 2011).

Caffeine

Caffeine is a strong activator of CICR: it greatly sensitizes RyR to activating Ca^{2+} and increases the maximum attainable level at mM range (Meissner 2017; Ogawa 1994). Caffeine binds at the interface between central, S2S3, and CTD (Ogawa et al. 2020; Zalk and Marks 2017) (Fig. 1c and d). Caffeine-binding site normally reduces the Ca^{2+} sensitivity through interaction between tryptophan in S2S3 and isoleucine in CTD. Caffeine binds to the tryptophan to break the interaction, resulting in increased Ca^{2+} sensitivity (Ogawa et al. 2020). Caffeine is frequently used for experimental evaluation of functional occurrence of RyRs. It is also used for diagnosis of MH: muscles biopsied from MH patients contract with a lower dose of caffeine than normal subjects, due to an enhanced CICR activity (Riazi et al. 2018) (see Disease).

4-Chloro-m-cresol (4-CmC)

4-CmC, a preservative in commercial preparations of some intravenous drugs, activates CICR in a way similar to that of caffeine (Meissner 2017). 4-CmC is more potent than caffeine and shows isoform-dependent activation profiles: it is much less effective in RyR3 than RyR1 or RyR2.

Inhalational Anesthetics

Inhalational anesthetics, such as halothane and isoflurane, stimulate CICR in RyR1 (Endo 2009). Administration of these agents to carriers of MH mutations in the *RYR1* gene will cause the MH episodes (Riazi et al. 2018).

FK506 and Rapamycin

These immunosuppressants increase the activity of RyR1 by deprivation of FKBP12 (Fill and Copello 2002). Their effect on RyR2 is controversial.

Dantrolene

Dantrolene is an antidote for MH which inhibits the CICR activity (Endo 2009). Dantrolene strongly inhibits RyR1 but is much less effective on RyR2. Action of dantrolene is temperature-dependent (more effective at 37 °C than at 25 °C).

Procaine and Tetracaine

Procaine and tetracaine, local anesthetics that block sodium channels, strongly inhibit all the RyR isoforms at mM range (Endo 2009; Meissner 2017; Ogawa 1994). Tetracaine is more potent than procaine.

Ruthenium Red

Ruthenium red inhibits all the RyR isoforms at μM range (Meissner 2017; Ogawa 1994). The site of ruthenium red action seems to be near or within ion channels.

S100 Proteins

Claus W. Heizmann
Department of Pediatrics, Division of Clinical Chemistry and Biochemistry, University of Zürich, Zürich, Switzerland

Synonyms

Allergy; Biomarkers; Calcium-binding; Cancer; Cardiomyopathy; Clinical chemistry; Diagnostics; Drug targets; EF-hand; Head injury; Inflammation; Laboratory medicine; Zinc-binding

Definition

S100 proteins are small acidic proteins and are characterized by two distinct EF-hand calcium-binding motifs with different affinities. They also bind zinc, copper, and iron at positions distinct from the Ca^{2+}-binding sites resulting in modulation of their activities. Most S100 genes are organized in a gene cluster on human chromosome 1q21, the basis of the S100 nomenclature approved by the HUGO nomenclature committee (Marenholz et al. 2004). Today, members of the S100 protein family are routinely used in Practical Laboratory Medicine to analyze and monitor disease conditions and are important diagnostic and prognostic biomarkers (Heizmann 2019a, b).

Basic Characteristics

S100 proteins constitute the largest subgroup within the EF-hand protein family. They are involved in many cellular activities (Marenholz et al. 2004; Heizmann 2019a, b; Leclerc and Heizmann 2011; Donato et al. 2002) and are mostly in the form of homo- or hetero-dimers but can also form tetramers and hexamers (Moroz et al. 2002; Ostendorp et al. 2007; Spratt et al. 2019). The crystal structures of S100Z and of other S100 proteins have recently been reviewed (Calderone et al. 2019).

S100A3 is a unique member of this protein family. It binds Ca^{2+} with poor but Zn^{2+} with an exceptionally high affinity. The crystal structure of S100A3 is shown in Fig. 1 and described in detail (Fritz et al. 2002). Molecular genetic investigations, performed on patients with pulmonary fibrosis (one of the leading indications for lung transplantation), revealed a hypomorphic variant in *S100A3* and a novel truncated mutation in *S100A13,* both segregating with the disease in an autosomal manner (Al-Mutairy et al. 2019). These were the first mutations detected in any of the S100 protein family members and suggest a calcium- or zinc-dependent therapeutic approach for the management of this disease of unknown etiology.

Besides their distinct intracellular functions, certain S100 proteins are secreted from cells and exert cytokine-like functions through the binding

S100 Proteins, Fig. 1 Overall structure of the Ca^{2+}-free S100A3 dimer. The subunits are shown in *red* and *blue,* respectively. The N termini are shown in dark colors and the C termini in bright colors. The Cys and His residues are shown as a *ball* and *stick* model. This research was originally published in the *Journal of Biological Chemistry*, G. Fritz et al. (2002) The Crystal Structure of Metal-free Human EF-Hand Protein S100A3 at 1.7-Å Resolution 277, 33092-33098 ©the American Society for Biochemistry and Molecular Biology

and activation of cell surface receptors such as the Receptor for Advanced Glycation End Products (RAGE), Toll-like Receptor 4 (TLR-4), the ErbB4 receptor, the dopamine D2 receptor, amyloid-β, and annexins (Marenholz et al. 2004; Heizmann 2019a, b; Leclerc and Heizmann 2011; Donato et al. 2002; Moroz et al. 2002; Ostendorp et al. 2007; Spratt et al. 2019).

Clinical Importance of S100 Proteins in Human Diseases

Cardiology

S100A1 is predominantly expressed in the heart and a decreased cardiac expression of S00A1 is characteristic of heart failure. S100A1 gene transfer to restore S100A1 protein levels in the failing myocardium is suggested as a future therapeutic strategy to support the injured heart and to reverse or prevent heart failure (Pleger et al. 2007).

S100A2 has the potential to differentially influence Ca^{2+}-cycling and contractility of cardiomyocytes. Therefore, S100A2 and S100A4, in addition to S100A1, may be further candidates for a differentiated heart failure therapy promoting survival of cardiac myocytes (Wang et al. 2014).

Oncology

S100 proteins associated with cancer progression, diagnosis, and treatment are listed in Table 1.

S100B is the best-studied melanoma biomarker incorporated into the American Joint Committee on Cancer (AJCC) melanoma staging system. S100B is routinely analyzed in practical laboratory medicine and elevated S100B levels closely correlate with a poor survival rate.

S100A2-A6. A prognostic significance of S100A2 in laryngeal squamous-cell carcinoma allows discrimination of high-and low-risk patients in the lymph node-negative subgroup for a better adjusted therapy. S100A2 has been found to be a marker for early stages of lung carcinogenesis.

S100A4 (metastasin), a key player in tumor progression and metastasis, is by far the best studied and prominent member of the S100 protein family. The importance of S100A4 in cellular invasion and metastasis is exemplified by its presence in a great variety of different types of cancer, as listed in Table 1. S100A4 can also act via an extracellular route, as an angiogenic factor inducing tumor progression. Inhibiting the process of tumor angiogenesis is a possibility by blocking either S100A4 secretion or its extracellular binding to targets/receptors.

S100A7 (psoriasin) and the homologous protein *S100A15* (koebnerisin) in psoriatric keratinocytes are associated with several malignant tumors.

S100A8/A9 proteins (calprotectin/Mrp8 and Mrp 14) are involved in different types of cancer. Their expression and proposed cytokine-like functions indicate key roles in inflammation-associated cancer and represent promising biomarkers to evaluate the risk potential of various types of cancer in molecular pathology.

S100A11 may become important for the diagnosis and treatment of ovarian cancer.

S100A13 was identified in thyroid tumors and its growth and invasion. A proteomics analysis of cutaneous malignant melanoma (CMM) revealed an association between the expression of

S100 Proteins, Table 1 S100 proteins in oncology

Proteins	Cancer association
S100B	Melanoma metastasis
S100A1	Ovarian cancer
S100A2	Lung carcinogenesis, laryngeal squamous-cell carcinoma
S100A2-A6	Classification of brain tumors
S100A3	Hepatocellular carcinoma, gastric cancer
S100A4/metastasin	Colon, rectal, gastric, ovarian, breast cancers; melanoma; oral squamous cell carcinomas
S100A7/psoriasin	Ovarian, cervical, pancreatic cancers
S100A8/A9/calprotectin	Inflammation-associated cancer, breast, colorectal cancers; ALL[a]; CLL[b]; AML[c]; cutaneous squamous, laryngeal, hepatocellular carcinoma, head, neck, bladder cancer
S100A11	Breast, ovarian, pancreatic cancers
S100A13	Thyroid tumors, cutaneous malignant melanoma
S100A14	Cervical, breast, gastric cancers
S100A16	Colorectal, breast cancers
S100 P	Breast cancer, pancreatic ductal adenocarcinoma, nasopharyngeal carcinoma

S100A13 and chemotherapy resistance. CMM is commonly unresponsive to standard dacarbazine (DTIC) and temozolomide (TMZ) chemotherapy, and the use of S100A13 as a predictive marker of therapy response would be of great clinical help.

S100A14 is overexpressed in several cancer tissues regulating proliferation, migration, and invasion and suppressing metastasis (e.g., in gastric cancer).

S100P is expressed in many pancreatic tumors, associated with growth and aggressiveness of this cancer type.

Inflammation, Autoimmune Diseases and Allergies

S100B is correlated with active vitiligo depigmentation (Birlea 2017), the most common depigmenting disorder. Serum levels of S100B were increased in patients with active non-segmental vitiligo and associated with disease progression. These findings imply that S100B may be a biomarker for this disease and a new target for treatment.

S100A4/metastasin is implicated in metastatic tumor progression and chronic inflammation. S100A4 induced the expression of acute-phase responsive proteins, serum amyloid A (SAA1), and SAA3 proteins and cytokines in an organ-specific manner. SAA proteins in connection with S100A4 serve as a link between inflammation and tumor progression (Hansen et al. 2014; Ambartsumian et al. 2019). S100A4 was also identified as a candidate gene in allergy. Treatment with an anti-S100A4 antibody resulted in decreased signs of allergy in a mouse model and in allergen-challenged T cells from allergic patients. This strategy may be generally applicable to identify diagnostic and therapeutic candidate genes in allergy.

S100A7/psoriasin, localized in epithelial cells, regulates cell proliferation and differentiation. An increase of S100A7 expression is found in response to inflammatory stimuli, such as in psoriasis (a chronic inflammatory autoimmune-mediated skin disease). This suggests that S100A7 may be a therapeutic target in psoriasis (D'Amico et al. 2016). Serum levels of S100A7 and S100A15 are potential markers of artherosclerosis in patients with psoriasis (Awad et al. 2018).

S100A8 and S100A9 proteins are characterized by a unique expression pattern with strong prevalence in cells of myeloid origin and are associated with a number of chronic inflammatory diseases (Holzinger et al. 2019). Sensitive and automated ELISA calprotectin (S100A8/A9) assays are routinely used in Clinical Chemistry Laboratories to diagnose the two main forms of inflammatory bowel diseases, Crohn's disease and Ulcerative colitis.

S100A11 (calgizzarin) was associated with rheumatoid- and osteoarthritis and is an additional biomarker to S100A/A9 and S100A12 for a more tailored diagnosis of inflammatory diseases.

S100A12/calgranulin C is associated with the Kawasaki disease and Mooren's ulcer as well as atherosclerosis.

Brain Injury and Neuropathologies

S100 proteins were first described as small acidic proteins in a 100% saturated ammonium solution of a brain extract. This extract mainly contained the S100A1 and S100B proteins. S100B represent 0.2% of total brain proteins, mainly synthesized by astrocytes, oligodendrocytes, and Schwann cells. S100 protein members (mainly S100B) are associated with neurodegenerative diseases such as Alzheimer´s disease, Down syndrome and in some psychiatric disorders such as schizophrenia (Table 2) and are routinely used in Practical Laboratory Medicine as neurobiomarkers for head injuries of children and adults.

Drugs

Developing inhibitors against S100B as an antagonist (Khan et al. 2018; Syed et al. 2018) to block the interaction with RAGE is a promising goal for future pharmaceutical interventions and cancer treatment. Targeting the S100A7/A15-receptor axis is suggested as a new targeted strategy for preventing the invasion and metastasis of these types of cancer. Another therapeutic strategy is using neutralizing monoclonal antibodies against S100A7 for cancer treatment. As a consequence

S100 Proteins, Table 2 S100 proteins in brain disorders

Proteins	Brain pathologies
S100B	Neurobiomarker for head injury in high-risk fetuses, newborns, children, and adults biomarker in asphyxiated infants treated with hypothermia intracerebral hemorrhage and ischemic stroke Alzheimer's disease, multiple sclerosis, psychiatric disorders (schizophrenia) acute cerebrovascular insults, seizures, delirium glyphosate and glufosinate poisoning pesticide-induced neurotoxicity
S100A4	Axonal regeneration, neuronal plasticity
S100A6	Amyotrophic lateral sclerosis

of the various proinflammatory properties of S100A8/A9 proteins, strategies targeting these molecules are an option for anti-inflammatory therapies, by in vivo administration of S100 antibodies, or by therapeutic drug targeting to inhibit the release of these cytokine-like molecules at sites of inflammation (Vogl et al. 2018).

The antiallergic drug cromolyn binds to S100P preventing RAGE activation inhibiting pancreatic tumor growth and metastasis in animal models. Cytotoxic treatment using cromolyn in combination with gemcitabine or applying a small RAGE antagonistic peptide appears to be a promising to treat pancreatic and possibly other types of cancer. Covalent small molecule inhibitors of S100B have been developed that inhibit S10B-p53 complex and restore active p53 in malignant melanoma (Cavalier et al. 2014). A similar approach was to target the estrogen receptor/S100 interface by a short peptide derived from S100P in order to reduce regression of tumor growth receptor positive breast cancer (Lee et al. 2016; Cho et al. 2016).

Outlook

Today, members of the S100 protein family are routinely used in Practical Laboratory Medicine to analyze and monitor disease conditions and are important diagnostic and prognostic biomarkers. S100 proteins and their targets/receptors are also considered as drug targets for future treatments. So far, only a small number of S100 proteins have been explored for their clinical relevance although more and more human diseases (Tables 1 and 2),

as well as, for example, obesity (Riuzzi et al. 2019) and the sexually-transmitted infection gonorrhea (Maurakis et al. 2019) are linked to S100 proteins. Methods of choice for a simultaneous analysis of Ca^{2+}-binding proteins and their post-translational modifications are the mass spectrometry and the focal molography (a next-generation biosensor that visualizes specific biomolecular interactions in real time). These techniques will have a future impact on the development of point-of-care diagnostic devices applied for analyses of the Ca^{2+}-binding proteins in human diseases.

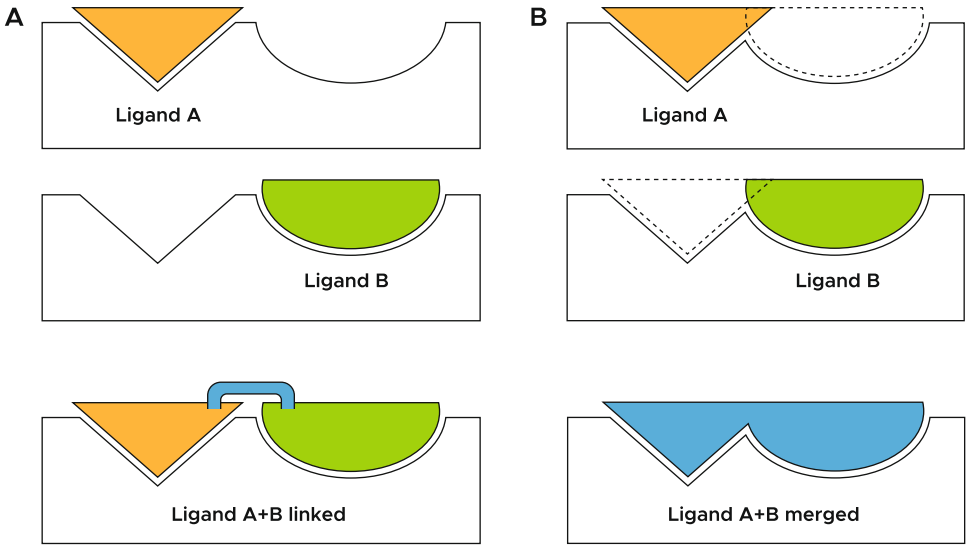
Fragment-based drug discovery; Lead discovery by NMR

Definition

Structure-activity-relationships (SAR)-by-NMR (Shuker et al. 1996) is originally the appellation of a method for generating systematically high-affinity small molecular weight protein ligands from small molecular fragments in the early stages of drug development. NMR is used for detecting weak protein-ligand interactions via chemical shift changes, usually monitored by $^{1}H–^{15}N$ correlation spectroscopy for amide proton and nitrogen signals (Shuker et al. 1996). Such chemical shift perturbations of individual backbone amide signals indicate also the protein binding site. The three-dimensional structure of a protein-ligand complex involving two ligands A and B simultaneously binding at adjacent sites is the basis for the design of a linker between the two fragments (Fig. 1a). This "linking" strategy produces a much tighter binding ligand from weakly binding fragments due to the saving of one entropic factor. In this procedure, protein-ligand interactions are detected via the protein NMR resonances, enabling the measurement or estimation of binding constants and a mapping of the binding site to detect suitably different locations for ligands to be linked.

Over time, SAR-by-NMR became an important element of fragment-based drug design approaches (Erlanson et al. 2016; Ribeiro de Souza Neto et al. 2020), in particular since low-affinity binding in the μM–mM range (as mostly occurring for fragments with a molecular weight between 150 and 300 Da) can be easily detected without creating too many "false positives." It is usually applied in concert with other biophysical techniques including structure determination methods. In this context, different experimental NMR approaches are also often used, detecting effects on the ligand NMR



SAR-by-NMR, Fig. 1 Schematics of SAR-by-NMR linking and merging procedures

spectrum (ligand-observed) rather than site-specific chemical shift changes of protein signals (protein-observed) (Gossert and Jahnke 2016). NMR techniques such as the saturation transfer difference (STD) and waterLOGSY experiments (Gossert and Jahnke 2016) observe ligand resonances to qualitatively detect binding, useful in screening campaigns or for hit validation. The path toward higher affinity is also often modified. Since the linking procedure is not always feasible, fragments A and B with overlapping binding sites may be improved by "merging" as depicted in Fig. 1b. In practice, individual fragments are often developed further by "growing," adding stepwise functional groups.

Basic Characteristics

The original SAR-by-NMR procedure (Fig. 1a) included searches for two fragment-like compounds (MW<250 Da) that bind close to each other near the active center and the structure-guided design of a linker to produce a tighter binding ligand (Shuker et al. 1996), characterized by the following steps:

- Screening of a compound library consisting of fragments in the molecular weight range of 150–250 Da to detect compounds that bind close to the active site of the protein, using correlation spectroscopy for detection
- Screening of derivatives of the initial hits, optionally supported by synthesis of a focused library yielding such derivatives to obtain compounds with improved affinity
- Screening for a second compound that binds in the vicinity of the first one using the same procedure
- Determination of a three-dimensional protein structure with both ligands bound
- Design of a linker for both ligands and synthesis of this compound
- Further improvement by synthesis of derivatives on the basis of the design

Key to the scheme above is the structure-based design of a linker. With its effect accounted for by ΔG_{link}, linking two fragments A and B produces a gain in affinity described by:

$$\Delta G_{AB} = \Delta G_A + \Delta G_B + \Delta G_{link}$$

The binding constant of the compound AB obtained after linking is then:

$$K_d(AB) = K_d(A) \times K_d(B) \times L,$$

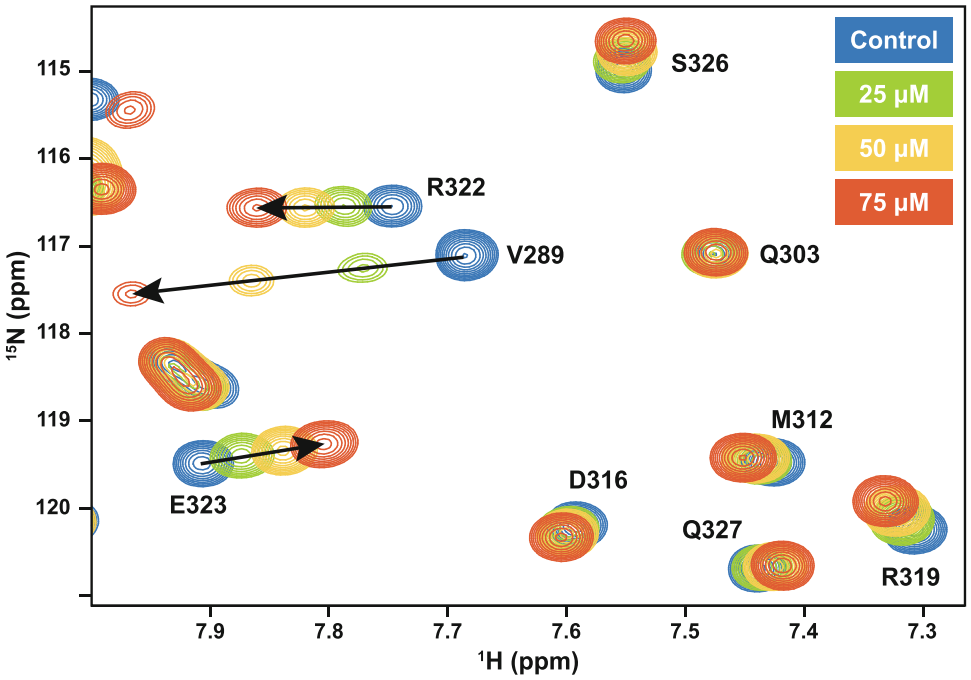
where L is the linking coefficient derived from ΔG_{link}.

In its modified forms (merging, growing), the first two steps of the original procedure are applied to obtain good starting points for choosing larger or merged compounds.

In current applications, between 500 and 10.000 substances are screened to find ligands binding in the mM–nM range. Often, a pre-selection by virtual screening approaches based on existing structural information is applied.

The methodology is often applied in a modified manner. Three-dimensional structures of complexes may also be obtained by X-ray crystallography or by molecular modelling making use of the detected chemical shift changes. The latter is often sufficient when individual hits of the screening phase are stepwise extended toward a tight-binding one. Due to the weak binding of fragments, and possible crystal packing effects, X-ray structures of complexes are sometimes difficult to obtain, requesting alternative methods.

An example for the initial NMR screening step is shown in Fig. 2. A region of a ^{1}H-^{15}N heteronuclear single quantum correlation (HSQC) shows the overlay of four different spectra obtained on ^{15}N-labelled dishevelled PDZ domain samples with four different ligand concentrations (0 mM, 25 mM, 50 mM, and 75 mM). The black NH signals are characteristic for the free protein, and the red signal is close to the chemical shift of the same signal from the complex. Only for a protein signal from an amino acid residue in the binding site, a journey from the signal position of the free to the equivalent of the liganded form may be observed (see R322, V289, and E323). For all other residues, signals in the four different spectra superimpose well within



SAR-by-NMR, Fig. 2 Superposition of regions from ^{1}H–^{15}N correlation spectra of the PDZ domain from the protein dishevelled obtained at different ligand concentrations. Chemical shift changes are indicated by arrows. Each cross peak originates from one particular amide group, as indicated by the amino acid one-letter code and its position in the protein sequence

certain limits, indicating that the chemical environment of the amide protons and nitrogen atoms did not change much through binding of the ligand or induced long-range structural effects.

In the example above, the effects of ligand binding were observed as gradual, concentration-dependent ^{1}H and ^{15}N chemical shift changes which are usually true for weak interactions with small molecular fragments below 300 Da. In general, two different effects may be observed depending on the binding constants and the chemical shift difference between the monitored signal of the complex and the signal of the free protein. At low fragment affinity, one travelling signal is observed that represents the weighted average of the chemical shifts of complex and free form of the protein. In the case of tight binding (nanomolar range and below) and large chemical shift differences, the signal of the free protein may decrease with increasing ligand concentration, and the signal of the complex will appear at its genuine chemical shift. These situations are called "fast exchange" (for the travelling signal) and "slow exchange" regimes. For intermediate cases, the signal may vanish at a certain point, called "coalescence."

The chemical shift changes observed in correlation spectra (the length of the vector in Fig. 2) may be taken directly as a measure of affinity differences when the effects of several ligands are compared. Such chemical shift (δ) changes (Δδ) are then quantified as a linear combination of proton (δ_H) and nitrogen (δ_N) shift contributions (Bertini et al. 2011).

$$\Delta\delta = \sqrt{\frac{(\Delta\delta_H)^2 + (\Delta\delta_N/5)^2}{2}}$$

This provides also a basis for the measurement of binding constants. The dissociation constant may be determined by fitting the observed chemical shift change with increasing ligand concentration, up to very large excess (Gossert and Jahnke 2016).

Early examples of the application of SAR-by-NMR include the design of stromelysin and human papillomavirus E2 protein inhibitors (Hajduk et al. 1997a, b).

A detailed analysis of designed inhibitors for stromelysin by thermodynamical methods (Hajduk et al. 1997a) showed that the combination of two ligands, a biphenyl derivative and acetohydroxamic acid, yield an increase in the enthalpic contributions to the binding energy, whereas the entropic factor remained constant. In the application of the method to the design of ligands for the virus E2 protein (Hajduk et al. 1997b), the potential of NMR to detect low-affinity binding was exploited by starting a ligand refinement from compounds that bound in the millimolar range and combining features of two compounds to one which finally showed an IC_{50} of 10 micromolar in the applied test.

With fragment-based drug design developing into a coherent methodology, making use of many techniques, NMR contributes in several aspects but dominantly with its feature of detecting low-affinity binding and concomitantly the binding site. This is outlined in an analysis of a large number of fragment-based drug design studies by Mortenson et al. and Erlanson et al. for the years 2017 and 2018, respectively (Mortenson et al. 2019; Erlanson et al. 2020).

Cellular senescence

Definition

The term senescence originates from the Latin word *senesce*, meaning "to grow old," and was used for many years to allocate both cellular and organismal senescence (aging). Nowadays it is well established that at the systematic level, senescence is a hallmark of aging, the latter representing the gradual functional decline of proper organismal processes with age. At the cellular level, the terms "senescent" and "aged" are not identical and should not be used interchangeably (López-Otín et al. 2013; Gorgoulis et al. 2019, Table 1). According to the recently proposed consensus definition by the International Cell Senescence Association (ICSA), senescence (from now on used for cellular senescence) is ***a cellular state characterized by prolonged and generally irreversible cell-cycle arrest with secretory features, macromolecular damage, and altered metabolism that is triggered by stressful insults and in certain instances by physiological processes*** (Gorgoulis et al. 2019).

Basic Mechanisms

Inducers

Any stressor that challenges and compromises cellular homeostasis – particularly genome and/or proteome integrity – can potentially induce the senescent phenotype, if the intensity and the duration of the noxious (yet still sublethal) stimuli exceed a specific threshold which overcomes cell's repair capacity (Gorgoulis et al. 2018, 2019). So far myriads of intrinsic and extrinsic senescence inducers have been reported, including, but not limited to, telomere erosion/dysfunction, diverse genotoxic insults, oncogenes, epigenetic modifiers, and oxidative stress/metabolic imbalance stemming from proper protein turnover impairment, mitochondrial dysfunction, and ribosomal and endoplasmic reticulum stress (Gorgoulis et al. 2018, 2019; Myrianthopoulos et al. 2019).

Hallmarks, Molecular Pathways, Markers

Senescence is appreciated as a stress response mechanism characterized by the following **main** interconnected hallmarks: **(1)** ***prolonged and generally irreversible cell-cycle arrest***, mediated predominantly by two signaling pathways that act in a temporal manner: that of p53-p21$^{WAF1/Cip1}$ and Rb-p16^{INK4a} (Gorgoulis et al. 2018, 2019; Myrianthopoulos et al. 2019). The senescence-associated cell cycle withdrawal is not universally an irreversible program as it is currently well established that in certain settings senescent cells can "escape" from the arrested state and re-enter the cell cycle (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019; Galanos et al. 2016; Komseli et al. 2018). **(2)** autocrine or paracrine **secretory properties** termed ***senescence associated secretory phenotype (SASP)***. The senescence secretome consists of cytokines, chemokines, growth factors, proteases, and other factors, depending on the nature of the stressor, cell type, and senescence endurance (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019). This feature exerts immunomodulatory functions that affect the tissue microenvironment and is controlled by various signalling cascades [e.g., mammalian target of rapamycin (mTOR), mitogen-

Senescence, Table 1 Differences between senescence and aging

Senescence	Aging
Well-orchestrated response	Unprogrammed, random process
Although the initial factors which trigger senescence (e.g., DNA damage) may itself be random, the accompanying cellular changes associated with cell senescence are not random, but a rather orchestrated response	Results from the accumulation of random(stochastic) damage leading to impairment in cell function with time
Senescence occurs throughout the lifespan, including during embryogenesis. Cells of any age can undergo senescence	Time (age)-dependent functional decline
Can be triggered not only by telomere attrition (which is definitely related to age), but also by nontelomeric, not aging-associated, acute genotoxic insults (stress-induced senescence)	Telomere attrition is a hallmark of aging, but other acute stimuli cannot elicit a specific aged cell phenotype
Cell-cycle arrested in G1, G1/S, or G2, depending on the activated checkpoint	May not be cell-cycle arrested??
It can be considered as a "sudden" phenomenon meaning that whatever the trigger (telomeric or nontelomeric) or the duration of the phenomenon, the establishment of the cell-cycle arrest coupled to phenotypic modifications is a rather immediate response, induced within relatively short periods of times	The loss of physiological cellular integrity that characterizes aged cell is gradual and progressive, not an "on-off" phenomenon
Both detrimental and beneficial depending on the biological context	Detrimental to the function of normal biological processes
Reversible ("escape" from senescence)	Terminal, permanent, nonreversible phenomenon (regeneration?)
Hyper-secretory phenotype, hyperfunction	–
SA-β-gal positive	?

activated protein kinase (MAPK)-p38, phosphoinositide 3 kinase (PI3K)/AKT, Notch1, and NOTCH/JAG1], eventually leading to NF-κB and CCAAT/enhancer binding protein beta (C/EBPβ) transcriptional upregulation. Cytoplasmic bridges and extracellular vesicles are also involved (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019). **(3)** ***macromolecular damage***, in the form of DNA, protein, and lipid damage, as a result of decline in quality control and damaged turnover mechanisms, commonly evident in the stressful environment of senescence (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019). Of note, macromolecular damage is a unique feature of senescent cells allowing their distinction from other non-dividing cells, such as quiescent or terminally differentiated cells (Gorgoulis et al. 2019). DNA damage, mainly in the form of persistent DNA damage foci, is the most well-established type of macromolecular damage occurring in most types of senescence (for instance, in developmental senescence DNA damage and DDR are absent). Persistent DNA damage foci include irreparable lesions principally related to telomeric DNA (TIFs, telomere dysfunction-induced foci; TAFs, telomere-associated foci) and DNA-SCARSs (DNA segments with chromatin alterations reinforcing senescence). DNA damage elicits the activation of the DNA damage response pathway (DDR), which in the case of oncogene-induced senescence (OIS) cooperates with members of the *CDKN2A* locus (*ARF*) to exert anti-tumor functions (Gorgoulis et al. 2018, 2019; Myrianthopoulos et al. 2019; Evangelou et al. 2013; Velimezi et al. 2013). Cytoplasmic chromatin fragments (CCFs), another form of DNA damage in the senescence context, are related to the activation of a proinflammatory reaction by the cGAS-cGAMP-STING network. Regarding protein and lipid damage, they are the result of damaged biomolecule accumulation due to excessive reactive oxygen species (ROS)

production and improper degradation (Gorgoulis et al. 2018, 2019; Myrianthopoulos et al. 2019; Vasileiou et al. 2019). **(4)** ***Altered metabolism***, related to (i) changes in mitochondrial function, dynamics, and morphology. Mitochondria appear abundant but dysfunctional, producing increased ROS levels and (ii) lysosomal aggregation and malfunction, associated with elevated senescence-associated b-galactosidase (SA-b-Gal) activity and intralysosomal accumulation of lipofuscin (Georgakopoulou et al. 2013; Evangelou et al. 2017). Altogether, aggregation within senescent cells of large dysfunctional mitochondria and lysosomes, the latter enriched in lipofuscin granules, is reflected by increased cytoplasmic granularity (Gorgoulis et al. 2019; Vasileiou et al. 2019).

Another potent property of senescent cells is their ***resistance to apoptosis***, and inhibition of the BCL-2 cell death regulator family of proteins has been exploited in senolytic strategies. The BCL-2 family consists of both pro-apoptotic and anti-apoptotic factors. Among anti-apoptotic ones are BCL-2, BCL-XL, BCL-w, BCL-2-related protein A1 BFL-1 (A1), myeloid cell leukemia 1 (MCL-1), and BCL-B/Boo, featuring four BCL-2 homology (BH) domains (BH1, BH2, BH3, and BH4). The pro-apoptotic fraction includes the multi-domain pro-apoptotic effectors, such as BAK and BAX and the so-called "BH3-only proteins" such as BAD, BID, BIK, BIM, BMF, HRK, PUMA, and NOXA, which harbor a short BH3 domain (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019). Depending on the initial stressor/signal and cell type, senescent cells can acquire numerous additional salient cellular and subcellular features (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019) related to: ***(i) morphological aspects***, such as cellular flattening/elongation, irregular shape, and enlargement due to cytoskeleton rearrangements and alterations in plasma membrane composition and increase in nuclear and nucleolar size as well as fragmentation of the nuclei (polyploidy), mitochondria, and endoplasmic reticulum; ***(ii) epigenetic traits*** that include chromatin modifications (e.g., elevated H4K20me3 and H3K9me, H4K16ac, H3K27me3 "canyons," H3K4me3 "mesas," senescence-associated distension of satellites (SADSs), senescence-associated heterochromatin foci (SAFHs), and others), accompanied by characteristic transcriptional signatures, miRNAs, and non-coding RNA expression; and ***(iii) protein markers*** that are either present (DCR2, NKG2D ligands) or absent (for instance, proliferation markers, Lamin B1). For the time being, none of the above-described markers (stemming from features and signaling pathways) is sufficient alone for the identification of senescent cells with absolute specificity. Based on the fact that some markers have a broader spectrum while others depict specific senescence types, the ICSA consortium has proposed a specific multi-marker approach for robust detection (Gorgoulis et al. 2019) that allows accurate estimation of the effectiveness of the anti-senescence strategies.

Physiological and Pathological Implications

Senescence could be metaphorically described as the Greek god Hermathena or the Roman god Janus both facing to two opposite directions depending on the situation. Of clinical importance, short-term induction of senescence has a favorable outcome during development (*developmentally programmed or embryonic senescence*) and in normal processes, like tissue repair *(acute senescence*) (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019). Additionally, cellular senescence plays a crucial role as an anti-tumor barrier at the early stages of tumorigenesis, preventing neoplastic cells from further expansion and propagation (Gorgoulis et al. 2019; Bartkova et al. 2006; Halazonetis et al. 2008; Gorgoulis and Halazonetis 2010). On the other hand, persistence of senescence is associated with harmful properties mediated mainly via paracrine and/or systematic SASP, while escape from OIS is implicated in tumor progression and remission (Galanos et al. 2016; Komseli et al. 2018). Accumulation of senescent cells results from chronic stress damage and/or insufficient clearance by the immune system (*chronic senescence*). As a consequence, not only the regenerative potential and function of tissues/organs are impaired, but also a "slow burning" inflammatory milieu is maintained, triggering the

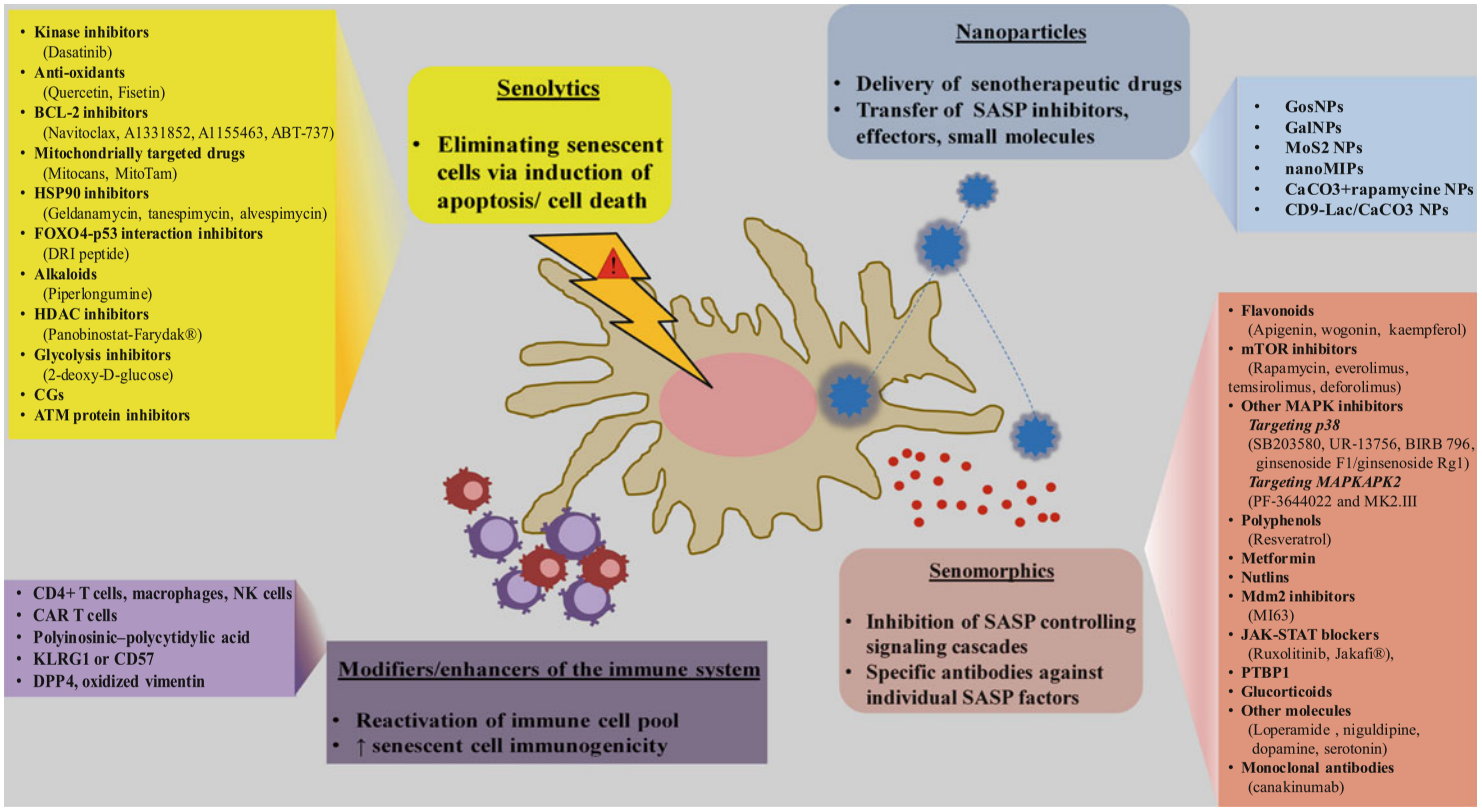
aging process and various pathological conditions such as cardiovascular, kidney, liver, and neurodegenerative diseases, cancer, type 2 diabetes, osteoarthritis, cataract, idiopathic pulmonary fibrosis, metabolic syndrome, and cahexia (Gorgoulis et al. 2019; Myrianthopoulos et al. 2019; Munoz-Espin and Serrano 2014).

Pharmacological (Therapeutic) Intervention

Given the continuously growing knowledge on the wide spectrum of adverse effects of chronic senescence, as already mentioned, the development of new therapies that selectively target senescent cells or neutralize their undesirable properties emerged as an attractive challenge. Research on senotherapeutic agents and their precise mode of action (molecular key players, pathways, and mechanisms, Fig. 1), although quite restricted, is rapidly expanding, and this information is currently exploited for clinical testing (Table 2). This exciting and relatively new field encompassing molecular and chemical biology and pharmaceutical chemistry along with sophisticated methodologies and advanced technologies (e.g., efficient process of "big data" via machine learning) for drug discovery (Sakellaropoulos et al. 2019; Vougas et al. 2019) has already provide aspects of its potential and future therapeutic opportunities. For the time being, the vast majority of available senotherapeutic compounds are either drugs already used for other research and clinical purposes or extensively investigated natural derivatives. Traditional and next-generation, direct or indirect, senotherapies are based on the following classes of molecules: ***(1) senolytics***, ***(2) senomorphics or senostatics*** (SASP inhibitors), ***(3) modifiers/enhancers of the immune system,*** and ***(4) nanoparticles***.

Senolytics

Senolytics are molecules that impede cardinal senescence pro-survival pathways rendering senescent cells vulnerable to cell death. The first described compounds with senolytic properties were dasatinib and quercetin (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Dasatinib is a kinase inhibitor that was traditionally used as an anticancer drug. Apart from the activity of various protein tyrosine kinases such as BCR/Abl, c-Kit, and Scr family members, dasatinib blocks Ephrin receptors, as well as promotes apoptosis. These receptors interact with two ligands known as Ephrin 1 (EFNB1) and Ephrin 3 (EFNB3) that have been shown to be upregulated in senescent cells, generating thus critical pro-survival (anti-apoptotic) signals. Quercetin, in turn, is a flavonoid with well-known antioxidant properties that can modulate various molecular cascades such as the NF-kB, PI3K/AKT, mTOR, p53/p21$^{WAF/CIP1}$, serpin, and estrogen receptor signaling pathways (Gorgoulis et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). Regarding senolysis by quercetin, inhibition of the PI3Kδ isoform has been favored as the most prevalent mechanism for apoptosis induction. Administration of dasatinib or quercetin has been reported to effectively but variably, depending on the cell type, alleviate aging and senescence *in vitro* and *in vivo* (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Interestingly, their combination exerts a broader senolytic outcome and has been demonstrated in clinical trials to effectively reduce the senescent cell "load" in humans (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019, Table 2). Among other recently demonstrated flavonoids exerting senolytic efficiency is fisetin that behaves similarly to quercetin, as expected by their slight structural differences (hydroxyl group at position 5 of the chromone scaffold). Fisetin affects a variety of cellular functions as well as molecular key players/pathways including topoisomerases; cyclin-dependent kinases; the NF-kB, PI3K/AKT/mTOR, PPAR, and PARP1 signaling pathways; and epigenetic modifiers (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). Based on such a multilevel activity, its several beneficial effects, for instance, on cancer prevention and neurodegenerative processes, seem to rely not only on the antioxidant potential but also on their impact on senescence and SASP, a feature that seems valid for the majority of flavonoids in promoting well-being and health.



Senescence, Fig. 1 Schematic overview of direct and indirect senotherapeutic approaches and corresponding drugs/agents currently applied or proposed (for details see text)

Senescence, Table 2 Senotherapeutics in clinical trials

Rapamycin (sirolimus)		NCT01649960	Coronary artery disease	Phase2

Another potent group of senolytic drugs includes first- and second-generation inhibitors of the BCL-2 (B CELL LYMPHOMA-2) cell death regulator family of proteins, implicated in triggering the intrinsic mitochondrial apoptosis pathway. Navitoclax (ABT263), an anticancer drug that specifically targets BCL-2, BCL-W, and BCL-XL, was the first described inhibitor of the BCL-2 family with senolytic properties (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). The molecule behaves as a protein-protein interaction inhibitor (PPI), disrupting the interaction between BCL-2 proteins and their endogenous inhibitory regulators (BH3 domain-containing proteins). Despite the severe side effects (platelet and neutrophil toxicity) that rendered clinical testing unfeasible, establishment of Navitoclax as a senolytic opened new horizons for the identification of other novel selective BCL-XL inhibitors that simultaneously eliminate senescent cells. Indeed, additional such compounds entered the scenery. A1331852 and A1155463 are members of the flavonoid family that were initially applied for cancer treatment (Paez-Ribes et al. 2019; von Kobbe 2019). They are high-affinity BH3 mimetic ligands of BCL-XL and selectively disrupt the BCL-XL-BIM complex, exerting senolytic properties in a cell type-specific manner but with lower toxicity that renders them attractive candidates for clinical applications (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). An additional BH3 mimetic compound and PPI inhibitor, the anticancer drug ABT-737, binds to the hydrophobic groove of BCL-2, BCL-XL, and BCL-W in contrast to pro-survival proteins MCL-1, BCL-B,

and BFL-1 (A1) that are resistant. Additionally, mitocans (mitochondrially targeted anti-cancer drugs) are also BH3 mimetics known to induce apoptosis in malignant cells. Given that senescent cells exhibit an increased mitochondrial load, these compounds emerged as intriguing candidates for putative senolytic interventions. Interestingly, the mitochondria-targeted tamoxifen (MitoTam) has been reported to selectively eliminate senescent cells *in vitro* and *in vivo* (Paez-Ribes et al. 2019; von Kobbe 2019). The molecule impedes mitochondrial oxidative phosphorylation (OXPHOS) in senescent cells resulting in the loss of mitochondrial integrity and eventually apoptosis.

The wide range of senolytics also includes molecules that belong to the following subclasses (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019): **(i)** FOXO4-p53 interaction inhibitors (DRI peptide), **(ii)** alkaloids (piperlongumine and analogues), **(iii)** heat shock protein (HSP90) inhibitors, **(iv)** histone deacetylase (HDAC) inhibitors (Panobinostat-Farydak®), **(v)** glycolysis inhibitors (2-deoxy-D-glucose), **(vi)** cardiac glycosides (CGs), and **(vii)** ataxia-telangiectasia mutated (ATM) protein inhibitors. FOXO4 (Forkhead box protein O4), a member of the forkhead family transcription factors, interacts with p53 at sites of DNA damage, up regulating the senescence master regulator $p21^{WAF1/CIP1}$. This interaction can be disrupted by a FOXO4 D-retro-inverso (DRI) peptide that selectively competes with FOXO4 for p53 binding, causing p53 nuclear exclusion in senescent cells and thus promoting their apoptosis, as shown in both *in vitro* and *in vivo* settings (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Piperlongumine is a natural compound shown to induce apoptosis in cancer cells by generating reactive oxygen species (ROS) or through modulation of the NF-kB cascade. The latter along with the fact that the exact mechanism of senolytic activity remains still unraveled but seems independent from ROS production raises the possibility of a common behavior between alkaloids and flavonoids in eliminating senescent cells (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). HSP90 inhibitors include the natural antitumor antibiotic geldanamycin and its analogues tanespimycin (17-AAG) and alvespimycin (17-DMAG). They belong to the macrocyclic lactam class of agents and inhibit HSP90 through binding to the N-terminal ATP pocket. This inhibition seems to be associated with AKT (protein kinase b) destabilization and apoptosis induction, reminding the mode of action of other senolytics such as quercetin (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Interestingly, in contrast to other senolytics, their spectrum of efficacy is likely broader in terms of cell type affected. Among the HDAC inhibitors recently described as senolytics, panobinostat is the most prevalent compound. Panobinostat has been shown to exert a senolytic potential and a synergistic effect on persistent senescent cells after their treatment with taxol or cisplatin (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). At a different level, altered (mainly hypermetabolic) activity and elevated glycolysis commonly evident in senescent cells are essential for their survival. In the context of therapy-induced senescence or OIS, treatment of senescent cells with 2-deoxy-D-glucose (2-DG), a pseudo-substrate for glycolysis, renders them selectively susceptible to apoptosis (Paez-Ribes et al. 2019). Cardiac glycosides (CGs) impose a similar vulnerability to senescent cells by affecting cell membrane Na/K-ATPas and altering thus the electrochemical gradient balance. Lastly, KU-60019 an ATM and DDR inhibitor seems also to exert an effective anti-senescence potential in *in vivo* settings recapitulating age-related processes, via regulation of lysosomal acidification, removal of dysfunctional mitochondria, and metabolic reprogramming (Paez-Ribes et al. 2019).

Senomorphics or Senostatics (SASP Inhibitors)

Senomorphics or senostatics are agents that exert inhibitory effects on SASP functions and not on senescent cell viability itself. They include compounds that target various SASP controlling signalling cascades or specific antibodies against individual SASP factors such as IL-1b, IL-6,

and IL-8. Given the huge diversity of putative targets, the number and the spectrum of described senomorphic compounds are extended (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). Flavonoids such as apigenin, wogonin, or kaempferol mediate suppression of SASP components and particularly IL-1a, IL-1b, IL-6, IL-8, GM-CSF, CXCL1, monocyte chemoattractant protein-2 (MCP-2), and MMP-3, partially via the NF-kB p65 subunit and the NF-kB inhibitor IkBz (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Rapamycin (Rapamune®) has also been shown to exert senomorphic functions. This natural macrolide is a well-known selective inhibitor of the mTOR pathway. mTOR activates MAPKAPK2 (MAPK activated protein kinase 2) translation, resulting in phosphorylation of the member of the TIS11 family of early response proteins ZFP36L1 (ZFP36 ring finger protein like 1) and direct induction of various SASP components (Paez-Ribes et al. 2019; von Kobbe 2019). In addition, IL-1α translation inhibition and IL-6 downregulation by rapamycin can be exerted via an Nrf2-independent mechanism. Rapamycin is also known to regulate prelamin A, a factor implicated in longevity. Novel mTOR inhibitors such as everolimus, temsirolimus, and deforolimus exerting superior pharmacological properties have also entered the scenery of senomorphics (Paez-Ribes et al. 2019). Among other inhibitors of the MAPK pathway, those targeting p38 (SB203580, UR-13756, BIRB 796, and ginsenoside F1/ginsenoside Rg1) and MAPKAPK2 (PF-3644022 and MK2.III) have been demonstrated to suppress several SASP components (for instance, IL-6 and IL-8) by inhibiting NF-κB transcriptional activation and paracrine effects in human senescent cells (Paez-Ribes et al. 2019; von Kobbe 2019).

A different class of agents presenting senomorphic activity includes polyphenols and especially resveratrol, a natural trans-stilbene polyphenol with a wide spectrum of bioactivities. Regarding its senomorpic properties, resveratrol modulates potent cellular signaling pathways such as NF-kB (IkB inhibition) and PI3K/AKT, controlling thus the release of multiple pro-inflammatory cytokines (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). Resveratrol also activates SIRT1, a class III histone deacetylase, the former with notorious properties in lifespan and AMPK (AMP-activated protein kinase) and the latter implicated in various processes including metabolism and aging. In addition, the molecule and its synthetic analogues (polar substitution on the 4' position) can restore the expression of mRNA splicing factors, and therefore these agents have been proposed as potential drugs for reversing the senescent phenotype (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019). This function was independent of SIRT1 activation and most probably related to enhanced telomere maintenance.

The intriguing beneficial impact of the antidiabetic drug metformin (Glucophage®) on aging and life span expansion led to initiation of drug repurposing research seeking for its putative role on senescence. These efforts revealed some targets/levels of senescence regulation by metformin (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019; von Kobbe 2019): ***(i)*** decrease inNF-κB nuclear translocation and inhibition of phosphorylation of the two catalytic subunits of IkB kinase, namely, IKK α and β, leading to downregulation of several SASP factors, namely, CXCL-5, IL-6, IL-8, and IL-1β; ***(ii)*** AMPKa stimulation causing mTOR pathway inhibition; ***(iii)*** tuning of mitochondrial electron transport, known to eventually affect regulation of pro-inflammatory cytokines such as IL-6; and ***(iv)*** mitochondrial glycerol-3-phosphate dehydrogenase (GPDH) and lysine-specific demethylase 6A (KDM6A/UTX) control. Based on the aforementioned beneficial effects on health and life span, testing for additional therapeutic opportunities in the frame of clinical trials is currently ongoing (Targeting Aging with MEtformin – TAME study, Table 2).

Nutlins utilized for cancer treatment can impose apoptosis and/or senescence by inhibiting Mdm2 and stabilizing p53. However, these molecules apart from inducing senescence exert also some anti-senescence properties. Nutlin-3a is known to suppress NF-κB in a p53-dependent manner, driving downregulation of certain SASP interleukins in human cells (Paez-Ribes et al.

2019; von Kobbe 2019). A similar potential for SASP inhibition has been reported for the next-generation Mdm2 inhibitor MI-63 (Paez-Ribes et al. 2019). Blocking of the JAK/STAT pathway by targeting JAK kinases (ruxolitinib, Jakafi®), eventually leading to inactivation of C/EBPβ, has also been linked with SASP alleviation. Among the JAK kinases, blocking of JAK1/2 drives the decrease of the SASP modulator activin A that is frequently found upregulated during aging (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). Likewise, NOTCH1 upregulation has been associated with SASP suppression, via C/EBPβ downregulation, in the context of OIS (Paez-Ribes et al. 2019). In addition, the alternative splicing modulator polypyrimidine tract binding protein 1 (PTBP1) has emerged as promising therapeutic target for SASP inhibition and is currently under investigation (Paez-Ribes et al. 2019). Another class of drugs harboring SASP inhibitory potential includes the glucocorticoids, steroid hormones with well-characterized anti-inflammatory properties (Myrianthopoulos et al. 2019; Paez-Ribes et al. 2019). The most effective compounds for SASP (IL-1a and IL-6) suppression, via control of NF-kB transcription, are corticosterone and cortisol. In contrast, dexamethasone has been demonstrated to induce senescence via SIRT1 inhibition and activation of the $p53/p21^{WAF/CIP1}$ axis, proving a putative explanation for its adverse side effects. Notably, some other clinically applied drugs such as loperamide and niguldipine as well as dopamine and serotonin antagonists have been reported to exhibit senomorphic properties (Myrianthopoulos et al. 2019). Lastly, an additional way to directly target SASP components (ligands or receptors) encompasses the use of monoclonal antibodies. Canakinumab that reacts against IL-1b and has been extensively used to treat autoimmune diseases comprises such an example (Paez-Ribes et al. 2019).

Modifiers/Enhancers of the Immune System

The immune system undergoes an age-related decline that has been associated with accumulation of senescent cells in tissues. Given that senescent cells are immunogenic, stimulation of the immune system by immunotherapy, currently used for treatment of cancer and other diseases, has also emerged as an attractive strategy. Senescent cell clearance is achieved by interventions that aim at two levels: reactivation of the immune cell pool or increase in senescent cell immunogenicity. Senescent cells are eliminated by $CD4^+$ T cells, macrophages, and NK cells (senescence surveillance). Chimeric antigen receptor (CAR) T cells against senescence occurring agents, similar to those developed for cancer therapies, seem a promising choice (Paez-Ribes et al. 2019; von Kobbe 2019). Moreover, restoration of T cell and NK functions that decline during the development of age-related pathologies and aging can be achieved via inhibition of AMPK by an p38 MAPK inhibitor or via downregulation of the killer cell lectin-like receptor G1 (KLRG1 or CD57) (Paez-Ribes et al. 2019; von Kobbe 2019). Treatment with polyinosinic-polycytidylic acid, a NK toll-like receptor 3 (TLR3) ligand and interferon-γ, increases in certain settings the cytotoxic activity of NK cells via the NK cell receptor NKG2D (Paez-Ribes et al. 2019; von Kobbe 2019). The latter interacts with corresponding ligands frequently upregulated in senescent cells. As for enhancing senescent cell immunogenicity, the surface marker DPP4 can be exploited in the context of an antibody-dependent NK cell-mediated cytotoxicity, for senescent cell elimination (Paez-Ribes et al. 2019; von Kobbe 2019). Similarly, an oxidized form of membrane-bound vimentin discovered in senescent fibroblasts could be recognized and targeted by humoral innate immunity processes (Paez-Ribes et al. 2019).

Nanoparticles

Nanoparticles (NPs) are not considered in a strict manner, as agents that can alone influence the viability or the function of senescent cells. In fact, NPs behave as carriers, able to efficiently deliver among other substrates, a senotherapeutic drug for targeted clearance or manipulation of the deleterious potential of the senescent cell. In this context, mesoporous silica nanoparticles capped with a mixture of galacto-oligosaccharides (GosNPs) of different lengths were the pioneer cargo delivery system

generated. GosNPs enter cells via endocytosis and fuse with lysosomes that in senescent cells are associated with elevated endogenous SA-βgal activity (Paez-Ribes et al. 2019). This interaction results in enzymatic hydrolysis of the cap and release of the cargo selectively in senescent cells. Subsequently, silica beads capped with 6-mer galacto-oligosaccharides (GalNPs) have been reported as superior mediators for effective and specific (with lower toxicity) transport of drugs in *in vivo* models of damage- and chemotherapy-induced senescence (Paez-Ribes et al. 2019). Such evidence opens new perspectives in enhancing the beneficial effect of chemotherapy by elimination of cancer cells undergoing chemotherapy-induced senescence. Moreover, molybdenum disulfide nanoparticles (MoS2 NPs) as well as molecularly imprinted nanoparticles (nanoMIPs) have been generated and tested *in vitro* (Paez-Ribes et al. 2019). MoS2 NPs seem to exhibit low preference for senescent cells. In contrast, nanoMIPs loaded with dasatinib can eliminate senescent cells by internalizing the drug, after the recognition of surface molecules such as b2 microglobulin (B2M) (Paez-Ribes et al. 2019).

Alternatively, other emerging nanovehicles aim to restrain SASP by transferring encapsulated inhibitors, effectors, and small molecules. Examples applied and tested in *in vitro* settings but still lacking in vivo evidence include (Paez-Ribes et al. 2019) (i) rapamycin containing porous calcium carbonate nanoparticles (CaCO3). These NPs are coated with a conjugate of lactose (Lac, galactose/glucose dimers linked with β-1,4- glycosidic units) that allows cargo release in the presence of increased SAβ-gal activity and polyethylene glycol imposing stability in the blood and opsonisation avoidance. (ii) The latter nanodevices, conjugated with a monoclonal antibody against CD9. CD9-Lac/CaCO3 exerts their delivery properties by interacting with CD9, commonly located at the surface senescent cells that simultaneously exhibit elevated SAβ-gal activity, thus strengthening cell specific uptake and cargo release.

Sepsis

Michael Bauer
Department of Anesthesiology and Intensive Care Medicine, Jena University Hospital, Jena, Germany
Center for Sepsis Control and Care (CSCC), Jena University Hospital, Jena, Germany

Synonyms

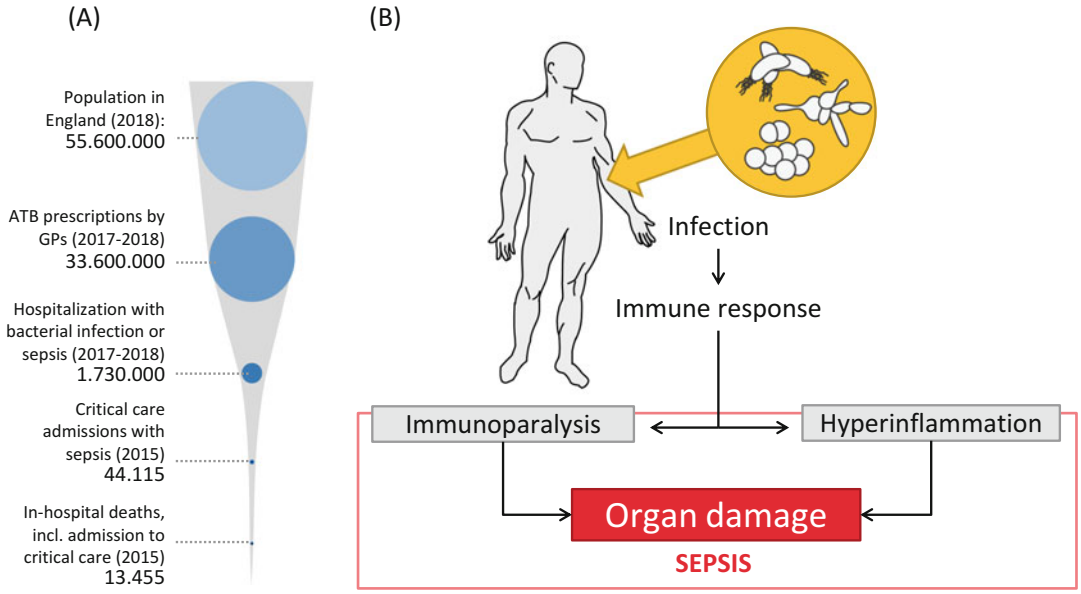
Blood poisoning; Infection; Organ dysfunction; Systemic inflammation; Septic shock

Definition

Sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction is the criterion that distinguishes sepsis from minor, self-limiting infections (Singer et al. 2016). Main clinical manifestations are altered mentation, high respiratory rates, and low blood pressure that occur in patients with suspected infection (Seymour et al. 2016).

Basic Mechanisms

Sepsis has long been interpreted as an excessive systemic inflammatory response due to infection ("systemic inflammatory response syndrome, SIRS"; Bone et al. 1992). Failing containment of invading pathogens and pathologic hyperinflammatory immune responses were thought causative of impaired organ function. The exclusive reliance on SIRS as the hallmark of sepsis has been challenged by the finding that SIRS criteria are absent in a significant proportion of patients (Kaukonen et al. 2015). Moreover, reduced immune responsiveness ("immunoparalysis") has been shown to dominate sepsis pathology, at least in later stages of the disease process (Hotchkiss et al. 2013). These opposing response patterns are both able to provoke remote organ



Sepsis, Fig. 1 Dysfunctional immune responses in sepsis (**a**) Infection is a frequent and typically self-limiting event. Approximately 2.5% of patients presenting in hospitals with infection will be admitted to an intensive care unit due to infection-triggered organ failure, i.e., sepsis (data adapted from (Singer et al. 2019), circle areas are proportional to population and case numbers). (**b**) Organ damage in sepsis can be provoked by either reduced immune responsiveness (immunoparalysis) or hyper-inflammatory responses to infections (immunopathology) in a minority of patients. Abbreviations: *ATB* antibiotic, *GP* general practitioner

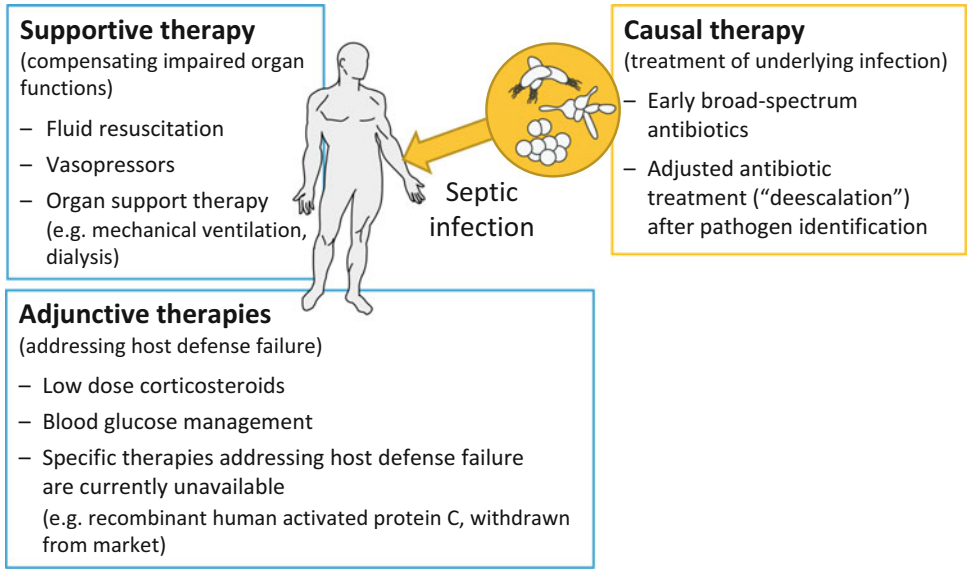
failure. The molecular mechanisms underlying sepsis are, though, not fully understood. However, epidemiological data point toward a rare event in the light of frequent uncomplicated infections receiving antibiotic prescriptions across the population (Singer et al. 2019) (Fig. 1).

Currently, sepsis is best conceptualized as an imbalanced and dysfunctional host response induced by failed control of pathogens at the site of infection. Numerous factors including age, gender, genetic predisposition, and comorbidities influence susceptibility to the disease (Paoli et al. 2018; Taudien et al. 2016). Importantly, damaging processes in the course of sepsis seem to differ depending on tissues, their regenerative capacity, and cell type. For example, sepsis-associated organ dysfunction is often reversible, and necrotic or apoptotic cell death is a rare event in parenchymal organs of septic patients (Hotchkiss et al. 1999). In contrast, immunoparalysis can be attributed to cell death of immune cells, in particular lymphocytes (Hotchkiss et al. 2013).

Despite tremendous research efforts during recent decades, no host-directed *adjunctive therapy* for sepsis exists (Fig. 2). Numerous clinical studies on candidate mediators failed, and only recently, meta-analyses of the clinical trials indicated that certain beneficial effects might have escaped notice due to the highly individual disease courses and etiologies. For example, analysis of data on antibodies neutralizing the pro-inflammatory cytokine anti-TNFα suggests a benefit for a subset of patients (Marshall 2014). Current efforts aim at identification of subgroups of patients that will respond to specific interventions, e.g., immune modulatory therapy or adjunctive therapies (Marshall 2014; Seymour et al. 2019). Besides individualized treatment approaches, targeted drug delivery might hold potential for improved sepsis therapies.

Immune Responses

The occurrence of hyperinflammation and immunoparalysis in sepsis patients raises



Sepsis, Fig. 2 Current options to treat sepsis
Sepsis therapy includes "causal" (anti-infective), "supportive" (replacing impaired organ function), and "adjunctive" (interfering with the failing host response) treatment options

questions concerning the causes of these fatal dysfunctions of the immune system.

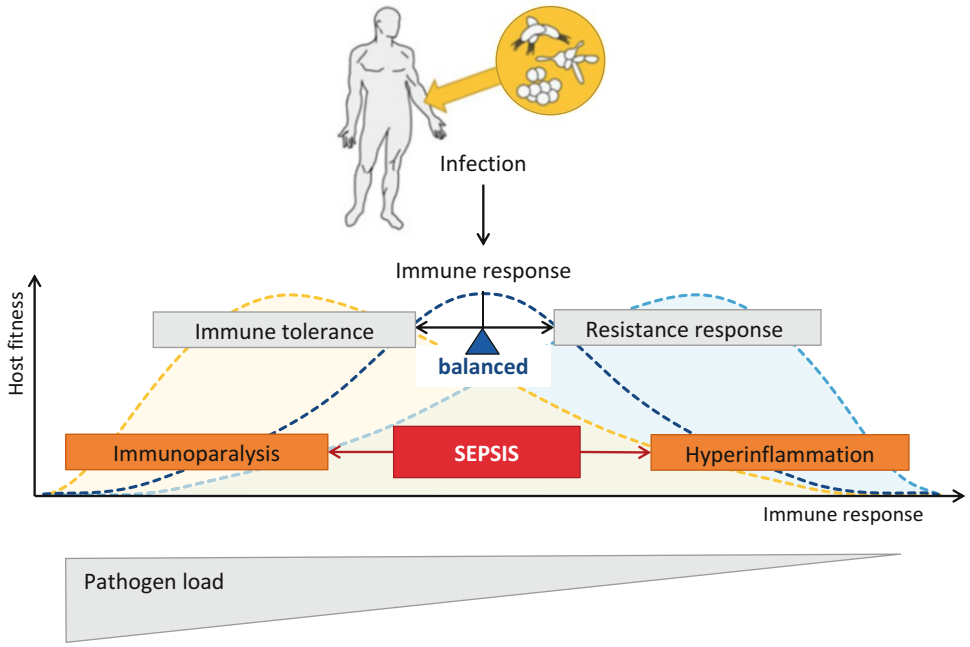
Regularly, higher organisms react to invading microbes with two alternative response patterns. In addition to the well-known resistance responses of the immune system, which result in pathogen clearance, "disease tolerance" has been acknowledged as an alternative adaptive strategy of the host (Medzhitov et al. 2012). Disease tolerance enables the organism to sustain a certain pathogen load without marked damage or disease symptoms (i.e., organ failure). Disease tolerance requires maintenance of cell and organ functions of the infected host by continuous repair reactions despite persistent pathogen burden. Immune resistance and disease tolerance responses enable the resolution of infection and the restoration of health.

In sepsis, the concerted resistance and tolerance responses of the host fail. Exuberant resistance responses cause a hyperinflammatory state, i.e., SIRS, and collateral tissue damage. Dysregulated disease tolerance might result in immunoparalysis, recurrent or chronic infections, and corresponding damage caused by disseminating pathogens (Fig. 3).

Significant progress has been made regarding the understanding of the causes of dysregulated resistance and tolerance and consequently of hyperinflammation and immunoparalysis in sepsis patients. Both response patterns have been attributed to specific traits of the infecting pathogen or the host. However, increasing evidence indicates pathogen dose as key for causing these opposing reactions (Bauer et al. 2018). Innate immune cells challenged with low amounts of pathogens were shown to generate energy-demanding resistance responses, whereas high pathogen load will increasingly perturb cell metabolism. Under these conditions, a shift from resistance reactions toward maintenance and repair activities seems to occur, which ultimately enables tolerance toward pathogens. Induction of resistance and tolerance depending on the pathogen burden might help the cells and tissues to integrate challenges by various microbes and other stressors, in particular in the critically ill, and thus fulfill the basic fitness and survival requirements of cells and organs (Fig. 3).

The Role of Parenchymal Tissues

While the activated immune system during phases of acute infections is highly energy demanding, the overall limited energy supply has to be



Sepsis, Fig. 3 Immune response patterns to infection and development of sepsis
In sepsis, the balanced interaction of immune cells, pathogens, and parenchyma upon local, uncomplicated infections gets out of control. Resistance responses progress to systemic hyperinflammation, whereas excessive tolerance might result in immunoparalysis. Both immune response patterns impact host fitness by causing organ damage. Pathogen load and energy metabolism have been suggested as key mediators of the dichotomous immune responses

redistributed, which might result in parenchymal metabolic shut-down. Indeed, critical illness is frequently associated with reduced oxygen consumption, metabolic adjustments, and decreased organ function. Importantly, this organ dysfunction is not associated with markedly increased cell death and is usually quickly restored after episodes of sepsis (Hotchkiss et al. 1999). This, together with drastically altered metabolism, has led to the concept of "hibernation" of the failing organs (Stanzani et al. 2020). These topics are active research areas aiming at alternative treatment approaches for the attainment of metabolic homeostasis and restoration of organ function during and after sepsis.

Molecular Mechanisms Mediating (Mal-) adaptive Responses to Infection

Molecular signaling events mediating resistance and tolerance responses to infections have been investigated in cellular and animal models. Given the crucial role of a balanced energy budget, the emerging involvement of energy sensing signaling pathways does not come as a surprise. Both in vitro and in vivo data indicate involvement of the mechanistic target of rapamycin (mTOR) signaling pathway in the induction of **resistance** responses to infectious microbes. mTOR is known as a central mediator of anabolic processes. Together with the signaling proteins of the phosphoinositide 3-kinase (PI3K) family, mTOR is controlling energy demanding cell functions, such as proliferation or differentiation, in addition to resistance responses of immune cells (Cheng et al. 2014).

Experimentally, sepsis-induced hyperinflammation could already be effectively treated by drugs targeting mTOR as the key mediator of enduring resistance responses (Yen et al. 2013). In septic mice, the mTOR inhibitor rapamycin significantly suppressed the hyperinflammatory response and decreased mortality.

Signaling reactions that trigger the development of disease **tolerance** are less well understood. Recent investigations revealed AMP-activated protein kinase (AMPK) as a critical mediator of tolerance responses to infections (Bauer et al. 2018). In contrast to mTOR, AMPK activity is induced at low cellular energy levels. In pathogen-challenged cells, the signaling protein mediates maintenance and repair reactions, including autophagy of cellular organelles. A key role of AMPK has been proposed for tissue damage control in parenchymal cells in states of disease tolerance (Soares et al. 2014).

Taken together, resistance and tolerance responses triggered by invading pathogens appear to be part of evolutionary conserved and interdependent reaction patterns of the organism to environmental stress in general (Bauer et al. 2018; Stanzani et al. 2020).

Pharmacological Intervention

Current Standard of Care

Current therapeutic concepts mainly focus on "*causal" therapy*, i.e., early anti-infective therapy, combined with circulatory support by volume resuscitation and additional vasopressors (*"supportive" therapy*), if a mean arterial pressure of 65 mm Hg cannot be achieved by volume resuscitation alone (Rhodes et al. 2017).

Antimicrobial therapy should be initiated as early as possible after diagnosis. Importantly, standard samples for microbiological assessment (including blood cultures) should be taken before starting antibiotics. Initial therapy will, in general, rely on empirical broad-spectrum therapy with one or more antimicrobials (including antifungal or antiviral therapy, if applicable). After identification of the causative pathogen, the antibiotic regimen should be narrowed as appropriate (Rhodes et al. 2017).

According to the Surviving Sepsis Campaign (SSC) guidelines, initial resuscitation from sepsis-induced hypoperfusion should be initiated immediately after sepsis diagnosis using IV crystalloids. If a target mean arterial pressure of 65 mm Hg cannot be achieved by fluid resuscitation alone, norepinephrine is recommended as first-choice vasopressor. Vasopressin or epinephrine can be added to raise the arterial pressure to the target values or to reduce norepinephrine dosage (Rhodes et al. 2017). The SSC as a "one world" initiative has been criticized as primarily suitable for limited income countries, and a more individualized approach regarding hemodynamic monitoring and catecholamine support will be applicable in high-income countries.

The present therapeutic approaches are summarized in Fig. 2.

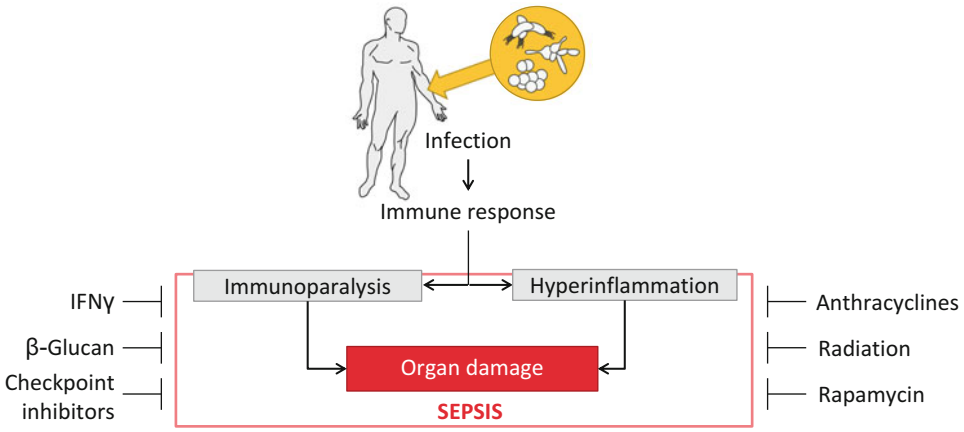
The only currently used immunomodulatory intervention in septic shock is the administration of "stress doses" of hydrocortisone. This approach yielded controversial results (Suffredini 2018) and reflects a prominent example for the need to define subgroups of patients prior to initiation of therapy (personalized medicine, "theranostics").

There is currently no approved therapy that targets the dysbalanced immune response. Moreover, no specific therapies exist to pharmacologically treat organ dysfunction, since recombinant human activated protein C was withdrawn from the market in 2011.

Novel Treatment Approaches – Restoring Immune and Organ Function

From the immunological point of view, the sepsis paradigm currently shifts from a focus on simple "hyperinflammation" to a multifaceted disruption of immune balance, as many patients present with signs of "immunoparalysis." This is best reflected in current trials studying the potential of immunostimulatory therapies, such as growth factors or check point inhibitors as adjunct options in sepsis therapy (Hotchkiss et al. 2013). Leentjens et al. demonstrated partial reversion of immunoparalysis of humans by treatment with IFN-γ in vivo (Leentjens et al. 2012). Immunostimulatory agents used in preclinical models cover a broad spectrum of agents, including pathogenic yeast *Candida albicans* and its cell wall component β-glucan (Novakovic et al. 2016). However, these approaches will have to rely on improved patient stratification.

In line with the critical balance of mTOR and AMPK, hyperinflammation during sepsis can be



Sepsis, Fig. 4 Evolving therapeutic concepts to modulate resistance and tolerance responses in sepsis models Currently studied options to modulate failing immune responses in sepsis. These specific interventions aim to suppress organ damage provoked by either immunopathology or immunoparalysis in the course of sepsis

suppressed by the immunosuppressive and anti-proliferative agent rapamycin (Yen et al. 2013). Additional options to treat hyperinflammatory sepsis have been revealed by Figueiredo et al. (2013). In a groundbreaking study, these authors screened a drug library for candidates that affect inflammatory reactions in a macrophage cell line. Anthracyclines – commonly applied for the therapy of solid cancers – were identified to prevent organ dysfunction in mouse models of polymicrobial sepsis independent of changes in pathogen burden. Apparently, low doses of anthracyclines induce a DNA damage response and autophagy, which are assumed to be the mechanisms underlying tissue protection and anti-inflammatory effects. Interestingly, irradiation produced similar effects. Together, these data indicate that low doses of stressors, such as toxins or irradiation, stimulate cellular repair and thereby induce cross-protection, i.e., generally increased resilience. The anti-inflammatory effects of anthracylines or radiation might be connected to energy demands. Reactions to environmental stressors and inflammatory responses compete for energy sources. The additional energy requirement also affects protein synthesis and cell proliferation. Accordingly, treatment of cells with anthracylines or radiation seems to lower the immune response in favor of tolerance reactions. Morbidity induced by systemic hyper-inflammation decreases, and the organism exhibits a state of "disease tolerance."

Together, these interventions (Fig. 4) targeting immunopathology and immunoparalysis during the course of sepsis might add to the therapeutic armamentarium of personalized care in the field of infection-driven organ dysfunction, which discriminates sepsis from uncomplicated infection.

Synonyms

5-hydroxytryptamine = 5-HT (= enteramine); Serotonin

Definition

The serotoninergic system is one of the oldest neurotransmitter/hormone systems in evolution, which may explain why 5-HT interacts with such a diversity of receptors of the G protein-coupled family (type A) and the ligand-gated family Cys-loop family, similarly to acetylcholine, GABA, or glutamate. 5-HT was discovered in the gut in the 1930s and called enteramine and then rediscovered in the 1940s in the blood and called serotonin, since it also constricted smooth muscle in the vessels. 5-HT is synthesized from l-tryptophan; there are two tryptophan hydroxylases forming 5-hydroxytrytophan (5-HTP), which by the l-amino acid decarboxylase leads to 5-HT. 5-HT can be conjugated with glucuronide or sulfate. In the nervous system, 5-HT is metabolized via monoamine oxidase to 5-hydroxyindolacetaldehyde and finally to 5-hydroxyindolacetic acid (via aldehyde dehydrogenase). It can also lead to 5-hydroxytryptophol by an aldehyde reductase in some peripheral nerves. Thus, 5-HT acts as a neurotransmitter with all the typical features, such as intracellular storage, activity-dependent release, the existence of both pre- and post-synaptic receptors, and an active uptake system, via the serotonin transporter and metabolizing/inactivating enzymes. 5-HT also acts as a hormone, released into the blood or gut to work more distantly.

Basic Characteristics

Physiology

The main source of 5-HT (95%) is from enterochromaffin cells of the gut, where 5-HT is synthesized from tryptophan. It can be released into the gut lumen, e.g., as a reaction to pressure and act on receptors located on the smooth muscle, or released into the portal blood circulation, by a variety of nervous or alimentary stimuli. 5-HT is also found in enteric neurons. In the blood, the vast majority of 5-HT is in storage granules from platelets, which are endowed with a very active uptake system (they do not synthesize 5-HT). Large amounts of 5-HT are released during platelet aggregation, and it can act locally on endothelial cells and vascular smooth muscle. 5-HT is also present in mast cells. In the central nervous system (CNS) and peripheral nervous system (PNS), 5-HT acts as a neurotransmitter on a variety of

receptors, which may be located pre- or postsynaptically. 5-HT is also found in the pineal gland, where it serves as a precursor for the synthesis of melatonin by 5-HT-*N*-acetyltransferase and hydroxyindole-*O*-methyltransferase, under the control of the clock genes of the suprachiasmatic nucleus, which modulates enzyme activity levels up to 50-fold during the circadian cycle.

Multiple 5-HT Receptor Subtypes

There are at least 15 different 5-HT receptors, and the system may be more complex (see Tables 1, 2, 3 and 4). With the exception of 5-HT_3 receptors (ligand-gated ion channels), 5-HT receptors belong to the G-Protein-Coupled Receptors (GPCR) superfamily, which is one of the most complex families of neurotransmitter receptors. Some 5-HT receptors have multiple splice variants (5-HT_{2C}, 5-HT_4, 5-HT_7) or RNA-edited isoforms (5-HT_{2C}). There is evidence that homo- and hetero-dimerization (e.g., 5-HT_{2C}, 5-$HT_{1B/1D}$, 5-HT_{2C}/GHS-R1a) can occur. We have proposed a classification system based on operational, structural, and transductional criteria (Humphrey et al. 1993; Hoyer et al. 1994; Hartig et al. 1996) which has been progressively refined (Hoyer and Martin 1997; Hannon and Hoyer 2008). The current classification (Barnes et al. 2021) favors an alignment of nomenclature with the human genome to account for species differences. Seven families of 5-HT receptors have been recognized, 5-HT_1 to 5-HT_7. Yearly updates about 5-HT receptors and ligands can be found in the BJP Concise Guide to PHARMACOLOGY (Alexander et al. 2019).

Most 5-HT receptors, except 5-HT_3 which are Cys-loop ligand-gated channels with structural analogy to nicotinic or $GABA_A$ receptors, belong to the GPCR family A. Lowercase denomination means that the receptor is not functionally defined in native in vitro or in vivo systems. The 5-HT_{1C} slot is empty, as it was renamed 5-HT_{2C}. There are no lowercase for 5-HT_3 receptor subunits, as they may form heteromers for which in vivo proof is not yet established, although probable.

The 5-HT_1 receptor class comprises five receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-ht_{1E}, and 5-HT_{1F}) which, in humans, share 40–63% overall sequence identity and couple somewhat preferentially to $G_{i/o}$ to inhibit cAMP formation (see Table 2). 5-ht_{1E} receptors have a lowercase appellation to denote that endogenous receptors with a physiological role have not yet been reported or may not even exist in rodents (rat, mouse). In contrast, 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors have been documented functionally. The 5-HT_{1C} designation is vacant, as the receptor was renamed 5-HT_{2C}, due to structural, operational, and transductional similarities with the other two members of the 5-HT_2 receptor family.

5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors exhibit 46–50% overall sequence identity and couple preferentially to $G_{q/11}$ to increase inositol phosphates and cytosolic [Ca^{2+}] (see Table 3).

5-HT_3 receptors belong to the ligand-gated Cys-loop ion channel receptor superfamily, similar to the nicotinic acetylcholine or $GABA_A$ receptors, and share electrophysiological and structural patterns. The receptors are found on central and peripheral neurons where they trigger rapid depolarization due to the opening of non-selective cation channels (Na^+, Ca^{2+} influx, K^+ efflux). The response desensitizes and resensitizes rapidly. The native 5-HT_3 receptor, as revealed by electron microscopy, is a pentamer. There are five potential different subunits, 5-HT_{3A}, 5-HT_{3B},

5-HT_{3C}, 5-HT_{3D}, and 5-HT_{3E}. Currently, the consensus is that native receptors are best reproduced by the heteromeric combination of 5-HT_{3A} and 5-HT_{3B} subunits. 5-HT_{3B} homomers lack functions (as is probably the case for either of 5-$HT_{3C,3D,3E}$). 5-HT_{3A} subunits can form homopentamers, but to become really functional, they have to form heteropentamers (with, e.g., 5-HT_{3B}) with two 5-HT_{3A} subunits. It has been suggested that 5-HT_3 receptors can heterodimerize with other members of the superfamily (e.g., nicotinic alpha$_7$), but this has not been demonstrated in situ.

5-HT_4, 5-HT_6, and 5-HT_7 receptors all couple preferentially to G_s and promote cAMP formation, yet they are regarded as distinct receptor classes due to their limited (<35%) overall sequence identities. This subdivision is arbitrary and may be subject to future modification.

Two subtypes of the 5-ht_5 receptor (5-ht_{5A} and 5-ht_{5B}), sharing 70% overall sequence identity, have been found in rodents. The human 5-ht_{5B} receptor gene does not encode a functional protein, due to the presence of stop codons in its coding sequence. Human recombinant 5-ht_{5A} receptors inhibit forskolin-stimulated cAMP production, although the receptor may also couple positively to cAMP production. Currently, a physiological readout for this receptor is still missing, although A-843277, a selective 5-ht_{5A} antagonist, has antidepressant/antipsychotic properties in rodent models.

Additional 5-HT receptors have been defined phenotypically and pharmacologically, although a corresponding gene product encoding the receptor has not yet been identified. As long as their structure is unknown, these receptors are regarded as orphans. However the so-called "5-HT_1-like" receptor mediating direct vasorelaxation actually corresponds to the 5-HT_7 receptor. The situation with the remaining orphan receptors (see Hoyer

[a]Also activates the 5-HT_{2C} receptor. [b]Multiple isoforms of the 5-HT_{2C} receptor are produced by RNA editing. [c]The 5-HT_3 receptor is a ligand-gated cation channel that exists as a pentamer of 4TM subunits. [d]Human, rat, mouse, guinea pig, and ferret homologues of the 5-HT_{3A} receptor have been cloned that exhibit species variation in pharmacological profile. A second 5-HT_3 receptor subunit, 5-HT_{3B}, imparts distinctive biophysical properties upon hetero-oligomeric (5-HT_{3A}/5-HT_{3B}) versus homo-oligomeric (5-HT_{3A}) recombinant receptors. The function of the 5-$HT_{3C,3D,3E}$ subunits and other putative members of the family requires further investigations

et al. 1994; Barnes et al. 2021) has not evolved further, and thus the status quo ante remains. In particular, no progress has been made with the "5-HT_{1P} receptor," which is described in the gut and whose pharmacology is reminiscent of the 5-HT_4 receptor, with the restriction that some of the ligands described as 5-HT_{1P} selective, like the 5-HT dipeptides, do not affect 5-HT_4 receptors. The 5-HT_{1P} receptor could be a heterodimer, hence the separate pharmacological profile; however the putative partners remain to be identified.

Pathophysiology/Clinical Applications

5-HT has been implicated in the etiology of numerous disease states, including depression, anxiety, social phobia, schizophrenia, Parkinson's disease and other movement disorders, obsessive compulsive disorders, aggression, panic and sleep disorders, migraine, vascular and pulmonary hypertension, eating disorders, addiction, nausea/vomiting, irritable bowel syndrome (IBS), and other functional GI disorders, by interacting at different receptors or transporters (see 6).

Indeed, 5-HT is also a substrate for the 5-HT transporter, itself an important target in the treatment of depression and the extended range of anxiety disorder spectrum (GAD, OCD, social and other phobias, panic and post-traumatic stress disorders). The 5-HT transporter is the target for SSRIs (selective serotonin reuptake inhibitors) such as fluoxetine, paroxetine, fluvoxamine, and citalopram or the more recent dual reuptake inhibitors (for 5-HT and noradrenaline, also known as SNRIs) such as venlafaxine. There are still efforts to develop triple uptake inhibitors (5-HT, NE, and DA) and/or drugs combining receptor modulation and uptake blockade.

5-HT_{1A} receptor agonists, such as buspirone, tandospirone, or gepirone, were developed for the treatment of anxiety and depression. Furthermore, the 5-HT_{1A} receptor and β-adrenoceptor antagonist, pindolol, was reported to enhance the therapeutic efficacy and shorten the onset of action of SSRIs upon co-administration in severely depressed patients. It is suggested that the combination therapy functions provided that sufficient 5-HT_{1A} receptor occupancy is reached. The antidepressants vilazodone and vortioxetine combine 5-HT uptake inhibition and 5-HT_{1A} agonism. A number of antipsychotics such as clozapine, ziprasidone, quetiapine, aripiprazole, lurasidone, and cariprazine also share 5-HT_{1A} agonism, which may help with hypofrontality and memory impairment.

5-HT_{1B} receptors have both a CNS and a vascular distribution and are the targets of the antimigraine drug sumatriptan, a non-selective 5-$HT_{1D/1B}$ receptor agonist, ergolines, and many other triptans (ergotamine, dihydroergotamine (DHE), zolmitriptan, naratriptan, rizatriptan, eletriptan, almotriptan, donitriptan, etc.).

However, most of the triptans have at least equal affinity to 5-HT_{1D} receptors, which are not expressed in vessels. The 5-HT_{1D} approach to target migraine with 5-HT_{1D} agonists, as a non-vascular target, did not succeed. Indeed, the selective 5-HT_{1D} receptor agonist PNU-142633 displayed no efficacy in migraine patients.

There is no evidence for any clinical relevance of the 5-ht_{1E} receptor. By contrast, since sumatriptan and naratriptan also bind to the 5-HT_{1F} receptor, it has been hypothesized that 5-HT_{1F} might be a target for antimigraine drugs. 5-HT_{1F} receptor mRNA is present in the trigeminal ganglia, stimulation of which leads to plasma extravasation in the dura, a component of neurogenic inflammation linked to migraine. Lasmiditan

(COL-144, LY573144), a selective 5-HT_{1F} receptor agonist, has been developed and registered for the treatment of migraine, with no evidence of cardiovascular side effects.

Ketanserin, a selective 5-HT_{2A} antagonist was initially developed to treat hypertension, but 5-HT_{2A} receptor antagonism as antihypertensive principle has failed. LSD and other psychedelics (e.g., psilocybin, MDMA, and N,N DMT) most probably produce their effects by activating central 5-HT_{2A} receptors, although their selectivity vis- à -vis 5-HT_{2B} and 5-HT_{2C} receptors is limited. Psilocybin and MDMA received FDA breakthrough therapy status for the treatment of treatment-resistant depression and PTSD, respectively. There is a renewed interest in LSD and other psychedelics for the treatment of a number of neuropsychiatric conditions, including substance use disorders. 5-HT_{2A} receptor antagonists such as risperidone, ritanserin, seroquel, olanzapine, volinanserin (MDL 100907), or cariprazine have been developed for the treatment of schizophrenia. The combination of dopamine D_2 and 5-HT_{2A} receptor antagonism may still explain the beneficial antipsychotic activity of drugs such as clozapine, olanzapine, seroquel, and many others. More recently, pimavanserin was approved by the US FDA to treat hallucinations and delusions associated with Parkinson's disease, although it did not meet clinical endpoints in schizophrenia.

BW 723C86 is a selective agonist for the rat 5-HT_{2B} receptor, less selective at human receptors, and was investigated in various neuropsychiatric indications. However, 5-HT_{2B} receptor activation is responsible for the valvulopathies reported for appetite suppressant preparations containing fenfluramine, dex-fenfluramine, or benfluorex; therefore 5-HT_{2B} agonism is strictly banned from all drug development programs. 5-HT_{2B} antagonists have been in clinical trials with indications such as migraine, pulmonary hypertension, irritable bowel syndrome, and various forms of fibrosis, but no compound has been registered so far.

The anxiogenic component of mCPP may be mediated by 5-HT_{2C} receptor activation, and selective 5-HT_{2C} receptor antagonists such as agomelatine display anxiolytic/antidepressant properties in animal models. Central 5-HT_{2C} receptor activation produces a tonic, inhibitory influence upon frontocortical dopaminergic and adrenergic, but not serotonergic transmission. Agomelatine a 5-HT_{2C} antagonist, combined with melatonin 1/2 receptor agonist, is a clinically effective antidepressant. Lorcaserin, a 5-HT_{2C} receptor agonist, was registered to treat obesity and eating disorders but was withdrawn (Tox issues). 5-HT_{2C} agonists are being investigated in obesity, substance use disorders, depression, and schizophrenia. The 5-HT_{2C} agonist vabicaserin entered phase II trials in schizophrenia, but the clinical outcomes were moderate, and development stopped.

5-HT_3 receptor antagonists, e.g., ondansetron, granisetron, and tropisetron, are used clinically to treat chemotherapy- and radiotherapy-induced nausea and vomiting. Since 5-HT_3 receptor activation in the brain leads to dopamine release, and 5-HT_3 receptor antagonists produce central effects similar to those of antipsychotics and anxiolytics, schizophrenia and anxiety were also considered as potential indications. 5-HT_3 receptor antagonists have been reported to have cognition enhancing effects and active in pain and migraine models, but neither of these did materialize in clinical studies. On the other hand, alosetron is now indicated for women suffering from IBS with diarrhea (IBS-D), although under very strict conditions (black box).

Selective 5-HT_4 receptor ligands have therapeutic utility in a number of disorders, including cardiac arrhythmia, neuro-degenerative diseases, depression, urinary incontinence, and GI motility disorders. Cisapride, a gastroprokinetic agent, acts as an agonist at the 5-HT_4 receptor but was withdrawn due to side effects (QT prolongation). Metoclopramide is a 5-HT_4 agonist, with dopaminergic activity. Tegaserod, a 5-HT_4 receptor partial agonist, was used to treat constipation-predominant IBS (IBS-C) and constipation and, after a withdrawal, has been reintroduced under a limited schedule. The 5-HT_4 agonist prucalopride increases bowel movement in volunteers and is registered to treat chronic constipation. Finally, the 5-HT_4 antagonist piboserod is used to treat atrial fibrillation.

Multiple antipsychotics (clozapine, olanzapine, fluperlapine, and seroquel) and

antidepressants (clomipramine, amitriptyline, doxepin, and nortriptyline) are 5-HT_6 receptor antagonists. This attribute suggested an involvement of the 5-HT_6 receptor in psychiatric disorders. Selective 5-HT_6 receptor antagonists have positive effects in preclinical models of memory impairment and cognition. The 5-HT_6 receptor antagonist idalopirdine shows positive clinical effects in Alzheimer's disease when administered in combination with the cholinesterase inhibitor donepezil.

The 5-HT_7 receptor has affinity for multiple atypical antipsychotics, e.g., clozapine, risperidone, amisulpride, aripiprazole, or lurasidone, and various antidepressants. The presence of 5-HT_7 sites in the limbic system and thalamocortical regions suggests a role in affective disorders, whereas the expression in the supra chiasmatic nucleus supports a role in circadian rhythms. Various 5-HT_7 antagonists were/are investigated in depression, psychosis, schizophrenia, and circadian disorders.

Definition

Sex steroid receptors are members of the steroid hormone receptor (SHR) family that ligand-

dependently regulate functions of the sexual organs. Sex steroid receptors are the androgen receptor (AR), the estrogen receptor α and β (ERα, ERβ), and the progesterone receptor (PR) (OMIM 313700, 2019; OMIM 133430, 2020; OMIM 601663, 2020; OMIM 607311, 2019; respectively).

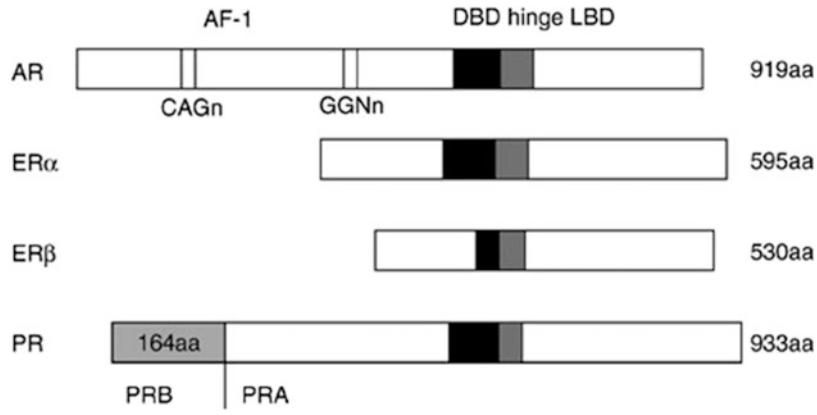
Basic Characteristics

The subgroup of SHRs belongs to the superfamily of nuclear receptors, which transactivate target genes ligand-dependently. Unliganded SHRs are associated with large multiprotein complexes of chaperones in the cytoplasm, in contrast to other nuclear receptors. SHRs comprise the glucocorticoid receptor and the mineralocorticoid receptor and the sex steroid receptors.

SHRs are built in a modular structure with similar structure elements. They contain a DNA-binding domain (DBD), a hinge region with a nuclear location signal (NLS), a ligand-binding domain (LBD), and several transcriptional activation functions (Fig. 1). Their ligands are fat-soluble steroid hormones derived from cholesterol that bind to the LBD of their specific intracellular SHR after diffusing into the cell. After binding of the steroid hormone (K_d between 0.1 and 4 nM), the conformation of the SHR changes, exposing the NLS and the complex of steroid hormone, and SHR gains access to the nucleus (Fig. 2). Utilizing the two zinc fingers of their DBD, SHRs bind as homodimers to unique DNA sequences called hormone response elements (HREs). The HRE is comprised of two half-sites organized as palindrome with a three nucleotide spacer. SHRs regulate the expression of target genes after association with large multisubunit complexes that contain transcriptional co-activators such as histone acetylases and several other proteins that facilitate transcription. Several signaling pathways furthermore influence the activity of SHRs, by modifying either SHRs directly or partner proteins. SHRs can also act without binding to DNA via interaction with other transcription factors, thereby altering their own or their partner's properties.

During the last years, there is increasing evidence that SHR is also associated with the plasma membrane. Rapid, membrane-initiated steroid signals (MISS) were characterized in cell and mouse models for all SHR. Selective pharmacological tools are on the way to dissect the role of genomic and non-genomic signals in vivo.

The physiological and pathophysiological roles of the sex steroid receptors are diverse and will be summarized separately for AR, ERα, ERβs, and PR in the following paragraphs. Estrogen-related receptors (ERRs) comprising ERR-alpha, ERR-beta, and ERR-gamma (gene symbol ESRRA, ESRRB, ESRRG) share structural and functional similarities with ERs. They are orphan receptors indicating that there is no known natural ligand and are therefore not grouped as SHR.



Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor, Fig. 1 Schematic structures of AR, ERα, ERβ, and PR

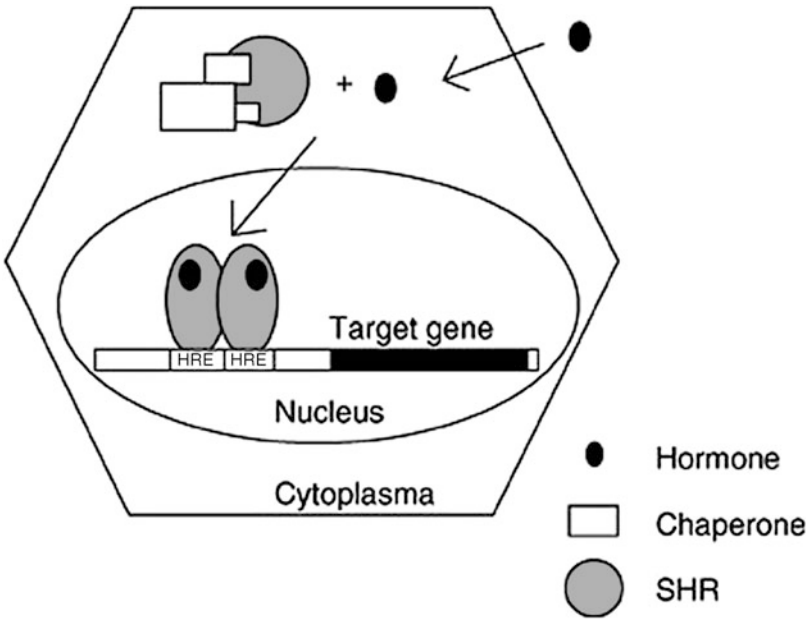
Androgen Receptor

Androgens act via the AR and play an important role in the development and differentiation of the male sexual organ. Furthermore, they are involved in several diseases, the most important being partial and complete androgen insensitivity syndrome (AIS; formerly known as the testicular feminization syndrome), spinal and bulbar muscle atrophy (SBMA; Kennedy's disease), and the neoplastic transformation of the prostate. The two natural occurring androgens are testosterone (T) and the more potent 5α-dihydrotestosterone (DHT). T is mainly produced by the Leydig cells of the testis and can also be produced in most peripheral tissues from the adrenal-produced inactive steroid precursors dehydroepiandrosterone, its sulfate, and androstenedione. T is converted into DHT by the 5α-reductase enzyme expressed in the urogenital tract. Besides positive regulation of target genes by the androgen-loaded AR, there is growing evidence of additional regulation pathways and indirect regulation mechanism of the AR. The expression of specific transcriptional coactivators of the AR in different tissues can fine-tune the transcriptional AR activity. Ligand-independent activation of the AR by protein kinase pathways can circumvent the need for androgens. Non-genomic AR signaling activates c-Src, a tyrosine kinase known to drive prostate metastasis, and p85α the regulatory subunit of PI3K (phosphatidylinositol 3-kinase). In addition, protein-protein interactions of the AR with other transcription factors regulate the transcriptional activity of these partner proteins.

Eight exons of the AR gene encode a protein of around 917 aa depending on two polymorphic regions of polyglutamines (CAG) and polyglycines (GGN) in the N-terminal activation domain. Two isoforms are detected in tissues: the predominant (80%) 110 kD (B isoform) and 87 kD (A isoform). It is under investigation whether the two isoforms also serve different functions.

The structure of the AR comprises an N-terminal transactivation domain of around 500 aa, a DBD of 66–68 aa, and a LBD of 250 aa. The hinge region contains the lysine-rich NLS. The AR possesses two activation functions (AFs): AF-1 in the N-terminal region and the AF-2 core domain in the LBD.

The AF-1 contains two polymorphic regions of CAG and GGN repeats. Normally the number of the 5′ CAG repeats is 11–31 (average 21), whereas up to 50 repeats are found in individuals affected with SBMA. Since the number of glutamines inversely correlates with the transcriptional



Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor, Fig. 2 The classical activation pathway of SHR. SHRs (gray circle) are associated with chaperones (rectangles). After binding of steroid hormones (black circle), SHRs activate target genes in the nucleus. Additional regulation mechanisms, e.g., phosphorylation, are described in the text. For non-genomic signaling, see Arnal (2017)

activity of the AR, these amplified repeats lead to a reduced activity of the AR. The increased size of a polymorphic tandem CAG repeat is associated with the X-linked spinal and bulbar muscular atrophy and may also be associated with oligospermic infertility in men and with low serum androgens in a subset of anovulatory female patients. On the other hand, a shorter CAG length correlates with a higher risk of more severe and earlier onset of prostate cancer probably resulting from a higher activity of the AR. Experimental evidence also correlates increased or prolonged induction of AR activation with a higher incidence or acceleration of prostate cancer.

In the beginning, prostate cancer cells are largely dependent on androgens for growth and survival. Observations that castration is beneficial in prostate cancer made androgen ablation and antiandrogen therapy a standard treatment for patients with metastatic prostate cancer following surgery of the tumor tissue. Antiandrogen therapy includes inhibition of androgen synthesis by aminoglutethimide or ketoconazole and inhibition of 5α-reductase by finasteride in combination with AR antagonists such as flutamide or cyproterone acetate. Second-generation antiandrogens are currently in clinical trials.

Unfortunately, remaining prostate cancer cells eventually adapt to grow in the low-androgen environment, rendering the tumor growth independent of androgens. Androgen-independent prostate cancer may result from one or more of the following mechanism: increased gene copy number; altered interaction of the AR with coregulatory proteins, e.g., resulting from AR mutations, bypassing of the AR pathway; or ligand-independent activation of AR, e.g., by protein kinase pathways and vice versa.

Estrogen Receptor

Estrogens mainly affect the growth and maturation of the female reproductive system and the maintenance of its reproductive capacity [5]. In addition, estrogens act on several other tissues, e.g., on lipid and bone metabolism. Uterus, placenta, and testis are the principal sites of 17-β-estradiol (E2) production. Agonists of ERs are used for treatment of menopausal symptoms, hormone replacement therapy (HRT), osteoporosis, and cardiovascular diseases, whereas antagonists of ERs such as tamoxifen are used for treatment of breast cancer. Pure antagonists of ER that are as effective as tamoxifen without having tamoxifen's partial agonistic effects on ERs are in different phases of testing. The pure antagonist fulvestrant (ICI 183,780) is licensed as treatment for advanced breast cancer. The main isoforms of the human ERs are ERα and ERβ, which display distinct expression patterns. Additional ER isoforms, generated by alternative mRNA splicing, have been identified in several tissues. A cell-specific localization for each of the ER subtypes is found in the majority of the reproductive organs studied. The role of the different ER isoforms in modulating the estrogen response or in tumorigenesis is not completely understood. In addition, ERRs which were coexpressed with ERs can influence the expression level of ER target genes either directly or by interaction with ERs. ERs bind most ligands with similar affinities and display equal transcriptional activation. However, in some assays ER isoforms respond differently to ligands. The naturally occurring phytoestrogen genistein or antiestrogens, such as tamoxifen or raloxifene, are examples of these selective ER modulators (SERMs). The characterization of SERMs that specifically regulate defined functions promises to increase efficacy and reduce side effects in estrogen-regulated processes (Table 1).

ERα

ERα (also called ESR1 and ESRA) is involved in the differentiation and maintenance of reproductive, neural, skeletal, and cardiovascular tissues. Two separate AFs mediate transcriptional activation, the ligand-dependent AF-2 in the LBD and the ligand-independent AF-1 in the N-terminus. After binding of estrogen to the LBD, ERα activates target genes such as the progesterone receptor gene by binding to the estrogen response elements (EREs). Besides this classical activation, nonestrogen-dependent activation of ERα has been described. Signaling pathways and extracellular signals such as EGF, IGF-I, or insulin

Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor, Table 1 Basic characteristics of sex steroid receptors

SHR	Gene map locus	cDNA size	Natural agonist	Binding half-site	Main expression
AR	Xq11–q12	Ca. 919 aa (see text)	5α-dihydrotestosterone (DHT), testosterone (T)	AGAACA	Prostate, male urogenital system, muscle
ERα	6q25.1	595 aa	17β-estradiol (E2)	AGGTCA	Ovary, uterus, mammary gland, vagina, testis (Leydig cells), bone
ERβ	14q22–q24	530 aa, 583 aa, further isoforms	17β-estradiol (E2)	AGGTCA	Ovary, testis (Sertoli and Leydig cells, efferent ducts), prostate, bone, thymus, spleen, brain
PR	11q22	Two isoforms:	Progesterone	AGAACA	Uterus, ovary, central nervous system
		PRA 769 aa			
		PRB 933 aa			

SHR Sex Steroid receptors, *AR* Androgen receptor, *ER* Estrogen receptors, *PR* Progesterone receptor

stimulate phosphorylation of the receptor. Phosphorylation of ERα affects all steps of transcriptional activation, such as ligand binding, dimerization, DNA binding, and interaction with cofactors. Heregulin (NRG1) also called Neuregulin 1 is an example of an extracellular signal modulating ER activity. After binding of NRG1 to its receptor ErbB2 (HER-2), ER is rapidly phosphorylated, followed by transcription of the *PR* gene. Since heregulin promotes hormone-independent growth of breast cancer cells, activation of ER by ErbB2 signaling may be involved in the development of E2-independent cancer cell growth.

Besides the classical activation model, ERα is also found associated with the plasma membrane via palmitoylation, from where it initiates rapid, non-nuclear signaling. These nongenomic, rapid, membrane-initiated steroid signals (MISS) are particularly relevant for endothelial effects of estrogen. MISS-selective agents such as estrogen-dendrimer conjugates and mouse models, e.g., carrying mutations for the palmitoylation site of ERα, will help to dissect genomic and membrane-initiated signals of ERα and their jointly actions.

In addition to the major 66 kDa full-length ERα (ESR66), a 46-kD isoform exists that lacks the 173 N-terminal amino acids which results either from alternative splicing, proteolysis, or translational variation. ESR46 can competitively inhibit the ligand-independent transactivation function of the larger receptor and modulate membrane-initiated estrogen actions. The regulation of its expression that is detected in various cell types and a majority of breast tumors is currently not understood.

ERα can also regulate gene expression by interacting with different transcription factors. For example, interaction of ERα with the c-Rel subunit of NF-κB prevents binding to NF-κB response element resulting in reduced interleukin-6 transcription. Here, ERα acts E2-dependently but without directly binding to DNA. However, the complex formation of ER with the transcription factor Sp1 is hormone-independent and enhances Sp1 binding to DNA. ERα as well as ERβ thereby enhances transcription of the retinoic acid receptor *α1* gene. Other partner proteins are fos/jun family members, which regulate gene expression via AP-1 sites. In this situation E2 can either act as agonist in the presence of ERα or as antagonist in the presence of ERβ. Another possibility to modulate ER signaling is the aryl hydrocarbon receptor (AhR). Ligands for AhR mediate antiestrogenic effects by several pathways.

The measurement of ER has become a standard assay in the clinical management of breast cancer. The presence of ERα identifies those breast cancer

patients with a lower risk of relapse and better clinical outcome. Receptor status also provides a guideline for those tumors that may be responsive to hormonal intervention. But only about half of ER-positive patients respond to hormonal therapies. Of those who respond initially, most will eventually develop an estrogen unresponsive disease following a period of treatment even though ERα is often still present. Mutant receptors and constitutively active receptors as well as hormone-independent activation of the ERα are discussed. The involvement of ERβ isoforms is under investigation.

Analysis of ERα-deficient mice showed that both sexes are infertile and display a variety of phenotypic changes associated with the gonads, mammary glands, reproductive tracts, and skeletal tissues. In addition, both hyperplasia and hypertrophy of adipocytes were found in these mice.

In females, ovariectomy or menopause leads to rapid loss of trabecula bone and osteoporosis indicating that E2 maintains bone mass. E2 enhances bone formation by osteoblasts and suppresses bone resorption by osteoclasts by regulating several important growth factors. In mice, ERα seems to induce growth but not maintenance of trabecular bone, whereas ERβ terminates growth during late puberty. However, while in humans the role of ERα and ERβ in bone is not completely clear, ESRA polymorphism is related to bone density and height during late puberty and at attainment of peak bone density in young men.

ERβ

In 1995 the discovery of ERβ (also called ESR2 and ESRB) explained many actions of estrogens in tissues where no ERα was found. ERβ shows high homology to ERα in the DBD and LBD but encodes a distinct transcriptional AF-1 domain. At least five isoforms, designated ERβ-1 through ERβ-5, are described that differ in their C-terminal sequences and tissue expression patterns or have extended N-termini. This new complexity of isoforms is further enhanced by the fact that ERβ isoforms cannot only heterodimerize with each other but also with ERα. The functional consequences for the action of estrogens depending on the expression pattern are only beginning to be evaluated.

ERβ is highly expressed in the ovary, male organs, and parts of the central nervous system (CNS), but also in other organs such as spleen and thymus. The phytoestrogen genistein binds better to ERβ than to ERα, whereas the partial ERα agonists tamoxifen, raloxifene, and ICI-164384 are antagonists for ERβ. It has been postulated that co-factor recruitment is different for the ERs; however knowledge about this interesting field of selective ER regulation is only beginning to accumulate. Since only ERβ is expressed widely in the male urogenital tract of several animals, it is now under evaluation whether the pronounced effects of E2 in men are caused by direct action of E2 on ERβ in these reproductive organs. The view that E2 acts only indirectly by reducing androgen levels via the CNS clearly has to be corrected.

Analysis of ESRB $^{-/-}$ mice showed fewer and smaller litters than wild-type mice as well as abnormal vascular function and hypertension. The reduction in fertility was attributed to reduced ovarian efficiency. Mutant females had normal breast development and lactated normally. Older mutant males displayed signs of prostate and bladder hyperplasia. *Esr2*-deficient mice furthermore display diverse regulatory defects in the function of the brain, lung, and white blood cells. The results indicated that ESRB is essential for normal ovulation efficiency but is not essential for lactation, female or male sexual differentiation, or fertility.

Progesterone Receptor

The PR is involved in diverse functions in female reproduction, such as implantation of the embryo, and in the maintenance of pregnancy. Progesterone is mainly produced in the corpus luteum in the second half of the menstrual cycle and in early pregnancy, later in the placenta. The PR is expressed in the uterus, ovary, and the CNS. In men there is no known function. Estrogens induce expression of the *PR* gene. PR agonists such as medroxyprogesterone or the synthetic R5020 are called progestins or gestagens.

The human PR exists as two functionally distinct isoforms PRA and PRB transcribed from two promoters from a single gene. PRA lacks the N-terminal 164 aa and is a 769 aa protein. PRB functions as a transcriptional activator in most cell and promoter contexts. In contrast, PRA is transcriptionally inactive and functions as a strong ligand-dependent transdominant repressor of SHR transcriptional activity. Different cofactor interactions were demonstrated for PRA and PRB, probably due to an inhibitory domain within the first 140 aa of PRA, which is masked in PRB. Both PR isoforms, however, repress estradiol-induced ER activity when liganded. Several other mRNA isoforms are present in PR-positive tissues such as breast cancer with unknown clinical significance.

In addition to the classical activation pathway, a substantial part of PR action is mediated by non-genomic signaling by interaction of PR with other signaling pathways. For example, rapid, non-genomic cytoplasmic signaling by PR is initiated by binding to c-Src via a specific polyproline motif in the N-terminal domain of PR, leading to downstream MAP kinase pathway activation.

Mice models reveal that both PR forms are physiologically important. Mice lacking the *PR* gene fail to ovulate, are infertile, and have impaired thymic function. Selective PRA-deficient female mice are infertile due to reduced oocyte and uterine deficiency in implantation. However, these mice had normal mammary epithelium proliferation and differentiation and showed normal thymic involution. In mice, PR regulates expression of proteases that degrade the follicular wall, thereby facilitating ovulation.

In breast cancer patients, total PR status is measured for hormonal treatment. The presence of PR is associated with increased survival rates and hormonal responsiveness of mammary tumors. PR agonists are widely used in contraception, hormone replacement therapy (HRT), breast cancer, and endometrial hyperplasia. Antiprogestins such as RU486 are used for blocking ovulation and preventing implantation, and in addition they are in clinical testing for the induction of labor and to control various neoplastic transformations.

Selective progesterone receptor modulators (SPRM) (mesoprogestins) are PR ligands with agonistic and antagonistic activities. Some SPRM show weak antiglucocorticoid or mixed androgenic/antiandrogenic activities. SPRM are currently tested and may be useful, e.g., for the treatment of endometriosis.

Drugs

Pure and partial agonists and antagonists (see individual SHR) are therapeutically used for contraception, hormonal ablation in breast and prostate cancer, and HRT in osteoporosis.

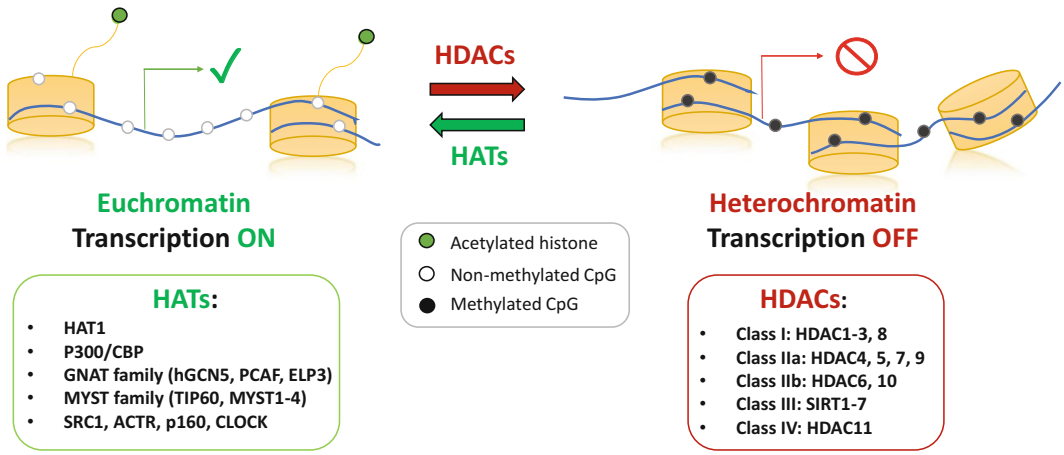
Definition

Histone lysine residues are modulated by post-translational modifications (PTMs) that specifically regulate the three-dimensional structure of chromatin as well as its accessibility to chromatin remodeling complexes and transcriptional factors, thus controlling the entire mechanism of gene expression. Acetylation pattern results from the balanced activities of two classes of epigenetic enzymes known as histone acetyltransferases (HATs) and histone deacetylases (HDACs) that, respectively, add (from acetyl-CoA) and remove the acetyl group from the ε-amino group of specific histone and non-histone lysine residues (Carafa et al. 2016; Schiedel et al. 2018b; Zwergel et al. 2019). HDAC enzymes have been grouped in four different classes, known as I, II, III, and IV, and based on sequence homology to their yeast orthologues Rpd3, HdaI, and Sir2. In particular, to the class III HDACs belong the silent information regulator 2 (Sir2) proteins also known as Sirtuins, which differ from classes I, II, and IV HDACs mainly because of their mechanism of action, which is nicotinamide adenine dinucleotide (NAD^+)- instead of Zn^{2+}-dependent (Carafa et al. 2016; Schiedel et al. 2018b; Zwergel et al. 2019).

► Histone acetylation always correlates with the activation of gene expression and transcription, thanks to the electrostatic change that this process entails at the chromatin level: the introduction of an acetyl group neutralizes the physiologically positive charge of the ε-amino group of histone lysine residues, thus counteracting the electrostatic interaction with the negatively charged DNA phosphate groups (Fig. 1) (Shahbazian and Grunstein 2007).

Sirtuins are involved in numerous biological processes such as cell survival and metabolism, aging, and DNA repair; thus they modulate crucial metabolic pathways.

The seven members of the Sirtuin family are more and more seen as potential targets for the treatment of cancer, metabolic, neurodegenerative, and cardiovascular diseases.



Sirtuins, Fig. 1 Illustration of the euchromatin/heterochromatin switch as a result of the HATs/HDACs balance

Basic Characteristics of Sirtuins

The Sirtuin family consists of seven distinct isoforms showing specific cellular localization, substrate, and catalytic activities which correlate with different physiopathological roles (Table 1) (Kupis et al. 2016).

In fact, despite that Sirtuins are mainly known for their deacetylating activity toward histone and non-histone proteins, such enzymes were firstly identified as ADP-ribosyltransferases, and, subsequently, also the capability to remove acyl moiety different from the simple acetyl group, including lipoyl, malonyl, glutaryl, 3-hydroxy-3-

Sirtuins, Table 1 SIRT1–7 characterization in terms of localization, substrates, catalytic activity, functions, and relative pathological roles

Sirtuin	Localization	Substrates	Catalytic activity	Functions	Pathology
SIRT1	Nucleus, cytosol	PGC1α, eNOS, FOXO, NF-kB, MyoD, PPAR α, H1K26ac, H3K9ac, H4K16ac	NAD^+-dependent protein deacetylation	Cell survival, insulin, signaling, inflammation, metabolism regulation, lifespan regulation, oxidative stress response	Colon, prostate, ovarian, lung, and breast cancer, glioma, melanoma, lung adenocarcinoma, acute myeloid leukemia (AML); neurodegenerative diseases
SIRT2	Nucleus, cytosol	H3K56ac, H4K16ac, α-tubulin, Foxo3a, p53, G6PD, MYC	NAD^+-dependent protein deacetylation, demyristoylation	Cell cycle regulation, nervous system development	Glioma; neurodegenerative diseases
SIRT3	Nucleus, mitochondria	AceC2, ShdhA, SOD2, PDMC1a, IDH2, GOT2, FoxO3a	NAD^+-dependent protein deacetylation	Regulation of mitochondrial energetic metabolism	B-cell chronic lymphocytic leukemia (CLL), mantle cell lymphoma (MCL), breast and gastric cancer; neurodegenerative diseases
SIRT4	Mitochondria	GDH, MCD, PDH	NAD^+-dependent protein deacylation (acyl, lipoyl, and 3-hydroxy-3-methyglutaryl) and ADP-ribosylation	Regulation of mitochondrial energetic metabolism, fatty acid oxidation, and insulin secretion	Breast, colorectal cancer and esophageal squamous cell carcinoma (ESCC)
SIRT5	Mitochondria	Histone H4, CPS1, cyt c	NAD^+-dependent deacylation (malonyl, succinyl, and glutaryl)	Urea cycle and apoptosis regulation	Breast, pancreatic, non-small cell lung carcinoma
SIRT6	Nucleus	H3K9ac, H3K56ac, PARP1	NAD^+-dependent protein deacylation (acyl and long-chain fatty acyl) and ADP-ribosylation	Genome stability, DNA repair, nutrient-dependent metabolism regulation	Breast and colon cancer
SIRT7	Nucleus	RNA pol I, p53, H3K18ac	NAD^+-dependent protein deacetylation	Regulation of rRNA transcription and cell cycle	Liver, spleen, testis, thyroid, and breast cancer

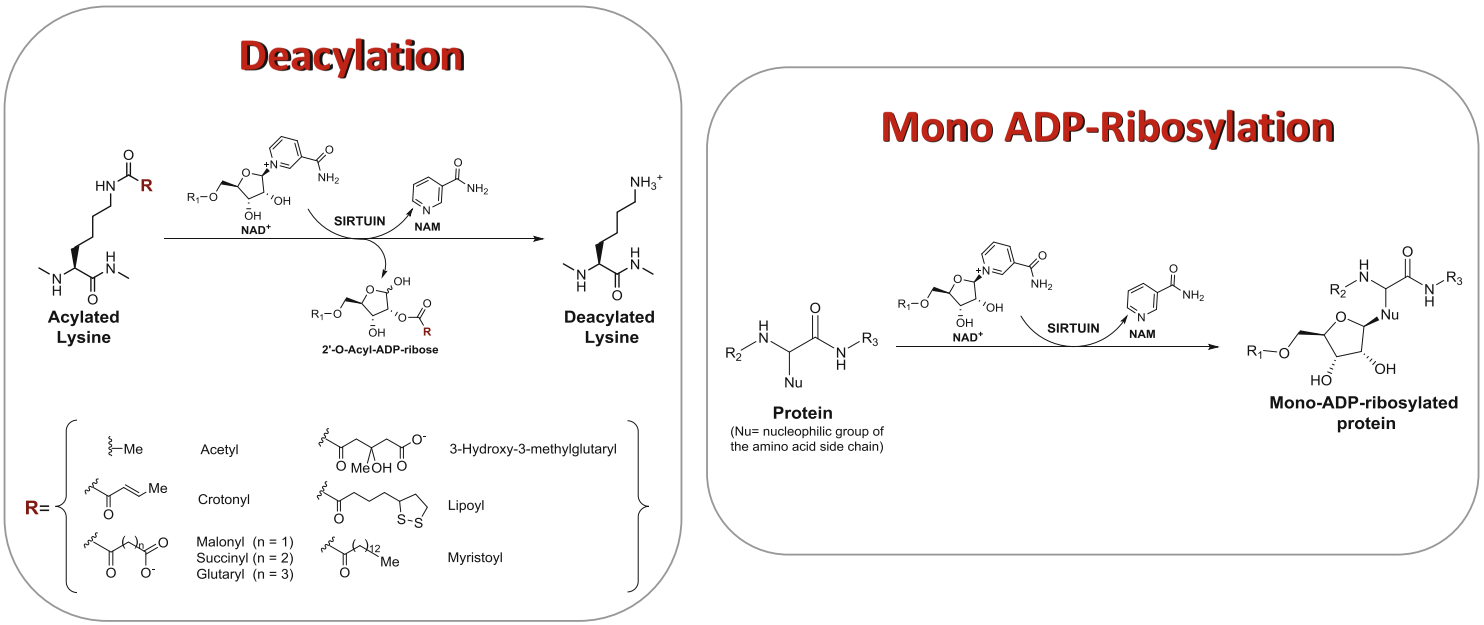
methylglutaryl, succinyl, crotonyl, fatty acyl, etc., has been highlighted (specifically for SIRT2,4–6). Given their mechanism of action (Fig. 2), Sirtuins can be described as metabolism sensors sensitive to cellular NAD^+/nicotinamide (NAM) cellular levels (Kupis et al. 2016). In particular, NAM acts as an endogenous inhibitor of their activity.

All Sirtuins show a conserved catalytic NAD^+-binding site, which consists of about 275 amino acids framed in between an *N*- and *C*-terminal sequences of different length susceptible to post-translational modifications, responsible for variability in their functions and localization (Fig. 3).

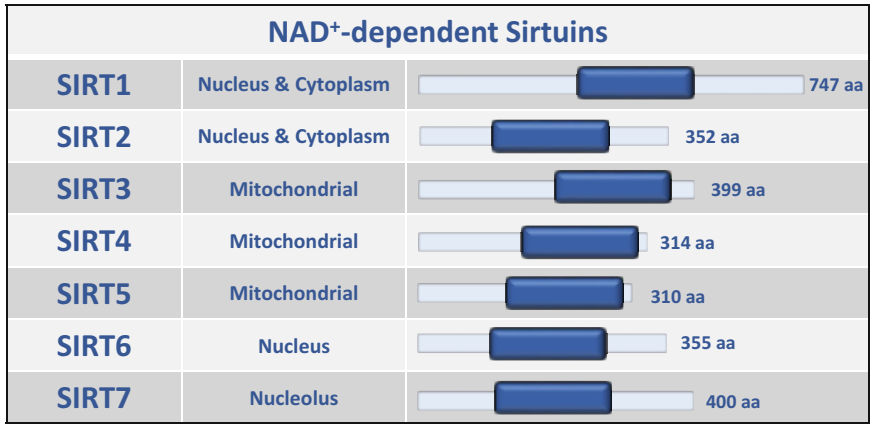
In addition to the essential α/β Rossmann-fold domain, which is typical of NAD^+-binding protein, Sirtuins are also characterized by a Zn^{2+}-binding domain that is composed of three stranded antiparallel β-sheets and a variable α-helical region. The loop responsible for the NAD^+ binding linked the Rossmann-fold with the Zn^{2+}-binding domain and is characterized by four loops, thus generating an extended cleft that forms the enzyme's active site. As previously mentioned, despite that the zinc ion does not take part into the catalysis since it is located too far from the active site, it results crucial for the structural stability of Sirtuins coordinating four different conserved cysteine residues and keeping the three β-strands together (Moniot et al. 2012). Despite that structural rearrangements at the base of the dynamic structure of this class of enzymes have been discovered, individual Sirtuins are characterized by specific preference(s) in sequence related to variables in their electrostatics properties and peptide-binding groove shape. Also, the capability of Sirtuins to recognize a huge number of substrate moieties proves their high adaptability.

Physiopathological Characteristics of Sirtuins

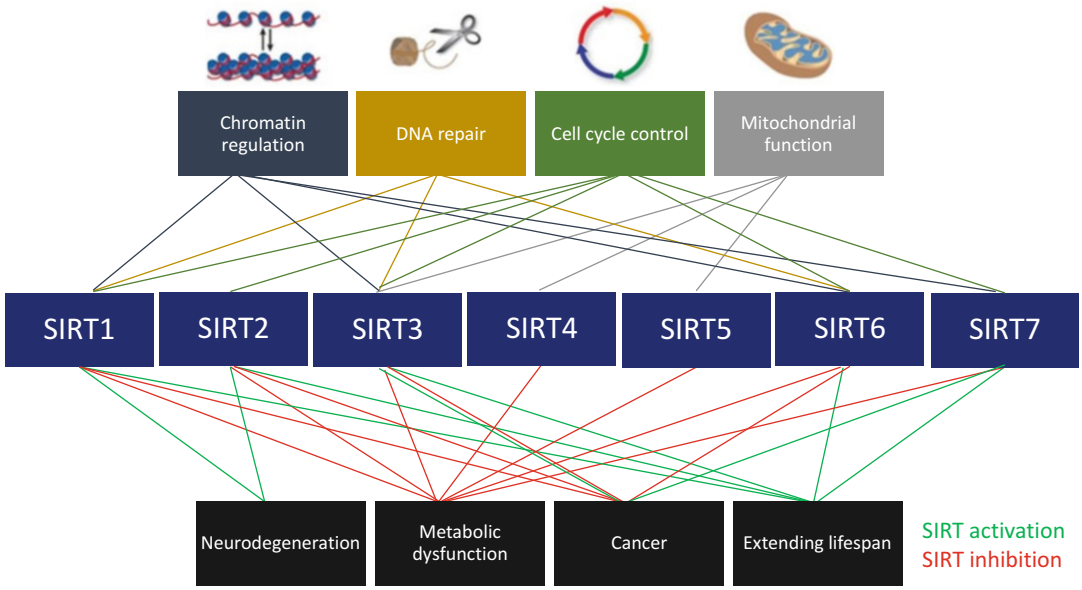
As previously mentioned, Sirtuins activities do not involve only histone substrates but also non-histone targets directly or indirectly related to chromatin regulation, apoptosis, stress response, or differentiation including p53, *c*-Fos, nuclear factor kappa-light-chain-enhancer of activated B-cells (NF-κB), α-tubulin, BubR1, E2F1, tumor necrosis factor-α (TNFα), *c*-Myc, Forkhead box class O (FOXO) factors, hypoxia-inducible factors (HIFs), as well as other epigenetic proteins such as HATs, including p300 and males absent on the first (MOF), the histone methyltransferase (HMT) Enhancer of zeste homolog 2 EZH2, and DNA methyltransferase 1 (DNMT1) (Martinez-Redondo and Vaquero 2013). Sirtuins are implicated in the regulation of a huge variety of crucial processes including transcription, metabolism, aging, cell homeostasis, senescence, apoptosis, and ► inflammation. Several pieces of evidence proved their connection with the onset and progression of metabolic (obesity and diabetes), neurodegenerative (Alzheimer's (AD), Huntington's (HD), and Parkinson's diseases (PD)), and inflammatory diseases (psoriasis) as well as with both hematological (B-cell chronic lymphocytic leukemia (CLL), acute myeloid leukemia (AML)) and solid tumors (breast, colon, lung, prostate cancer, etc.); (see Fig. 4) (Carafa et al. 2016; Schiedel et al. 2018b; Zwergel et al. 2019). SIRT1 is the first SIRT family member to be identified and is the isoform for which the most exhaustive information has been collected to date. Through its deacetylase activity, SIRT1 activates the peroxisome proliferator-activated receptor-γ (PPARγ) coactivator 1α (PGC1α) and FOXO1, thus promoting gluconeogenesis, whereas it inhibits glycolysis via the repression of the glycolytic enzyme phosphoglycerate mutase 1 (PGAM-1). In addition, liver kinase B1 (LKB1) SIRT1-mediated deacetylation in the skeletal muscle activates ► AMP-activated protein kinase (AMPK), thus establishing a reciprocal positive regulating loop in which AMPK in turn activates SIRT1 enhancing the level of NAD^+, thanks to the upregulation of NAD^+ synthetic enzyme nicotinamide phosphoribosyltransferase (NAMPT) encoding genes. While SIRT1 seems to exert a neuroprotective role modulating the expression and survival of brain-derived neurotrophic factor (BDNF), it also correlates with tumorigenesis leading to the inhibition of p35 and p73 via their deacetylation and to the activation of the oncoprotein BCL6, thus favoring an antidifferentiating and anti-apoptotic effect through the deacetylation of different



Sirtuins, Fig. 2 Schematization of Sirtuins mechanisms of action: on the left is represented the diacylation, and on the right the ADP-ribosylation process



Sirtuins, Fig. 3 Schematic representation of human Sirtuins in which the shared NAD^+-catalytic domain is highlighted in blue



Sirtuins, Fig. 4 Schematic representation of the involvement of SIRT isoforms in various diseases and their possible modulation

transcription factors (FOXO3a, Ku70, E2F1, etc.). Despite that an overexpression (OE) of SIRT1 has been registered in different kind of chemotherapy-resistant tumors such as prostate, breast, liver, colorectal, ovarian, melanoma, and epithelial cancer, also a downregulation of such Sirtuin correlates with malignancies (glioblastoma, bladder and colon cancer). SIRT1 functions within the oncological scenario seem to be context specific since SIRT1 modulates the expression of various DNA repair and tumor suppressor genes.

SIRT2 is principally localized in the cytoplasm and is responsible for the deacetylation of the Lys40 of α-tubulin, but several data showed that, during cell cycle progression from phase G_2 to M, it moves toward the nucleus providing the deacetylation of H4K16 which correlates with metaphasic heterochromatin. In addition, also

p300, FOXO1, FOXO3, and glucokinase regulatory protein (GKRP) have been identified as other targets of its deacetylase activity. Glucokinase (GCK) is crucial for retaining the glucose homeostasis modulated by the binding of GKRP, which, in its acetylated state, correlates with diabetes mellitus. In addition, other evidence emphasized the role covered by SIRT2 in other metabolic processes, such as adipogenesis. Unlike SIRT1, SIRT2 possesses a neurodegenerative role in neurological pathologies, and it modulates cell progression and mitotic and apoptotic events displaying both tumor promoter and suppressor capability.

SIRT3, together with SIRT4 and SIRT5, is one of the three mitochondrial Sirtuins. Specifically, SIRT3 takes part in the modulation of mitochondrial activities by providing the deacetylation and consequent activation of various electron transport chain complexes (I and II) components as well as acetyl-CoA synthetase (ACS). SIRT3 is known to be involved in the counteraction of the oxidative stress protecting cells from reactive oxygen species (ROS) in microglia and activating, under calorie restriction condition, the essential mitochondrial ► antioxidants actor superoxide dismutase 2 (SOD2) in cochlea neurons, thus playing an overall neuroprotective role. SIRT3 controls differentiation, proliferation, and survival of cells acting as a tumor suppressor through the deacetylation and activation of pyruvate dehydrogenase (PDH) that correlates with the repression of glycolysis metabolism. However, also the role covered by SIRT3 in tumors still needs to be clarified.

Until recently, SIRT4 was the less-investigated Sirtuin, and it was firstly described for its ADP-ribosyltransferase activity toward glutamate dehydrogenase (GDH). Effects of SIRT4 are a reduced amino-acid-stimulated insulin secretion in pancreatic B-cells and an increased genome stability as a consequence of the SIRT4-mediated inhibition of glutamine anaplerosis, a crucial step for an effective cell cycle arrest after DNA damage. Thus, SIRT4 seems to act as a tumor suppressor, but, in this framework, further investigations are necessary since the delayed cell cycle in DNA-damaging condition mediated by SIRT4 can also reduce the sensitivity of tumors cells to cytotoxic treatment. As proof of this, overexpression of SIRT4 correlates with increased mortality rate during cisplatin treatment (Jeong et al. 2016). SIRT4 inhibits the PDH via its lipoamidation and shows a weak deacetylase activity toward the malonyl Co-A decarboxylase (MCD), which is the main way, in addition to the indirect interaction with ANT2 and AMPK, whereby SIRT4 represses the β-fatty acid oxidation. SIRT4 also mediates the sensitivity to cardiac performance to hypertrophic stress modulating the activity of manganese superoxide dismutase (MnSOD). Recently, Pannek et al. reported the 3-hydroxy-3-methylglutaril (HMG) residue as new acyl toward which SIRT4 shows an efficient enzymatic activity solving also the crystal structure of SIRT4 from *Xenopus tropicalis* (xSIRT4, 81% similarity with human SIRT4 (hSIRT4)) (Pannek et al. 2017).

SIRT5 is mainly expressed in the heart, liver, kidney, and brain and exhibits as main targets the restricting enzyme of the urea cycle carbamoyl synthetase 1 (CPS1) and poly-(ADP-ribose) polymerase 1 (PARP1), which is responsible for the stimulation of DNA repair mechanisms upon oxidative-induced damage, toward which SIRT5 acts as a deacetylase and ADP-ribosyltransferase, respectively. Despite that SIRT5 OE was detected in non-small cell lung carcinoma (NSCLC), overlapping with poor prognosis, further evidence is required to explain in a comprehensive way its role in cancer.

SIRT6 catalyzes the removal of fatty acyl moiety from Lys19 and Lys20 of TNF-α regulating its release. SIRT6 controls metabolism, cellular homeostasis, telomere maintenance, and DNA repair and for these reasons has been defined as "epigenetic guardian of cellular differentiation."

The last component of this family, SIRT7 thanks to its capability to mediate the deacetylation of H3K18ac leading to the malignant transformation marker H3K18, is being considered a promising and challenging target in the context of the epigenetic fight against cancer. OE levels of SIRT7 were typically registered in cancers with poor prognosis, but also its depletion is associated with aggressive tumors. Also, non-

histone interactions have been identified for this protein such as those with HIF-1α and HIF-2α, thus reducing their expression.

Sirtuin Modulators

Sirtuin modulators are today applied alone or in combination with either approved drugs or other epigenetic agents. They have been investigated for the treatments of neurodegeneration or metabolic diseases as well as various types of cancer (Villalba and Alcain 2012; Schiedel et al. 2018b). Table 2 is summarizing all the SIRT modulators discussed herein.

Sirtuin Inhibitors (SIRTi)

Small Molecules

The first SIRTi splitomicin (**1**) appeared in literature in 2001 and was identified via a yeast-based phenotypic screening. This compound was inactive against human Sirtuins but was the initial point for the discovery of numerous human SIRT1/2i (Carafa et al. 2016; Zwergel et al. 2019).

One important splitomicin derivative is the SIRT1i HR-73 (**2**) able to block the HIV transcription via TAT protein deacetylation (Carafa et al. 2016; Zwergel et al. 2019).

EX-527 or selisistat **3**, discovered in 2005, was the first potent and selective cell-permeable SIRT1i. Even if this compound increased p53 acetylation levels, only poor effects were observed in cancer. Compound **3** is now being investigated with promising results in Huntington's disease also in a clinical context. Additionally, **3** blocked via a SIRT1 inhibition-mediated mechanism the viral amplification of human papillomavirus (Carafa et al. 2016; Zwergel et al. 2019).

Cambinol (**4**) is a moderate SIRT1/2i, and its treatment led to hyperacetylated p53, α-tubulin, FOXO3a, and Ku70 in lymphoma and HeLa cancer cells decreasing the tumor burden also in xenograft mice (Carafa et al. 2016; Zwergel et al. 2019). Auspicious anticancer features were also described for hepatocellular cancers and neuroblastoma (Carafa et al. 2016; Zwergel et al. 2019). Following studies resulted in various optimized derivatives with improved potency and/or selectivity for either SIRT1 or SIRT2. One example of such a strategy is MC2141 (**5**) (Carafa et al. 2016; Zwergel et al. 2019).

AGK2 (**6**) possesses a selectivity against SIRT2 over SIRT1/3, being a low micromolar SIRT2i able to maintain the acetylation of α-tubulin in HeLa cells. Compound **6** rescues dopaminergic neurons from α-synuclein toxicity in Parkinson's disease and leads to caspase-3-dependent apoptosis in glioma cells (Carafa et al. 2016; Zwergel et al. 2019).

Tenovin1 (**7a**) and its water-soluble derivative (**7b**) are micromolar SIRT1-3i able to activate p53 in melanoma, leukemia, and gastric cancer in vitro and in vivo (Carafa et al. 2016; Zwergel et al. 2019).

Also, sirtinol (**8**), a SIRT1/2i, identified in 2001 via a high-throughput screening, possesses numerous anticancer effects in human MCF7 and H1299 cells as well as in adult T-cell leukemia/lymphoma (ATL). Furthermore **8** increases the chemosensitivity to cisplatin and camptothecin in PC3 and HeLa cells (Carafa et al. 2016; Zwergel et al. 2019).

Salermide (**9**) is an optimized form of compound **8**. Besides the numerous anticancer effects through SIRT1 inhibition which result in the H4K16ac deacetylation and ultimately in the repression of pro-apoptotic genes such as *CASP8*, *TNF*, *TNFRSF10B*, and *PUMA*, salermide treatment also protects muscle cells in a dystrophy model (Pasco et al. 2010). Interestingly, **9** has beneficial effects upon *Schistosoma mansoni* (Sm) infections via *Sm*SIRT inhibition leading to apoptosis, death of schistosomula, and reduced egg laying (Carafa et al. 2016; Zwergel et al. 2019).

Subsequently, selective SmSIRT2i were identified from a commercial library and afterward optimized. Compound **10** possesses a good efficacy against larval and adult worms without affecting human Sirtuins and human cells (Monaldi et al. 2019).

Compound **11** and its analogues are one of the most potent SIRTi discovered so far. Even though the crystal structure has been solved and a

nanomolar biochemical activity against SIRT1–3 has been observed, no biological activity has yet been described (Carafa et al. 2016; Zwergel et al. 2019).

SirReal2 (**12**) is a highly selective sub-micromolar SIRT2i (>1000 fold over all SIRT isoforms) (Carafa et al. 2016; Zwergel et al. 2019).

Crystallography studies revealed a previously unexploited SIRT2-binding mode inducing a structural rearrangement in the active site of SIRT2. Hyperacetylation of α-tubulin and destabilization of the SIRT2 substrate BubR1 upon SirReal2 treatment confirmed the involvement of SIRT2 inhibition in HeLa cells. Recently the SirReal hybrid compounds with thalidomide were created to apply the proteolysis-targeting chimeras (PROTACs) approach, being the first example of chemical induction of SIRT2 degradation (Schiedel et al. 2018a).

Another micromolar, selective, and brain-penetrating SIRT2i, AK-7 (**13**), possesses SIRT2-dependent neuroprotective properties in neurodegenerative diseases such as HD and PD; furthermore it is capable to downregulate the neuronal cholesterol biosynthesis, confirming the crucial role of SIRT2 as a target in neurodegenerative disorders (Carafa et al. 2016; Zwergel et al. 2019).

SIRT2i can be applied for cancer treatment as well. The compounds **14a** and **14b** out of a 1,2,3-oxadiazole series are selective single-digit micromolar SIRT2i (inactive at 100 μM against Sirt1, Sirt3, and Sirt5) able to induce pro-apoptotic and antiproliferative effects in diverse leukemia cell lines (Carafa et al. 2016; Zwergel et al. 2019).

An example of a selective submicromolar SIRT3i has been described SDX-437 (**15**); however biological data are not yet available (Carafa et al. 2016; Zwergel et al. 2019).

The first SIRT6i **16** was found through an in silico high-throughput screening approach, a greater than eightfold selectivity over SIRT1/2 (Carafa et al. 2016; Zwergel et al. 2019). This compound might be a promising first step toward optimized SIRT6i and an eventual therapeutic application, since it hyperacetylates the SIRT6 substrate H3K9, and increases glucose uptake via GLUT-1 upregulation

Peptides and Pseudopeptides

Besides small molecules, also peptide-based SIRTi are described in literature. In the first one, the N^{ε}-acetyl-lysine residue was substituted with a thioacetylated moiety, and the *C*-terminal was prolonged with a p53 protein tail (Schiedel et al. 2018b), resulting in a SIRT1/2i with also a moderate effect on SIRT3. Thereafter other quite potent thioacetylated peptide-based inhibitors as well as other lysine N^{ε}-modifications (such as propionyl, α-hydroxyacetyl, homocitrulline, or homoarginine residues) were synthesized and tested resulting in the inhibition of SIRT1/2/3 using different SIRT substrates such as human α-tubulin or acetyl-coenzyme A synthetase 2 (AceCS2) (Schiedel et al. 2018b).

Most of the peptidic or pseudopeptidic SIRTi (**17a, 17b**) reported to date are SIRT1/2/3i; nevertheless some of them were slight active also toward SIRT6 (Carafa et al. 2016; Zwergel et al. 2019) or SIRT5 (Rajabi et al. 2017; Kalbas et al. 2018).

A specific peptide-based SIRT5i MC3482 (**18**) has been shown to increase ammonia production in non-liver cells leading to autophagy via modulation of the glutamine metabolism (Zwergel et al. 2019).

SIRT Activators

Besides the above presented SIRTi, also SIRT activators (SIRTa) have been described in literature (Schiedel et al. 2018b). The first and most prominent example is the natural polyphenol resveratrol (**19**), a SIRT1a. This compound can extend the lifespan of rather simple organisms such as yeasts, worms, fishes, and insects. Later on these promising outcomes, **19** was also published to improve mitochondrial functions in mammals such as normal and obese rodents (Carafa et al. 2016; Zwergel et al. 2019).

The selective SIRT1a SRT1460 (**20**) was identified via a high-throughput screening. Interestingly, it shows similar effects like **19** in vivo however associated with a higher potency (Carafa et al. 2016; Zwergel et al. 2019). Compound **20** and its analogues exhibited encouraging results in preclinical studies for age-related diseases; thus some of them are now evaluated in clinical trials (Carafa et al. 2016; Zwergel et al. 2019).

In the past, SIRT1 activation was much debated due to the fact that the initial studies had positive outcome only with artificial substrates such as carboxytetramethylrhodamine (TAMRA)-

labeled ones, whereas SIRT1 activation was only recently confirmed by the delicate structural and positional requirements of SIRT1 in the presence of its natural substrates such as FOXO3a and PGC-1α (Carafa et al. 2016; Zwergel et al. 2019) and by the crystal structure of an engineered human SIRT1-sirtuin-activating compound (STAC) complex, which revealed the STAC-binding site within the *N*-terminal domain of hSIRT1 (Dai et al. 2015).

1,4-Dihydropyridines (DHPs) of the general structure **21** are SIRT1a able to decrease the acetylation state of α-tubulin in U937 cells, to increase the NO release in HaCat cells, and to improve wound healing and skin repair in a mouse model via the activation of the SIRT1/AMPK pathway. Additionally, a water-soluble DHP analogue increased H4K16ac deacetylation resulting in antiproliferative effects in diverse cancer cell lines at a micromolar level (Carafa et al. 2016; Zwergel et al. 2019).

SIRT3 can be directly activated and overexpressed by the natural compound honokiol (**22**) resulting in reduced acetylation levels of the mitochondrial SIRT3 substrates MnSod or oligomycin-sensitivity conferring protein (OSCP). The compound **22** showed beneficial properties in a mouse model of hypertrophy via SIRT3 activation (Carafa et al. 2016; Zwergel et al. 2019).

Compound **23** is the first small molecule identified as SIRT6a. The biochemical and crystallographic data revealed a direct, specific, and substrate-independent binding mode of **23** within the catalytic site of SIRT6 and its subsequent potent activation which results in the deacetylation of peptide substrates and entire nucleosomes (Zwergel et al. 2019). The possibility of SIRT6 activation by small molecules has been recently further confirmed by a more potent compound **24** (Huang et al. 2018).

Low molecular mass GTPases; Small G proteins

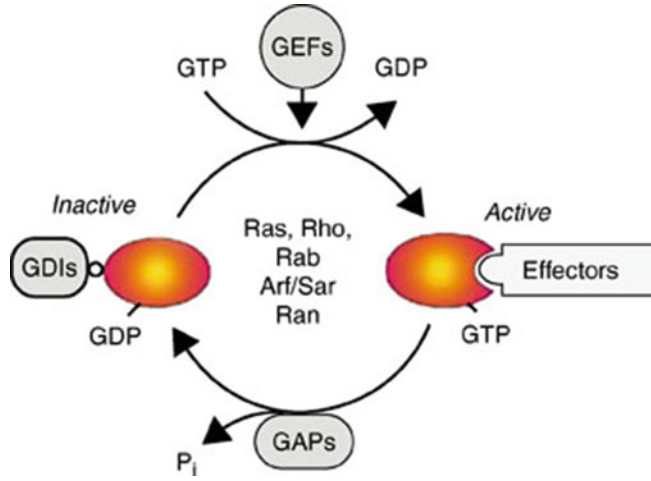
Definition

Small GTPases are monomeric 20–40 kD GTP-binding proteins that interconvert between an active (GTP-bound) and an inactive (GDP-bound) state. As molecular switches they are involved in the regulation of complex cellular processes.

Basic Characteristics

Regulation

Activation of small GTPases occurs by GDP/GTP exchange catalyzed by guanine nucleotide exchange factors (GEFs) (Fig. 1). They stimulate the dissociation of GDP in response to an upstream signal which results in binding of GTP. In the GTP-bound form the GTPases are active, and bind to and activate a number of effector molecules. The small G proteins are able to hydrolyze the bound nucleotide to GDP. This inactivation step is accelerated by GTPase activating proteins (GAPs). In the GDP-bound form the GTPases are inactive. Some GTPases bind to guanine nucleotide dissociation inhibitors (GDIs) that stabilize the inactive form and cover the lipid modification of the GTPase forming a cytosolic complex. Novel roles of GDI in GTPase regulation like the delivery of GTPases to specific sites within the cell are discussed. Moreover, local synthesis and degradation of GTPases seem to



Small GTPases, Fig. 1 The GTPase cycle: GTPases are inactive in the GDP-bound form. In a complex with guanine nucleotide dissociation inhibitors (GDIs) the inactive form is stabilized (note: not all small GTPases are regulated by typical GDIs, e.g., not Ras, Ran, and Arf subfamily proteins). Guanine nucleotide exchange factors (GEFs) cause the release of GDP and binding of GTP, and thereby the activation of the proteins. The active state of the GTPases is turned off by GTP hydrolysis catalyzed by GTPase activating proteins (GAPs)

play additional roles in the spatial regulation of small GTPases. In mammalian cells, each family of the regulating proteins GAPs, GEFs, and GDIs comprise numerous members that are more or less specific for individual GTPases, cell types, GTPase functions, and signaling pathways.

General Structural Properties

All small GTPases are folded in a similar way. They possess four consensus amino acid sequences in common, which are involved in nucleotide binding and hydrolysis: GXXXXGK, DXXG, NKXD, and EXSAX. Two highly flexible regions (Switch I and Switch II regions) determine the nucleotide-dependent activation state of the GTPases and the protein–protein interactions with effectors and regulatory proteins.

Posttranslational Modification

All small GTPases (except Ran) are posttranslationally modified. Most important is the isoprenylation of the C-terminus. The type of modification is determined by the COOH-terminal amino acid sequence. GTPases with a C-terminal CAAX-box (A = aliphatic amino acid, X = any amino acid) are farnesylated at the cysteine residue followed by the proteolytic degradation of the last three amino acids and subsequent methylation of the carboxy-terminus. In the case of CAAL or CAC, the cysteines are modified by geranylgeranylation. In some cases an additional cysteine is palmitoylated or N-terminal myristoylation occurs. All these post-translational modifications allow the interaction of GTPases with the phospholipid bilayer. Lipid modification of the GTPases is required for membrane localization and GDI binding.

Families

The superfamily of small GTPases consists of more than 100 members from yeast to human with more than 80 members expressed in mammalian cells. Based on structural and functional similarities the GTPases are subdivided into five major classes.

Ras GTPases

The mammalian family of Ras GTPases consists of more than 15 members, which share high homology to each other and include Ha-Ras, Ki-Ras, N-Ras, R-Ras, Rap, Ral, Rheb, Rin, and Rit proteins (Hancock 2003). Ras proteins have achieved attention with the discovery that they contain point mutations in 15% of all human

tumors (more than 90% in pancreatic tumors), leading to the exchange of conserved amino acids, for example, at positions 12 and 61. Amino acid exchanges at these positions block the GTP hydrolyzing capacity of the GTPases, resulting in constitutive activation. Ras GTPases are involved in proliferation and/or differentiation. They couple receptor tyrosine kinases with a cascade of cytosolic kinases termed Raf/ERK kinase pathway (also known as MAP kinase cascade). Activation of this pathway leads to phosphorylation and activation of transcription factors like Elk-1, and stimulate gene expression. Activated Ras has been shown to transform culture cells and to produce tumors in nude mice. Besides the Raf kinase, also RalGDS, which is an activator of the Ral subfamily proteins, and the PI3 kinase involved in inositol signaling are important effectors of Ras signaling. Ral GTPases (<50% identical with Ras) control cell proliferation, Ras-mediated cell transformation, vesicle traffic, phospholipase D, and cytoskeleton organization. Rap GTPases have been identified in a screen for cDNAs that are able to revert the transforming phenotype of Ki-Ras (Kirsten Ras) and, therefore, were also termed K-rev proteins.

Rho GTPases

Members (>20) of the Rho family of GTPases, including RhoA, B and C, Cdc42 and Rac1, 2 and 3, share more than 50% sequence identity. These GTPases are important regulators of the actin cytoskeleton (Etienne-Manneville and Hall 2002). RhoA regulates the formation of actin stress fibers, whereas Cdc42 is known to induce filopodia. Rac is involved in the formation of lamellipodia and membrane ruffles. Rho GTPases are involved in migration, phagocytosis, endo- and exocytosis, and cell–cell and cell–matrix contact. Rac regulates NADPH oxidase. Furthermore, Rho GTPases are involved in transcriptional activation, cell transformation, and apoptosis. Considering their diverse functions, Rho GTPases are regulated by a large number of GEFs and GAPs (>60 members of each family have been identified), suggesting spatiotemporal, function-specific regulation.

A subfamily of Rho proteins, the Rnd proteins are always GTP-bound and seem to be regulated by expression and localization rather than by nucleotide exchange and hydrolysis. Many Rho GTPase effectors have been identified, including protein and lipid kinases, phospholipase D, and numerous adaptor proteins. One of the best characterized effector of RhoA is Rho kinase, which phosphorylates and inactivates myosin phosphatase; thereby RhoA causes activation of actomyosin complexes. Rho proteins are preferred targets of bacterial protein toxins (► Bacterial Toxins).

Rab GTPases

The largest family of small GTPases with more than 40 members identified is the family of Rab GTPases (Zerial and McBride 2001). Rab proteins are important regulators of specific steps of intracellular vesicle trafficking, including budding, targeting, docking, and fusion with acceptor membranes. Each Rab protein has an organelle-specific subcellular localization and seems to be functionally specialized. Rab1A and Rab1B are two of the most extensively studied members of the Rab family. Both proteins are found in membranes of the ER, Golgi apparatus, and intermediate vesicles between these compartments. They appear to function in the anterograde trafficking of proteins from the ER to the Golgi compartment. Rab4 and Rab5 are present on early endosomes and are involved in the endocytic process, whereas Rab6 is localized at the Golgi apparatus regulating processes of the secretory pathway. One of the best studied members of the Rab protein family is Rab3a. This GTPase is a key regulator of Ca^{2+}-induced exocytosis, particularly in nerve terminals. Several effectors of Rab proteins like Rabphilin, Rabaptin, and Rim have been identified and characterized as essential for vesicle trafficking. Recently, the Rab effector Rabkinesin6 has been identified that links Rab proteins to the microtubule cytoskeleton. Rabkinesin6 may be the motor driving vesicles along microtubules from the Golgi apparatus to the periphery.

Arf/Sar1 GTPases

The name Arf (ADP-ribosylation factor) stems from its discovery as a cytosolic factor with the

ability to enhance the ADP-ribosylation of the α-subunit of the G protein G_S by cholera toxin. Arf is known to regulate phospholipid metabolism. Studies with dominant active or dominant negative mutants of Arf proteins in mammalian cells suggest the involvement of these GTPases in the trafficking of coated vesicles, and it is now known that Arf1 regulates the formation of COPI-coated vesicles for retrograde transport between Golgi apparatus and endoplasmic reticulum (Souza-Schorey and Chavrier 2006). Sar1, which is 37% identical to Arf1, is needed for the assembly of COPII proteins for vesicle transport in the opposite direction. Taken together, Arf and Sar proteins play crucial roles in the recruitment of COP components to vesicles thereby regulating vesicle budding. In contrast to the other small GTPases, Arf/Sar1 proteins are not regulated by GDI proteins, whereas different GEF and GAP proteins have been identified. Myristoylation of Arf proteins at the N-terminus is required for its membrane localization.

Ran GTPases

In mammalian cells there is only one *Ran* gene, which was discovered as a Ras-like gene (Ran: Ras-related nuclear protein) (Dasso 2002). In contrast, in yeast more than one related *Ran* genes have been identified. The predominant nuclear localization of the GTPase was the first hint that Ran is involved in nucleocytoplasmic transport processes. Interestingly, the only Ran GEF present in mammalian cells, RCC1 (regulator of chromatin condensation), is localized exclusively in the nucleus, whereas the single Ran GAP (Ran GAP1) is in the cytoplasm. This specialized localization of the regulators is the prerequisite for the asymmetric distribution of the GDP- and GTP-bound form of Ran and for its role as a nucleocytoplasmic transporter. In contrast to other GTPases, the activity of Ran is dependent on the gradient of the GTP-bound GTPase from cytoplasm to nucleoplasm that allows the transport of cargo proteins. Ran is involved in nuclear import as well as in export of proteins through the nuclear pore complex. Both processes require the formation of protein complexes, including Ran, the cargo protein, and Ran-binding proteins like importins or exportins. In addition to its transporter function, Ran has been shown to participate in microtubule organization during the M phase of the cell cycle.

Cascades and Cross-Talk

Small GTPases are not isolated molecular switches. Signaling cascades within one subfamily and cross-talk between members of different subfamilies are known. For example, Cdc42/Rac/Rho is sequentially activated after extracellular stimuli in quiescent Swiss 3T3 cells. Moreover, reciprocal modulation between Rho GTPases has been described. Ras and Rho proteins act in a cooperative manner in Ras-induced transformation. A further example of cross-talk between GTPase families is the cooperative function of Rho and Rab proteins during cell migration, with Rho proteins controlling the actin cytoskeleton, and Rab proteins regulating vesicular traffic for the recruitment of membrane material, and the recycling of proteins like integrins. Arfaptin connects signaling via Arf and Rac in regulating fundamental processes like endocytosis and secretion.

Drugs

Small GTPases, among other activities, regulate cell growth, neurite outgrowth, and signaling of immune cells involved in inflammation. Pharmacological modulation of the activity of small GTPases is thus a useful aim in cancer and anti-inflammatory therapies. Despite many years of scientific work, specific inhibition of Ras is not yet possible; however, the prenyl binding protein PDEdelta sequesters oncogenic Ras within the cytosol to suppress its membrane localization and signaling. Moreover, inhibitors for an activating mutation of the Ras effector Raf are in clinical use. Farnesyltransferase inhibitors block the posttranslational modification of several GTPases, to block correct cellular localization and therefore the transforming activity of Ras or Rho GTPases. Moreover, inhibitors of Rho effectors like Rho kinase inhibitors have been generated.

Small-Molecule Screens

Jens Peter von Kries
Department Chemical Biology, AG: Screening Unit, Leibniz-Forschungsinstitut fuer Molekulare Pharmakologie, FMP, Berlin, Germany

Synonyms

Chemical biology; Drug screening; High-throughput screening (HTS); Small molecules

Definition

Methods to search for compounds of low molecular weight which modulate biological experiments, typically using libraries of several thousands to millions of small molecules. Robotic automation is typically used for a precise and simultaneous transfer of reagents and biologically active probes such as enzymes or living cells to microtiter test plates. Automated detection systems measure biological responses, such as a decrease of fluorescence through the inhibition of an enzyme by a small molecule. Other studies examine the effects of compounds on proteins or other purified components to measure their interactions or functions. More complex experiments analyze the effects of small molecules on living cells, such as cancer cells from patients, or pluripotent stem cells as they develop into other cell types or organ-like structures. Screens may also be based on animal models such as C. *elegans* or zebrafish embryos. Identifying small molecules that modulate biological functions has become crucial to studying molecular mechanisms in health and disease, validating novel drug targets, and developing novel diagnostics and drugs.

Description

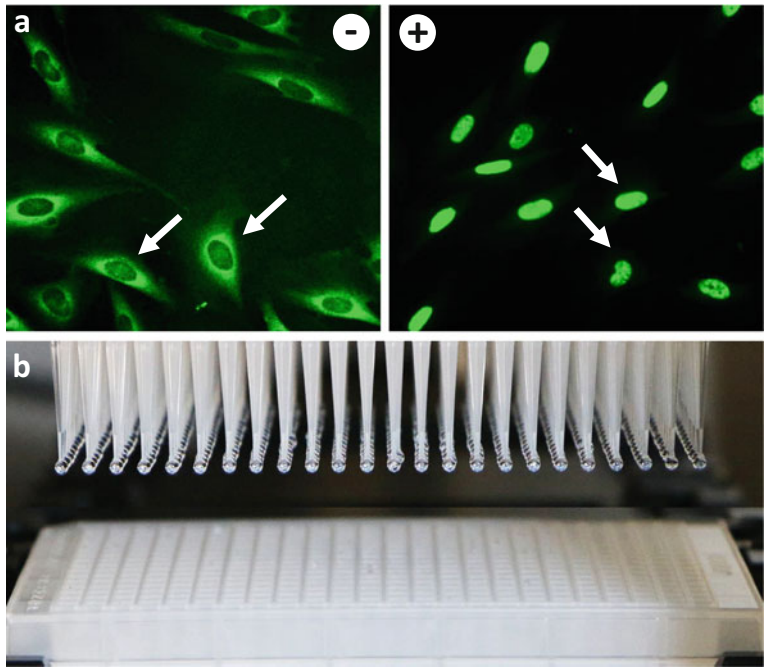
Small Molecule

A compound of natural or synthetic origin, defined by a low molecular mass of less than 1,000 daltons. Common small molecules include nucleotides in DNA, which have molecular masses of about 330 daltons; amino acids lie between 89 and 204 daltons.

Small-Molecule Screens

The process of using a library to search for small molecules that affect a biological system or experiment. Screens are often carried out using high-throughput screening (HTS), based on robotic systems and high-speed detection systems to ensure the precise transfer of reagents and accurate measurements.

The screening process comprises several steps, starting with development of a robust biological assay (Fig. 1a, b). Depending on the complexity of the biological test system, which may involve purified enzymes, cancer cells (Fig. 1a), or animal models, developing an assay for image-based screen may take up to one year. The next steps include optimizing the assay so that it can be used for moderate- to high-throughput screening in a



Small-Molecule Screens, Fig. 1 The figure summarizes the process from the development of the biological assay for high-throughput screening of compound libraries to the identification of small molecules that modulate biological functions. (**a**) *Cellular assay development:* An appropriate test is set up, with positive and negative controls such as reference drugs or an inducible cellular response. In inducible biological responses, a fluorescent protein (green color) may be sequestered in the cell cytoplasm (−); after the addition of an inducer (+), the protein may translocate to the nucleus. This example shows a transcription factor translocation to the nucleus in cancer cells, after induction and labeling by a green fluorescent protein-specific antibody. Nuclei are marked by arrows. (**b**) *Assay miniaturization:* For HTS, biological assays must be downscaled to microtiter plates containing either 1536 (48 × 32), 384 (24 × 16) or 96wells (12 × 8) per single plate and typical assay volumes ranging from 1–100 µl. Plates have a standardized footprint for robotic assay automation and are labeled by machine-readable barcodes encoding for library probes on a given test plate. Robotic grippers transport test plates from climate-controlled incubators to pipetting positions of pipetting heads with up to 1536 tips (example shows 384 disposable tips mounted at a 384-channel head pipetting liquid to a 384-well plate) or to detection systems such as microscopes or plate readers. Data are often collected and analyzed in parallel. Detection systems are either sequentially analyzing plate wells or support whole-plate imaging, for faster testing. The analysis of hits from primary screening combines different types of information, including a clustering of structurally related hits (structure-activity relationships), measurements made to detect interference with the test system, dosage-dependent interference, data regarding the purity and integrity of hits, and the frequency of hit detection in distinct tests (frequent hitters). Results are compared to public databases to assess the already known activity of structurally similar molecules

microtiter plate format with robotic automation (Fig. 1b). It needs to pass an assay acceptance test, plus a pilot screen in which a few thousand compounds are used to control the robustness of the assay in the presence of compounds and their solvent. Next comes the primary screen against the whole library of molecules. Often a counter-screen is needed to identify false positive hits which interfere with the detection reagents, coupled enzyme reactions or a cellular reporter system in an unspecific manner. Finally, primary hits are validated by testing for dosage-dependent modes of action, to exclude compounds which catalyze chemical reactions and have toxic effects. These steps depend on computational support in data documentation, the automated analysis of huge datasets, and the conversion of images into multiparameter tables. The selection of hits for further characterization and chemical optimization typically requires automatically searching

for structurally related small molecules and their known effects in public databases such as PubChem or ChEMBL, and patent databases such as Espacenet (for Europe) or USPTO (USA).

Assay development for small-molecule screens: Biological tests based on purified proteins such as enzymes, transcription factors, or scaffolding proteins provide rather simple and robust systems for screening. Often these targets play key roles in diseases due to mutations in their corresponding genes that cause hyperactivation or an impairment of their functions. Enzyme assays often use synthetic substrates whose fluorescence is altered when the enzyme is activated or inhibited. Interactions between two distinct proteins can be studied using protein-specific antibodies that only transfer a fluorescent signal if they are brought into close proximity through an interaction of the proteins. Small molecules that interfere with their interaction decrease the fluorescence, as measured with plate readers and multiwell microtiter plates. Tests with purified components permit inhibitors to be chemically optimized, altering substructures that affect their affinity and specificity for proteins and enzymes. Further tests in cells and animal models are essential to testing the bioactivity of small-molecule hits and their roles in diseases.

Cellular systems represent a next level of complexity in identifying bioactive compounds, to determine whether they can cross the cellular membrane (membrane permeability), reach proper concentrations in the cytoplasm (biostability) and act specifically on the target protein (specificity). Such tests often use cancer cells in which the endogenous target protein has become permanently activated by a mutation. The cells are genetically manipulated through the stable integration of a reporter gene into the genome whose expression depends on the activity of the protein. This reporter may encode a fluorescent protein (GFP, YFP) or an enzyme (luciferase) that produces luminescence in the presence of its substrate. Small-molecule inhibitors reduce the fluorescence or luminescence. These experiments require a counter-screen using a second, unspecific reporter cell line to identify compounds which target the reporter enzymes or fluorescent proteins themselves. Plate readers or automated microscopes are used to quantify fluorescent signals, to image the translocation of fluorescent proteins within living cells or to document cellular signal transduction. Induced pluripotent stem cells (IPSCs) have become a major source for cellular assays for screens involving heart muscle, neurons, and many other types of cells. They can be also used to generate small organ-like structures (heart or brain organoids) for screens.

Animal models for disease like nematodes or zebrafish embryos present the next level of complexity, to determine whether small molecules enrich in specific tissues and maintain sufficient concentrations over time to affect pathological processes despite the activity of secretory and metabolic clearance processes. Such screens may rely on analyses of reporter genes that encode fluorescent proteins or morphological analyses of tissues and organs.

Assay optimization: Screens of tens of thousands to a million small molecules require robust biological assays in which negative and positive controls should generate consistent readouts. Potential counteracting factors include variability between biological sample preparations, systematic variations in the measurement process, and unsystematic noise due to random influences. Biological tests need to be optimized to obtain an optimal signal-to-noise ratio and exclude an overlap due to weak signals and strong variations. Optimization affects buffer conditions for enzyme tests, enzyme and substrate concentrations, and also an optimal choice of test plates and enzyme stability. Requirements for cellular testing include an optimal density of cells and the best time window for measurements; the significant parameters for cellular responses that are to be detected with automated microscopes and image recognition software need to be identified and optimized. Assays using animal models must also be optimized for the number of animals per test and the well sizes on test plates. Furthermore, the number of repeats for compound addition and amount of compounds that are applied must be optimized for appropriate dosage using known references.

Pilot screen: After an assay passes the acceptance test, a sublibrary of a few thousand

compounds is used to test the robustness of the assay in the presence of small molecules solubilized in DMSO as a solvent. This tests for interference that arises through the physical properties of compounds (fluorescence, colored compounds) and hit rates. The pilot and primary screen may use either single point or duplicate tests and measurements at single or multiple concentrations for each compound.

Primary screen: Batches of compound plates are selected for automated processing in robotic liquid handling systems with incubators and detection systems like plate readers or automated microscopes within a single day. Depending on incubation and processing times, 10,000–50,000 tests can be finished per day. Biological responses to compound addition are analyzed on the fly to immediately identify systematic variations. Measurements of the responses are presented on a colored plate map, generally using shades of red to represent the intensity of inhibition and blue colors for activation. Each plate contains wells with compounds and negative and positive control wells to normalize the signal output for each plate over the course of the screen. This is necessary to normalize results because enzymes or reagents may become less active over time. Primary hits (activators or inhibitors) are selected and tested for dosage-dependent activity.

Primary hit validation: Depending on the complexity of the test, a counter-screen may be applied to remove primary hits that act nonspecifically. This requires controls in which signal is produced by alternative pathways or regulatory elements, rather than those specifically targeted by the test compound. Generally, selecting hits for further characterization depends on dosage-dependent effects. They are applied at a range of dosages, from those that achieve complete inhibition to low concentrations in which activity remains at 100%. Analysis reveals an IC50-value for each small-molecule inhibitor: a concentration at which the system is inhibited to 50% of its maximal activity. Selected hits are either repurchased from vendors or resynthesized to test for impurities to cause biological effects. The structures of validated small molecules are then used to search for similar molecules and select drugs for continued experiments, drawing on publicly available data on known bioactivity and patents.

Small-molecule screening libraries: Libraries contain compounds which conform to certain rules on physiochemical and structural properties that correlate with the oral availability and the success rate in drug development (Lipinski et al. 2001). These rules limit the size of drug-like compounds to a molecular mass of less than 500 daltons, the number of hydrogen bond donors and acceptors to less than 5 and 10, respectively, and the water solubility to a log P value of less than 5.

Pharmacological Relevance

The majority of drugs currently used in treatments or diagnosis are small molecules of natural or synthetic origin. This toolbox is complemented by biopharmaceuticals generated by genetically modified cells, including antibodies, peptide hormones, DNA, and RNA. In academia, small-molecule screens are mainly used in the context of chemical biology to identify bioactive small molecules for use as research tools. As dosage-dependent modulators of biological functions which can be applied and withdrawn, bioactive compounds are important complements to methods such as gene ablation or CRISPR-Cas9 gene editing.

The use of cellular screens as disease models is based on the work of Rudolf Virchow, whose theory of cellular pathology states that diseases are based on changes at the cellular level (Morrison and Weiss 2006; Virchow 1855). Paul Ehrlich established the principle of chemotherapy and launched the first small-molecule screen to search for chemicals that were toxic to pathogenic bacteria causing Syphilis (Ehrlich and Bechhold 1906). His work resulted in the development of the first effective drug against Syphilis, Salvarsan (1910–1970). The success of this systematic approach combining chemical synthesis with biological screening made this technology a standard for drug identification and development in the pharmaceutical industry.

In academia, its systematic use started with the roadmap published in 2004 by the NIH (National Institutes of Health, USA), which provided

funding for small-molecule libraries and specialized technology centers for chemical biology. European academic platforms were launched a few years later. Academic platforms and research projects are not restricted to cellular targets for modulation – the "druggable genome" which represents about 10% of human genes. They can also explore diverse other targets, such as the motor proteins that separate chromosomes during cell proliferation as anticancer targets (Overington et al. 2006; Mayer et al. 1999). There has been a steady increase in the impact of academic chemical biology projects on the validation of novel targets (first in class drugs), the development of novel technologies for screening, combinations of drug interference with genome-wide interference via RNA interference (specific degradation of gene transcripts and depletion of encoded proteins), and CRISPR-Cas9 editing (gene-specific modification or deletion of coding sequences) due to their systematic use in research.

Common Screening Technologies

Fluorescence intensity (FI): In HTS, radioactive labeling has largely given way to fluorescent labeling, thanks to progress in the development of synthetic enzyme substrates that generate fluorescence quenching and emitting side chains in one molecule, only becoming fluorescent after cleavage. Fluorescently labeled antibodies detect proteins and their interactions, exposing biochemical pathways that are activated in cells or animal models, in health or disease. Changes of the intensity of fluorescence may indicate a modulation of an enzyme's activity or the translocation of a protein in a cell. Fluorescent proteins such as GFP or YFP and others can be fused with cellular proteins to permit live-cell analyses of their locations and quantities and how they change through the activation of cellular pathways or addition of pathogens. Generally, FI detection methods provide an ideal readout for small-molecule screens (Janzen 2014).

Fluorescence polarization (FP): Exciting fixed fluorophores with polarized light results in emissions that can be detected through polarization filters. The FP technique requires a fluorescently labeled small molecule or peptide which binds to a larger binding partner such as a protein. Without the binding partner, the small-molecule label is free for dynamic rotation and emits fluorescence into all directions. Specifically binding to a protein, either as a substrate of an enzyme or as a peptide hormone to a receptor, restricts the tumbling of the labels. Applying fluorescence polarization filters during excitation and detection permits quantifying the change in rotation, which correlates to the proportion of small-molecule or protein peptide complexes that have formed. This method permits screening for small molecules which interfere with the binding of labeled ligands such as hormones or enzyme substrates. Components are only added to start the reaction, which makes the method well suited for HTS.

Fluorescence resonance energy transfer (FRET): In principle a pair of fluorophores is selected for which the first (donor) – after excitation by light –emits fluorescence at a wavelength which excites the second fluorophore (acceptor) to emit fluorescence. This only happens efficiently if the fluorophores are brought into extremely close proximity. In a FRET experiment, the two fluorophores are attached to specific proteins using, for example, antibodies which are each linked with either the donor- or acceptor-fluorophore. If two proteins bind to each other, in an in vitro or cellular assay, the energy transfer occurs after the addition of antibodies and this results in generation of a measurable fluorescent signal at the site of interaction.

Time-resolved fluorescence (TRF): Related to FRET screens, this method uses a long-wavelength donor fluorophore with a long decay time (μsec). The purpose is to avoid interference by fluorescent screening molecules, whose fluorescence generally decays within nanoseconds. Introducing a time gap to measure the signal from the second fluorophore eliminates this type of interference. This technique is widely used in very high-throughput screens of biochemical and cellular assays.

Luminescence: Isolating enzymes which use small-molecule substrates and oxygen to produce

light (bioluminescence) from a range of organisms has provided key tools to study cellular gene expression. These methods combine regulatory sequences with genes encoding these enzymes to create reporter genes. An example of their use is to monitor the binding of transcription factors to regulatory DNA elements. Permanently activated oncogenes in cancer cells, for example, can be constructed which generate luminescence if their activation is not inhibited by small molecules. In contrast to the expression of fluorescent proteins, enzymes strongly amplify transcription factor–mediated activation and thus provide a more sensitive detection of oncogenic activities. Other luminescence methods couple enzyme activity to protein interactions by fusing the enzyme and luminescence substrate to different proteins. Luminescence requires close proximity, so only sites of interaction will produce a signal. Luciferase reporter systems are also widely used in HTS.

Alpha screen: This technology delivers a chemiluminescent quantification of interactions. Two distinct proteins or interacting factors are coupled to donor or acceptor beads. The surface of each bead class is constructed to specifically bind only one type of factor. If the factors interact, this puts the beads in close proximity, triggering a laser-induced release of reactive oxygen from donor beads to acceptor beads and a chemiluminescent reaction. If small molecules inhibit binding, the beads are not coupled and the reactive oxygen becomes neutralized before reaching the acceptors. This method delivers a high number of false positive compounds which interfere with the release of reactive oxygen, which strip coupled factors from beads or interfere directly with the chemical luminescence reaction. Due to its high sensitivity, it is used, for example, to quantify levels of second messengers such as cAMP in cellular assays set up to detect G-protein-coupled receptor signaling.

Surface plasmon resonance: A protein is immobilized on a detection surface in a microfluidic chamber and a ligand such as a second protein or a small-molecule compound is added. Their binding and stability can be analyzed by measuring increases and the persistence of reflected light from the detection surface. This method permits a determination of binding constants for affinity and stability, and to detect irreversible binding or denaturation of proteins.

Capillary electrophoresis (microfluidic chips): This technology is based on hand-sized chips with up to 12 microfluidic channels and sippers which aspirate simultaneously a few nanolitres of 12 enzyme test reactions. They are capable of separating enzyme substrates and products by electrophoresis in high throughput that differ in charge – for example, after phosphorylation by kinases (which increases the negative charge of the product) or dephosphorylation by phosphatases. The enzymatic incubation is stopped after 50% of peptide substrate has been converted to product, resulting in two bands of equal amount after separation, if no inhibitor is present. The substrate is labeled by a fluorophore. This permits laser-mediated excitation and detection with a charge-coupled device camera (CCD). Applying an inhibitor decreases the fluorescence of the product band. The system permits profiling about 20.000 reactions per day and provides high-quality data, because detection is not affected by fluorescence quenching or unspecific physical properties of compounds.

Flow cytometry: This method is used to analyze cells in suspension, not adhered to a surface. Cells are marked by fluorescent dyes or antibodies of biological relevance, indicating, for example, their proliferative state or developmental stage, then excited by a laser. This permits very sensitive detection and readouts. Tens of thousands of cells in one test well can be sorted by size and fluorescence intensity, which means, for example, that a cancer marker can be detected on different cell types in a single experiment.

High-content screening and machine learning: Automated microscopes with 2D or 3D functions through confocal imaging are currently widely used to profile morphological alterations of cells derived, for instance, from patients. This broad data collection is termed high-content screening, and it is currently being used in conjunction with iPSC technologies to study 3D organoids and other structures. Applying drugs to organoids for colon cancer, for example, has been shown to

produce results that more closely resemble those of clinical trials than other current methods.

High-content screening requires the automated, software-guided identification of cellular objects such as nuclei, filaments, and membrane compartments. These structures are automatically recognized and converted to parameters representing size, fluorescence intensity, etc. Sometimes, small changes in specific parameters may provide a more significant readout for cellular responses than larger ones which may be more obvious in a visual examination. Therefore, machine learning is combined with a human visual sorting of experimental outcomes to develop computer-guided, positive, and negative correlations and filter a training set of data. Afterwards this artificial intelligence can be used to analyze image-based HTS data.

Impedance (label free): This method makes use of microtiter plates with golden electrodes at the bottom. A low electric current is applied to analyze changes in the electric resistance of cells adjacent to the electrodes. The impedance may change, for example, through signaling processes which cause a release of calcium from endogenous stores, or induce a stronger attachment to electrodes. In contrast to other methods, no chemical fixation of cells and membrane permeabilization for antibody detection is required, resulting in dead cells, instead living cells can be analyzed over time without further treatment (label free).

Automated data documentation and analysis: The high-throughput screening of large small-molecule libraries requires the automated documentation and analysis of the data that is acquired. This can be achieved by adapting commercial and free open-source software. Biological and chemical data such as compound identifiers and structure information must be linked in the documentation. Scripts that are appropriate to the screening technology must be written to filter and analyze hits and to set curves to fit kinetic or end-point data collections. A conversion of measurements to colored heat maps reflecting biological activities permits a rapid detection and correction of systematic errors. Researching structural similarities and known bioactivities in public databases is essential in designing follow-up tests and selecting candidates for further study. Small-molecule screening represents a dynamic marriage of technologies with biological, chemical, and computational expertise in an inherently interdisciplinary enterprise that holds great promise for the future identification and development of potent new drugs.

Regulation of smooth muscle contractility

Definition

The following organs contain as major functional part smooth muscle layers: arterial and venous

vessels; lung and bronchia; oesophagus, stomach, and small and large intestine; urinary tract and bladder; and uterus. Hormones, locally released transmitters and shear stress or pressure regulate the tonus of these organs. Each organ has a slightly different regulation of its contractility, but the basis for this regulation, i.e. the intracellular signaling pathways, is very similar or identical. This article will focus on major findings that may be identical in all smooth muscles.

Basic Mechanisms

Key mechanism of smooth muscle tone regulation is the phosphorylation of Ser-19 of the regulatory myosin light chain II (rMLC) (Pfitzer 2001). Phosphorylation and dephosphorylation are catalysed by myosin light chain kinase (MLCK) and the type 1 myosin phosphatase (MLCP), respectively. Calcium-dependent and calcium-independent signal pathways regulate the activity of both enzymes and thereby the phosphorylation status of rMLC. An increase in the cytosolic calcium concentration leads to phosphorylation of the rMLC and contraction within 4 s. The correlation between percent phosphorylated rMLC and developed force is quite variable. Maximal force can be attained at 0.2–0.3 mol phosphate per mol rMLC. Phosphorylation can decline during maintenance of tension suggesting that even dephosphorylated cross-bridges can contribute to force maintenance.

Calcium-dependent regulation involves the calcium-calmodulin complex that activates smooth muscle MLCK, a monomer of approximately 135 kDa. Dephosphorylation is initiated by MLCP. MLCP is a complex of three proteins: a 110–130 kDa myosin phosphatase targeting and regulatory subunit (MYPT1), a 37 kDa catalytic subunit (PP-1C) and a 20 kDa subunit of unknown function. In most cases, calcium-independent regulation of smooth muscle tone is achieved by inhibition of MLCP activity at constant calcium level inducing an increase in phospho-rMLC and contraction (Fig. 1).

Calcium-Dependent Contraction

Different agonists such as norepinephrine, acetylcholine or angiotensin II activate smooth muscle contraction by binding to a heptahelical receptor, i.e. α-adrenergic, muscarinergic or AT-1 receptors, followed by an increase in cytosolic calcium (Figs. 1 and 2). The activation of the trimeric G proteins G_q or G_{11} increases the activity of phospholipase Cβ (PLC) generating inositol trisphosphate (IP_3) and diacylglycerol (DAG) and other fatty acid-derived compounds. Classical

findings suggested that IP_3 stimulates calcium release from intracellular stores that binds to calmodulin and activates MLCK. This simple scheme is not in line with the fact that a block of the L-type Ca^{2+} channel inhibits contraction. The importance of the L-type calcium channel is further supported by genetic deletion of the corresponding $Ca_v1.2$ gene. Mice lacking the smooth muscle Cav1.2 channel have severe difficulties to contract intestinal and other smooth muscle. It is therefore likely that activation of a heptahelical receptor leads to depolarization of the membrane and activation of the L-type calcium channels (Fig. 2). Possible candidates are TRP channels (most likely TRPC6) activated either by DAG or by interaction with empty IP_3 stores. The inflowing cations may depolarize the membrane to potentials that activate T- and thereafter L-type calcium channels or directly L-type channels. A second channel depolarizing the membrane is the calcium-activated chloride channel present in many smooth muscle cells. Calcium released from IP_3 stores or flowing in through TRP channels could activate this chloride channel and depolarize thereby the membrane. The L-type calcium channel provides calcium to trigger calcium release from ryanodine receptor-controlled calcium stores and for refilling various intracellular calcium stores (Jaggar et al. 2000). The mechanism behind pressure- or shear stress-induced contraction is unsolved but may again involve TRP channels and mechanosensitive cation channel Piezo1. Piezo1 is mainly expressed in endothelial cells. Shear stress activates the endothelial Piezo1 and contributes thereby to endothelial-dependent hyperpolarization (EDH) and relaxation of arterial resistance vessels (Douguet et al. 2019).

Calcium-Independent Contraction

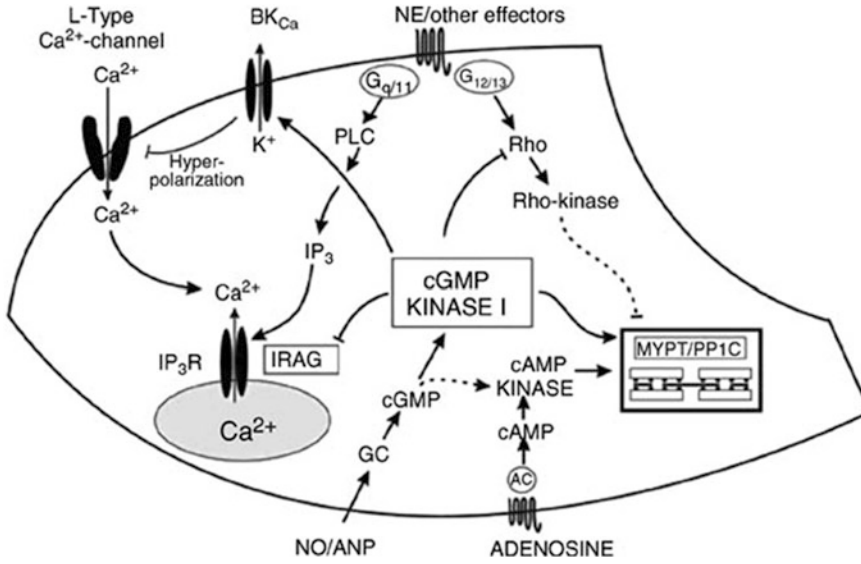
Agonist-activated receptors can induce contraction at a constant intracellular calcium concentration (Somlyo and Somlyo 2000), if the receptor activates the G proteins G_{12} or G_{13} (Fig. 1). Activation of these G proteins recruits the monomeric GTPase Rho to the membrane, where Rho exchanges GDP against GTP and activates Rho kinase. By a still unsolved cascade eventually involving ZIP kinase, the MYPT1 subunit of MLCP is phosphorylated at Thr-697 and Thr-854 (rat MYPT1) which reaction inhibits MLCP activity. Since the activity of MLCK is not affected by this cascade, rMLC is phosphorylated to a higher level. Phosphorylation and inhibition of MLCP activity are only observed, if a central exon of MYPT1 is present. These results could explain the old finding that certain agonists induce calcium sensitization of the contractile machinery in most but not all smooth muscles. MLCP activity is also affected by a smooth muscle-specific

inhibitor protein of PP-1C, named CPI-17. Protein kinase C (PKC) phosphorylates CPI-17, which becomes then a high affinity inhibitor of the catalytic subunit of MLCP. The nature of the PKC subtype is not clear. It is possible that it is one of the atypical PKC enzymes that is activated directly (?) by arachidonic acid (AA). Rho kinase which phosphorylated CPI-17 in vitro apparently may affect directly in vivo the phosphorylation status of CPI-17 (Dimopoulos et al. 2007). Arachidonic acid inhibits dephosphorylation of MLCs, i.e. by a second mechanism by dissociating the MLCP holoenzyme.

Relaxation of Smooth Muscle

The major relaxing transmitters are those that elevate the cAMP or cGMP concentration (Fig. 3). Adenosine stimulates the adenosine receptor A_2, increases cAMP and activates thereby the activity of cAMP kinase. The next step is not clear, but evidence has been accumulated that cAMP kinase decreases the calcium sensitivity of the contractile machinery. In vitro, cAMP kinase phosphorylated MLCK and decreased thereby the affinity of MLCK for calcium-calmodulin. However, this regulation does not occur in intact smooth muscle. Possible other substrate candidates for cAMP kinase are the heat-stable protein HSP 20, a heat stable protein of 20 kDa that is phosphorylated by cGMP kinase. It has been postulated that phospho-HSP 20 interferes with the interaction between actin and myosin allowing thereby smooth muscle relaxation without dephosphorylation of the rMLC. Rho A and MLCP are phosphorylated also by cGMP kinase I (Fig. 3).

A major relaxing factor is NO, a signal molecule synthetized by three different NO synthases (NOS). NO synthetized in the endothelial layer of the vessels diffuses into the smooth muscle layer, where NO activates soluble guanylate cyclase (GC) and generates high concentrations of cGMP. In non-vascular systems such as the intestinal smooth muscle, NO is released from non-adrenergic, non-cholinergic neurons. An alternative pathway for the production of cGMP is the stimulation of particulate GC by the natriuretic peptides ANF, BNF and CNF. ANF and BNF are released from cardiac atrial and ventricular muscle, respectively, and lower blood pressure. These effects of the natriuretic peptides are mediated through cGMP and cGMP kinase I. NO has additional effects which



Smooth Muscle Tone Regulation, Fig. 3 Major mechanisms leading to relaxation of smooth muscle. See text for the abbreviations

are not mediated by cGMP kinase I. CNP is released from the vascular endothelial layer and exerts its relaxing effects either through activation of the particulate guanylyl cyclase B identical with the NPR-B or through the NPR-C receptor. The endothelial layer of the vessels initiates a number of diverse signaling pathways that lead to endothelium-dependent hyperpolarization (EDH) and relaxation of vascular smooth muscle (Garland and Dora 2017).

Smooth muscle contains the two cGMP kinase isozymes Iα and Iβ and a number of identified substrates (Hofmann et al. 2006). The NO/cGMP/cGMP kinase pathway interferes with the calcium-dependent and the calcium-independent contraction. A number of researchers have shown that cGMP-dependent phosphorylation of the BK_{Ca} channel increases its open probability resulting in hyperpolarization of the membrane potential and closure of voltage-dependent calcium channels. The activity of the BK_{Ca} channel is upregulated by the intracellular calcium concentration establishing a negative feedback loop. It is well established that cGMP kinase decreases the release of calcium from intracellular stores. Recently, it was found that cGMP kinase Iβ is associated with the IP_3 receptor type 1 and the 130 kDa protein IRAG. Phosphorylation of IRAG inhibited the release of calcium from IP_3-sensitive stores in COS cells. However, isozyme-specific reconstitution of cGMP kinase I-deficient mice suggested that, in murine aortic smooth muscle cells, cGMP kinase Iα and Iβ lowered norepinephrine-stimulated increases in the cytosolic calcium concentrations. This result is in line with the recent notion, which calcium-dependent contraction of smooth muscle requires membrane depolarization and calcium influx through membrane localized ion channels (see above). It is possible that the IP_3-sensitive calcium pool associated with IRAG and cGKIβ controls other smooth muscle functions such as phenotype changes and smooth muscle growth.

It was demonstrated that cGMP kinase I inhibits also smooth muscle contraction due to the calcium-insensitive pathway. A possible mechanism could be phosphorylation of Rho by cGMP kinase I. The phosphorylation site is identical with a cAMP kinase site identified in Rho from non-smooth muscle cells. It was reported that phosphorylation of Rho by cGMP kinase I prevents membrane association of Rho that is required to stimulate the GDP/GTP exchange. Alternatively, phosphorylation of telokin may interfere with the calcium sensitization of contraction. cGMP kinase Iα interacts specifically with a leucine zipper present at the C-terminus of MYPT1. Depending on the tissue, this leucine zipper is present or not. MLCP activity increased when MYPT1 is phosphorylated by cGMP kinase Iα at Ser-696.

Pharmacological Intervention

A large number of drugs interfere with the smooth muscle contraction. These compounds lower blood pressure and are referred to as antihypertensive. In this section, only those compounds will be mentioned that have a direct effect on smooth muscle tone. Phenylephrine is an agonist on most smooth muscles and activates α_1 adrenoceptors. Carbachol is an agonist on some smooth muscles and activates contraction through muscarinic receptors. Blockers of the α_1-adrenoceptors such as prazosin and urapidil are competitive inhibitors of the α_1-receptor in vascular and bladder smooth muscle. Phenoxybenzamine is an irreversible blocker of α_1 receptors, and phentolamine blocks α_1 and α_2 receptors. Ca^{2+} channel blockers such as the dihydropyridines, phenylalkylamines and benzothiazepines lower smooth muscle tone by blocking the L-type calcium channel.

Nitrates (glyceryl trinitrate, isosorbide dinitrate, pentaerythritol tetranitrate, molsidomine, sodium nitroprusside) that generate NO increase cGMP concentrations and lower smooth muscle tone by activation of cGMP kinase I. Nitrates relax in vivo mainly the capacitive part of the circulation system, i.e. the venous part. Sildenafil, a specific inhibitor of phosphodiesterase 5, a cGMP hydrolysing enzyme, increases cGMP in the corpus cavernosum and lowers together with nitrates the blood pressure by the combined effect on cGMP level. An additional potentially important drug family is compounds that stimulate the soluble guanylyl cyclase independent of NO (Evgenov

et al. 2006) and lower elevated blood pressure. The inhibitor of Rho-kinase, Y-27632, lowers elevated blood pressure in hypertensive animals, without affecting significantly the blood pressure of non-hypertensive animals (Uehata et al. 1997).

Soluble Epoxide Hydrolase

Nalin Singh and Bruce D. Hammock
Department of Entomology and Nematology and UC Davis Comprehensive Cancer Center, University of California Davis, Davis, CA, USA

Synonyms

EPHX2; Epoxide hydrolase 2; sEH

Definition

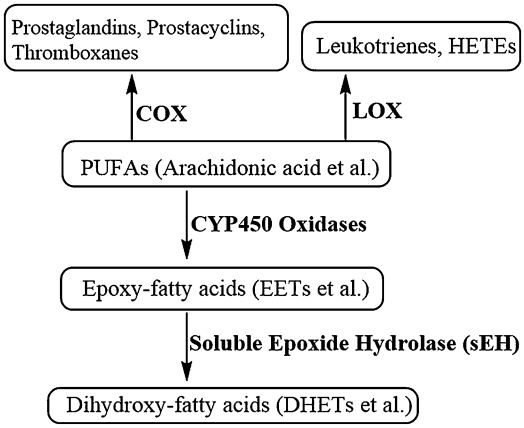
The epoxide hydrolase (EH) family of enzymes is responsible for converting the epoxide residue of various endogenous and exogenous compounds to the corresponding vicinal diols (Morisseau and ammock 2005). Soluble epoxide hydrolase (sEH) is an enzyme in the α-/β-hydrolase fold protein family, primarily found in the cytosolic and peroxisomal fractions of cells (Chiamvimonvat et al.

2007). It is encoded by the EPHX2 gene. It is a bifunctional homodimer that has EH activity at the C-terminal domain and phosphatase activity at the N-terminal domain (He et al. 2016). sEH is abundantly expressed in the liver, but it is also present in most organs including the kidney, brain, smooth muscle, intestines, and lungs (Morisseau and Hammock 2005). Its substrate selectivity is largely restricted to noncyclic 1,2-disubstituted epoxides, and hence, unlike the microsomal epoxide hydrolase (mEH), it is generally not involved in the metabolism or detoxification of xenobiotics (Morisseau and Hammock 2005). On the other hand, polyunsaturated fatty acid (PUFA)-derived bioactive lipid mediators are usually good sEH substrates and are subject to hydrolysis. These epoxy fatty acids (EpFAs) have demonstrated numerous tissue healing and organ-protective effects. sEH inhibitors (sEHI) help stabilize endogenous levels of EpFAs, thus enhancing their bioavailability and facilitating their biological action. Hence, targeting sEH with novel and potent small-molecule inhibitors is a pharmacological tool employed to capitalize on the beneficial effects of EpFAs and potentially treat several disease conditions (Morisseau and Hammock 2005). Alternative approaches involve (i) administration of EpFAs themselves, (ii) synthesis and application of EpFA mimics, and (iii) stimulation of EpFA biosynthesis.

Basic Characteristics

Metabolism of PUFAs

Arachidonic acid (20:4, ω-6) is a PUFA derived from the phospholipids of cell membranes and is metabolized by three main enzymatic pathways (Fig. 1) (Imig and Hammock 2009). The cyclooxygenase (COX) and lipoxygenase (LOX) routes generate largely pro-inflammatory mediators and are the target of several pharmaceuticals currently available on the market (e.g., nonsteroidal anti-inflammatory drugs a.k.a. NSAIDs and selective COX-2 inhibitors a.k.a. COXIBs). The third pathway primarily involves cytochrome P450-mediated epoxidation to epoxy metabolites known as epoxyeicosatrienoic acids (EETs). Other ω-3



Soluble Epoxide Hydrolase, Fig. 1 Schematic depicting major pathways of polyunsaturated fatty acid (PUFA) metabolism

PUFAs such as docosahexaenoic acid (DHA, 22:6) and eicosapentaenoic acid (EPA, 20:5) are similarly metabolized, and the CYP450 branch generates epoxydocosapentaenoic acids (EDPs) and epoxyeicosatetraenoic acids (EEQs), respectively (He et al. 2016). EETs and other EpFAs are mono-epoxides that are chemical mediators and act in both autocrine and paracrine manners. However, the chemically stable EpFAs have transient metabolic half-lives due to rapid sEH-mediated degradation. Recently, epoxides of omega-3-derived endocannabinoids with anti-inflammatory, anti-tumorigenic, and analgesic function have been reported, suggesting a still broader role of sEH in regulatory biology (Das et al. 2019).

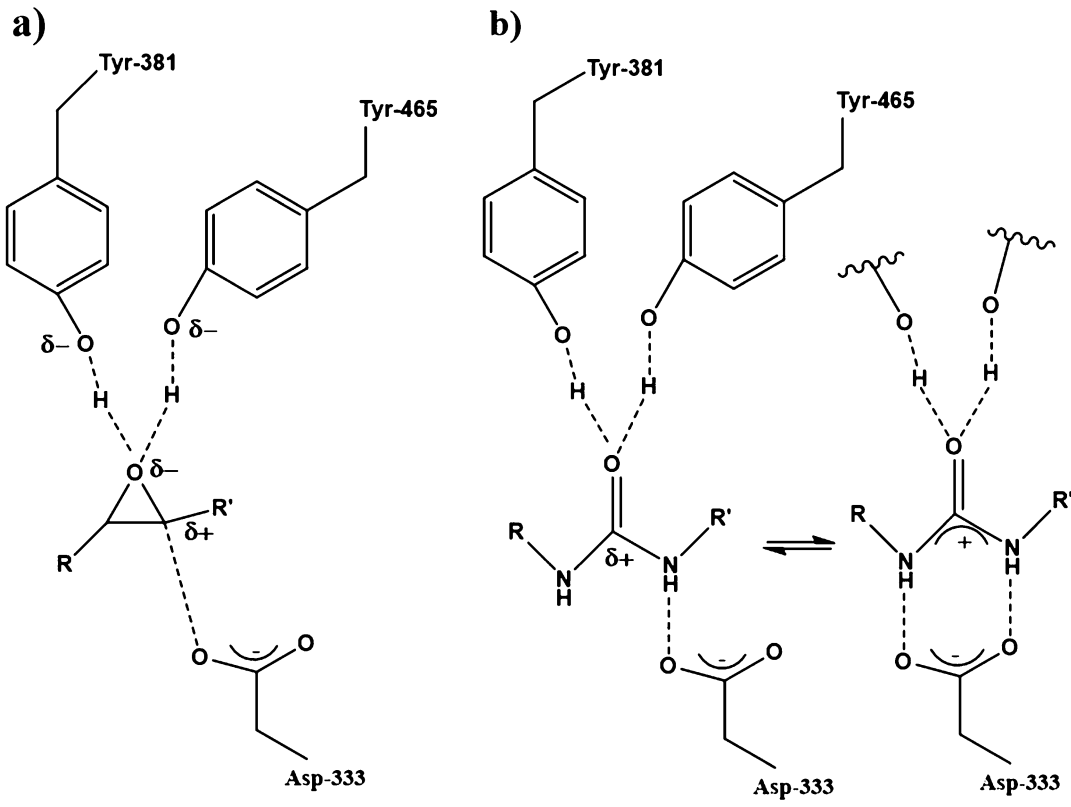
Hydrolysis of EpFAs

sEH hydrolyzes EETs and other EpFAs by an exothermic, two-step base-catalyzed mechanism (Morisseau and Hammock 2005). It involves the formation of a covalent hydroxyl-alkyl-enzyme ester intermediate via a catalytic aspartic acid, followed by the attack of water on the enzyme ester carbon that releases the 1,2-diol product. Within the hydrophobic active site, two tyrosine residues hydrogen bond to the epoxide oxygen, polarizing it. A nucleophilic aspartate acid conducts a backside attack on the epoxide, forming the covalent intermediate, while an

additional aspartate residue acts as orienting and activating acid for the histidine general base. This activates a water molecule which conducts the described hydrolysis step. sEH metabolism of EpFAs is regioselective and stereoselective (Chiamvimonvat et al. 2007). For example, the EET regioisomer with the epoxide furthest from the carboxylic acid end (14,15-EET) is hydrolyzed the fastest, while the one closest is hydrolyzed most slowly (5,6-EET).

Mechanism of sEH Inhibition

Enzyme inhibitors acting to mimic reaction intermediates or transition states have been found as potent inhibitors in many α-/β-hydrolase fold enzymes (Morisseau and Hammock 2005). Based on the catalytic mechanism of sEH, the transition states of epoxide ring opening are effectively mimicked by the urea functional group (Fig. 2). The C=O moiety accepts hydrogen bonds from the two tyrosine residues and hence acts as a surrogate for the epoxide oxygen. One mechanism suggests that one of the urea NH groups donates a hydrogen bond to the nucleophilic aspartate, mimicking the electrophilic center (Fig. 2). Alternatively, both NH groups donate hydrogen bonds to the aspartate, stabilizing a partial salt bridge with the enzyme, and thus mimic the interaction between the enzyme and substrate during the transition states (Fig. 2). Accordingly, a series of small-molecule 1,3-disubstituted ureas as well as amides, carbamates, and heterocycles have been developed which act as slow, tight-binding, competitive, and highly potent (low nanomolar to picomolar IC_{50}) inhibitors of sEH (Morisseau and Hammock 2005). The functional groups attached to the primary urea pharmacophore are generally hydrophobic to allow effective interaction with



Soluble Epoxide Hydrolase, Fig. 2 (**a**) Transition state of epoxide ring opening within the sEH active site. (**b**) Two possible binding modes of 1,3-disubstituted urea inhibitors mimicking multiple transition states and reaction intermediates along the reaction coordinate

the sEH active site, with a smaller group on one side and a typically larger group on the other. A polar moiety (e.g., ether, ester, alcohol, or ketone) added to the side with the larger group can act as a secondary pharmacophore and improve water solubility, pharmacokinetic parameters, and drug formulation properties, without lowering its potency (Imig and Hammock 2009).

Biological Action of EETs and EpFAs

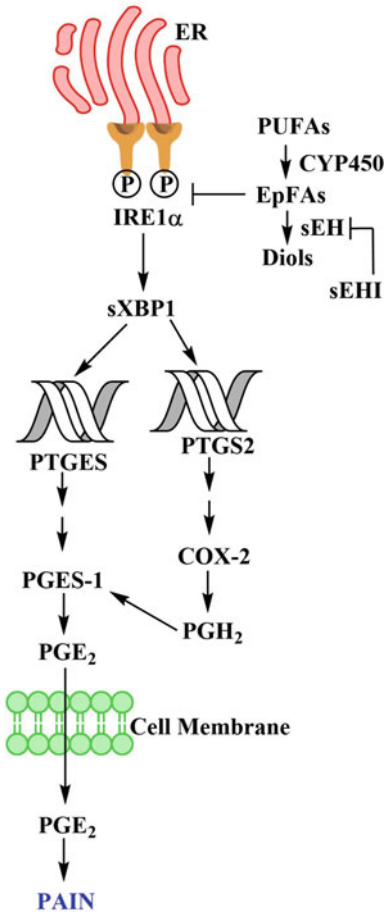
The inhibition of sEH has yielded therapeutic potential in models for various inflammatory, hypertensive, metabolic, fibrotic, and neurodegenerative diseases. The physiological effects of sEH inhibitors stem from the upregulation and subsequent action of EpFAs. The lack of a defined receptor for EETs and other EpFAs makes the assessment of the specific mode of action more challenging. Nevertheless, EpFAs are known to exert several biological effects and are hypothesized to act through multiple pathways.

Inhibition of sEH attenuates and resolves chronic inflammation through multiple pathways (Imig and Hammock 2009). Certain EETs such as the 11,12-regioisomer prevent nuclear translation of NF-κB and thereby block transcription of genes that encode pro-inflammatory enzymes (e.g., iNOS, LOX-5, COX-2, PGE2 synthase). 11,12-EET reduces IKK activity, which decreases phosphorylation and degradation of IκB, allowing it to sequester NF-κB in the cytosol. Other pathways include STAT3 tyrosine-705 phosphorylation by 14,15-EET, PPAR-alpha and PPAR-gamma agonism, inhibition of cytokine-induced VCAM-1, reduced TNFα secretion and, as discussed later, the endoplasmic reticulum (ER) stress response.

sEH inhibition has also been associated with smooth muscle relaxation and vasodilatory function (Imig and Hammock 2009). EETs, specifically the 11,12- and 14,15-regioisomers, are endothelium-derived hyperpolarizing factors (EDHFs). They stimulate calcium-activated potassium channels (K_{Ca}^{+}), triggering an efflux of K^{+} from vascular smooth muscle cells. This results in membrane hyperpolarization and subsequent dilation of blood vessels. cAMP activation of protein kinase A (PKA) and ADP ribosylation of the alpha subunit of G_s are mechanisms by which EETs have been demonstrated to activate K_{Ca}^{+} channels and promote vascular relaxation (Imig and Hammock 2009).

Disruptions in endoplasmic reticulum (ER) homeostasis caused by reactive oxygen species (ROS), high glucose, or xenobiotic perturbations result in ER stress. The ability of EpFAs to attenuate ER stress and downregulate the triggered unfolded protein response (UPR) pathways has been shown to underlie the amelioration of multiple metabolic disorders including fibrosis, inflammatory, and neuropathic pain (Fig. 3) (Inceoglu et al. 2017). sEHI modulation of the PERK/eif2α branch of the UPR enhances systemic insulin sensitivity and improves glucose tolerance (Inceoglu et al. 2017). It is also considered to play a role in ensuring proper pancreatic exocrine functionality and preventing pancreatitis. Mitigation of the IRE1α and ATF6 UPR pathways by sEH inhibition decreases the TGF-β-induced myofibroblastic differentiation of lung fibroblasts and helps prevent the development of lung fibrosis. The inhibition of sEH has also exhibited a promising analgesic action toward diabetic neuropathy and other types of chronic pain. One proposed mechanism suggests downregulation of the three UPR arms in peripheral nerves, which reduces predisposition to aberrant axonal firing and decreases apoptotic signaling and oxidative stress (Inceoglu et al. 2017).

The inhibition of sEH and resulting elevated EpFA levels in the brain is considered to increase brain-derived neurotrophic factor (BDNF) levels in the prefrontal cortex and hippocampus (Hashimoto 2019). BDNF binding to tropomyosin receptor kinase B (TrkB) and enhanced BDNF-TrkB signaling promotes synaptogenesis and corrects dopaminergic dysfunction, leading to an improvement in depressive and schizophrenic symptoms. EpFAs also seem to play a role in preventing phosphorylation of α-synuclein and sequentially reducing the aggregation of α-synuclein in multiple brain regions (Hashimoto 2019). By blocking the deposition of phosphorylated α-synuclein aggregates (a.k.a. Lewy bodies), the loss of dopaminergic neurons from the



Soluble Epoxide Hydrolase, Fig. 3 Epoxy fatty acids (EpFAs) preserved by sEH inhibitors (sEHI) stabilize mitochondria against disruption, reduce reactive oxygen species (ROS), and shift the endoplasmic reticulum (ER) stress response away from initiating cell damage and inflammation and back toward maintaining homeostasis (Inceoglu et al. 2017). Downstream from mitochondrial stabilization and reduction in ROS, EpFAs alter ER stress-induced unfolded protein response (UPR) pathways. For one pathway acting through IRE1α (shown above), sEHI reduce protein and message for COX-2 (Schmelzer et al. 2005) and PGES-1 (Chopra et al. 2019), thus dramatically reducing PGE_2 and other inflammatory and pain-initiating eicosanoids

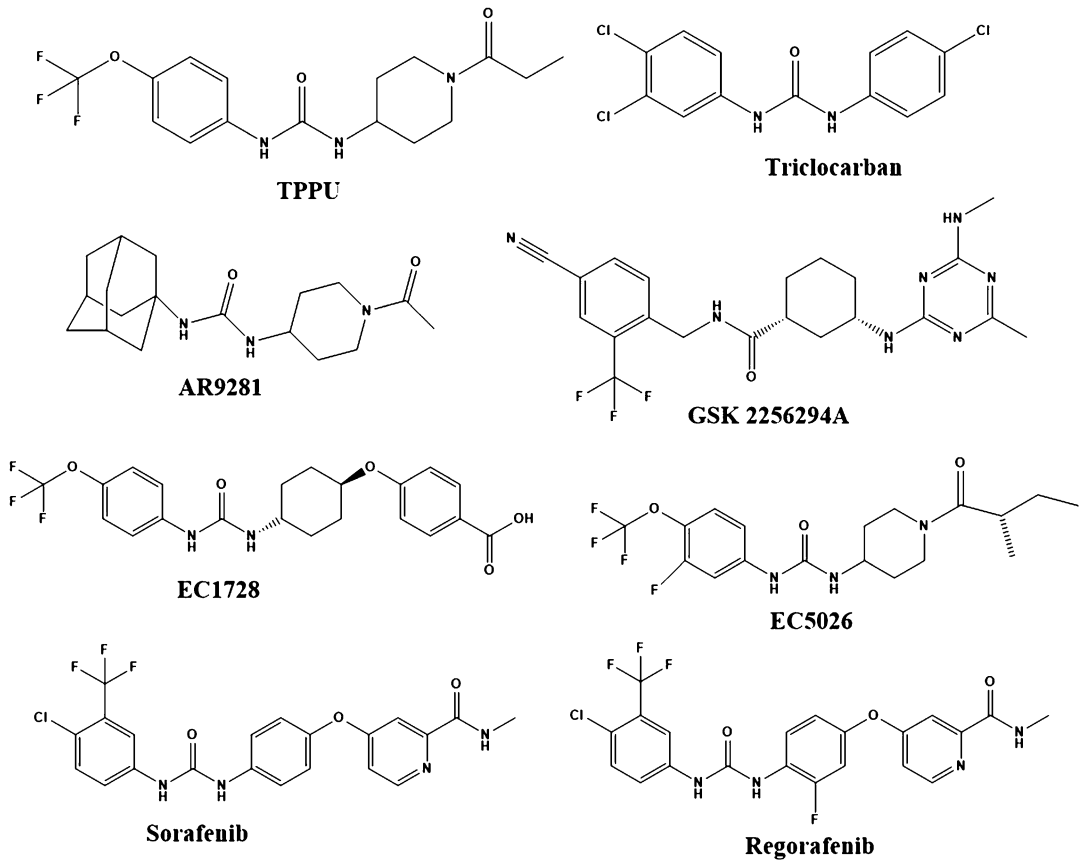
substantia nigra is potentially mitigated, and the pathogenesis of Parkinson's disease and dementia with Lewy bodies (DLB) may be controlled.

For pain as an endpoint in animal studies, the inhibition of sEH forgoes the common adverse side effects of NSAIDs and COXIBs (e.g., GI ulceration, cardiovascular issues) (Wagner et al. 2017). Additionally, it displays none of the reward-seeking addictive potential associated with the use of opioid narcotics (Wagner et al. 2017). EETs can be angiogenic at very high doses, and sEHI upregulation of EETs is considered to slightly promote tumor growth. This phenomenon has been attributed to downstream COX metabolites of EETs (Rand et al. 2017). Combining sEH inhibitors and COX inhibitors has been shown to have significant anti-angiogenic effects and blunt tumor growth, as has the use of sEHI in animals with an enhanced omega-3 and depleted omega-6 diet.

Drugs

Representative sEH Inhibitors

TPPU (i.e., UC1770) is extensively used in animal disease models because it is orally bioavailable and has favorable pharmacokinetic characteristics in addition to high potency (Fig. 4). Currently, no clinical drug on the market is used as an sEH inhibitor. However, antineoplastic agents sorafenib and regorafenib, inhibitors of vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), and Raf family kinases are powerful sEH inhibitors (Fig. 4) (Liu 2019). This activity likely reduces severe toxicity associated with the use of protein kinase inhibitors. Triclocarban, a commonly used antibacterial, has also displayed sEH inhibitory potential (Fig. 4) (Liu 2019). These compounds contain the ideal disubstituted urea substructure which indicates the diversity of structures that can inhibit the sEH. Several pharmaceutical companies have been or are in the process of discovering and developing potent sEH inhibitors in order to treat several clinical indications. These include Arête Therapeutics, Boehringer Ingelheim, Taisho, Merck, GlaxoSmithKline (GSK), and EicOsis. One compound, AR9281 (i.e., UC1153 or APAU) from Arête, was designed to target moderate hypertension and impaired glucose tolerance (Fig. 4). It completed Phase I and Phase IIA clinical trials. AR9281 was well tolerated for both a single oral dose and multiple doses.



Soluble Epoxide Hydrolase, Fig. 4 Chemical structures of representative sEH inhibitors

However, as expected from the adamantane in the structure, AR9281 had poor pharmacokinetic and pharmacodynamic parameters suggesting at least a twice- or thrice-daily dosing regimen for effective sEH inhibition (Liu 2019). Not only was the inhibition of the human enzyme weak, but the target occupancy was also poor. Despite no safety concerns in clinical trials, AR9281 failed to show efficacy in early-stage hypertension indicating hypertension might not be a suitable primary clinical indication for sEHI and AR9281 was not appropriate for sustained inhibition of the target sEH. Another inhibitor, GSK2256294A from GSK, was targeted to treat chronic pulmonary obstructive disease (CPOD) and completed Phase I clinical trials (Fig. 4). It has shown no adverse effects and a dose-dependent increase in plasma drug levels and sEH inhibition (Liu 2019). EicOsis designs pain therapeutics, and the compound EC1728 (i.e., *t*-TUCB) has been shown to successfully treat equine laminitis as well as inflammatory pain in dogs and cats (Fig. 4). Currently, EC1728 is pending an FDA review to begin Phase 1 trials in horses in 2020. The inhibitor EC5026 has been selected for treating diabetic neuropathy and other forms of neuropathic pain in patients while promoting opioid-sparing effects (Fig. 4). It has displayed considerable efficacy in preclinical studies as well as ideal pharmacokinetic properties and stability. The IND has been filled, and it entered Phase 1 clinical trials in December of 2019.

So far, sEHI have generally demonstrated few to no adverse side effects even at relatively high doses, and they have an excellent therapeutic

index. However, the broad range of biological effects observed with the use of sEHI, like other drugs acting on the arachidonate cascade, suggest they should be utilized with caution.

Definition

Somatostatin, also known as somatotropin-release inhibitor factor (SRIF), is a cyclic neuroendocrine peptide that was first isolated and identified as a hypothalamic peptide that inhibited growth hormone (GH) secretion from anterior pituitary cells (Brazeau et al. 1973). SRIF is expressed in the central nervous system (CNS) and in peripheral tissues and exerts potent inhibitory actions on neuronal excitability, hormone secretion, and exocrine secretion. SRIF also negatively affects smooth muscle cell contraction and cell proliferation. Its physiological functions are mediated by five G protein-coupled receptors (GPCRs) called somatostatin receptors ($SST_{1–5}$).

Basic Characteristics

Somatostatin and Somatostatin-Related Peptides

SRIF exists in two main isoforms: the tetradecapeptide SRIF-14 and the 28-amino-acid peptide SRIF-28. The two isoforms are generated from the same precursor through post-translational processing at a distinct cleavage site and are expressed at variable amounts in the same tissues. The SRIF-14 primary structure and cleavage sites generating the two isoforms have been highly conserved

during evolution in vertebrates (Conlon et al. 1997). In humans, the somatostatin precursor (pre-proSRIF) is encoded by the SS1 gene, which is localized on chromosome 3q27.3. Two additional products of the SRIF precursor have been isolated in mammals. Neuronostatin is a 13-amino-acid noncyclic amidated peptide whose sequence immediately follows the signal peptide (Samson et al. 2008; Yosten et al. 2015). A second peptide expressed in enteric neurons comprises the N-terminal 13 amino acids of SRIF-28 (Ensinck et al. 2002, 2003). In 1996, a neuropeptide showing high similarity to SRIF was identified and termed cortistatin (CST) (de Lecea et al. 1996). CST is encoded by the *CORT* gene (Liu et al. 2010). Cleavage of preproCST gives rise to two mature products, CST-17 and CST-29, in humans. CST is also structurally and functionally related to the urotensin II peptide family. The CST precursor is mainly expressed in the cerebral cortex and hippocampus. It is also expressed in the periphery but at lower levels than SRIF.

Tissue Distribution

In the CNS, SRIF has been localized in the mediobasal hypothalamus and median eminence, amygdala, preoptic area, hippocampus, striatum, cerebral cortex, and the brainstem (Johansson et al. 1984). SRIFergic neurons can be distinguished in hypophysiotropic neurons, long-projecting GABAergic neurons, and GABAergic interneurons (Viollet et al. 2008; Urban-Ciecko and Barth 2016). In the periphery, SRIF is expressed in secretory cells in gastrointestinal mucosa, δ-cells in pancreatic islets, and a subpopulation of C cells within the thyroid gland. SRIF is also produced by inflammatory and immune cells (Patel 1999) and has been localized in human epidermis (Merkel and dendritic cells) (Vockel et al. 2010, 2011). Finally, SRIF is believed to function as a neurotransmitter, neuromodulator, or trophic factor in the retina (Cervia et al. 2008). Plasma levels of SRIF are very low because of rapid degradation by ubiquitous peptidases.

Physiology

SRIF is a neurotransmitter, neuromodulator, and paracrine factor acting in the same tissues where it is expressed. Hypothalamic SRIF is the main inhibitory factor involved in the control of GH secretion and reduces the release of prolactin and thyroid-stimulating hormone (TSH) (Müller et al. 1999). In the brain, SRIF actions are mediated by presynaptic or postsynaptic mechanisms. SRIF modulates neuronal excitability, and in the hippocampus, cortex, and hypothalamus, it causes presynaptic inhibition of excitatory neurotransmission (Peineau et al. 2003). Finally, it is co-released with GABA from axonal terminals in different brain areas (Olias et al. 2004). SRIF has a role in cognitive functions, learning, memory, control of locomotor activity, food intake, nociception, and autonomic functions. SRIF is highly expressed in regions associated with seizures and has been suggested to act as an endogenous antiepilectic (Stengel et al. 2015). In the gastrointestinal tract, SRIF exerts a generalized inhibitory effect on release of gut hormones and exocrine secretion (gastric acid, digestive enzymes, bile, and colonic fluid). SRIF also negatively affects gallbladder contraction, small intestinal segmentation, and gastric emptying. In pancreatic islets, release of SRIF inhibits secretion of insulin, glucagon, and other peptides. SRIF may affect key cellular processes in diverse tissues by regulating the release of growth factors and cytokines as well as cellular responses to these stimuli. SRIF can contribute to control of lymphocyte and inflammatory cell proliferation and activity, tumor cell growth, and normal tissue plasticity (Patel 1999; Rai et al. 2015). In the human skin, SRIF has been suggested as a negative regulator of epidermal wound healing (Vockel et al. 2011). Cortistatin binds to all SRIF receptors with similar affinity (Siehler et al. 2008) than SRIF and shares many functional properties with SRIF in the brain, within the hypothalamus-pituitary system and in the periphery (Spier and de Lecea 2000). Actually, cortistatin may activate GPCRs other than SSTs, i.e., the ghrelin receptor 1a (GHS-R1a) (Callaghan and Furness 2014).

Somatostatin Receptor Subtypes

Between 1990 and 1997, five distinct SRIF receptor subtypes were cloned in mice, rats, and humans. According to the International Union of Basic and Clinical Pharmacology (IUPHAR)

guidelines, these receptors are now referred to as SST_1 to SST_5 (Gunther et al. 2018) (Table 1). In the early 2000s, it was shown that some SSTs were capable of forming homodimers as well as heterodimers with other subtypes of the same family or with other GPCRs (Rocheville et al. 2000a, b; Pfeiffer et al. 2001, 2002). This kind of interaction between cell surface receptors may further enlarge the number of distinct receptor sites with differential functional properties for the same ligand. SSTs can be separated into two groups on the basis of their structural homologies and pharmacological properties. The first class comprises SST_2, SST_3, and SST_5. The second class comprises SST_1 and SST_4. All the SSTs are class A GPCRs that belong to the rhodopsin-like family of receptors (Table 1). They all possess seven transmembrane domains according to the structure of a prototypical GPCR. There is high sequence similarity between different subtypes and for a given subtype across different species. Moreover, all the five subtypes share some primary structural features:

- The conserved YANSCANPILY sequence in the seventh transmembrane domain is regarded as a mammalian SST signature.
- The DRY motif in the second intracellular loop is involved in coupling to G proteins.
- The consensus motif X-[S/T]-X-Φ at the end of the carboxyl-terminal tail is a potential PDZ domain binding site and is crucial for interaction with scaffolding proteins.
- N-glycosylation sites.

In recent years, variants of SST5 mRNA formed by splicing of non-canonical donor and acceptor splice sites have been identified in humans, pigs, and rodents. The human SST_5 variants may generate truncated receptors containing five or four transmembrane domains (SST_5TMD5 and SST_5TMD4, respectively) and distinct carboxyl termini (Durán-Prado et al. 2009), which display distinct tissue distribution and subcellular localization, compared with canonical full-length SST_5 (Córdoba-Chacón et al. 2011). The truncated receptors are highly expressed in tumor tissues and can interact with full-length SST_5 and SST_2 to retain them in intracellular vesicles. Hence, they may act as functional dominant-negative partners for the full-length receptors.

Canonical SSTs share many structural characteristics and also the main intracellular signaling pathways they are coupled to. All SSTs mediate the inhibitory actions of SRIF on endocrine and exocrine secretion and neuronal excitability by recruitment of G_i/G_o proteins, members of heterotrimeric, pertussis toxin (PTX)-sensitive guanine-nucleotide-binding proteins. The activation of G_i/G_o proteins by SSTs is coupled to the suppression of the second messenger cyclic AMP (cAMP) by inhibition of adenylyl cyclase activity and the decrease of cytosolic Ca^{2+} caused by inhibition of Ca^{2+} influx. To this end, SRIF can inhibit calcium channels both directly and indirectly by opening G-protein-activated-inward-rectifier K^+ channels (GIRK) to induce membrane hyperpolarization that leads to inhibition of Ca^{2+} influx via voltage-operated calcium channels (VOCC). The signaling events mediating the inhibitory effects of SRIF on cell proliferation are debated. The activation of protein tyrosine phosphatases (i.e., Src homology region 2 domain-containing phosphatase SHP-1 and SHP-2) may counteract growth factor-stimulated tyrosine kinase activity and inhibit multiple mitogenic pathways. The modulation of the extracellular-signal-regulated kinase (ERK) pathway may also play a role. Finally, the second class of SSTs and SST_3 is able to exert an inhibitory activity on sodium/hydrogen exchanger-1 (NHE1) via a PTX-insensitive mechanism. A decrease in NHE1 activity results in extracellular medium acidification that may be involved in inhibition of cell migration by SRIF (Buchan et al. 2002). SSTs can be better differentiated according to their expression in normal and tumor tissues, cellular localization, functional and pharmacological properties, and differential modes of activity regulation.

Agonist-Dependent Receptor Regulation

SRIF binding to its receptors results in desensitization, followed by internalization of receptor-

Somatostatin, Table 1 Class II and Class I somatostatin receptor subtypes: tissue distribution and role in physiology

Receptor	Expression in normal tissues	Expression in human tumors	Phenotype of mice lacking receptor	Receptor function
SST_1	Brain and spinal cord, anterior pituitary, pancreatic islets, GI tract Subcellular localization: when expressed in transfected HEK293 cells, localized to intracellular vesicles In primary cells and in sections from diverse human tumors, localized both at the plasma membrane and in the cytoplasm	GH adenomas, NET, prostate cancer	Altered insulin homeostasis	Presynaptic localization, autoreceptor in the CNS Within hypothalamus, inhibition of GHRH release and SRIF release Control of gastric emptying and colonic mobility Control of inflammatory response and nociception transmission Control of GH release from pituitary and insulin from beta-cells
SST_4	Brain, retina, dorsal root ganglia, placenta		Increased seizure susceptibility Increased anxiety Increased inflammatory and nociceptive response	Post-synaptic localization in the CNS Expressed in areas involved in learning and memory processes Involved in the modulation of behavioral and neuroendocrine response to acute and chronic stress (related to anxiety and depression-like behavior) Anticonvulsant effects Therapeutic target for development of anti-inflammatory and/or analgesic drugs without endocrine side effects (airway inflammatory diseases and bronchoconstriction)
SST_2	Brain (including cerebellum), spinal cord, retina, dorsal root ganglia, pituitary, GI tract, pancreatic islets, lymphatic tissue, adrenals (reticular zone), kidney	Brain tumors, GH adenomas, TSH adenomas, pheochromo-cytomas, NET	High basal acid secretion, inhibition of glucagon release, impaired motor coordination	Inhibitory neuromodulation in the CNS, main role in transduction of SRIF action in hippocampal formation Antiepileptic activity Antinociceptive activity Control of extrapyramidal motor system Increase of food intake and rapid-onset water consumption Control of stress response (autonomic and behavioral) Control of GH and TSH release from pituitary, glucagon, and insulin release from pancreatic islets Retinal neuroprotection

(continued)

Somatostatin, Table 1 (continued)

Receptor	Expression in normal tissues	Expression in human tumors	Phenotype of mice lacking receptor	Receptor function
SST_3	Brain, anterior pituitary, pancreatic islets, GI tract, lymphatic tissue, adrenal cortex and medulla, kidney Subcellular localization: primary cilia (but not restricted to) in neurons and endocrine cells	GH adenomas, ACTH adenomas, non-functioning adenomas	Impaired novel object recognition	Involved in object recognition memory mediated by primary neuronal cilia (rodent brain) Anticonvulsant activity Control of GH from pituitary, insulin release from pancreatic islets
SST_5	Anterior pituitary, pancreatic islets, GI tract, lymphatic tissue, adrenal cortex and medulla, kidney, parotid glands, thyroid (C cells) Subcellular localization: both at the plasma membrane and in the cytoplasm	GH adenomas ACTH adenomas Thyroid carcinomas, NET, breast, cervical, ovarian, and prostate carcinomas, differentiated colorectal cancers	Increased insulin secretion, basal hypoglycemia	Physiological control of pituitary function (GH, ACTH, TSH secretion) and endocrine pancreas activity (insulin secretion) SST5 displays constitutive activity (tonic inhibition of cAMP and ERK1/2 signaling) contributing to the control of pituitary hormone secretion

ligand complexes, a critical process that leads to receptor recycling to plasma membrane and resensitization or, alternatively, to receptor degradation in intracellular vesicle compartments. Regulation of GPCRs depends upon molecular events starting from phosphorylation at the cytoplasmic C-terminal tail by different GPCR kinases (GRKs), followed by recruitment of β-arrestins and receptor endocytosis. β-Arrestins may also act as scaffolding proteins involved in intracellular signaling cascades. Studying SST phosphorylation and trafficking has received great attention because the fate of internalized receptors following agonist exposure may affect cell responsiveness to endogenous ligands and drugs of therapeutic interest. The distinct SST subtypes undergo differential events upon agonist binding. Moreover, as to a given subtype, internalization and trafficking may differ across species (Tulipano and Schulz 2007).

SST_1 In heterologous cell system, rat SST_1 undergoes endocytosis and recycling upon SRIF binding, whereas human SST_1 displays very slow internalization despite rapid desensitization and uncoupling of adenylyl cyclase. One amino acid change at a putative phosphate-acceptor site (Thr383-Cys384-Thr385-Ser386) in the rat versus human receptor C-terminal tail (human Ser386 has been replaced by alanine in rat SST_1) may explain the differential interaction with β-arrestin1 and differential trafficking.

SST_2 This receptor subtype is almost completely confined to the plasma membrane. Agonist binding (SRIF, octreotide) causes multiple phosphorylation events within the C-terminal tail by GRK_2 and GRK_3 followed by receptor internalization. The following phosphorylation sites have been identified in both rat and human SST_2: S341, S343, T353, T354, T356, and T359. Unlike SRIF and octreotide, pasireotide (also known as SOM230) stimulates the phosphorylation of S341 and S343 residues only and causes partial receptor internalization (Lesche et al. 2009; Lehmann et al. 2014). The activation of SST_2 results in marked recruitment of both β-arrestin-1 and β-arrestin-2. The β-arrestin-dependent trafficking of the SST_2 somatostatin

receptor resembles that of a class B GPCR receptor (Oakley et al. 2000) in that upon receptor activation, β-arrestin and the receptor form stable complexes and internalize together into the same endocytic vesicles. Unlike other class B receptors, however, the SST_2 receptor undergoes rapid resensitization and recycling to the plasma membrane after activation by SRIF-14. Actually, receptor recycling is dependent on endosomal acidification and endothelin-converting enzyme-1 (ECE-1)-dependent degradation of the ligand. SRIF-28 and octreotide are resistant to cleavage by ECE-1. Hence, upon activation by these ligands, SST_2 remains in the intracellular vesicular compartment for a prolonged period of time (Zhao et al. 2013).

SST_3 A unique feature of this subtype is its long carboxyl-terminal tail. Upon agonist binding, the receptor is phosphorylated by GRK_2 and GRK_3. Phosphorylation sites have been identified in human and rat SST_3. The human SST_3 receptor is phosphorylated at S337, T341, T348, and S361 (Lehmann et al. 2016). The rat SST_3 receptor is phosphorylated at S341, S346, S351, and T357 (Roth et al. 1997). Receptor phosphorylation triggers β-arrestin recruitment and internalization. The β-arrestin mobilization of the SST_3 resembles that of a class A receptor in that upon receptor activation, β-arrestin and the receptor form relatively unstable complexes that dissociate at or near the plasma membrane. Unlike other class A receptors, SST_3 receptor undergoes substantial downregulation upon agonist exposure by ubiquitin-dependent lysosomal degradation and does not rapidly recycle to the plasma membrane (Tulipano et al. 2004; Lesche et al. 2009; Lehmann et al. 2016). Finally, synthetic analogs such as pasireotide and octreotide have been reported to act as partial agonists with regard to SST_3 phosphorylation and internalization compared to SRIF-14 (Lehmann et al. 2016).

SST_4 In heterologous cells, rat SST_4 is not subject to SRIF-induced phosphorylation or internalization and does not recruit β-arrestin. The absence of internalization was also shown in brain tissue after in vivo treatment with SRIF (Kreienkamp et al. 1998; Schreff et al. 2000). A single amino acid residue (Thr331) in the rat SST_4 sequence confers resistance to agonist-induced internalization (Kreienkamp et al. 1998). As to human SST_4, poor internalization occurs in transfected cells. A rapid dissociation of the SRIF-receptor complex and rapid recycling of the receptor to the plasma membrane has been suggested. Actually, in contrast to the rat receptor, human SST_4 signaling (NHE1 activation and ERK phosphorylation) was shown to be subject to sustained desensitization. Hence, this event can be regarded as not linked to receptor sequestration (Smalley et al. 2001).

SST_5 Two phosphorylation sites have been mapped in the SST_5 carboxyl-terminal tail. T347 is phosphorylated even in the absence of ligand, whereas T333 is phosphorylated by GRK2 in response to agonist binding and is involved in β-arrestin recruitment and receptor internalization. The third intracellular loop plays a key role in the interaction between the receptor and β-arrestin (Peverelli et al. 2008; Petrich et al. 2013; Schulz et al. 2014). Like SST_3, SST_5 forms relatively unstable complexes with β-arrestin, which rapidly dissociate before SST_5 trafficking to early endosomal vesicles. In contrast to SST_3 and SST_2, the proportion of SST_5 internalized after exposure to SRIF is rather low. The 36 terminal residues of the carboxyl-terminal tail are believed to contribute to the inhibition of receptor internalization. As to the internalized receptors, in heterologous cells, it has been shown that ligand-receptor dissociation leads to receptor recycling to the cell surface, accompanied by recruitment of receptors residing in an intracellular pool to the plasma membrane (Stroh et al. 2000). Finally, it should be noted that the phosphorylation and trafficking following to agonist binding to SST_5, are ligand- and cell context-dependent. SRIF-14 induces rapid phosphorylation, whereas octreotide does not. Pasireotide

has been shown to induce SST5 phosphorylation to a lesser extent than SRIF-14.

Drugs

Ligands

Receptor	Endogenous agonists	Synthetic agonists	Synthetic antagonists
SST_1	SRIF-14, SRIF-28; CST-17, CST-19	L-797,591 BIM-23926 Pasireotide	SRA880

SRIF Analogs in Clinical Practice

Octreotide and **lanreotide** are the two SRIF analogs still most widely used in clinical practice. Increased metabolic stability, potent suppressing activity on GH secretion, and low insulin suppressing activity have made them useful for treating acromegaly (Bauer et al. 1982; Heiman et al. 1987). SRIF analogs were also shown to reduce GH-secreting pituitary tumor size (Giustina et al. 2012). The partial dissociation of the inhibitory effects on GH and insulin secretion compared to native SRIF was explained with the identification of distinct SRIF receptor subtypes which can be differentiated in relation to their expression levels in normal and tumor tissues. Indeed, octreotide and lanreotide have greater affinity (subnanomolar) for SST_2 and moderate affinity for SST_5. Both receptors are involved in the control of GH secretion in humans. On the other hand, SST_5 plays a main role in the control of insulin secretion from ß-cells. If the rationale for developing SRIF analogs showing subtype selectivity to limit side effects is still valid, the concept of targeting multiple SSTs by a multisubtype-selective analog or targeting complexes formed by multiple receptors (heterodimers) is regarded as attractive for possible enhanced efficacy. Indeed, octreotide and lanreotide do not allow to achieve normalization of GH and IGF-1 levels in a significant percentage of acromegalic patients, and there is pre-clinical evidence that greater SST_5 activation may lead to a better control of GH hypersecretion in patients which are only partially responsive to these analogs. BIM-23244 can be regarded as a bi-selective analog targeting SST_2 and SST_5. Actually, its high activity at SST_5 discouraged its development for the risk of unwanted pancreatic side effects. Veldoreotide is a ligand with moderate affinity for multiple subtypes (SST_2, SST_5, and SST_4) and is in phase 2 trials for the treatment of acromegaly. Finally, the concept of targeting the interaction between receptors has been extended to multi-ligands able to interact with a given SST subtype and receptors outside of the SST family, i.e., dopamine receptor subtype-2 (D_2). So-called chimeric dopastatins are no longer in development.

Pasireotide is a cyclohexapeptide with high affinity for SST_1, SST_2, and SST_3 and subnanomolar affinity for SST_5. Pasireotide is called a pan-receptor-specific ligand. Pre-clinical and clinical data suggest that pasireotide may be helpful to achieve control of GH secretion in a subgroup (15–20%) of patients resistant to octreotide or lanreotide. In detail, pasireotide can be more effective than octreotide in tumors showing lower expression of SST_2 and lower SST_2/SST_5 ratio

(Gadelha et al. 2014; Gatto et al. 2017). Moreover, in contrast to lanreotide and octreotide, pasireotide has shown potential efficacy in a subset of patients with Cushing's disease. However, in keeping with its high affinity at SST_5, pasireotide may worsen glucose control related to insulin resistance in both acromegaly patients and in Cushing's disease, and monitoring blood glucose and electrocardiogram is important.

Disease	Analog	Therapeutic effects
Acromegaly	Lanreotide Octreotide Pasireotide (long-acting formulations for i.m. or s.c. administration)	Biochemical control (decreased GH and IGF-1 levels) Decreased tumor size Beneficial impact on disease comorbidities (determined by age, degree of achieved biochemical control, duration of the disease)
Cushing's disease	Pasireotide	Decreased urinary-free cortisol (UFC) Decreased mean tumor size Beneficial impact on symptoms related to hypercorticolism (however, blood glucose and glycated hemoglobin levels may increase)
Neuroendocrine tumors (carcinoids, GI and pancreatic NETs)	Lanreotide Octreotide (long-acting formulations)	Symptomatic improvement due to suppression of hormone release Decreased or stabilized tumor mass Improved survival

The efficacy rates of therapies with SRIF analogs vary depending on tumor type and individual patient. As to GH-secreting pituitary tumors, some tumors are resistant to SRIF analogs. Moreover, SRIF analogs do not enable GH and IGF-1 normalization in a subset of responsive patients. To this end, a personalized approach to acromegaly classification and management has been proposed. Adverse determinants of SRIF analog responsiveness include advanced age, tumor size, levels of GH and IGF-1, and a series of molecular markers in pituitary tumor cells (Cuevas-Ramos et al. 2015). Corticotroph tumors are usually resistant to octreotide and lanreotide. About 20% of patients with Cushing's disease achieve biochemical normalization with pasireotide (Colao et al. 2012). Tachyphylaxis has not been observed in acromegaly, but it has been described at variable time intervals in patients harboring NETs.

SRIF-Based Radiopharmaceuticals

Radiolabelled somatostatin analogs are used for tumor imaging (peptide receptor-targeted scintigraphy) and peptide receptor radionuclide therapy (PRRT) of neuroendocrine tumors. A radioiodinated analog of octreotide ($[^{123}I]Tyr^3$-octreotide) was synthetized in 1989 (Krenning et al. 1989) and allowed the first successful non-invasive imaging of SST-rich tumors. This compound can be regarded as a starting point for the development of radiolabeled ligands for SST-targeted imaging and radionuclide therapy. Current ligands include a chelator conjugated to the N-terminus of a peptide structure derived from SST-targeting drugs (i.e., octreotide or lanreotide). The chelator (DTPA, DOTA, NOGADA) ensures the stable complexation of radiometals (^{68}Ga, ^{111}In, ^{177}Lu, ^{90}Y). These compounds exhibited agonistic behavior and high affinity for SST_2 (^{111}In-DTPA-OC, ^{68}Ga-DOTA-TOC, ^{68}Ga-DOTA-TATE, ^{177}Lu-DOTA-TATE). Radiolabelled ligands that bind with high affinity to multiple SST receptor subtypes are in development (^{68}Ga-DOTA-NOC). Metabolic stability, low lipophilicity, renal clearance, and absence of accumulation in the upper abdominal region due to hepatobiliary excretion are favorable properties of currently applied radiolabeled SRIF analogs compared to radioiodinated octreotide. The high sensitivity of SST-targeted has been assumed to be dependent on internalization of the receptor after

radioligand binding that leads to retention of radiometals in target cells. Nevertheless, in the last decade, evidence has accumulated that SST-targeted imaging with radiolabelled antagonists, which poorly internalize, can be more sensitive and effective than that employing corresponding receptor agonists that are highly internalized. The molecular mechanism underlying tumor imaging performance using SST antagonists needs to be elucidated. Actually, it has been suggested that a full antagonist can label receptors in all states (active or inactive), whereas a corresponding agonist binds to an active conformation, only.

Specialized Pro-resolving Lipid Mediators

► Pro-resolving Mediators

Sphingosine-1-Phosphate

Dagmar Meyer zu Heringdorf
Institut für Allgemeine Pharmakologie und Toxikologie, Goethe-Universität, Frankfurt am Main, Frankfurt, Germany

Definition

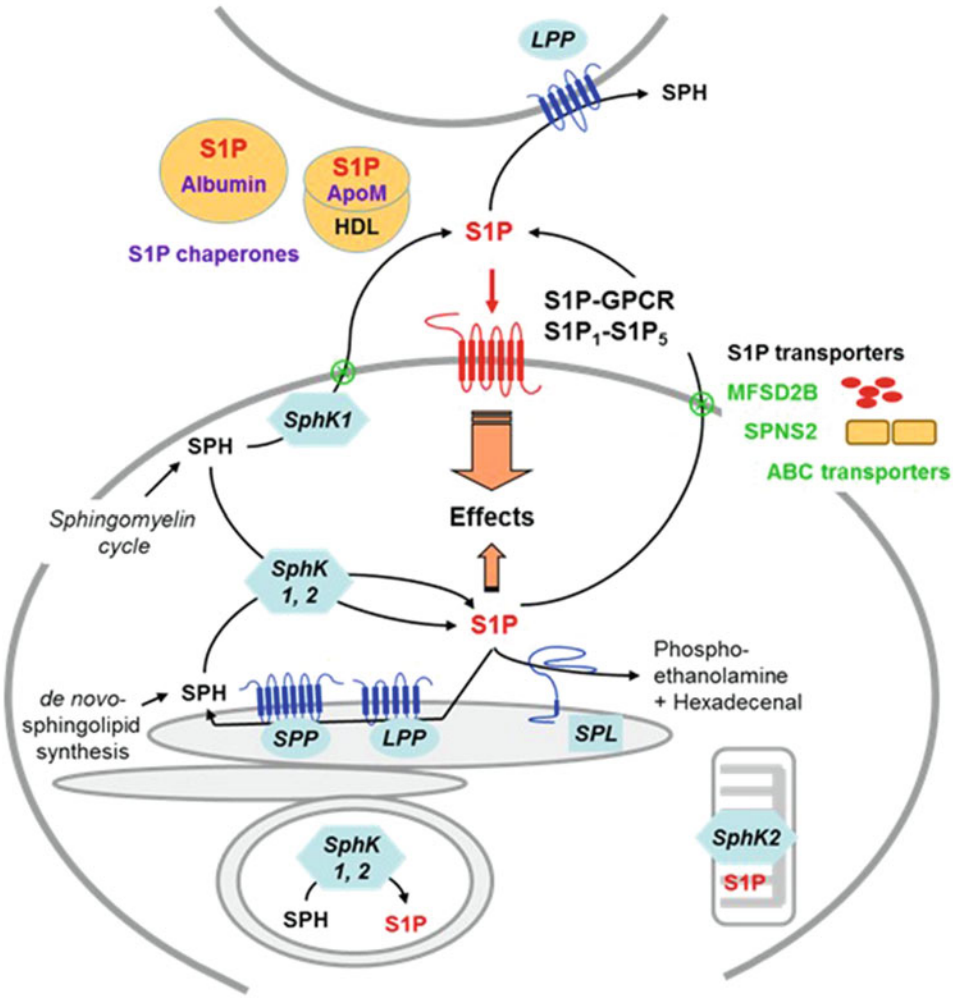
Sphingosine-1-phosphate is a lysophospholipid, and product of sphingolipid metabolism.

Basic Characteristics

Metabolism and Occurrence

Sphingosine-1-phosphate (S1P) is formed by phosphorylation of sphingosine by sphingosine kinases (SphK1,2; human gene names, *SPHK1,2*) (Chan and Pitson 2013; Pyne et al. 2016). Prototypical S1P d18:1 contains the (E,2S,3R)-2-aminooctadec-4-ene-1,3-diol sphingoid base backbone (D-erythro-C18-sphingosine). This structure results from sequential reactions starting with condensation of serine and palmitoyl-CoA by serine palmitoyltransferase (SPT; human gene names, *SPTLC1-3*). The double bond is introduced by delta-4-desaturases (human gene names, *DEGS1,2*) (Maceyka and Spiegel 2014; Obinata and Hla 2019). Under certain conditions, SPT may also use other amino or fatty acids and thereby produce sphingoid base backbones with other chain lengths and substitutions. Degradation of S1P occurs reversibly by non-selective lipid phosphate phosphatases, $LPP_{1–3}$, or by selective S1P phosphatases ($SPP_{1,2}$). S1P lyase (human gene name, *SGPL1*) cleaves S1P irreversibly (see Lysophospholipids, Fig. 1b).

S1P is usually generated intracellularly and needs to be exported for interaction with its specific G-protein-coupled receptors (S1P-GPCR; Fig. 1). SphK1 and SphK2 differ in tissue expression and subcellular localization, regulation and function. Their expression and activity are regulated in diverse ways, for example, by growth factors, cytokines, or GPCR agonists (Chan and Pitson 2013; Pyne et al. 2016). Some stimuli induce a translocation of SphK1 from the cytosol to the plasma membrane, enabling S1P secretion and so-called inside-out signalling. Both SphK isoforms can occur in cytosol and nucleus; however, SphK2 is more abundant in the nucleus and also found at the ER and in mitochondria. Nuclear and mitochondrial SphK2 address intracellular effectors of S1P. These may be, for example, histone deacetylases or prohibitin-2 (Pyne et al. 2016; Spiegel et al. 2019), but these targets still await independent confirmation. S1P excretion is mediated by sphingolipid transporter-2 (SPNS2), major facilitator superfamily domain containing 2B (MFSD2B) and several ATP-binding cassette



Sphingosine-1-Phosphate, Fig. 1 The S1P signalling system. *ApoM* apolipoprotein M, *HDL* high-density lipoprotein, *LPP* lipid phosphate phosphatase, *MFSD2B* major facilitator superfamily domain containing 2B, *SPH* sphingosine, *SphK* sphingosine kinase, *SPL* S1P lyase, *SPNS2* spinster homologue-2, sphingolipid transporter-2, *SPP* S1P phosphatase

(ABC) transporters (Spiegel et al. 2019; Riboni et al. 2020). S1P occurs in plasma at high concentrations (~0.2–0.4 μM). Main sources of circulating S1P are erythrocytes expressing MFSD2B and endothelial cells expressing SPNS2 (Obinata and Hla 2019). S1P is furthermore stored in platelets, released via MFSD2B upon platelet activation, and occurs in serum at ~0.5–0.8 μM. About 65% of plasma S1P is bound to apolipoprotein M (ApoM) within high-density lipoproteins (HDL); the remainder is bound to albumin. These S1P chaperones fine-tune S1P's interaction with S1P-GPCR, with ApoM producing a sustained S1P release (Obinata and Hla 2019). Of note, tissue S1P levels are very low, and there are S1P gradients between tissues and circulation and within tissues. These chemotactic gradients are essential for trafficking of immune cells and positioning of cells within tissues (Dixit et al. 2019).

S1P Receptors

An overview of G protein-coupled S1P receptors as listed in the IUPHAR/BPS Guide to Pharmacology is presented in Table 1. These receptors

Sphingosine-1-Phosphate, Table 1 G protein-coupled S1P receptors

Receptor (previous names)	Signalling	Main biological effects
$S1P_1$ (EDG1)	$G_{i/o}$	Cell migration ↑, cell proliferation, survival, cell-cell contacts, lymphocyte trafficking, angiogenesis, vascular barrier ↑, heart rate and atrioventricular conduction ↓ in humans
		-/- mice: embryonic lethality, defective vascular maturation
$S1P_2$ (EDG5, H218, AGR16)	$G_{i/o}$, $G_{q/11}$, $G_{12/13}$	Cell migration ↓, vascular barrier ↓, vascular development
		-/- mice: hearing loss, B cell lymphoma at high age, neuronal hyperexcitability
		Human mutations: hearing impairment
$S1P_3$ (EDG3)	$G_{i/o}$, $G_{q/11}$, $G_{12/13}$	Vascular development, NO-dependent vasorelaxation, heart rate ↓ in mice
		-/- mice: no obvious abnormalities
$S1P_4$ (EDG6)	$G_{i/o}$, $G_{12/13}$	Expression limited to haematopoietic tissues. Anti-inflammatory activity, proliferation and cytokine secretion of T-cells ↓, 5-lipoxygenase ↓, terminal megakaryocyte differentiation
		-/- mice: delayed recovery from thrombocytopenia
$S1P_5$ (EDG8, NGR-1)	$G_{i/o}$, $G_{12/13}$	Cell proliferation, mitotic progression, cell rounding, oligodendrocyte functions, natural killer cell trafficking
		-/- mice: altered natural killer cell homing and tissue invasion

comprise the class A GPCR and $S1P_{1–5}$ (human gene names, *S1PR1-5*) (see the IUPHAR GPCR database). S1P-GPCR differentially couples to $G_{i/o}$, $G_{q/11}$ and $G_{12/13}$ proteins (Table 1). Thus, these receptors regulate classical signalling pathways such as ▶ adenylyl cyclase, phospholipase C $[Ca^{2+}]_i$, protein kinases C, mitogen-activated protein kinases, Akt, Ras, Rac and Rho. Thereby, they modulate cell growth, survival, re-arrangement of the cytoskeleton, cell migration, Ca^{2+} signalling and other responses. The $G_{12/13}$-coupled receptors also activate the Hippo pathway, which controls cell growth, immunity, fibrosis and cancer (Noguchi et al. 2018). $S1P_{1-3}$ are widely expressed, while $S1P_4$ is rather restricted to haematopoietic tissues and $S1P_5$ is preferentially expressed in the brain, immune cells, skin and other tissues. Functional studies have demonstrated that also S1P can act independently of the known S1P-GPCR. Several intracellular targets for S1P have been described but still await independent confirmation (Pyne et al. 2016; Spiegel et al. 2019).

Biological Actions

The components of the S1P signalling system are widely expressed. They regulate tissue homoeostasis in many organs, including the heart, kidney, liver, intestine, pancreas, adipose tissue, bone, skin and immune and nervous systems.

Development The S1P signalling system plays a role in angiogenesis, neurogenesis, and limb development in mice and regulates cardiogenesis in zebrafish (Mendelson et al. 2014). Mice lacking *S1pr1* die during embryonic development from haemorrhages caused by a failure of pericytes to migrate around newly formed capillaries. Additional deletion of *S1pr2* or *S1pr3* leads to more severe vascular defects. Mice lacking both SphK isoforms do not have measurable S1P concentrations and die during embryonic development from haemorrhages and defective vasculogenesis. Furthermore, they exhibit disturbed neurogenesis and impaired neural tube closure. Defective neurogenesis is also observed in *S1pr1* knockouts, indicating that the *Sphk/S1pr1* axis is important for angio- and neurogenesis (Mendelson et al. 2014). Both the $S1P_2$ receptor and SPNS2 are essential for function of the inner ear. Mice lacking *S1pr2* or *Spns2* suffer from hearing loss early after birth, and mutations of *S1PR2* in humans are associated with deafness (Romero-Guevara et al. 2015). Furthermore, both the $S1P_2$ receptor and SPNS2 are required for migration of cardiac precursors to the midline in zebrafish (Mendelson et al. 2014). Finally, deletion of *Sgpl1*, which represents the only exit point of sphingolipid metabolism, leads to multiple organ defects and early death in mice. Similarly, loss-of-function mutations in *SGPL1*

cause S1P lyase insufficiency syndrome (SPLIS) in humans, with steroid-resistant nephrotic syndrome, damage of the central and/or peripheral nervous systems, adrenal insufficiency and other symptoms (Choi and Saba 2019).

S1P Gradients and the Immune System SphK, LPP, S1P lyase and SPNS2 contribute to formation of S1P concentration gradients between tissues and circulation and within organs (Dixit et al. 2019). S1P-GPCRs regulate cell migration and positioning within these gradients, with $S1P_1$ and $S1P_2$ acting antagonistically. $S1P_1$ activates Rac and stimulates migration, while $S1P_2$ activates Rho, induces stress fibre formation and inhibits migration. This is of particular importance for immune cell trafficking: $S1P_1$ is required for lymphocyte egress from lymphatic tissues, while $S1P_2$ mediates confinement of B cells and follicular T helper cells to lymph node germinal centres. The $S1P_5$ receptor is essential for natural killer cell trafficking. While S1P regulates migration of many types of immune cells, the S1P signalling system also regulates development, differentiation and polarization of these cells (Blaho and Hla 2014; Weigert et al. 2019).

Cardiovascular System S1P is an important mediator in the cardiovascular system. Not only angio- and vasculogenesis but also vascular permeability is regulated by S1P: $S1P_1$ stimulates endothelial cell adherens junction assembly and improves the vascular barrier, while $S1P_2$ disrupts adherens junctions and induces vascular leak (Obinata and Hla 2019). The $S1P_2$ receptor induces contraction of diverse types of smooth muscle, including vascular, bronchial, intestinal and bladder smooth muscle, via $[Ca^{2+}]_i$ increases and activation of Rho/Rho kinase (Blankenbach et al. 2016). Endothelial $S1P_1$ and $S1P_3$ receptors, on the other hand, cause NO-dependent vasorelaxation. S1P has both pro- and anti-atherosclerotic effects (Kurano and Yatomi 2018). $S1P_2$ retains macrophages in atherosclerotic plaques, and knockout of this receptor was beneficial in models of atherosclerosis. $S1P_1$ acts anti-atherosclerotic via activation of NO synthase and suppression of endothelial adhesion molecules and is preferentially activated by ApoM-bound S1P (Kurano and Yatomi 2018). $S1P_3$ in mice and $S1P_1$ in humans, respectively, activate $I_{K(ACh)}$ in atrial myocytes, leading to bradycardia and delay of atrioventricular conduction (Dyckman 2017).

Inflammation, Fibrosis and Cancer The S1P signalling system also affects **inflammation, fibrosis and cancer**. This is due to S1P's role in cell proliferation, cell survival, migration and invasion and its eminent effects on cells of the innate and adaptive immune systems. In particular, the importance of $S1P_1$ for lymphocyte trafficking makes it a target in many inflammatory and autoimmune diseases, such as multiple sclerosis, inflammatory bowel disease, psoriasis, lupus erythematosus and others (see Drugs). Key pro-inflammatory mediators, for example, interleukin-1β and tumour necrosis factor-α, activate and induce SphK (Chan and Pitson 2013), which can lead to either intracellular S1P formation or S1P export and cross-activation of S1P-GPCR. Extracellular S1P can act both pro- and anti-inflammatory (Maceyka and Spiegel 2014; Nagahashi et al. 2018). For example, the $S1P_2$ receptor activates NF-κB and/or induces cyclooxygenase-2 and prostaglandin production in several cell types (Blankenbach et al. 2016). Also the key mediator of fibrosis, transforming growth factor-β (TGF-β), induces SphK1. In inflammatory kidney diseases, SphK1 is often upregulated and appears to act as a brake in kidney fibrosis (Huwiler and Pfeilschifter 2018). Extracellular S1P, on the other hand, can cross-activate the TGF-β/Smad signalling cascade and increase the production of extracellular matrix (Huwiler and Pfeilschifter 2018). In cancer, S1P affects both tumour cells and cells of the tumour microenvironment (Pyne et al. 2018; Riboni et al. 2020).

Drugs

There are currently three drugs approved that target the S1P signalling system: fingolimod and ozanimod for relapsing-remitting multiple sclerosis and siponimod for secondary progressive multiple sclerosis. Fingolimod (FTY720), which structurally resembles sphingosine, is phosphorylated by SphK2

Sphingosine-1-Phosphate, Table 2 Drugs targeting the S1P signalling system

Drug	Target	Indication	Stage
Fingolimod	S1P receptor modulator	Relapsing-remitting multiple sclerosis	Approved
	$S1P_{1/3/4/5}$		
Siponimod (BAF-312)	S1P receptor modulator	Secondary progressive multiple sclerosis	Approved
	$S1P_{1/5}$		
Ozanimod (RPC1063)	S1P receptor modulator	Relapsing-remitting multiple sclerosis	Approved
	$S1P_{1/5}$	Ulcerative colitis	Phase III
Etrasimod (APD334)	S1P receptor modulator	Ulcerative colitis	Phase III
	$S1P_1$ ($S1P_4$, $S1P_5$)	Atopic dermatitis	Phase II
Ponesimod (ACT-128800)	S1P receptor modulator	Multiple sclerosis	Phase II
	$S1P_1$ ($S1P_3$, $S1P_5$)	Chronic plaque psoriasis	Phase II
Cenerimod (ACT-334441)	S1P receptor modulator	Systemic lupus erythematosus	Phase II
	$S1P_1$ (selectivity unknown)		
Amiselimod (MT-1303)	S1P receptor modulator	Relapsing-remitting multiple sclerosis, Crohn's disease, psoriasis, systemic lupus erythematosus	Phase II
	$S1P_1$ ($S1P_5$)		
Ceralifimod (ONO-4641)	S1P receptor modulator	Relapsing-remitting multiple sclerosis	Phase II
	$S1P_{1/5}$		
Mocravimod (KRP-203)	S1P receptor modulator	Ulcerative colitis, cutaneous lupus erythematosus	Phase II
	$S1P_{1/5}$		
Opaganib (ABC294640)	SphK2 inhibitor	Pancreatic cancer, unspecified adult solid tumour	Phase I

and then acts as agonist at all S1P-GPCR except $S1P_2$. The immunosuppressive activity of fingolimod is caused by super-agonistic activation and subsequent downregulation of the $S1P_1$ receptor which is required for lymphocyte egress from lymphatic tissues (Huwiler and Zangemeister-Wittke 2018). Lymphopenia induced by loss of $S1P_1$ represents fingolimod's principle mechanism of action in multiple sclerosis. Undesired effects include bradycardia and atrioventricular block induced by $S1P_1$-mediated activation of cardiac G protein-coupled inwardly rectifying potassium channels, macular oedema caused by disturbance of the vascular barrier, mild increase in arterial blood pressure, bronchoconstriction, increases in liver enzymes and elevated risk for infections (Huwiler and Zangemeister-Wittke 2018). The risk for bradycardia is high during the initial phase of therapy and declines with $S1P_1$ desensitization. Siponimod has a high selectivity for $S1P_1$ and $S1P_5$ and a shorter half-life compared to fingolimod. Despite sparing $S1P_3$, it still causes adverse effects in the cardiovascular system (Al-Salama 2019). Several other S1P receptor modulators with greater S1P-GPCR subtype selectivity are in clinical development (Dyckman 2017) (Stepanovska and Huwiler 2020); some of them are shown in Table 2. All act as super-agonists/functional antagonists at the $S1P_1$ receptor and thereby induce immunosuppression. Consequently, these compounds are developed for diverse autoimmune diseases (Table 2). While pharmaceutical development thus strongly focuses on $S1P_1$, other S1P-GPCR and SphK1/2 might as well be worthwhile targets. However, the only SphK inhibitor in clinical development is ABC294640, a SphK2 inhibitor with its K_i in the micromolar range, which is being evaluated as anticancer agent (Table 2).

Stroke

Markus Schwaninger
Institute for Experimental and Clinical Pharmacology and Toxicology, University of Lübeck, Lübeck, Germany

Definition

Traditionally, stroke has been defined according to its clinical presentation as a focal neurological deficit with a sudden onset that probably has a vascular cause. The advent of computer tomography, magnetic resonance imaging (MRI), and other imaging techniques has allowed a stronger focus on the cerebrovascular pathology and has led to a broadening of the definition. Now, it includes ischemic infarcts and intracerebral hemorrhages, both with and without symptoms, transient ischemic attacks, subarachnoid hemorrhages, and cerebral venous thrombosis (Sacco et al. 2013). Global cerebral ischemia is usually excluded from the definition of stroke as it differs in clinical presentation and is caused by conditions, such as cardiac arrest or hypotensive shock, that lie outside of the cerebrovascular system.

Its high incidence and mortality make stroke one of the most important causes of death worldwide. The most common form of stroke is an ischemic infarction that is about four times as frequent as intraparenchymal hemorrhage. Based on the vascular origin, ischemic strokes are classified as cardioembolic, atherosclerotic, microvascular, and cryptogenic, each of which represents approximately a quarter of cases (Saver 2016). Additional classification builds on the involved vascular territory or the area of the CNS, including retina and spinal cord. Hypertensive intracerebral hemorrhages occur at preferred sites, such as the basal ganglia and the pons. Outside of these predilection sites, hemorrhages often have another aetiology. In the case of subarachnoid hemorrhage and cerebral venous thrombosis, the identification of an aneurysm or the site of thrombosis is important for the exact definition of the disease.

Basic Mechanisms

Ischemic Penumbra

All forms of stroke are associated with focal ischemia in the brain, spinal cord, or retina. Even in hemorrhagic strokes, compression of vessels or vasospasms leads to secondary ischemia of the tissue contributing to the neurological deficits. However, in contrast to global ischemia, focal ischemia is associated with some residual blood flow through collateral vessels, which provides a route for drugs to reach the lesion. Low perfusion in the core of the ischemia triggers rapid tissue loss. In the border zone between core and healthy tissue, blood flow gradually increases. The tissue, in which blood flow is high enough for acute survival but still so low to put it at risk for subacute demise, is called penumbra. Salvaging the penumbra is the target of stroke therapy. Size and distribution of the penumbra are dynamic and depend on individual factors, such as collateral blood vessels. For patient care, it is therefore important that MRI techniques are available that allow determining a proxy of the penumbra.

Pathomechanisms of Ischemic Brain Damage

Ischemia has a profound impact on the CNS. Four complexes in the pathophysiology explain the high vulnerability to ischemia: periinfarct depolarization, excitotoxicity, regulated cell death, and inflammation.

The CNS spends a lot of energy to maintain the polarization of neurons. Due to the loss of cellular energy in cerebral ischemia, neurons depolarize. A wave of **depolarization** spreads into the penumbra (Dreier 2011). There, the attempt of cells to repolarize strains the energy balance of the tissue that is already at risk due to the reduced perfusion. Depolarization of cells is associated with a shift of extracellular water into cells. This phenomenon is the basis of diffusion-weighted MR imaging that is used in clinical practice to detect early signs of cerebral ischemia. Lesions identified in diffusion-weighted MRI represent the core infarct area in which tissue usually does not recover.

Due to the energy loss in the ischemic tissue, excitatory neurotransmitters, mainly glutamate, are released and their re-uptake is impaired. This

is the basis of **excitotoxicity**. Activation of glutamate receptors, particularly those outside of synapses, triggers a detrimental cascade of events. Accordingly, the inhibition of glutamate receptors is neuroprotective in experimental stroke models, but clinical trials did not show an effect (Lai et al. 2014). A key problem in translating this and other findings seems to be the therapeutic time window in preclinical studies that is often too short for clinical practice. Targeting the events downstream of glutamate receptor activation might help to extend the therapeutic window. The stimulation of glutamate receptors leads to a calcium overload of cells and mitochondria. This damages mitochondria and enhances the production of reactive oxygen species. Another important consequence of glutamate receptor activation is the synthesis of NO by the neuronal NO synthase. This enzyme is coupled by the adaptor protein PSD-95 to glutamate receptors and is activated by elevated intracellular calcium levels. NO and superoxide anions form the highly reactive peroxynitrite that damages numerous macromolecules.

The death of neural cells denotes an irreversible step in the ischemic cascade. Evidence that many cells succumb to some form of **regulated cell death** raised hope that an intervention is possible. Apoptosis, necroptosis, autophagy, ferroptosis, and pyroptosis have all been reported in stroke models. Variants of cell death are often interrelated and blocking one form promotes another. For example, caspase inhibitors reduce apoptosis and ameliorate ischemic damage, but the effect seems to be dampened by enhanced necroptosis. Also, necroptosis inhibitors are protective in cerebral ischemia suggesting that a cocktail of cell death inhibitors may have a superior effect.

Dying cells release damage-associated molecular patterns, such as HMGB1 or ATP, that elicit a sterile **inflammation** in the CNS. Damage-associated molecular patterns act on microglia and other neural cells. In all cells of the CNS including neurons, cerebral ischemia stimulates pro-inflammatory signalling, such as the NF-κB pathway. In addition, neutrophils, monocytes, and lymphocytes are allured to the ischemic tissue. The complex tissue response has both detrimental and beneficial effects. On the damage side, inflammatory cytokines contribute to the demise of neurons. They also open the blood-brain barrier and promote vascular brain edema. In its worst form, brain edema critically elevates the intracranial pressure lowering cerebral perfusion and causing herniation and death of patients. On the protection side, activated microglia or brain macrophages reduce the damage by counteracting excitotoxicity, releasing anti-inflammatory mediators and removing tissue debris. The line between damage and protection seems to be fluid. Local properties including perfusion or systemic factors, such as body temperature, have a profound influence. In addition, timing is very important after stroke. Anti-inflammatory interventions may protect in the acute phase but impair recovery when administered too late (Lo 2008).

Pharmacological Intervention/ Pharmacotherapy

When treating patients with ischemic stroke, the first aim is to **reinstall perfusion**. Since 1996, tissue plasminogen (tPA, alteplase) has been used for thrombolysis and has recently been supplemented by mechanical intravascular thrombectomy. Often intravenous thrombolysis and intravascular thrombectomy are combined in individual patients. tPA variants with enhanced fibrin selectivity and prolonged half-life, such as tenecteplase, may be superior, but in 2020, alteplase is still the only approved agent for thrombolysis within 4.5 h after symptom onset. Imaging of the ischemic territory allows extending the therapeutic window in selected cases (Thomalla et al. 2018). However, with increasing time since onset of ischemia, the efficacy of thrombolysis decreases while the risk for intracerebral hemorrhage rises. Despite successful recanalization of occluded arteries, cerebral perfusion may remain low. This phenomenon, called no reflow, is attributed to a disturbance of the microvasculature. Apparently, small vessels are obstructed by constricting pericytes, swollen

astrocytes, or clogging immune cells (Bai and Lyden 2015). A disturbance of the microvasculature is also a likely cause of intracerebral hemorrhage that can be life-threatening after thrombolysis. Depending on local settings, up to 20% of patients with acute ischemic stroke are eligible for thrombolysis.

Besides acute recanalization therapy, **secondary prevention** is the most successful treatment option for stroke patients. After a stroke or transient ischemic attack, the risk for another event is elevated for several weeks. If cardiac embolism is not the cause of stroke, inhibitors of platelet aggregation significantly lower the risk of recurrence. The standard therapy is aspirin. Clopidogrel or aspirin plus dipyridamole are slightly more effective. Aspirin is also transiently combined with clopidogrel to further enhance its efficacy. Whether other P_2Y_{12} antagonists, like prasugrel or ticagrelor, could provide advantages is the subject of ongoing trials. In patients with cardioembolic stroke, anticoagulant drugs are administered to prevent a secondary event. In the very acute phase of ischemic strokes, anticoagulants are associated with an increased risk for intracerebral hemorrhages. Therefore, a lag time of 4–14 days between stroke onset and start of the anticoagulant therapy is recommended. In the treatment of patients with intracerebral hemorrhage, lowering high blood pressure is beneficial to reduce further bleeding (Moullaali et al. 2019). This is also the rationale why the blood pressure should be below 185 mmHg systolic and 110 mmHg diastolic before recanalization therapy in ischemic stroke. For the acute control of hypertension, the competitive α1 and β adrenergic receptor antagonist labetalol and the dihydropyridine calcium channel blocker nicardipine are used. After the acute phase, a strict control of hypertension has proven to be most effective in lowering the stroke rate. Finally, lipid-lowering drugs, mainly potent HMG-CoA reductase inhibitors, have an established place in the secondary prevention of ischemic stroke. Statins are afflicted with a low risk of causing intracerebral hemorrhages that is, however, outweighed by their beneficial effects in the presence of atherosclerotic diseases (Goldstein et al. 2008).

Future Directions

Stroke has served as a model disease for neurodegenerative disorders. Its pathophysiology has been intensively studied leading to an impressive armamentarium of neuroprotective drugs that work in preclinical experiments. However, translation of neuroprotection into clinical treatments proved to be difficult. In contrast, thrombolysis was more successful and shows that pharmacotherapy of ischemic stroke is possible. Therefore, an obvious aim is to improve thrombolysis further. Optimizing the pharmacokinetics or the fibrin selectivity of thrombolytics as well as limiting its inhibition by the plasma proteins PAI-1 and TAFI may increase the recanalization rate in acute stroke. In addition to plasminogen, alteplase cleaves NMDA receptors and basement membrane proteins which may contribute to its adverse effects. Limiting off-target cleavage may improve its safety profile (Thiebaut et al. 2018).

Blood coagulation is closely linked to inflammation and cell death. Along these lines, it may be possible to extend the success of anticoagulants and thrombolytics and to develop agents that manipulate cell death and inflammation in addition to blood coagulation. Activated protein C and thrombomodulin are endogenous factors that have this potential dual activity. Many inflammatory factors proved to be Janus-faced with both beneficial and detrimental actions. However, this is unlikely to be a universal principle and further anti-inflammatory strategies await to be tested. Other appealing targets are proteins that induce both apoptosis and necroptosis, a possible example being RIPK1.

To evaluate the potential of these and other targets, preclinical models should investigate the **long-term functional outcome** that is essential for clinical efficacy. Clinical trials usually evaluate the neurological deficit over 90 days. In contrast, this aspect has often been neglected in basic research. Long-term recovery is determined by post-insult plasticity and regeneration. The pharmacology of these processes is still largely unexplored but may be worthwhile to study.

In the future, progress may come from a **precision medicine** approach towards stroke. So far, clinical studies have often lumped all stroke patients into heterogeneous groups, irrespective of the aetiology, the size of the penumbra, or the presence of inflammation. New imaging techniques or biomarkers may help identify stroke patients that benefit most from specific therapies. NMR- and mass spectrometry-based lipidomics and metabolomics provide unprecedented insight into the molecular events underlying injury in individual patients and may increase therapeutic precision in the future.

Neurotransmission

Definition

Synaptic transmission is the transfer of biological information between two neurons (Fig. 1) (Chua et al. 2010). Major events during synaptic transmission are as follows:

(1) An action potential arrives at the presynaptic axon terminal.
(2) The ensuing depolarization triggers the opening of voltage-dependent Ca^{2+} channels (VGCCs).
(3) The increase of Ca^{2+} concentration in the axon terminals triggers the exocytosis of synaptic vesicles.
(4) The neurotransmitter released from the vesicles diffuses through the synaptic cleft.
(5) The neurotransmitter activates receptors in the plasma membrane of the postsynaptic neuron.
(6) Activated postsynaptic receptors mediate ion fluxes through the plasma membrane of the postsynaptic neuron, leading to changes in the membrane potential. The postsynaptic receptors may also mediate manifold biochemical changes within the postsynaptic neuron.

There are numerous transmitter substances. They include the amino acids glutamate, GABA, and glycine; acetylcholine; the monoamines dopamine, noradrenaline, and serotonin; the neuropeptides; and ATP. Nitrergic transmission, i.e., transmission by NO, differs from transmission by other transmitters and is not covered in this essay. Chemical synaptic transmission is by far the dominating kind of synaptic transmission in the human body. However, in a few regions of the nervous system, electrical synapses, based on gap junctions, can mediate bidirectional communication between adjacent neurons (Alcami and Pereda 2019).

Drugs that influence synaptic transmission play an eminent role in therapy, for two reasons. First, the nervous system controls all tissues. Second, with few exceptions synaptic transmission is chemical, operating by means of transmitter substances, and synapses therefore provide a large number of drug targets, for example, transporters and enzymes that remove transmitters from the synaptic cleft. Poisons like sarin and cocaine also target synaptic transmission.

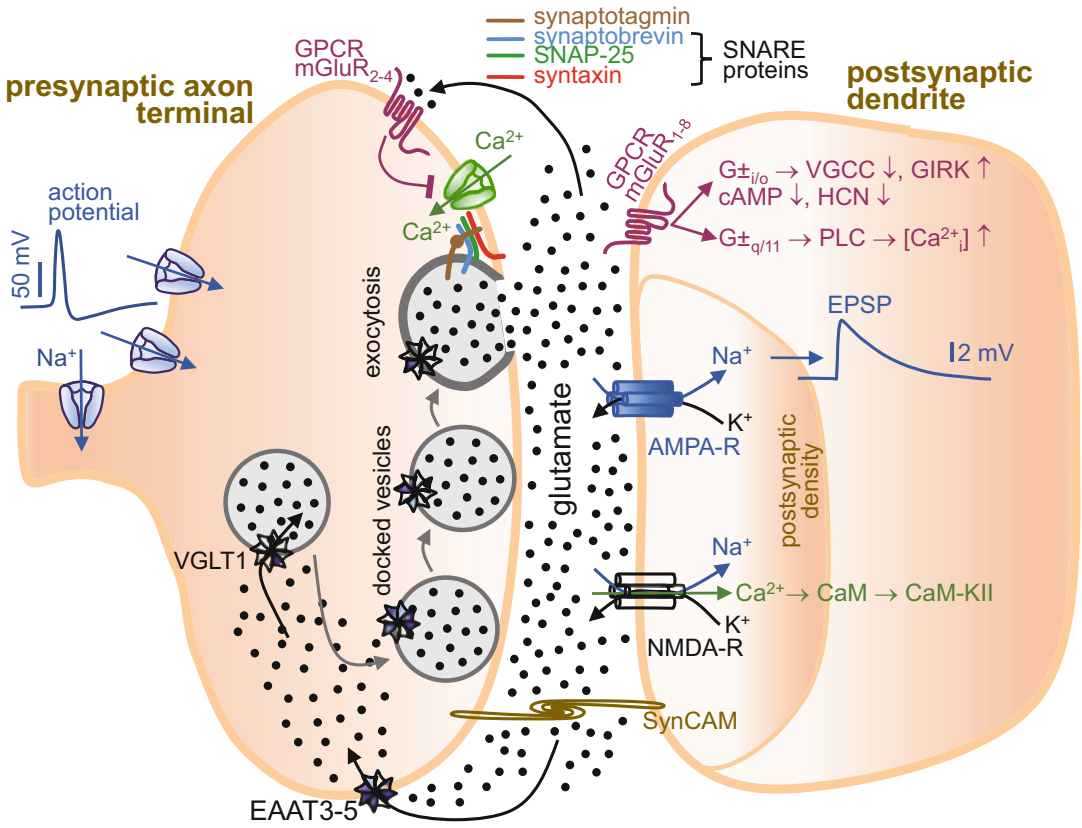
Basic Mechanisms

Transmitter Synthesis and Vesicular Storage

All non-peptide neurotransmitters are produced in the axon terminals, which possess the necessary enzymatic machinery. After synthesis, most of the transmitters are brought into synaptic vesicles by transporters belonging to the solute carrier transporter family (SLC transporters) (Fig. 1). The vesicular SLC transporters mostly utilize the proton electrochemical gradient across the vesicle membrane.

Glutamate and GABA

In neurons glutamine is transformed into glutamate by the enzyme glutaminase. After synthesis glutamate is transported into synaptic vesicles mostly by the vesicular glutamate transporter 1 (VGLT1; SLC17A7). Glutamate itself is the source for the synthesis of GABA: Glutamic acid decarboxylases (GAD1 and GAD2) convert the main excitatory neurotransmitter glutamate into the main inhibitory neurotransmitter GABA. GABA is then carried into the synaptic vesicle by the vesicular inhibitory amino acid transporter (VIAAT; SLC32).



Synaptic Transmission, Fig. 1 Glutamatergic synaptic transmission. The presynaptic terminal contains voltage-dependent Na^+ and Ca^{2+} channels, docked vesicles, a vesicle during exocytosis, the Ca^{2+} sensor synaptotagmin, and the SNARE proteins which are involved in the exocytosis. The vesicular glutamate transporter VGLT1, a group of plasmalemmal glutamate transporters (EAAT3–EAAT5), and a group of presynaptic GPCRs ($mGluR_{2-4}$) are also shown. The postsynaptic cell contains two ligand-gated glutamate receptors (AMPA-R and NMDA-R) and a group of GPRCs ($mGluR_{1-8}$). The axon terminal and the postsynaptic density are held together by the synaptic cell adhesion molecule SynCAM

Acetylcholine

Cholinergic axon terminals contain choline acetyltransferase, which acetylates choline to acetylcholine. In these axon terminals, the synaptic vesicles are filled with acetylcholine by the vesicular acetylcholine transporter (VAChT, SLC18A3).

Monoamines

Dopaminergic axon terminals contain tyrosine hydroxylase, which converts tyrosine into levodopa, and aromatic l-amino acid decarboxylase, which decarboxylates levodopa to dopamine. Noradrenergic terminals contain in addition dopamine β-hydroxylase, which oxidizes dopamine to noradrenaline. The synthesis of serotonin starts with the essential amino acid tryptophan. Tryptophan is at first hydroxylated by tryptophan hydroxylase and then decarboxylated by aromatic l-amino acid decarboxylase to yield serotonin. The vesicular monoamine transporter 2 (VMAT2, SLC18A2) is responsible for the vesicular transport of dopamine, noradrenaline, and serotonin.

Neuropeptides

In contrast to the small transmitter molecules, the neuropeptides (e.g., opioid peptides) are synthesized in the rough endoplasmic reticulum of the neuronal perikarya. They are enclosed in vesicles in the Golgi apparatus. The vesicles travel down to the terminals by axonal transport.

Transmitter Release

Neurotransmitters are released from the active zone of the presynaptic axon terminal by the following cascade: arrival of the action potential at the terminal, depolarization, opening of voltage-sensitive Ca^{2+} channels (VGCCs), and exocytosis (Fig. 1) (Südhof 2013). The nerve action potential is mainly carried by Na^{+} entry through voltage-dependent Na^{+} channels. Axon terminal voltage-sensitive Ca^{2+} channels are mainly of the N and P/Q types.

Docking and Priming

During the first step, which is called "docking," complete synaptic vesicles are positioned in the vicinity of the presynaptic plasma membrane (Fig. 1). During the next "priming" step, docked synaptic vesicles are prepared for "fusion" with the presynaptic plasma membrane. Calcium influx through N- and P/Q-type Ca^{2+} channels triggers the vesicle fusion. The calcium channels are clustered in the close vicinity of the Ca^{2+} sensor synaptotagmin in the membrane of the synaptic vesicle. The activation of only a few of calcium channels is sufficient to trigger vesicle fusion.

Exocytosis

Exocytosis consists of the fusion of the vesicle membrane with the plasmalemma, the opening of a pore in the fused membranes, and outward diffusion of the neurotransmitter. Three proteins, the so-called SNARE proteins, are essential in exocytosis. One, synaptobrevin, is a protein of the vesicle membrane; the other two, syntaxin and SNAP-25 (synaptosome-associated protein of 25 kD), are proteins of the plasmalemma (Fig. 1). Upon an increase in cytoplasmic Ca^{2+} from about 0.1 to about 100 μM, the vesicular synaptobrevin grabs hold of the plasmalemmal SNAREs, and the three proteins intertwine into a complex that then tightens like a zipper. This "zippering" of the SNAREs pulls the vesicle and plasma membranes together so that the lipid bilayers merge. Ca^{2+} channels and SNAREs lie closely together. Syntaxin and SNAP-25 in fact interact physically with the α1 subunit of N- and P/Q-type Ca^{2+} channels. The close neighborhood permits the fastness of exocytosis; the time from the arrival of the action potential to pore formation is only 100 μs or less. This fast presynaptic component of synaptic transmission contributes to the overall high speed of synaptic transmission: The time period between the appearance of the presynaptic action potential and the postsynaptic response is frequently less than 1 ms (synaptic delay).

After exocytosis, the synaptic vesicle membrane with its lipids and proteins is recycled, either by immediate re-filling with transmitter or by passing through a vesicle resting pool deeper inside the axon terminal.

Stochastic Release

Action potential-elicited neurotransmitter exocytosis is a probabilistic process (Pulido and Marty 2017). Only a fraction of the action potentials elicits transmitter release: release probability varies greatly among synapse types; probability values of 5–20% are not uncommon. Moreover, even in the case of regular presynaptic action potentials, release events are not regular but occur at variable intervals. The probability of release can be modulated by presynaptic receptors in the axon terminal membrane (Fig. 1). Through these receptors, transmitter substances from neighboring neurones and hormones can increase or reduce the release probability. Axon terminals thus integrate the release command of the action potential and various modulatory chemical messages from the neighborhood to release an appropriate amount of transmitter.

Postsynaptic Receptor Activation

The neurotransmitter released from the presynaptic active zone diffuses through the synaptic cleft to the postsynaptic neuron. The postsynaptic receptors are mostly localized in the cell membrane of the dendrites or dendritic spines, in a region called postsynaptic density (Fig. 1). The presynaptic active zone and the postsynaptic density are closely held together with the help of cell adhesion molecules anchored in the axon terminal and the postsynaptic neuron.

Of the several classes of receptors for endogenous chemical signals (Hofmann 2017), two are used as postsynaptic receptors in synaptic

transmission: ligand-gated ion channels (LGICs) and G-Protein-Coupled Receptors (GPCRs). Due to the large number of transmitters and the existence of several receptor types for almost all, postsynaptic receptor activation is the most diversified step of synaptic transmission. Table 1 shows selected neurotransmitter receptors.

Ligand-Gated Ion Channels (LGIC)

LGICs are hetero- or homo-oligomeric proteins consisting of three, four, or five peptide chains, of which each spans the membrane several times (Alexander et al. 2019a). The three to five subunits surround a pore, which in the absence of transmitter is closed. The nicotinic receptor for acetylcholine, the $GABA_A$-receptor, the glycine receptor, and the 5-HT_3-receptor for serotonin are pentamers. The ionotropic glutamate receptors (iGluRs) are tetramers. The P2X-receptors for ATP are trimers. When transmitter is bound to a ligand-gated ion channel receptor, the open probability of the pore is increased. Ions may then

enter or leave the cell, but a selectivity filter in the channel lets only certain ions pass.

LGIC/Glutamate Receptors

The AMPA and kainate receptors for glutamate are cation channels; they are permeable for Na^+ and K^+ (some AMPA receptors also for Ca^{2+}) (Table 1) (Henley and Wilkinson 2016). When they open, the major consequence is a sudden entry of Na^+, and the ensuing depolarization is called excitatory postsynaptic potential (EPSP; Fig. 1). The NMDA receptor is also activated by glutamate, but glycine is needed as a co-activator. The NMDA receptor is blocked by Mg^{2+} at resting membrane potentials, and this blockade is relieved by depolarization. The NMDA receptor ion channel is permeable for Na^+, K^+, and Ca^{2+}. Ca^{2+} entering into the postsynaptic neuron via the NMDA receptor can activate intracellular event cascades involving calmodulin and Ca^{2+}/calmodulin-dependent protein kinase II (CAMKII).

LGIC/$GABA_A$- and Glycine Receptors

The $GABA_A$-receptor and the glycine receptor are Cl^- channels (Table 1). When they open at a resting membrane potential of about −60 mV, the consequence is an entry of Cl^- which elicits hyperpolarization. This hyperpolarization is called inhibitory postsynaptic potential (IPSP).

All these postsynaptic events last only for a few milliseconds; synaptic transmission through LGICs is fast. When the postsynaptic cell membrane is sufficiently depolarized, voltage-dependent Na^+ channels open, and an action potential is generated.

G Protein-Coupled Receptors (GPCRs)

GPCRs are proteins that span the postsynaptic cell membrane seven times (heptahelical receptors) (Alexander et al. 2019b). Small ligands are usually bound within a pocket formed by the seven transmembrane helices. The large neuropeptides bind to the extracellular domains. When the receptors are activated, they interact with the appropriate G proteins that are bound to the inner surface of the cell membrane. The G proteins then pass the information on to various effectors (Fig. 1).

GPCR/$G\alpha_{i/o}$ Coupling

The $mGluR_{2,3,4,6,7,8}$ glutamate receptors; $GABA_B$ receptors; M_2 and M_4 muscarinic receptors; D_2, D_3. and D_4 dopamine receptors; α_2-adrenoceptors; $5\text{-}HT_{1A–F}$ serotonin receptors; and μ, δ, and κ opioid receptors all couple to $G\alpha_{i/o}$ proteins. Via G protein Gβγ subunits, G protein-gated inwardly rectifying potassium (GIRK) channels are activated, and the membrane potential becomes more negative. Activation of $G\alpha_{i/o}$ protein-coupled receptors also lowers the open probability of N- and P/Q-type Ca^{2+} channels. The cytoplasmic level of the second messenger cyclic AMP (cAMP) is lowered as well: less cAMP means less activation of the hyperpolarization-activated cyclic nucleotide-gated (HCN) ion channel family. Neurotransmitters acting on postsynaptic $G\alpha_{i/o}$-coupled receptors usually slow the firing rate of postsynaptic neurons by opening GIRK channels but also by attenuating the cAMP-dependent activation of HCN channels. Presynaptically localized $G\alpha_{i/o}$-coupled receptors inhibit the transmitter release from the axon terminal.

GPCR/$G\alpha_{q/11}$ and $G\alpha_s$ Coupling

The $mGluR_{1,5}$ glutamate receptors; the M_1, M_3, and M_5 muscarinic receptors; and the α_1-adrenoceptors couple to $G\alpha_{q/11}$ proteins and thereby increase the cytoplasmic levels of the messengers inositol trisphosphate, diacylglycerol, and Ca^{2+}. Finally, the D_1 and D_5 dopamine receptors and the β-adrenoceptors couple to $G\alpha_s$ and thereby increase the cytoplasmic level of cyclic AMP.

These cascades of reactions need time in the range of seconds: synaptic transmission through GPCRs is slow. All further postsynaptic changes depend on the type of the postsynaptic cell. For example, activation of β_2-adrenoceptors causes in the heart an increase of the rate and force of contraction; in skeletal muscle glycogenolysis and tremor; in smooth muscle relaxation; in bronchial glands secretion; and in sympathetic nerve terminals, an increase in transmitter release.

Termination of Synaptic Transmission

Once released, neurotransmitters are inactivated by diffusion into the neighboring extracellular space, combined with one of two specific

pathways: either extracellular degradation by enzymes that face the extracellular space or uptake into cells.

Extracellular Degradation of Transmitters

Extracellular degradation removes acetylcholine, the neuropeptides, and ATP. Acetylcholine is rapidly hydrolyzed to choline and acetate by acetylcholinesterase (Rotundo 2017). The enzyme is localized in the presynaptic and postsynaptic cell membrane and in the extracellular matrix and splits about 10,000 molecules of acetylcholine per second. High concentrations of butyrylcholinesterase are found in the brain and many peripheral tissues. Although butyrylcholinesterase is also capable of cleaving acetylcholine, under physiological conditions its contribution to the elimination of acetylcholine released by neurons is minimal.

Elimination of Transmitters by Transporters

Glutamate, GABA, glycine, dopamine, noradrenaline, and serotonin are taken up into adjacent cells by plasmalemmal neurotransmitter transporters (Fig. 1). The transporters for GABA, glycine, dopamine, noradrenaline, and serotonin belong to the SLC6 transporter family (Kristensen et al. 2011). These transporters possess 12 transmembrane domains and use the electrochemical driving force of Na^+ across the neuronal membrane for moving the neurotransmitters against their concentration gradients into the neurons. The GABA transporter GAT1 is responsible for the re-uptake of GABA from the synaptic cleft into the axon terminal. GAT3 and BGT1 transfer GABA into adjacent glial cells. Glycine is transported into glycinergic axon terminals and glial cells by GLYT2 and GLYT1, respectively. The dopamine (DAT), noradrenaline (NAT), and serotonin transporters (SET) are located almost exclusively in the dopaminergic, noradrenergic, and serotoninergic terminals, respectively. In all these cases, cellular uptake means re-uptake into the presynaptic neurone. Re-uptake by the plasmalemmal transporter may be followed by vesicular re-uptake, an economical way of inactivation, reminiscent of the recycling of the storage vesicle membrane.

The glutamate transporters belong to the SLC1 transporter family, possess 12 transmembrane segments, and also use the transmembrane electrochemical gradient of Na^+ to pay for the transport work. Both neuronal (EAAT3, EAAT4, and EAAT5) and glial (EAAT1 and EAA2) transporters can remove glutamate from the synaptic cleft (Fig. 1).

Modulation of Synaptic Transmission

Synaptic plasticity. The strength of synaptic transmission (size of the postsynaptic response to a presynaptic action potential) is often modulated under physiological conditions, and this process is called "synaptic plasticity." The strength can be increased (potentiation) or decreased (depression). The duration of the change in synaptic strength can be short term (under 1 min) or long term (longer than ~30 min, up to life-long). Synaptic plasticity is important for memory and learning.

The mechanisms of synaptic plasticity are manifold. Transmitter release can be rapidly changed by altering the number of docked vesicles in the active zone. The number of postsynaptic receptors within the postsynaptic density can also be quickly changed. Longer time periods are necessary for the synthesis of new synaptic proteins and for morphological changes of the postsynaptic dendrites and dendritic spines. A classical form of long-term potentiation (LTP) is the NMDA receptor-dependent associative LTP of glutamatergic synaptic transmission (Lüscher and Malenka 2012). In this case, the presynaptic axon and the postsynaptic neuron are simultaneously depolarized (associative inputs). Glutamate released from the axon terminal activates postsynaptic AMPA and NMDA receptors. The postsynaptic depolarization enables the NMDA receptor to conduct Ca^{2+}. Ca^{2+} triggers intracellular effectors, and as a result, more AMPA receptors are moved into the postsynaptic density. Thus, the associative stimulus elicits an LTP of the AMPA receptor-mediated glutamatergic synaptic transmission.

Presynaptic Receptors

Transmitter release can be modulated also by activation of presynaptic receptors in the axon terminals. The presynaptic receptors are often autoreceptors (i.e., they respond to the transmitter which was released from the axon terminal) and

mostly $G\alpha_{i/o}$ protein-coupled receptors. Thus, presynaptic autoreceptors mediate negative feedback to limit further transmitter release – this is a presynaptically expressed short-term homeostatic synaptic plasticity. α_2-Adrenoceptors on noradrenergic axon terminals are prototypic presynaptic autoreceptors and were much studied (Starke 2001).

Retrograde Signaling

In the case of retrograde signaling, synaptic information flows retrogradely, i.e., from the postsynaptic neuron to the presynaptic axon terminal. Endocannabinoid-mediated retrograde signaling is probably the most ubiquitous form of retrograde signaling. The endocannabinoid 2-arachidonoylglycerol is released from postsynaptic neurons upon depolarization and subsequent calcium influx or after activation of $G\alpha_{q/11}$ protein-coupled receptors (Araque et al. 2017). After crossing the synaptic cleft, 2-arachidonoylglycerol activates presynaptic CB_1 cannabinoid receptors, which leads to a decrease of transmitter release from the axon terminal. This is an endocannabinoid-mediated short-term synaptic plasticity.

Clinical Pharmacology: Drugs Interfering with Synaptic Transmission

Transmitter Production and Vesicular Storage

Levodopa is administered as the precursor of dopamine to compensate for the loss of dopaminergic neurones in Parkinson's disease (see Chapter "Dopamine System"). After passing the blood-brain barrier, levodopa is converted into dopamine by aromatic l-amino acid decarboxylase. Reserpine blocks VMAT2; thus it depletes noradrenaline from the sympathetic axon terminals, and it was used in the past to treat hypertension. Because reserpine simultaneously empties noradrenergic, dopaminergic, and serotoninergic synaptic vesicles in the brain, many central nervous system side effects occur. A major component of the anticonvulsive effect of valproate is enhancement of GABAergic synaptic transmission in the brain by enhancing GABA synthesis in GABAergic axon terminals.

Transmitter Release

A large number of natural poisons inhibit transmitter release from axon terminals. Tetrodotoxin, produced by the puffer fish, occludes voltage-gated Na^+ channels by binding to the external side of the channel pore: as a consequence, the axon terminal is no longer depolarized. The cone snail *Conus geographus* produces 9-conotoxin GVIA, which blocks N-type Ca^{2+} channels. P-/Q-type Ca^{2+} channels are selectively blocked by the funnel-web spider venom 9-agatoxin IVA.

The most ingenious exocytosis toxins, however, come from the anaerobic bacteria *Clostridium botulinum* and *Clostridium tetani*. The former produces seven botulinum neurotoxins (BoNTs) A–G; the latter produces tetanus neurotoxin (TeNT) (Dong et al. 2019). All eight toxins consist of a heavy (H) chain and a light (L) chain that are associated by an interchain S–S bond. The L-chains enter the cytosol of axon terminals and then specifically split one of the three core proteins of exocytosis: synaptobrevin, syntaxin, or SNAP-25 (SNARE proteins; Fig. 1). BoNT L-chains mainly enter peripheral cholinergic terminals: the inhibition of acetylcholine release is followed by flaccid paralysis, the main symptom of botulism. The TeNT L-chain mainly enters cerebral and spinal cord GABAergic and glycinergic terminals: the inhibition of GABA and glycine release is followed by spastic paralysis, the main symptom of tetanus. BoNT and TeNT are the most potent toxic substances known, able to kill vertebrates at a dose of 0.1 to 1 ng/kg body weight. Due to its ability to inhibit acetylcholine release from cholinergic neurons, BoNT is increasingly used in therapy, for example, for the treatment of muscle spasticity, migraine, axillary hyperhydrosis, and overactive bladder. Undoubtedly, BoNT is most frequently used to alleviate wrinkles on the face – a cosmetic indication (in this setting BoNT is commonly called "Botox").

Mirtazapine is one of the most often-used antidepressant drug: it increases the release of noradrenaline and serotonin from axon terminals by blocking presynaptic α_2 adrenoceptors. The anticonvulsive drug levetiracetam lowers glutamate release by interfering with the docking and fusion

of synaptic vesicles after a primary interaction with the vesicle protein SV2.

Postsynaptic Receptor Activation

The most diversified step of synaptic transmission is also the target of the greatest variety of drugs. Some are included in Table 1. Many drugs and poisons stem from plants, for example, muscimol, bicuculline, strychnine, nicotine, tubocurarine, muscarine, atropine, scopolamine, and morphine.

The therapeutic impact of drugs acting at transmitter receptors is enormous. All volatile (isoflurane) and intravenous (propofol) anaesthetics and also ethanol act primarily on cerebral LGICs, above all $GABA_A$-receptors. All neuromuscular blocking agents are agonists (suxamethonium) or antagonists (pancuronium) at the skeletal muscle nicotinic receptor. There would be no surgery worth mentioning without these drug actions on neurotransmitter receptors. The anti-Parkinson drug pramipexole activates D_2 and D_3 dopamine receptors. Another drug used in Parkinson's disease, amantadine, is an antagonist at the NMDA glutamate receptor. Morphine and related opioid agonists are the most effective analgesics. The benzodiazepines (diazepam, midazolam) are positive allosteric modulators of the $GABA_A$-receptors and possess sedative, anticonvulsive, and anxiolytic actions. Neuroleptics such as haloperidol and olanzapine block D_2 dopamine receptors and are standard drugs to treat schizophrenia.

β_1 adrenoceptor antagonists such as metoprolol are mainly used in cardiology and belong to the most frequently prescribed drugs. The α_1 adrenoceptor antagonist tamsulosin is a first-line drug for the treatment of benign prostatic hyperplasia. Antagonists of muscarinic acetylcholine receptors are used to treat asthma and COPD (ipratropium, tiotropium), overactive bladder (trospium), and biliary and renal colic (butylscopolamine).

Transmitter Inactivation

The cholinesterase inhibitors are the classical drugs that interfere with transmitter inactivation. The prototype was the plant poison physostigmine, and derivatives of physostigmine are used to treat myasthenia gravis. The highly toxic nerve gases such as sarin are also cholinesterase inhibitors. Monoamine oxidases (MAOs) metabolize noradrenaline, dopamine, and serotonin. MAO inhibitors are used in the treatment of depression and Parkinson's disease (tranylcypromine and rasagiline, respectively). The GABA transporter is blocked by tiagabine, an antiepileptic that owes its effect to the ensuing increase of the concentration of GABA in the synaptic cleft. Cocaine is abused because it blocks the dopamine and serotonin transporters and, hence, enhances dopaminergic and serotoninergic transmission in the mesolimbic "reward system." Inhibitors of the serotonin (fluoxetine, citalopram, amitriptyline) and noradrenaline (amitriptyline) transporters are the main antidepressant drugs.

TGF-β signaling pathway; TGF-β/SMAD pathway (Transforming growth factor-beta receptor signaling pathway; TGF-beta receptor signaling pathway; TGF-β receptor/SMAD signaling pathway; TGF-beta signaling pathway; TGFβ pathway); Transforming growth factor-beta pathway

Definition

The transforming growth factor-beta (TGF-β) signaling pathway plays important roles in embryogenesis and tissue homeostasis, by controlling cell proliferation, differentiation and apoptosis, as well as cell migration and immune surveillance. A key step in the TGF-β pathway is the binding of secreted TGF-β ligand to TGF-β receptors at the cell surface that convey the signals via activation of intracellular SMAD transcription factors. The pleiotropic functions of TGF-β are highly dependent on cellular context; in diverse differentiation states and/or microenvironments they can have distinct, and even opposing, functions. Aberrant TGF-β signaling has been associated with multiple human diseases, including fibrosis, immune disorders, and cancer. In cancer, TGF-β can act both as a tumor suppressor in early stages of tumorigenesis, and as a tumor promoter in later stages. Altogether TGF-β is an attractive, but challenging, drug target due to its pleiotropic nature. Nevertheless, several drugs targeting the TGF-β pathway have been developed and are currently being tested in clinical trials.

Basic Characteristics

TGF-β Pathway

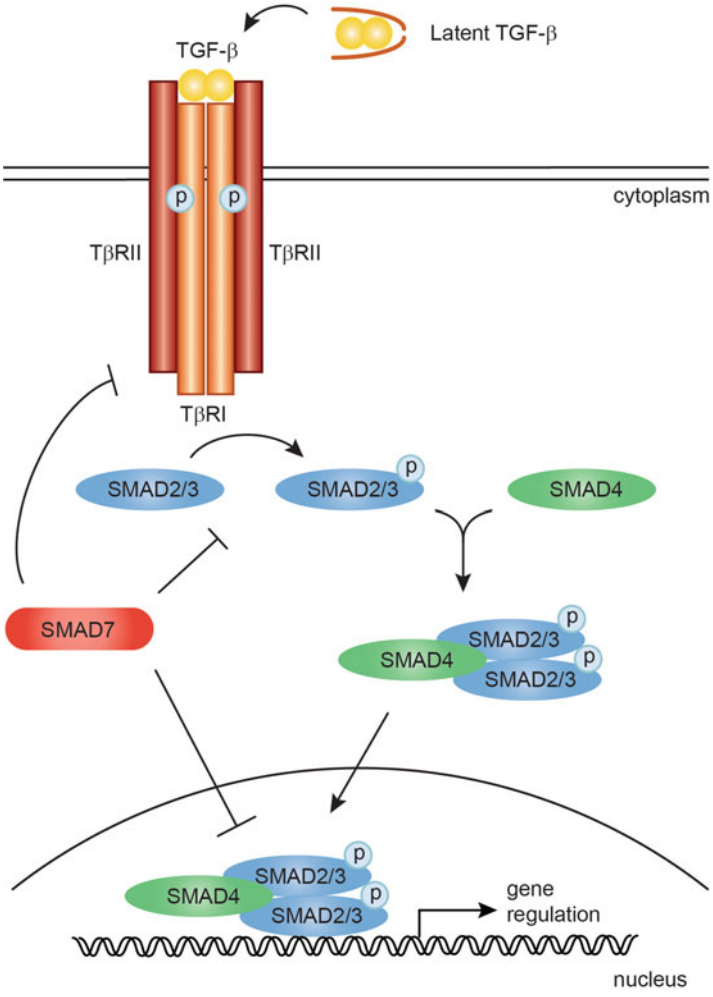
TGF-β1 is the prototypic member of a large family of structurally and functionally related proteins, which includes its close relatives TGF-β2 and TGF-β3 but also activins, nodal, inhibins, Mullerian-inhibiting substance (MIS), growth and differentiation factors (GDF), and bone morphogenetic proteins (BMPs) (Morikawa et al. 2016). Here we do not specify different TGF-β isoforms, and use TGF-β, unless a specific role was shown for a specific isoform.

TGF-β proteins are synthesized as larger precursor proteins consisting of a signal peptide, a pro-domain (which is called latency-associated polypeptide (LAP) for TGF-β) and the mature polypeptide. After the removal of the signal peptide the precursor is proteolytically processed, separating the pro-domain from the carboxy terminal mature polypeptide, which remain however, non-covalently associated (Derynck and Budi 2019). The activation of latent TGF-β occurs via specific proteases that cleave the LAP and/or by mechanical forces generated by cell-surface integrins, resulting in the release of mature, active TGF-β (Derynck and Budi 2019).

TGF-β induces cellular responses by binding to its cognate TGF-β type I and type II receptors (i.e., TβRI and TβRII). The basic structure of type I and II is similar, they both contain a cysteine-rich extracellular domain, a single transmembrane domain and an intracellular region harboring a serine/threonine kinase domain. TGF-β initially engages TβRII, which drives the recruitment of TβRI and the formation of a heteromeric receptor complex. Upon this complex formation, the constitutive active kinase domain of TβRII phosphorylates TβRI in its glycine-serine (GS) juxtamembrane region, leading to its activation. In turn, active TβRI then phosphorylates specific intracellular SMAD effector proteins (Derynck and Budi 2019; Heldin and Moustakas 2016). SMADs can act as transcription factor complexes that relay the extracellular TGF-β signal into the nucleus (Fig. 1).

Canonical TGF-β-SMAD Signaling

The SMAD family can be divided into three groups; (1) receptor-regulated (R-) SMADs (in vertebrates R-SMAD1,-2,-3,-5,-8) that interact with activated type I receptors and are subsequently phosphorylated, (2) the common (Co-) SMADs (in vertebrates SMAD4) that form heteromeric complexes with activated R-SMADs, and (3) inhibitory (I-) SMADs (in vertebrates I-SMAD6/7) which antagonize canonical SMAD signaling. The R- and Co-SMADs contain two conserved *Mad homology* (MH) domains, the



TGF-β Pathway, Fig. 1 Schematic overview of the canonical TGF-β/SMAD pathway. Upon activation, TGF-β induces heteromeric complex formation between TGF-β receptors type II and type I receptors (i.e., TβRII and TβRI). Constitutively active TβRII then (trans)phosphorylates TβRI, which in turn relays the signal to intracellular receptor regulated SMADs (R-SMAD) 2 and 3. The R-SMADs form heteromeric complexes with the common (Co-) SMAD4 and translocate to the nucleus, where they regulate transcription of target genes in collaboration with various cofactors. Inhibitory (I-) SMAD7, inhibits TGF-β signaling through multiple mechanisms, for instance by preventing SMAD2/3 phosphorylation or induction of receptor degradation. The non-SMAD signaling pathways that can be initiated downstream of TβRI are not indicated in the Figure. TGF-β; transforming growth factor-beta, TβR; TGF-β receptor

MH1 domain localizes to the N-terminal side and the M2 domain is located at the C-terminal side of these SMADs, which are connected by a flexible linker region. The MH1 domain of SMADs can bind to DNA, whereas the MH2 domain mediates SMAD heteromeric complex formation and receptor interaction. Heteromeric complex formation of R-SMADs with SMAD4 results in the exposure of nuclear import signals and shielding of nuclear export signals, thus inducing nuclear localization of these complexes. In the nucleus, heteromeric SMAD complexes can act as transcription factors together with other DNA binding transcriptional regulators, such as coactivators, repressors, and chromatin remodelers. This enables diverse transcriptional responses depending on the

combination of DNA binding and regulatory proteins (Derynck and Budi 2019; Massague 2012).

The I-SMADs can inhibit canonical SMAD signaling via multiple mechanisms, including by competing with R-SMADs for binding to activated receptors via their homologous MH2 domain, thereby preventing R-SMAD phosphorylation, or by binding to SMAD4, thereby preventing the interaction between SMAD4 and phosphorylated R-SMADs. Additionally, I-SMADs can recruit E3 ubiquitin ligases SMURF1 and SMURF2 to ubiquitinate activated type I receptors for subsequent proteasomal and lysosomal degradation. Moreover, I-SMADs can attenuate signaling by recruiting phosphatases to the activated TGF-β receptor, thereby mediating receptor inactivation via dephosphorylation of specific residues (Fig. 1) (Derynck and Budi 2019; Massague 2012).

Of note, the TGF-β canonical SMAD pathways can be divided into two branches, one is employed predominantly by TGF-β and activins and signals via R-SMAD2 and -3, the other branch is mainly used by BMPs and signals through R-SMAD1, -5, and -8. Mixed complexes between SMAD2/3 and SMAD1/5 have also been described. I-SMAD6 mainly antagonizes BMP pathways and I-SMAD7 inhibits TGF-β, activins and BMP pathways (Derynck and Budi 2019; Massague 2012). Here we focus on the TGF-β signaling pathway.

Non-SMAD Signaling

In addition to the canonical SMAD pathway, TGF-β family members can trigger so-called non-SMAD pathways to initiate a multitude of intracellular changes. This can either happen directly downstream of TGF-β receptors, or indirectly, for example, via TGF-β/SMAD-induced expression of growth factors, such as epidermal growth factor (EGF) or platelet-derived growth factor (PDGF) that subsequently initiate non-SMAD responses. Among the various non-SMAD signaling pathways that can be activated directly downstream of TGF-β receptors are p38, Jun N-terminal kinase (JNK) and Extracellular Signal-Regulated Kinase (ERK) mitogen-activated protein kinases (MAPK) pathways, phosphoinositide 3 kinase (PI3K)-AKT-mTOR, Janus Kinase/Signal Transducer and Activator of Transcription (JAK-STAT), tumor necrosis factor (TNF)-receptor associated factor 6 (TRAF6) – TGF-β activated kinase 1 (TAK1), nuclear factor kappa B (NF-κB), and the small Rho-like GTPase pathways. Of note, the activation level of these pathways downstream of TGF-β receptors occurs generally to a lower extent as compared to their natural growth factor/tyrosine kinase or cytokine pathways. Furthermore, extensive crosstalk exists between SMAD and non-SMAD pathways (Zhang 2017).

Physiological Roles of TGF-β Signaling

Almost 40 years of TGF-β research has revealed that cellular responses to TGF-β are different and sometimes even opposite, and strongly depend on the cellular context. For example, TGF-β can induce both cell growth and growth inhibition of the same cells depending on the cell culture conditions. TGF-β is a multifunctional cytokine regulating a large range of biological processes, both during embryogenesis and adult tissue homeostasis. Here, we discuss some of the key functions of TGF-β signaling in human physiology, such as regulation of cell proliferation and differentiation and TGF-β-mediated regulation of wound healing and the immune system.

TGF-β Mediates Regulation of Gene Expression

As described above, SMADs can bind directly or indirectly to DNA and thereby regulate gene expression. Several genes, such as *SERPIN1*, encoding plasminogen activator inhibitor protein (PAI-1), inhibitory *SMAD7*, and cyclin dependent kinase inhibitor *p21*, have been established as direct SMAD target genes that are generally and rapidly induced after TGF-β stimulation in many cell types. However, depending on the cofactors SMADs may either activate or repress gene expression. These cofactors, e.g., transcription factors and coregulators, act as DNA binding partners of SMADs for recognition of specific target genes. Importantly, the cofactors themselves are controlled by other (context dependent) signaling pathways. Also, cell-type or lineage-specific transcription factors are responsible for the induction of specific responses in certain cell

types. Additionally, canonical SMAD pathways can be complemented by TGF-β-induced non-SMAD pathways, adding another level of complexity. The combination of signaling crosstalk at multiple levels, together with differences in physiology of different cell types, provides a basis for the context dependency for TGF-β responses (Morikawa et al. 2016). Of note, in addition to protein-encoding genes, TGF-β also regulates expression of noncoding RNAs, such as microRNAs (miRNAs) and long noncoding RNAs (lncRNAs) (Hao et al. 2019).

TGF-β Controls Cell Proliferation and Differentiation

In most cell types, TGF-β has strong growth inhibitory effects, including epithelial, endothelial, and hematopoietic cells. This cytostatic effect happens mainly through two distinct mechanisms; (1) induction of cyclin-dependent kinase inhibitors, such as $p21^{cip1/waf1}$ and (2) elimination of proliferative drivers, such as c-myc. TGF-β ligands have also been suggested to inhibit cell growth indirectly by counteracting the activity of specific mitogens, such as EGF (Morikawa et al. 2016; Siegel and Massague 2003).

In contrast, TGF-β ligands have also been shown to induce proliferation of some cell types, including chondrocytes, osteoblasts, mesenchymal stem cells (MSCs), and fibroblasts under certain conditions. The effects are often context-dependent, as the same cells can undergo growth inhibition or promotion upon TGF-β. The underlying molecular mechanisms of TGF-β-induced growth promotion are largely undefined, and in some contexts, it was suggested to be a secondary effect to the induction of other cytokines, such as PDGF (Morikawa et al. 2016; Siegel and Massague 2003).

During development, TGF-β family members regulate the function of diverse cell types by regulating pluripotency and differentiation of embryonic stem cells (ESCs) and lineage-committed progenitors. BMP ligands, for example, stimulate ESC self-renewal, while TGF-β ligands are implicated in the differentiation of stem and pluripotent cells towards a wide variety of lineages, such as chondrocytes, immune, blood, and neuronal cells. TGF-β is a key regulator of stem-cell state and differentiation from the earliest stages of development to homeostasis of the adult organism (Mullen and Wrana 2017).

TGF-β Induces Epithelial-to-Mesenchymal Transition

Epithelial-to-mesenchymal transition (EMT) is a dynamic and multistep process by which epithelial cells lose their cell polarity and cell-cell adhesion, and gain migratory and invasive properties and become mesenchymal cells. EMT is a crucial morphogenetic event in gastrulation, embryonic tissue formation, and regeneration. TGF-β is a key driver of EMT and triggers this process in, for example, heart development and palate fusion. Furthermore, (partial) EMT due to the induction of increased cell motility contributes to tissue regeneration, e.g., wound healing as discussed below. Lastly, pathological versions of EMT triggered by TGF-β contribute to fibrosis and cancer, which is discussed in more detail in the next paragraph. EMT is characterized by down-regulation of E-cadherin and upregulation of N-cadherin and vimentin, these molecular changes are the cause of the observed polarity changes and loss of adherence. EMT is driven by an interactive network of transcriptional repressors, such as SNAIL, SLUG, and many others. TGF-β does not only induce EMT via its canonical signaling route, but often in collaboration with various other (non-SMAD) signaling cascades (e.g., ERK or Wnt signaling) (Hao et al. 2019).

TGF-β Regulates Wound Healing

TGF-β has been shown to control various steps in the wound healing process by regulating multiple cell types. In response to injury, TGF-β expression and activation is rapidly induced and platelets, crucial for wound healing, store large amounts of (latent) TGF-β, which are released at the site of injury. TGF-β is a chemoattractant and, in turn, recruits monocytes and fibroblasts to induce tissue repair. TGF-β also induces production and prevents degradation of various extracellular matrix (ECM) proteins, thus stimulating wound healing. Lastly, at the site of injury epithelial cells undergo TGF-β-induced (partial) EMT and the increased

motility contributes to epithelial wound healing. Cells then reacquire their epithelial phenotype. Combined, TGF-β is a strong contributor to tissue injury repair (Morikawa et al. 2016).

TGF-β Mediates Regulation of the Immune System

TGF-β has a crucial role in immune homeostasis, as illustrated by TGF-β1 knockout mice that suffer from lethal autoimmunity and inflammation and die at 2 or 3 weeks. TGF-β is a powerful immunosuppressant by regulating both cell differentiation and proliferation. It can regulate both innate and adaptive immune cell activities and has diverse effects on different immune cells. TGF-β has potent growth-suppressing activity on most precursor cells of the immune system, and specifically on T and B cells of the adaptive immune system. It is a strong suppressor of cytotoxic T cell proliferation and induces B cell apoptosis. TGF-β also suppresses Th1 and Th2 cell differentiation and stimulates suppressor Treg cells. Overall, TGF-β regulates various aspects of the immune system, mainly exhibiting an immune-suppressive response (Chen and Ten Dijke 2016).

Pathologies Resulting from Deregulated TGF-β Signaling

TGF-β holds crucial roles in various homeostatic processes as described above, and perturbation of this signaling cascade can therefore have catastrophic consequences and induce different diseases. Here, we describe the two most prominent examples of diseases where deregulated TGF-β holds a central role: fibrosis and cancer.

Fibrosis

Fibrosis is a pathological wound healing in which connective tissue replaces healthy parenchymal tissue leading to considerable tissue remodeling and the formation of permanent scar tissue. TGF-β is well-known as a key pro-fibrotic cytokine. Dysregulation and sustained activation of TGF-β signaling mediates both the initiation and progression of fibrosis in various tissues, such as lungs, kidneys, and heart. The pro-fibrotic effects of TGF-β signaling has mainly been attributed to TGF-β/SMAD3 signaling and involves a combination of mechanisms and cell types. For example, in idiopathic pulmonary fibrosis (IPF), TGF-β, that is secreted by alveolar epithelial cells, drives fibrosis by inducing the proliferation, migration, and differentiation of resident mesenchymal cells, resulting in scar tissue formation. Furthermore, TGF-β can promote the activation and differentiation of fibroblasts into myofibroblasts, specialized contractile cells that deposit aberrant extracellular matrix (ECM), which results in altered tissue architecture and thus reduced function. This occurs not only in lung fibrosis, but is especially apparent in cardiac fibrosis. Also, TGF-β-induced EMT plays a crucial role in the induction of fibrosis. For example, in renal fibrosis, TGF-β also mediates to the pathological process by inducing the transformation of tubular epithelial cells into myofibroblasts through EMT. This also occurs in IPF in a similar manner. Of note, endothelial cells have also been identified as a source of fibroblasts in fibrosis. For instance, in heart fibrosis approximately 30% of fibroblasts are estimated to originate from endothelial cells through so-called endothelial-mesenchymal transition (EndoMT). TGF-βs or activators of latent TGF-β, such as integrins, are often highly expressed in fibrotic regions. Altogether, localized excessive TGF-β signaling drives fibrosis via several distinct mechanisms (Hao et al. 2019; Morikawa et al. 2016; Massague 2012).

Cancer

TGF-β has a dual role in cancer and can act as both a tumor suppressor and a tumor promoter. In its tumor suppressive role, TGF-β can cause cell cycle arrest and exert growth inhibitory effects of premalignant cells. Moreover, it can induce apoptosis of these cells. Cancer cells often adapt to avoid these cytostatic effects by inactivating or deletion mutations of genes encoding key players of the TGF-β pathway. For instance, colorectal cancers often harbor *TβRII*, *SMAD2*, or *SMAD4* mutations, thereby rendering the cancer cells insensitive to TGF-β cytostatic effects (Colak and Ten Dijke 2017; Akhurst 2017).

On the other hand, however, elevated TGF-β expression and activity is frequently observed in

many cancers. Additionally, high TGF-β pathway activity has been correlated with tumor progression and poor prognosis, pointing towards a tumor supportive function of TGF-β. Indeed, TGF-β signaling exerts tumor promoting activities through direct effects on the cancer cells themselves and on the tumor microenvironment. First, TGF-β can promote tumorigenesis by inducing EMT by driving tumor cells towards a stem cell-like state, that is, characterized by increased expression of stem cell markers and enhanced tumor initiating capacity. EMT enables increased migration and invasion of cancer cells. These migratory and invasive mesenchymal-like tumor cells extravasate from primary lesions into blood (or lymphatic) vessels and subsequently extravasate at distant secondary sites where they can then form metastases upon undergoing mesenchymal-to-epithelial transition. Moreover, mesenchymal cancer cells are correlated with poor prognosis and associated with chemo- and immunotherapy resistance (Hao et al. 2019).

Angiogenesis, the process of formation of new blood vessels to supply tumors (both primary and metastases) with nutrients and oxygen, is also controlled by TGF-β. TGF-β secreted by tumor cells can bind TβRI on endothelial cells and induce a pro-angiogenic response. Furthermore, TGF-β is a potent inducer of vascular endothelial growth factor (VEGF) expression, thereby promoting angiogenesis as well. In addition, TGF-β can activate so called cancer associated fibroblasts (CAFs) that can contribute to increase cancer cell invasion and immunotherapy resistance. Interesting, failure to respond to immune check point inhibitors was found to be in certain cancer patients caused by overactivated CAFs that excluded cytotoxic T cells from reaching and killing cancer cells. Furthermore, TGF-β has potent direct immunosuppressive effects on both innate and adaptive immune cells, including natural killer cells and T lymphocytes, cells which can normally recognize and clear tumor cells. In addition to inhibiting the proliferation of T cells, it stimulates the differentiation of immune-suppressive regulatory T cells (Tregs) (Chen and Ten Dijke 2016; Colak and Ten Dijke 2017). In summary, TGF-β has a biphasic action in tumorigenesis as in early stages it suppresses tumorigenesis, while at later stages it promotes tumor progression.

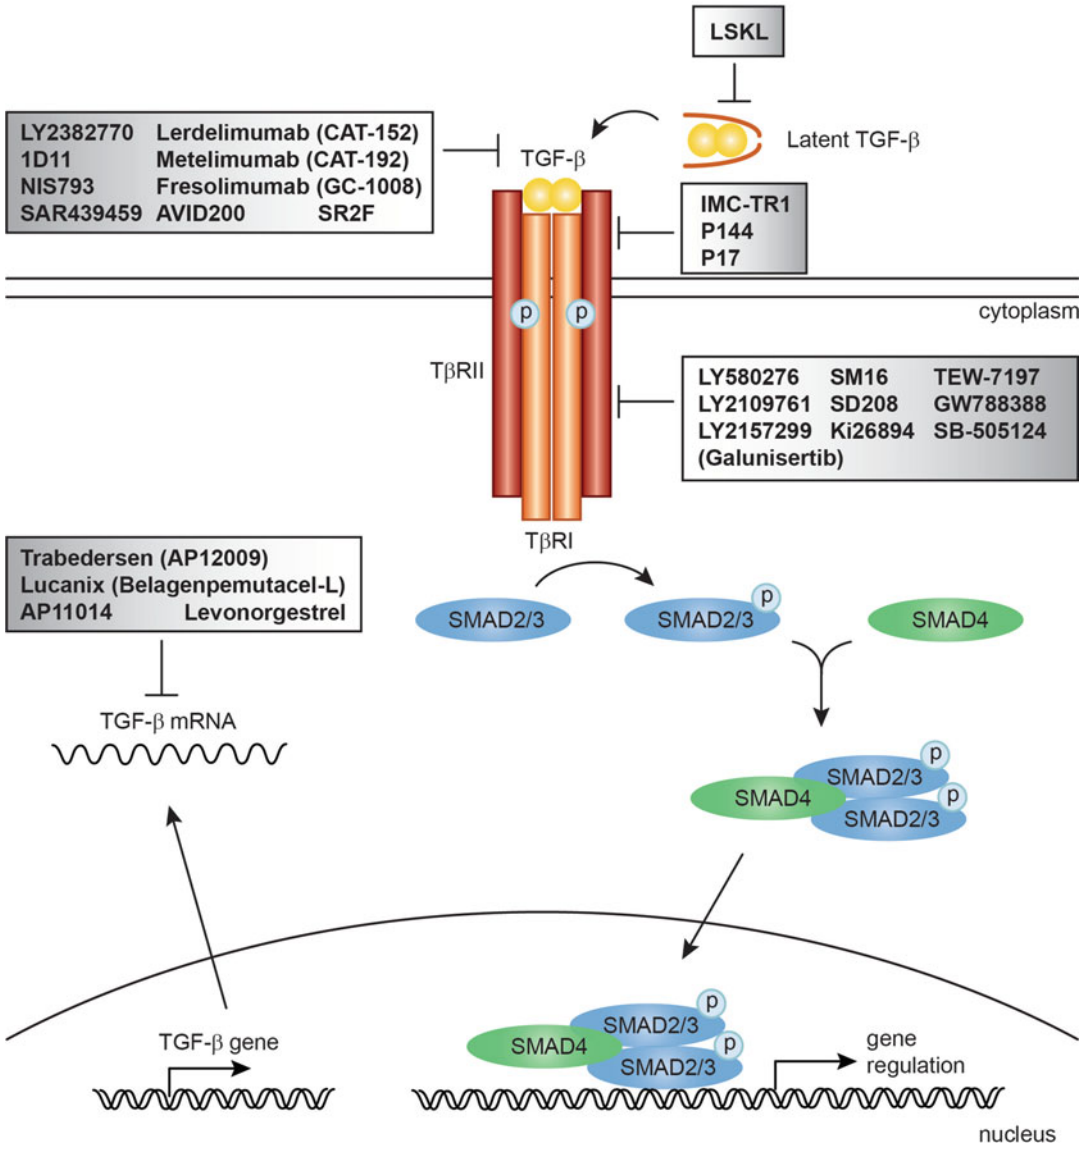
Drugs

Pharmacological Agents Targeting TGF-β Signaling

Pharmacological agents that target different components of the canonical TGF-β signaling pathway have been developed, including antisense oligonucleotides (AONs) that inhibit expression of TGF-β or TGF-β receptor, neutralizing antibodies against TGF-β or TβRII and receptor domain-immunoglobin fusions that interfere with ligand-receptor interactions, and receptor kinase inhibitors also known as small molecule inhibitors (SMIs) (Fig. 2; Table 1) (Akhurst 2017; Akhurst and Hata 2012; Colak and Ten Dijke 2017). The TβRI kinase inhibitors have been tested most extensively in (pre)clinical studies. The translation of anti-TGF-β therapy has been most intensively pursued in the area of oncology, but also for fibrosis and other diseases progress is made, illustrated for instance by the Europe approved drug pirfenidone to treat IPF (Akhurst and Hata 2012).

The number of preclinical examples of TGF-β inhibitors that reduce cancer progression and metastasis continues to increase. Moreover, an expanding number of studies is testing preclinical efficacy of targeting tumors with combinations of TGF-β blockade and cytotoxic drugs or immunotherapy, demonstrating promising combinations for novel treatment opportunities for various cancers (Akhurst 2017).

Because TGF-β inhibitors are not directly cytotoxic, their combined use with chemo-, radio-, or immune therapies gained extensive interest as this may be more efficacious. Several papers have shown the preclinical efficacy of targeting tumors with combinations of TGF-β blockade and cytotoxic drugs, such as doxorubicine or paclitaxel in breast cancer. Combining TGF-β inhibition with radiotherapy is another focus point, and TGF-β pathway inhibition was shown to sensitize glioma



TGF-β Pathway, Fig. 2 Schematic representation of TGF-β pathway blockade. TGF-β signaling can be inhibited in various manners; by antisense oligonucleotides (AONs) that inhibit expression of TGF-β or TGF-β receptor, neutralizing antibodies against TGF-β or TβRII and receptor domain-immunoglobin fusions that interfere with ligand-receptor interactions, and receptor kinase inhibitors also known as small molecule inhibitors (SMIs). TGF-β; transforming growth factor-beta, TβR; TGF-β receptor

cells to radiotherapy and enhance radiotherapy efficiency in breast cancer cells. Of note, radiation can cause fibrosis, which is itself a target for TGF-β therapy, so providing an added benefit of TGF-β inhibition. Also, the combination of TGF-β inhibitors and immunotherapy is suggested to improve the anti-tumor effect of immune cells, as TGF-β has immunosuppressive functions. TGF-β inhibition combined with PD-L1 inhibitor Atezolizumab was suggested to enable T cells to enter the interior of the tumor, illustrating benefits of combination therapies (Akhurst 2017; Colak and Ten Dijke 2017; Hao et al. 2019; Mariathasan et al. 2018).

TGF-β Pathway, Table 1 Summary of pharmacological agents targeting the TGF-β signaling pathway

Drug	Type	Target	Disease (application)	Phase	Clinical trial identifier	Status
Traberdersen (AP12009)	AON	TGF-β2	Glioblastoma and anaplastic astrocytoma	II	NCT00431561	Completed
			Glioblastoma and anaplastic astrocytoma	III	NCT00761280	Terminated
			Melanoma, pancreatic cancer and CRC	I	NCT00844064	Completed
Lucanix (Belagenpumatucel-L)	AON	TGF-β2	NSCLC		NCT00676507	Completed
			NSCLC		NCT01279798	No longer available
			NSCLC		NCT01058785	Completed

Some of the main concerns in TGF-β drug development are the inadvertent inhibition of the tumor-suppressive arm of TGF-β signaling in cancer and the development of adverse side effects, such as inflammation, autoimmunity, and cardiovascular defects, as discovered in several mouse studies. Clinical safety studies have now provided promising results and considered specific TGF-β blockers, e.g., Galunisertib or LY2157299, a SMI for TβRI kinase, relatively safe in humans, especially compared with cardiotoxicities of other standard chemotherapeutic anti-cancer drugs (Akhurst 2017; Kovacs et al. 2015). Other concerns are appearance of novel unrelated neoplasms, enhanced outgrowth of the primary tumor, and the awakening of dormant cancer cells in response to TGF-β signaling blockade. To date, no clinical report was published describing any of these adverse effects, yet it is important to note that this could be due to the focus on severely ill patients who might have not survived long enough to present these effects. Careful dosing and the use of drug holidays are crucial to avoid on- and off-target side effects of TGF-β therapies. Additionally, as there is considerable phenotypic diversity in the range of responses to decreased TGF-β signaling depending on genetic background, it is key to perform patient stratification and identify which patients will benefit the most from TGF-β therapies and to predict therapy responses. A simple and easy biomarker for patient selection in oncology could be high levels of circulating TGF-β. Phospho-SMAD2 levels or TGF-β target gene expression in ex-vivo cultured blood cells could be noninvasive biomarkers for prediction of patient responses to TGF-β inhibitors (Akhurst 2017; Akhurst and Hata 2012; Colak and Ten Dijke 2017).

The next stage in TGF-β pharmacology will be discovering the most efficacious drug combinations for each disease application and the right dosing regimens. Furthermore, investment to identify novel predictive biomarkers and patient selection criteria for TGF-β therapies is required.

Acknowledgments Our research on TGF-β signaling is supported by Cancer Genomics Center Netherlands (CGC.NL). M. S. is supported by a Dutch Cancer Society (KWF) fellowship (BUIT 2015-7526).

Definition

The term "trace amines" was introduced in 1970 (Boulton 1974) and related to amines, contrary to classical monoamines, having low endogenous concentrations (<100 nM). For a long time, trace amines were considered solely as "false neurotransmitters" modulating function of classical monoamines, such as dopamine and serotonin, via amphetamine-like action. It all changed with the discovery of G protein-coupled trace amine-associated receptors (TAARs) in 2001 (Borowsky et al. 2001; Bunzow et al. 2001).

Traditionally trace amines belong to by-products of amino acid metabolism – β-phenylethylamine (PEA), tyramine (TYR), octopamine (OCT), tryptamine (TRP), and p-synephrine. Later studies revealed much diverse group of endogenous agonists of one or more TAARs. Such compounds include the endogenous thyroid hormone metabolite 3-iodothyronamine (3IT); the catecholamine neurotransmitter metabolites 3-methoxytyramine (3-MT) and normetanephrine, trimethylamine, and isoamylamine; the polyamines putrescine and cadaverine; and possibly agmatine, spermine, and spermidine (Liberles and Buck 2006; Borowsky et al. 2001).

Basic Characteristics

Invertebrates

In invertebrates trace amines play a role of one of major neurotransmitters functioning as invertebrate versions of vertebrate adrenergic systems.

Tyramine and octopamine in invertebrates are not so "trace" as they can be found at high concentration. Invertebrates have also evolutionary distinct receptors – octopamine and tyramine receptors. Both types of receptors have several subtypes and all of them are GPCRs.

Octopamine in invertebrates acts analogous to vertebrate adrenaline system, both peripheral and in the brain: enhances locomotion, mobilizes fat stores, and increases cardiac rate and breathing. Apart from that octopamine regulates immune responses and sensory inputs and has effect on reproductive, feeding, aggressive behavior, learning, and memory. Tyramine action opposes action of octopamine, decreasing locomotion, flying, and foraging. It is also involved in regulation of sensory inputs (Roeder 2005).

Synthesis, Storage, Release, and Degradation

Trace amines are synthesized by decarboxylation of amino acids. β-Phenylethylamine (PEA), p-tyramine (TYR), and tryptamine (TRP) are produced by aromatic L-amino acid decarboxylase (L-AADC)-mediated decarboxylation of phenylalanine, tyrosine, and tryptophan, respectively. OCT and p-synephrine can subsequently be formed by the sequential action of dopamine-b-hydroxylase and phenyl-ethanolamine-N-methyl transferase. Trace amine can also undergo N-methylation forming additional TAAR ligands (Gainetdinov et al. 2018).

Gut microbiota can also be another source of trace amines. Prokaryotes have a large array of decarboxylase enzymes and therefore can synthesize trace amines. With TAARs established to be present throughout the body, it is expected that the role of trace amines and their receptors in mediating host-microbiota interactions will become a growing area of interest.

Ability of prokaryotes to synthesize trace amines brings to us another source – food – that underwent anaerobic fermentation process. Aged cheeses, fermented meats, red wine, soy products, and chocolate are well established as being enriched in one or more of PEA, TYR, and TRP. Another rich source of food-derived trace amines is seafood, from mollusks and crustaceans to fish. In normal conditions consumption of trace amine-rich food does not result in sufficient concentration for receptor activation, but in some cases such possibility should be considered.

Unlike classical neurotransmitters, trace amines appear not to be stored in vesicles. It has been shown that PEA, TYR, and TRP can pass through lipid bilayer. K^+-induced depolarization does not affect trace amine release, and that also strongly suggests that trace amines are not stored in synaptic vesicles and their release is actually a diffusion through membrane. However, some data suggests that there should be regulation of trace amine synaptic levels by transporters. The possible candidate for that is organic cation transporter 2 (OCT2).

The degradation of trace amines mainly occurs by monoamine oxidase. Genetic deficiency in MAO can result in sufficient increase in trace amine levels. There is also well-known "cheese syndrome" in patients treated with MAO inhibitors that could be due to indirect elevation of blood norepinephrine resulting in hypertension, migraine, and even death.

Another way of degradation is via cytochrome P450 pathway.

Involvement in Disorders

Trace amines were for a long time implicated in various human disorders (Gainetdinov et al. 2018). In patients with depression, decreased levels of PEA were found. Other disorders that trace amines are suggested to be involved in are migraine, cluster headache, anxiety disorders, and epilepsy (Berry 2007). There are several studies showing possible involvement of trace amines in schizophrenia. Elevated levels of PEA were shown in urine of schizophrenia patients. Multiple studies have shown an association of schizophrenia with key enzymes involved in the synthesis and degradation of trace amines, particularly aromatic L-amino acid decarboxylase (AADC) and catechol-O-methyl transferase. Also, a decrease in postmortem schizophrenia brain tissue of AADC-positive neurons that have no tyrosine hydroxylase was observed. In Parkinson disease patients after chronic treatment of L-DOPA, the level of TAAR1 agonist 3-MT was elevated that may be

relevant to the development of L-DOPA-induced dyskinesia.

Mechanisms of Action

The mechanisms of trace amine action on brain neurochemistry actually started long before TAARs were discovered. It was shown that application of PEA does not alter basic neuronal activity but influences response on activation of dopamine and norepinephrine, therefore acting as a modulator of activity of other neurotransmitter systems.

PEA was considered to be an "endogenous amphetamine." Indeed, application of high doses of PEA (and TYR also) causes amphetamine-like behavioral stereotypy. Mechanism of that action likely involves amphetamine-like dopamine transporter-mediated elevation of dopamine extracellular levels. Indeed, rapid, short-acting effects of PEA on extracellular dopamine levels were absent, and corresponding locomotor activation and stereotypy were not observed, if the dopamine transporter (DAT) was knocked out. It was observed also that PEA can exert a paradoxical calming effect in hyperactive mice without DAT similar to amphetamine, suggesting similar action on serotonin system to counteract dopamine-mediated hyperactivity. Chronic elevation of PEA also induces downregulation of dopamine D1 receptor, but not D2-like receptors.

TYR has similar effects to PEA: TYR is able to potentiate neuronal responses of dopamine and norepinephrine. No effect of TYR was seen on responses to GABA, glutamate, or serotonin. On the periphery, PEA and TYR were shown to be released from activated platelets being possible mechanism of TAAR-mediated chemotactic responses of leukocytes. TRP action differs from PEA and TYR. TRP is able to promote serotonin inhibitory effects, whereas excitatory responses were either unaltered or ever reversed for inhibitory.

Receptors

Trace amine-associated receptors (TAARs) were initially discovered in 2001 by two separate scientific groups (Borowsky et al. 2001; Bunzow et al. 2001). The new family of receptors was identified for their high affinity to PEA and TYR. At first there was no consistency in nomenclature of receptors. These receptors were identified as TA, TAR, TRAR, or GPR. Not only different nomenclatures were used, but also isoform identification was various resulting in different numbering of same receptors depending on nomenclature system. In 2005, the nomenclature was standardized based on gene sequencing, phylogenetic relationships, and chromosomal organization and these receptors were renamed as TAARs (Lindemann and Hoener 2005).

It is thought that evolutionary TAAR-like proteins first appeared in lamprey, getting conservative TAAR pattern later in evolution, after divergence of jawed vertebrates from jawless fish. Mammal TAARs generally are divided into nine subfamilies (TAAR1–TAAR9). The largest number of TAAR receptor subtypes is found in flying foxes having 26 functional genes. The only known vertebrate species having no TAAR receptors are bottlenose dolphin. Humans have six identified TAAR receptors – TAAR1, TAAR2, TAAR5, TAAR6, TAAR8, and TAAR9. All TAAR receptors, except TAAR2, have one exon. TAAR2 receptors have two exons.

All TAAR are G protein-coupled receptors (GPCRs). Single specific endogenous ligand is not identified for each of the receptor. However, some preferable ligand can be identified. TAAR1–TAAR4 are more potent for primary amines and TAAR5–TAAR9 for tertiary amines. Some (TAAR6 and TAAR8) can even be activated by diamines.

In 2006, TAARs were found in the mammalian olfactory epithelium and showed to be a new class of olfactory receptors sensing innate odors encoded by volatile amines. Moreover, it has been postulated that all TAAR receptors, with exception of TAAR1, are only olfactory and are not present in other cells (Liberles and Buck 2006). Later it has been recognized that not only TAAR1 but other TAARs are also expressed in the body and the brain (Gainetdinov et al. 2018). However, their low expression level and lack of specific ligands make them difficult to study.

TAAR1

TAAR1 is the best characterized receptor among all TAARs. As all TAARs, TAAR1 is a GPCR receptor. It is coupled to Gs proteins, and activation of TAAR1 results in increase of cAMP level (Grandy 2007). There is some evidence that TAAR1 is present both pre- and postsynaptically in neurons. Apart from neurons, expression of TAAR1 was found in astrocytes. TAAR1 is expressed in several brain regions: ventral tegmental area, substantia nigra, dorsal raphe nucleus, amygdala, rhinal cortices, subiculum, prefrontal cortex, nucleus accumbens, hypothalamus, preoptic area, spinal trigeminal nucleus, medullary reticular nucleus, nucleus of the solitary tract, and area postrema (Gainetdinov et al. 2018). Endogenous agonist with high affinity includes PEA, TYR, TRP, OCT, dopamine metabolite 3-MT, and thyroid hormone metabolite 3-iodothyronamine (3IT). Dopamine and serotonin show partial agonism at high but physiologically relevant concentrations (Lindemann and Hoener 2005).

Known to be expressed in regions with dopamine neurons, TAAR1 is considered to be a potent modulator of dopamine system (Lindemann and Hoener 2008). Application of TAAR1 agonists decreases firing frequency of dopamine neurons in the VTA. Consistent with that, deletion of TAAR1 receptors in knockout animals results in increased firing rate of DA neurons in VTA. TAAR1 knockout mice have increased extracellular dopamine level in the nucleus accumbens showed by microdialysis. Agonists and antagonists show corresponding changes in evoked dopamine release that is present only in WT and not in TAAR1-KO mice. However, no difference in dopamine uptake rate was noticed. It seems unlikely that TAAR1-mediated effects occur by regulation of dopamine transporter function, but rather via D2R-mediated mechanism. Indeed, TAAR1 can physically interact with D2 receptor postsynaptic long isoform forming heterodimers. TAAR1 knockout animals have increased expression of D2R, but not D1R, and show supersensitivity of D2 receptors. TAAR1 is also able to transduce the signal via beta-arrestin2 cascade via TAAR1-D2R interaction. TAAR1 normally poorly interacts with beta-arrestin2, whereas TAAR1-D2R heterodimerization significantly increases interaction that results in decrease of GSK3β activation.

TAAR1 receptors are also expressed in serotonergic neurons. TAAR1 agonist inhibits firing rate of serotonin neurons, and lack of TAAR1 in knockout mice results in opposite effect. Overexpression of TAAR1 in mice results in higher level of extracellular serotonin in medial prefrontal cortex. The molecular mechanisms of these effects are not yet understood, but it could be suggested that they are similar to mechanisms involved in dopamine system regulation.

It is also suggested that TAAR1 can regulate glutamatergic transmission. TAAR1 knockout mice have altered glutamate transmission – patch clamp methods revealed deficient NMDA receptor function in prefrontal cortex, together with decrease in the expression of the GluN1 and GluN2B subunits.

Ability to modulate dopamine, serotonin, and glutamate transmission makes TAAR1 a perspective target for the treatment of schizophrenia, mood disorders, narcolepsy, and addiction. TAAR1 variants were reported to be associated with schizophrenia. Preclinical testing indicates that TAAR1 agonists potentially can be used to treat schizophrenia, being able to normalize both dopamine hyper-active and glutamate hypo-responsive circuitry. Schizophrenia is also known to be characterized by development of cognitive symptoms. TAAR1 agonists showed their ability to normalize cognitive deficit. TAAR1 agonists show also some potential antidepressant-like properties together with antipsychotic activity profile. TAAR1 partial agonist has shown to have generalized increase of wakefulness, decreased latency to sleep, and decreased and lighter NREM sleep.

There is growing amount of evidence that TAAR1 agonists can be used in treatment of substance dependence. TAAR1 agonist can prevent the rewarding, pleasurable effects of psychostimulant compounds and decrease craving and drug-seeking behavior. Another application of TAAR1 agonists is related to their abilities

to influence reward system – treatment of feeding behavior disorders. Indeed, it has been shown that TAAR1 agonists can be beneficial in controlling compulsive overeating. TAAR1 agonists decreased food intake in diet-induced obese mice, resulting in weight loss and improved insulin sensitivity. Influence of TAAR1 on feeding behavior is even more evident as TAAR1 is expressed in periphery in the stomach, neuroendocrine cells of the intestine, and beta-cells of the pancreas. Activation of TAAR1 increases glucose-stimulated insulin secretion. As the effect on insulin secretion was observed only at elevated glucose concentrations, reducing the risk of hyperglycemia, TAAR1 agonists have the potential to become novel treatment agents for diabetes. TAAR1 receptors were found also in various populations of leukocytes with shown increase in TAAR1 level after leukocyte activation.

Other Receptors

Other receptors are less studied than TAAR1, and not much information about them is yet available. But what is certain that other TAAR receptors should not be considered only as olfactory as their expression was shown in other areas, including the brain.

For now, TAAR2 expression is shown in lymphocytes and in duodenal mucosal cells of the gastrointestinal system; however it could be suggested that further studies can identify TAAR2 expression also in other areas. Defunctionalizing single nucleotide mutation of TAAR2 is found in 10% of population. It was shown that this mutation is more frequent in patients with schizophrenia; however this data was shown on a small population which is still a matter of discussion, as it was not replicated so far. No information about TAAR2 function is yet known.

TAAR3 and TAAR4 are not expressed in humans and are present only as pseudogenes.

TAAR5 mRNA has also been reported in several mouse brain regions such as the amygdala, arcuate nucleus, and ventromedial hypothalamus, with an overlapping localization of TAAR1 and TAAR5 in the amygdala and ventromedial hypothalamus.

TAAR5 has been also reported to be expressed in various leukocyte populations, the spinal cord, the intestines, and the testes (Gainetdinov et al. 2018).

TAAR6 is predicted to be activated by tertiary amines and/or diamines. TAAR6 was found to be expressed in several brain regions: basal ganglia, amygdala, hippocampus, frontal cortex, and substantia nigra. There is no information yet about TAAR6 function, but there are several studies showing single nucleotide mutations and other genetic variations in patients with schizophrenia and affective disorders.

TAAR6 expression was also found in the spinal cord, but only in rats and not in humans. TAAR6 was also found in several other organs: the intestines, testes, kidney, and leukocyte cells (Gainetdinov et al. 2018).

TAAR7 is a pseudogene in humans but has representation in other mammals: in fact, mice have 15 functional TAAR receptors and one pseudogene, and rats have 17 functional receptors and two pseudogenes (Borowsky et al. 2001).

TAAR8 expression was found in the amygdala, cerebellum, cortex, and spinal cord. Outside nervous system, TAAR8 is found in the islets of Langerhans, intestines, spleen, testes, heart, lungs, kidney, and leukocytes. Like TAAR6, TAAR8 is predicted to be activated by diamines. So far, no information about TAAR8 function is known.

TAAR9 expression was found in the leukocytes, pituitary gland, skeletal muscles, spinal cord, intestines, spleen, and kidney. Loss of function mutation in the TAAR9 gene was shown in up to 20% of human population; however so far, no relevance to any disorder was identified.

TAAR Receptors in Olfaction

TAAR2–TAAR9 receptors are found in the olfactory epithelium, but not in the vomeronasal organ. TAARs serve to detect social or ecological relevant innate cues. TAAR5 has been suggested to be activated by trimethylamine that was proposed to be mouse pheromone. Trimethylamine is present in much higher concentration in male mice urine (compared to female mice urine) and can activate sex-specific behavior (Liberles and Buck 2006).

In rats and humans, smell of trimethylamine has aversive action.

TAARs are also thought to be involved in avoidance reaction for rotting food source (rarely attraction). TAAR6 and TAAR8 are predicted to be responsive for that reaction. Cadaverine and putrescine, substances that are thought to be responsive for "rotten" smell, are suggested to be agonist of these two receptors.

Drugs

Studies showed that a broad number of substances, including psychotropic agents, have high activity agonism at TAAR1. However, ability of such substances to activate TAAR1 differs by species, for example, endogenous hallucinogen N,N-dimethyltryptamine (DMT) and lysergic acid (LSD) show limited activity in human isoform. Also, TAAR1 can be activated by beta-adrenergic agonist ractopamine and dopaminergic agonist apomorphine. A number of TAAR1 full and partial agonists were developed, like RO5263397, RO5166017 (full agonists), and RO5203648 (partial agonist). A mixed 5-HT 1A/TAAR1 agonist was developed by Sunovion Pharmaceuticals and currently being tested clinically in patients of schizophrenia with very promising results (Berry et al. 2017; Gainetdinov et al. 2018).

One putative non-selective TAAR5 agonist was described – 2-(a-naphthoyl)-ethyltrimethylammonium iodide (alpha-NETA) (Belov et al. 2019). The data obtained with alpha-NETA suggests that TAAR5 receptors can be a novel molecular locus for several conditions seen in schizophrenia: sensory gating deficits, cognitive paradigm known to be reflective of schizophrenia-related cognitive deficits. This hypothesis is supported by the fact that injection of alpha-NETA modulated dopamine transmission in the brain.

Conclusion

There are many gaps in our knowledge about trace amine system yet. Only for TAAR1 receptors there is some information on its action in the brain. The discovery of TAARs is not only unraveling new modulatory system in the brain but might bring also a host of new therapeutic target for treatment of various human disorders, from schizophrenia to diabetes.

Chromatin remodeling; Hormonal regulation of transcription; Transcription factors

Definition

Transcriptional regulation encompasses the modulation of the synthesis rate of mRNA due to cell-type-specific factors that may be triggered by external stimuli.

Basic Mechanisms

Background

Frequently prescribed drugs lead to alterations of gene expression in cells, often in a cell-type-specific manner, which are decisive for drug action. For example, cortisol and its synthetic derivatives, a frequently prescribed drug for acute and chronic inflammation, have very specific actions in different types of cells, leading to its potent anti-inflammatory effects and – unfortunately – to its devastating side effects, including atrophies of tissues, fat redistribution, and diabetes.

We will consider the nature of transcriptional regulation in general and will refer to the specific example of the response to cortisol, because much of has been learned about the dynamics of genome-wide transcriptional regulation in response to this hormone.

Gene regulation links a cell-type-specific cellular response to external stimuli, which is predominantly coordinated in the nucleus. Cells must be able to respond to a variety of different conditions, exerted by hormones, cytokines, pathogens, and drugs, all acting on cells out of the extracellular environment. Similarly, cells must also respond to cues from within the cells themselves, for example, to nutrient or oxygen deprivation. To receive an external or internal stimulus, cells must possess sensors (receptors). To allow a cell-type-specific response, they have, in addition, so-called lineage-specific transcriptional regulators that are either unique for a certain cell type or are present in a cell-type-specific combination of factors. Together with the stimuli receiving receptors and their signal transduction, the transcription factors integrate a cell-type-specific gene regulatory response. This leads to the unique gene expression signature that regulates a subset of the approximately 22,000 protein-coding genes present in every cell.

Cortisol-regulated transcription is an excellent example of such cell-type specificity. Cortisol causes in macrophages a transcriptional response that leads to an anti-inflammatory activity of macrophages, dampening inflammation and inducing repair processes. On the other hand, cortisol stimulates adipocytes (fat cells) to proliferate, differentiate, and enhance lipolysis and by this contribute to the metabolic side effects of steroid therapy including fat redistribution and insulin resistance, eventually leading to diabetes. Thus, very different genes are regulated by cortisol in macrophages in comparison to those regulated by cortisol in fat cells.

Gene regulation occurs on several levels, including regulation of transcription, regulation of mRNA splicing and alternative splicing, regulation of mRNA stability by microRNAs and other mechanisms, and protein stability.

Cell-type-specific regulation of transcriptional initiation is the best investigated and understood, and some researchers consider this the main regulatory step of gene regulation.

Transcription Initiation

Transcription of protein-coding genes is performed by RNA-polymerase II (RNApol-II). It synthesizes mRNA from genes. The genes carry a transcriptional start site (TSS) which the RNApol-II must find. Because genes are packed in chromatin, the process of finding the TSS requires specific opening steps that depend on the integration of intracellular signals. These are elicited by activated transcription factors and already expressed cell-type-specific and lineage-specific transcription factors (to be described in paragraphs "Enhancers" and "Epigenetic Regulation" below). The TSSs are located 5′ upstream of the coding region of the DNA. The TSS is part of the, so-called, *promoter* (see below). Often, but not exclusively, this DNA region comprises a TATA box (T/A-rich sequence) preceding the TSS. RNApol-II binds this site with the help of general transcription factors such as TATA binding protein (TBP), along with other co-factors. For binding and subsequent transcription, a large complex of proteins is assembled at the promoter, in a hierarchical manner. TBP-associated factors (TAFs) function in this assembly. TAFII250 (TAF, associated with RNApol-II, 250 kDa molecular weight) catalyzes the formation of other essential elements of the transcriptional initiation machinery: TFIID along with TAFs and TBP bind the TATA box upstream of the TSS. Together, a large assembly of numerous factors together with RNApol-II is formed at the transcriptional start site. It is now called **the initiation complex**. In a manner similar to DNA replication, a DNA helicase is necessary to open the double helix and allow cognate RNA molecules to bind to the DNA. Eventually, RNApol-II is released from the other components of the initiation complex and proceeds to synthesize nascent RNA. To summarize, the precise binding of RNApol-II to the start site requires numerous helper components whose association with RNApol-II must then be disrupted for the enzymatic action to start (Haberle and Stark 2018).

After start of transcription, RNApol-II frequently pauses, stopping the synthesis of RNA and a step that is also subject to regulation. The pausing was discovered by a method which permits to localize RNApol-II on genes in the process of transcription. Using chromatin immunoprecipitation (ChIP) followed by either microarray analysis or next-generation sequencing of the DNA precipitated, the RNApol-II location could be determined. These data revealed that RNApol-II occupancy on a gene does not always correlate with mRNA synthesis. Thus, it became clear that the RNApol-II action can be regulated by recruitment to the gene but also by the starting or pausing during the elongation process. As with initiation, the pausing process is regulated by phosphorylation.

After start of elongation, the TSS is cleared of RNApol-II, important to permit restart by a subsequent new initiation complex. Also paused RNApol-II molecules block transcription, in that prior to release of the pause, subsequent RNApol-II molecules cannot initiate transcription. Arrested RNApol-II thus causes turnoff of transcription. It is yet not clear how to explain the results of recent analyses which identified "bursts" of transcription, the synthesis of large amounts of mRNA, which is then followed by immediate turnoff. These findings add to the complexity of gene regulation. However, the physiological relevance of transcriptional bursts is still not fully understood (Core and Lis 2008).

The initiation of specific gene transcription in response to external stimuli is a complex interplay between transcription factors and specific DNA sequences: the promoters and enhancers.

How is it now ensured that cortisol induces in macrophages and in adipocytes the transcription of different sets of genes leading to cell-type-specific responses? One key feature is cell-type-specific opening of the chromatin accomplished by lineage-specific pioneering transcription

factors which mediate the accessibility of hormone-inducible enhancers and promoters (Zaret and Carroll 2011).

Promoters

The promoter is defined as a DNA sequence that regulates the initiation of transcription, usually located at short distance upstream of the TSS. A general eukaryotic promoter can be broken down into three main parts, the core promoter, the proximal sequences, and distal sequences. The core promoter, which is the site of RNApol-II binding, comprises the TATA box and the TSS. The core promoter consists of many DNA motifs, namely, specific DNA sequences (often called consensus motifs) that interact with specific factors. For example, the TATAWAWR motif binds TBP. Mutagenesis experiments in fruit flies have demonstrated that specific motifs define the assembly of the different components of the transcription initiation complex. Single nucleotide exchanges in these motifs prevent transcription. The proximal promoter 5′ upstream of the core promoter houses regulatory sequences which can be bound by transcription factors which modify the activity of or binding of RNApol-II.

Core promoters have been classified according to nucleosome positions and functional roles. The type of core promoter relevant here for cell-type-specific genes is called "sharp." Sharply defined TATA-dependent promoters are often tightly regulated in response to specific stimuli, also linked to transcriptional bursting, whereby transcriptional activity is turned on quickly, a lot of mRNA is produced, and then turned off immediately after the activation stimulus.

Proximal sequences of the promoter contain regulatory sequences with transcription factor binding sites that are similar to those than enhancers, with the difference that they are still close to the core promoter up to 250 base pairs. Distal sequences contain further regulatory sequences (Haberle and Stark 2018; Lenhard et al. 2012).

Enhancers

Enhancers are DNA sequences required to increase (or decrease) transcriptional rates of their regulated genes. While promoters are found in the vicinity of the TSS acting in *cis* on a given gene, enhancers can be found near or far from, upstream or downstream, or even within the sequence of the gene they regulate. They may even act in *trans*, i.e., affecting gene expression on other chromosomes. The action of an enhancer is mediated by regulatory factors binding to the enhancer DNA sequence. The location close to, or far from the promoter does not affect the stimulatory strength of the enhancer, i.e., a distant enhancer is not necessarily less potent than an enhancer close to the promoter.

Enhancers carry short DNA sequences, sequence motifs to which transcription factors and co-regulators bind. Enhancers may contain multiple such short sequences, which can function independently when cloned and tested in vitro, but when combined bind several specific transcription factors whose action defines a specific gene expression signature for their target gene (Long et al. 2016).

For instance, the enhancer sequence motif for the cortisol-induced transcription factor that elicits so many differential cell-type-specific responses is ACAnnnTGT. To this sequence motif, a dimer of the transcription factor GR ("glucocorticoid receptor") binds if associated and activated by its ligand cortisol. The symmetry of the sequence motifs favors often the interaction with transcription factor dimers. Proteins make contact with DNA through either one of four different DNA amino acid sequences which form specific three-dimensional structures: basic helix-loop-helix, helix-turn-helix, leucine zippers, and zinc (Zn) finger motifs. They all have in common that they make specific contacts to bases in the DNA, e.g., in the major groove of DNA. Often, they are also involved in the dimerization of the transcription factors. In our example of the cortisol-bound receptor, this DNA binding amino acid motif is represented by two zinc fingers. Fingerlike are stabilized by a Zn^{2+} ion that is complexed by cystidine and histidine residues. The amino-terminal Zn finger contacts the major groove of the DNA, whereas the carboxy-terminal Zn Finger stabilizes a dimerization interface that allows dimerization with the second GR molecule (Vandevyver et al. 2014).

One may think that identifying enhancers in the genome via such DNA sequence motifs should be trivial. This is however not the case. The motifs do not tell whether they are within active enhancers. Many enhancer-like sequences found in the genome may not exert any activity, and some are only active in one cell type, but not in another. Complicating the definition of an enhancer motif is variation recognized by a given transcription factor. Certain nucleotide positions can be changed without affecting the interaction.

The chromatin structure determines the functional activity of an enhancer. This is particularly evident in enhancers that respond to inducers such as cortisol. The chromatin must first be opened for the GR. This depends on the repertoire of lineage-specific transcription factors that bind in close proximity to the GR enhancer motif ACAnnnTGT.

In adipocytes members of the CCAAT/enhancer binding proteins (C/EBP) transcription factor family and the decisive lineage transcription factor peroxisome proliferator-activated receptor gamma (PPARγ) perform the chromatin opening. In macrophages, for instance, Pu.1 fulfils this function. These factors are considered as "pioneering factors" because they often precede the binding of the inducible transcription factors such as the GR. The pioneering factors assist the binding of the inducible factors leading to so-called hot spots of transcription factor binding characteristic for certain cell types. The combined binding forces the chromatin to be opened and catalyzes access for the promoter transcription initiation complex and thus enables transcription (Farmer 2006; Greulich et al. 2016).

Chromatin opening results in regions of DNA that are extremely sensitive to experimental digestion with the DNA-cutting enzyme, DNase. They are known as DNase hypersensitivity sites. Open chromatin is assumed to indicate sites of high regulatory and transcriptional activity. However, within these sites of DNA that are easily cut, it is possible to find small regions of protected DNA cut less often by DNase. These are known as "footprints," locations bound by transcription factors and protecting the DNA from being digested. Experimenters can then, by assessing the sequence not digested, predict which transcription factor is likely to be bound, by comparing the protected sequence to the known consensus sequences to which the transcription factors are known to bind (Zaret and Carroll 2011).

Intriguingly the occupancy of enhancers by transcription factors is not static, rather highly dynamic with rapid on and off rates. Approaches using fluorescence lifetime microscopy have shown that transcription factors are resident on DNA only for fractions of a second, before moving on to another site. The functional correlation of residence time of transcription factors with chromatin remodeling and initiation of transcription is still far from being understood (Liu and Tjian 2018).

Chromatin remodeling, i.e., the dynamic opening and closure and thus access of DNA for transcription factors, is regulated by epigenetic mechanisms.

Epigenetic Regulation of Transcription

The chromatin architecture determines when and where a transcription factor and RNApol-II can bind to DNA. In eukaryotes, DNA is tightly wound around so-called nucleosomes which consist of proteins called histones. The nucleosome core is formed by a histone octamer, consisting of the proteins H2A, H2B, H3, and H4 all in duplicate. The DNA is then wrapped around this core, with the DNA-associated histone H1 linking individual nucleosomes. This winding of the DNA makes it relatively inaccessible to transcription factors and polymerases. In addition, the chromatin strings (chains of nucleosomes) are ordered into complex higher structures by winding around themselves. The degree of packaging is regulated by various posttranslational modifications of the histones. These modifications can increase or decrease access for transcription factors and RNApol-II to the DNA. The study of histone and DNA modifications not associated with changes in DNA sequence is known as epigenetics. Unlike the fixed inherited genetic code, histone modifications are under control of regulatory stimuli to cells.

The different chromatin-modifying enzymes can be roughly divided into three formal categories: **readers**, **writers**, and **erasers,** classified by their principal molecular action. Readers recognize

epigenetically modified chromatin, writers add modifications, and erasers remove them. The recruitment to specific chromatin locations is mainly catalyzed by the transactivation functions of enhancer- or promoter-bound transcription factors and is therefore often designated as co-regulators.

Writers, for example, are the histone acetyltransferases (HATs) and histone methyltransferases (HMTs), enzymes which catalyze the addition of an acetyl group or a methyl group, respectively, to lysine residues of histone proteins.

One common co-regulator with HAT activity is the protein EP300. Because EP300 is often involved in inducing transcription, it is also designated as a co-activator. EP300 is recruited to the DNA by many different transcription factors, such as RELA (part of the inflammatory NFκB complex, e.g., in macrophages), PPARγ (a nuclear receptor involved in lipid storage in adipocytes), and the GR, the target of cortisol. These different transcription factors with extremely different physiological roles all recruit EP300 to their binding sites at enhancers or promoters and utilize the HAT activity of EP300 to relax the nucleosomal structure, in order to promote transcriptional activity.

Histone methyltransferases (HMTs), the second example belonging to the category of writers, on the other hand, play almost a role opposite to HATs, at least in general. HMTs catalyze the addition of mono-, di-, or even trimethyl modifications to histone lysine residues, which are involved in silencing of gene expression due to contraction of the chromatin structure (Calo and Wysocka 2013).

Erasers remove modifications. Histone deacetylases (HDACs) remove acetyl groups, while histone demethylases remove methyl groups. Because small-molecule inhibitors inhibit selectively individual HDACs, it has been recognized that each HDAC exerts specific functions. Such studies have revealed that HDACs interact with different preferred partners and regulate different genes.

Histone demethylases (HDMs) are less well characterized than HDACs, but nonetheless, research has identified important roles of these enzymes in physiology. Methyl groups from lysine residues are removed by two major classes of demethylases, flavin adenine dinucleotide (FAD)-dependent amine oxidases, and Fe(II) and α-ketoglutarate-dependent hydroxylases. These enzymes utilize and create elements of the Krebs cycle during their activity and thus link chromatin modification and modulation of transcription to energy demands and metabolic status of the cells (Hyun et al. 2017).

Finally, the *readers*, as their name suggests, have less to do with actively altering the epigenetic modifications, but rather with identifying epigenetic changes. However many readers also have writer or eraser functions. Readers have protein domains with extremely high affinity for specific histone modifications. The plant homeodomain (PhD) and malignant brain tumor (MBT) domains recognize methyl histones, while the bromodomain recognizes acetylated histone. The SWI/SNF (SWItch/Sucrose Non-Fermentable) complex is a bromodomain containing protein complex involved in nucleosome reorganization. The bromodomain is essential for SWI/SNF in its ability to identify locations marked for full opening of the chromatin. SWI/SNF then catalyzes a complete nucleosomal shift in an ATP-consuming manner. This results in a loop of DNA, devoid of nucleosomes and thus completely available for binding of transcription factors and RNApol-II (Calo and Wysocka 2013).

The Histone Code

As introduced above, the degree of chromatin packaging determines the access of regulatory proteins to DNA and transcription. Chromatin density in turn is regulated by histone modifications. Active promoters and enhancers can be now recognized by certain modifications of histones, designated as the histone code. For instance, active TSSs are usually depleted of nucleosomes and thus accessible for DNase hypersensitivity assays. However, the first nucleosomes downstream of the TSS are enriched for acetylated histone H3 lysine 27 (H3K27Ac) and trimethylated lysine 3 (H3Kme3) (Andersson and Sandelin 2020).

Nucleosomes bordering active enhancers carry high H3K27Ac and H3K4me1, which now serves as an epigenetic definition of active enhancers. In

contrast, repression of transcription is associated with different histone modifications, in particular with H3K9 di- and trimethylation and H3K27 di- and trimethylations. Using chromatin immunoprecipitation against these histone modifications, followed by sequencing in combination with the genome-wide determination of DNase hypersensitivity sites (see Box), these codes could be established (Calo and Wysocka 2013).

Cortisol leads to differential patterns of enhancer and promotes activity depending on whether it acts on macrophages or on adipocytes. This is orchestrated by the presence of cell-type-specific repertoires of additional transcription factors which together with the DNA-bound GR recruit co-regulators that lead to the histone modifications and eventually the transcription of macrophage- and adipocyte-specific cortisol-regulated genes that execute the particular physiological responses.

Pharmacological Relevance

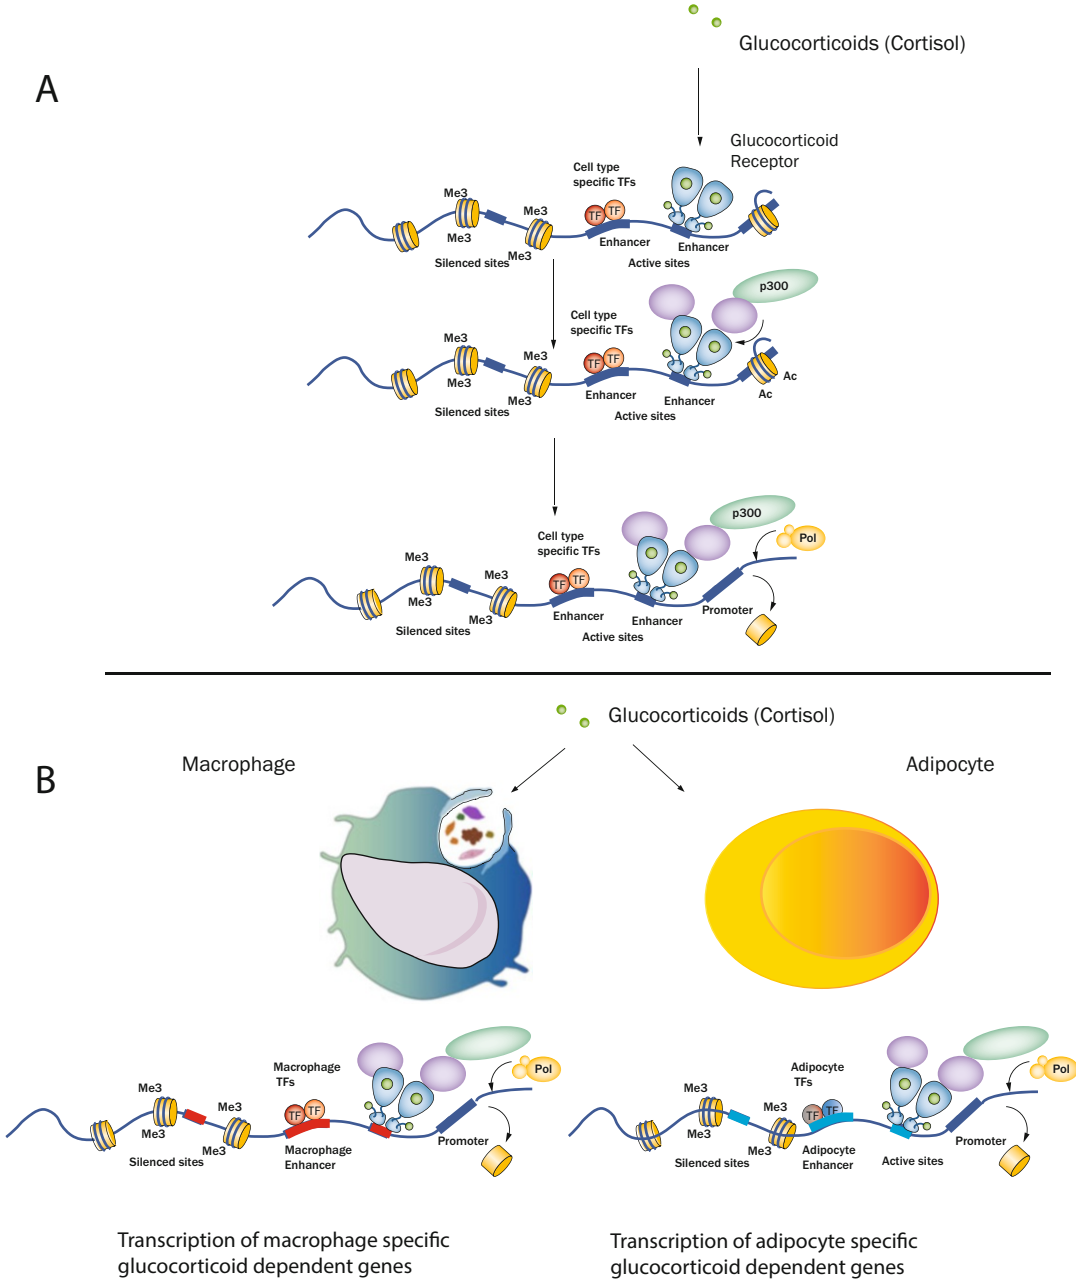
As transcriptional regulation is central to cellular function, its manipulation is therefore of therapeutic value for a number of diseases including chronic inflammation and cancer. The use of ligands, which directly interact with a transcription factor and activate or inactivate the factor or alter histone-modifying enzymes, is an elegant case of transcriptional interference.

Ligands for nuclear receptors have been the first widely applied agents targeting transcription, e.g., estrogens, retinoic acids, and glucocorticoids (e.g., cortisol). More recent pharmaceutical attempts to inhibit the interactions between transcription factors with their coactivators by small molecules have yet been successful in only a few cases. For example, interference with the interaction between the transcription factor p53 and the coactivator CBP hinders the transcriptional activation of p53-dependent target genes, which trigger cell death. As an interesting other approach, the abundance of a transcription factor can be modulated by specifically blocking degradation, again exemplified by small molecules inhibiting the binding of Mdm2 to p53, the first step which targets p53 for degradation. Elevated p53 can be desirable if cancer cells are to be destined for cell death (Grossman 2001; Zhao et al. 2015).

Not all transcription factors can be targeted by small-molecule inhibitors or activators, and thus the concept of oligodeoxynucleotide decoys became of interest. These decoys are short sequences of DNA with specific high-affinity transcription factor binding sites, unique to each transcription factor. These nucleotides are able to enter mammalian cells either through liposome-mediated transfection, viral transduction, or by an active transport by the target cell (e.g., endocytosis). Once inside, the short decoy sequences are bound by their target transcription factor, preventing the target from binding genomic DNA at enhancer or promoter regions, therefore preventing their activity. Early clinical trials of oligodeoxynucleotide decoys have shown safety, but unfortunately not efficacy. For example, a topical application using decoys for the pro-inflammatory transcription factor NFκB was unable to help dermatological conditions over the placebo-treated group (Hecker and Wagner 2017).

Another approach to inhibiting transcription factor function is the use of small molecules, or peptides, to block protein-protein interactions of transcription factors. Many transcription factors have essential dimerization functions, for example, the signal transducer and activator of transcription 3 protein (STAT3). Besides its physiologic life-essential function, STAT3 also acts as an oncogene, promoting cellular growth of cancer cells. It would therefore be a prime target for cancer therapy. STAT3 functions by binding as a homodimer to promoters in the nucleus in order to regulate transcription. Targeting the interface of homodimerization, the Src homology 2 domain (SH2), using peptides which bind SH2, researchers have been able to inhibit the transcriptional activity of STAT3. These types of drugs however have not yet made it past the clinical trial stage (Sgrignani et al. 2018).

The modulation of transcription nicely demonstrates how results of basic science can be translated into medical application. These few examples of drugs in successful use stimulate at



Transcriptional Regulation, Fig. 1 Transcriptional regulation exemplified on cortisol-induced transcription. (A). Glucocorticoids (cortisol) bind to the transcription factor dubbed glucocorticoid receptor, GR. GR binds to DNA in open chromatin that is free from nucleosomes caused by the activity of cell lineage transcription factors. These regions are considered as "active sites." The DNA elements that bind lineage-specific transcription factors or hormone-inducible transcription factors such as the GR are called enhancers. Closed chromatin is covered with nucleosomes that have histone modification that mark them as transcriptional silenced sites, such as trimethylation at H3K9 or H3K27 amino acid residues. Following binding of transcription factors, co-regulatory molecules are recruited with enzymatic activities for chromatin modification. P300, for instance, acts as acetyltransferase. Acetylation on histones such as H3K27Ac by histone acetyltransferases and also methylation by histone methyltransferases leading to trimethylated lysine 3 (H3Kme3) take place. These modifications allow

the same time the intensive study of gaps in our understanding of transcriptional control, hoping to find new specific ways of interference. The extensive research into transcription factors is key to the progression of pharmacological strategies to treat disease. However, due to the vast array of actions that each transcription factor has, by their ability to regulate gene expression on a genome-wide scale, it is essential to understand the mechanisms of transcriptional regulation. The number of fail attempts, which work in vitro, or in a preclinical model, but are unable to show efficacy in human trials, is mounting. Transcription factors, while essential for gene regulation in the cell, are extremely difficult to target therapeutically, especially those without endogenous (and known) ligands.

However, in case that ligands are known and available, such as in the example of cortisol therapy, pharmacologic use has profound effects to attack acute, chronic, and overshooting inflammation. The challenge remains how to develop strategies how to define cell-specific actions and modifications that avoid the odds of side effects.

Given the central role of transcription in gene regulation, modifying this process remains an ultimate goal of pharmacology (Fig. 1).

Box: Assays for Measuring Transcriptional Activity, Transcription Factor Binding, and Chromatin Modifications

GRO-seq

To measure directly regulated transcripts, methods such as global nuclear run-on sequencing (GRO-seq) have been established. While there are many different ways of purifying newly synthesized RNA, they all follow a similar principle – enrichment of labeled RNA molecules by tags, which allow purification before processing and sequencing. GRO-seq uses labeling, by incubating cells with a specific nucleotide (5-bromouridine 5′-triphosphate, BrUTP) which is incorporated into the synthesized RNA and then pulled out specifically using an antibody directed against BrUTP. The importance of these methods is that they show currently regulated transcripts, as opposed to other methods which only identify total, fully processed mRNA molecules, which are not only regulated by transcriptional control and RNApol-II recruitment but also by posttranscriptional processing, decay, or stabilization. GRO-seq can also be used to identify new TSS locations or cryptic promoters in the genome not predicted by genome sequencing.

ChIP-seq

Chromatin immunoprecipitation sequencing (ChIP-seq) is a method used to identify locations of transcription factors, co-regulators, and modified histones that are bound to the genome. These can then be annotated to known promoter or enhancer sites in order to determine which gene they are likely regulating. The tool is even more powerful when combined with other technologies such as GRO-seq or whole-transcriptome mRNA sequencing (RNA-seq) to further identify how transcription factor binding loci can influence transcription. First cells are fixed using formaldehyde to lock the transcription factors in place, bound to the DNA.

(continued)

Transcriptional Regulation, Fig. 1 (continued) to remodel chromatin or even disrupt nucleosomes. Eventually basic transcription factors can occupy the promoter and allow recruitment of mRNA polymerase II to allow initiation of transcription. (B) Glucocorticoids activate the same transcription factor GR in macrophages and adipocytes. Due to different lineage-specific transcription factors however, the hormone-induced genes could differ between macrophages and adipocytes, leading to the cell-type-specific induction of cortisol-regulated genes. (Figure is modified after Baschant et al. 2012)

The DNA is then fragmented, either by kinetic means such as sonication or by enzymatic digestion, and the transcription factors and its covalently associated DNA sequence are fished out using targeting antibodies. The DNA that accompanies the transcription factors is then sequenced in order to identify the specific binding site in the genome. This technique has now become a workhorse for the transcription factor research community, able to identify new binding locations of transcription factors, binding sites that are occupied by multiple proteins, and even finding RNApol-II binding sites to determine transcriptional potential or promoter regions. Furthermore, it is possible to also find sequences marked by histone posttranslational modifications, linking the histone code to transcriptional regulation.

DNase-seq

To determine open, generally active, areas of the genome, DNA can be treated with DNaseI, an enzyme which digests DNA. However, DNaseI can only access chromatin, which is open and thus accessible to the enzyme. This means that areas of DNA bound closely to histones, and therefore closed and not accessible, or bound by transcription factors, are protected from the DNaseI and are sequenced. This allows for an approach called "footprinting" whereby the sequences protected from the DNaseI can be used to predict which transcription factors are binding, by comparing the protected sequence to known specific transcription factor binding sites (Shlyueva et al. 2014.

Transient Receptor Potential Channels

► TRP Channels

TRP Channels

Veit Flockerzi and Barbara Wardas
Institut für Experimentelle und Klinische Pharmakologie und Toxikologie, Universität des Saarlandes, Homburg, Germany

Synonyms

Transient receptor potential channels

Definition

A superfamily of cation channels conserved in mammals, flies, fish, sea squirts, and worms. All TRP proteins bear sequence similarities to the founding member of this superfamily, transient receptor potential (TRP), a light-activated cation channel in the *Drosophila* photoreceptor.

Basic Characteristics

The human genome contains 27 TRP channel-encoding genes and 2 genes encoding the closely related endo-lysosomal two-pore channels. So far, only few examples of TRP genes have been identified in nonland plants and fungi, and no TRP channels have been identified in archaea or bacteria (Hilton et al. 2019). Initially, TRP channels were identified solely on the basis of primary sequence similarity and presumed shared overall transmembrane topology. Based on their amino-acid sequence similarities, the TRP proteins fall into eight subfamilies, seven of which are found in humans: canonical (TRPC), vanilloid (TRPV), melastatin (TRPM), mucolipin (TRPML), ankyrin (TRPA), polycystin (TRPP), and the closely related two-pore channels (TPC) (Table 1). The TRPN (NOMP, NO-Mechano-Potential) has so far only been detected in worm, fly, and zebra fish and is proposed to be a mechano-sensing channel (Flockerzi and Nilius 2007; Nilius and Flockerzi 2014). Almost all TRPs have been shown to form ion channels in the plasma membrane (Vangeel and Voets 2019) or in the membranes of intracellular compartments, the later dubbed "organellar" TRP channels (Zhang et al. 2018). Both plasma membrane and organellar TRP channels essentially contribute to cellular Ca^{2+} signaling, and some like the

TRPC7		TRPM7					
		TRPM8					

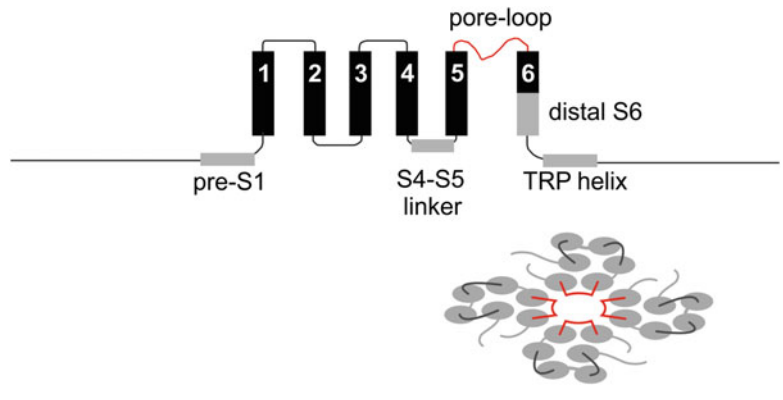
organellar members of the mucolipin subfamily might function as Ca^{2+}, Ni^{2+}, or Zn^{2+} release channels (Nilius and Flockerzi 2014; Vangeel and Voets 2019; Zhang et al. 2018).

Recently, TRP channel structures obtained by electron cryo-microscopy and X-ray crystallography validated many previous assumptions such as the tetrameric architecture in which subunits are arranged in fourfold symmetry around a central ion-permeation path. Up to now, structures of 19 TRP channels have been solved at resolutions between 2.9 and 5 Å (Hilton et al. 2019; Vangeel and Voets 2019; Zhang et al. 2018). These structures provide an unprecedented insight into the molecular architecture of TRP channels. A single TRP protein comprises six transmembrane helices followed by the amphipathic TRP helix which runs parallel to the cytoplasmic plane of the plasma membrane.

Notably, four amino-acid sequence motifs turned out to define a unique signature common to almost all TRP channel proteins (Fig. 1), the pre-S1 helix (motif 1), the S4–S5 linker (motif 2) connecting the S1–S4 helices and the S5-pore-loop-S6 segment, the distal part of helix S6 (motif 3), and the TRP helix (motif 4, also dubbed "TRP box") (Flockerzi and Nilius 2007). According to functional and recent structural data, the motif 3 is part of the S6 helix, and its residues essentially define the lower gate within the central ion-permeation path, whereas the TRP helix (motif 4) interacts with both the pre-S1 helix (motif 1) and the S4–S5 linker (motif 2). The pre-S1 helix and the TRP helix are flanked by large cytoplasmic domains. According to the channel structures, four identical TRP proteins form a tetrameric channel. The central ion-permeation path, which is formed by tetramerized transmembrane helices 5 and 6 and their connecting linker, the pore-loop, comprises an outer vestibule followed by two constriction sites. The outer site formed by the pore-loop defines the selectivity filter, the inner site comprising the distal part of the S6 helix (motif 3), the lower gate, which may close the ion-permeation path. In addition to homo-tetrameric channels, hetero-tetrameric channels composed of more than one type of TRP protein have been identified and characterized *in vitro* and *in vivo*. The hetero-tetrameric channels have different functional properties compared to the homo-tetrameric channels of either protein.

Ion Channel Properties

Most TRP channels do only poorly discriminate between monovalent and divalent cations, especially Na^+ and Ca^{2+}, and, accordingly, are dubbed "non-selective" cation channels. Only TRPV5 and TRPV6 form highly selective Ca^{2+} channels. In these two channels, the permeability to



TRP Channels, Fig. 1 (Top) Cartoon of a single TRP protein/channel subunit depicting pre-S1 helix, transmembrane helices 1 to 6, S4–S5 linker, pore-loop, distal S6, and TRP helix. The four amino-acid sequence motifs, pre-S1, S4–S5 linker, distal S6, and TRP helix, unique to almost all TRPs, are indicated. (Bottom) View from top on a tetrameric TRP channel

Ca^{2+}(P_{Ca}) is more than 100-fold higher than its permeability to Na^{+}(P_{Na}). A single negatively charged aspartic acid residue conserved in the selectivity filter of both channels is responsible for the high Ca^{2+}selectivity (Nilius and Flockerzi 2014; Vangeel and Voets 2019). TRPM4 and TRPM5 are members of a third subgroup, yielding currents carried by Na^{+} but not by Ca^{2+}. Ca^{2+} itself facilitates activation of some TRP channels by directly binding to Ca^{2+} recognition sites formed by the distal cytosolic domains of helices S2 and S3 (TRPM4, TRPM8, TRPC5) or an EF-hand-like structure in the amino-terminal domain of TRPA1. In addition, Ca^{2+} via binding to Ca^{2+} binding proteins like calmodulin modulates channel activity either as an activating (e.g. TRPV3) or inactivating modulator (TRPV5, TRPV6) (Nilius and Flockerzi 2014; Vangeel and Voets 2019).

Modes of Activation

The gating of many TRP channels critically depends on phospholipase C activation by G-protein-coupled receptors or receptor tyrosine kinases. Activation of PLC could be coupled to TRP channel activation via relief of phosphatidylinositol-4,5-bisphosphate (PIP_2)-mediated channel repression (TRPV1, TRPM7) and/or production of inositol-1,4,5-trisphosphate and diacylglycerol, which contribute to TRPC channel activation. Members of the TRPV subfamily are activated by a broad range of stimuli including heat (TRPV1), ligands such as capsaicin (TRPV1) and (endo)cannabinoids (TRPV1, TRPV2, TRPV4), osmolarity and cell volume (TRPV4), hydrolysis of PIP_2, and protons (TRPV1). The Ca^{2+}-selective TRPV5 and TRPV6 channels are also unique in that they represent the only channels within the TRP superfamily which are activated by low intracellular Ca^{2+}. TRPM8 can be activated by a drop in temperature below 26 °C or by agents, such as menthol and icilin, that evoke a cool sensation. Other channels activated by temperature drops are TRPC5, TRPA1, and TRPM3.

Three TRPM proteins, TRPM2, TRPM6, and TRPM7, are distinguished from other TRPs and other known ion channels, in that they consist of enzyme domains linked to the C-termini of the ion channel domains resulting in "chanzymes". TRPM6 and TRPM7 encode TRP proteins linked to functional atypical protein kinases. Currents through TRPM2 channels are activated by ADP-ribose and changes in the redox status within the cell.

Pharmacological Relevance

A clear limitation of studies on some TRP channels is the lack of specific channel agonists and blockers. Organic compounds (e.g., ruthenium red, econazole, miconazole, SKF 96365) and anorganic blockers (e.g., La^{3+}, Gd^{3+}) have been generally found to be of insufficient potency and specificity. The few exceptions include compounds such as capsaicin ($EC_{50} \sim 0.7$ μM) and resiniferatoxin ($EC_{50} \sim 0.04$ μM) as activators and capsazepine ($IC_{50} \sim 0.3$ μM) as blockers of the TRPV1 currents, the endogenous cannabinoid receptor agonist anandamide ($EC_{50} \geq 4.9$ μM) and related endocannabinoids as activators of TRPV1 and TRPV4 currents, and 4α-PDD, a phorbol derivative, as activator of TRPV4 currents ($EC_{50} \sim 0.2$ μM). Several newly discovered compounds proved to be very potent and specific agonists or antagonists for single TRP channels, such as the TRPC4/C5 activating compound englerin A ($EC_{50} \sim 8$ to 12 nM) and inhibiting compound Pico145 ($IC_{50} \sim 0.35$ nM to 1.3 nM).

Biological Relevance and Emerging Roles for Mammalian TRP Channels

While TRP proteins have initially become renowned as cellular and organismal sensors for a wide spectrum of chemical and physical cues, an increasing number of gene deletion approaches in animals and human diseases associated with mutations in TRP genes have made a strong case for a global (patho)physiological role of TRP channels extending well beyond the sensory nervous system. TRP channels control an exceptionally broad spectrum of homeostatic physiological functions such as maintenance of body

temperature, transmitter release from neurons, mineral and trace element homeostasis, energy metabolism, and reproduction. Almost 20 hereditary human diseases in areas as diverse as neurology, cardiology, hematology, pulmonology, nephrology, dermatology, and urology are caused by mutations in 12 TRP genes (Table 2). However, a detailed understanding of the underlying pathophysiology is still missing, thereby obviating targeted therapeutic strategies. It still remains a mystery why the same gene mutations can cause completely different phenotypes and why TRP channel mutations sometimes have a low penetrance and no overt phenotype, while they entail lethal phenotypes in other instances. Accumulating evidence links TRP channels to a wide array of human diseases beyond the hereditary TRP channelopathies, and some TRPs, especially TRPM8 and TRPV6, appear to be upregulated in certain human cancers, for example, of the prostate and breast. Accordingly, TRP proteins are not only most appealing therapeutic targets, but, in addition as "oncochannels", they may represent prognostic markers for cancer diseases.

Tuberculosis

Tobias K. Dallenga and Ulrich E. Schaible
Cellular Microbiology, Research Center Borstel, Leibniz Lung Center, Borstel, Germany

Synonyms

Consumption; Phthisis; White plague

Definition

Tuberculosis is the most frequent infectious disease in humans worldwide commonly caused by bacteria of the *Mycobacterium tuberculosis* complex, generally affecting the lungs but potentially all parts of the body. Closely related members of the *Mycobacterium tuberculosis* complex cause similar infectious disease in animals such as *M. bovis* and *M. caprae* in ruminants and wild boars. Following the primary infection, a latent phase without any clinical symptoms precedes the reactivation phase, which is characterized by chronic cough, fever, weight loss, and lung tissue destruction. WHO estimations suggest that one fourth of the world population is latently infected with *Mycobacterium tuberculosis*. However, only 5–10% of the latently infected develop active tuberculosis during their lifetime (WHO 2020). *Mycobacterium tuberculosis* is transmitted via infectious aerosols generated by coughing from the respiratory tract of active tuberculosis patients. If untreated, half of all patients succumb to the disease. Prolonged treatment with combinations of different antibiotics has been proven a successful cure. However, recent multi-drug- and extensively drug-resistant isolates display a new threat (WHO 2020).

Basic Mechanisms

The Disease

According to the World Health Organization's estimates, approximately 10 million individuals develop tuberculosis annually. With 1.4 million fatalities in 2018, infections with *Mycobacterium tuberculosis* complex strains are still the most common cause of death from infectious diseases worldwide (WHO 2020). Highest incidences (ca. 300–500 cases per 100,000 population) occur in countries of South Africa, Southeast Asia, and Mongolia (WHO 2020). Patients infected with drug-susceptible strains of *Mycobacterium tuberculosis* can be successfully treated with a four-drug regime of antibiotics. On top of this pandemic, a public health crisis regarding cases of multi-drug- and extensively drug-resistant strains evolved. Nearly half a million patients were infected with *Mycobacterium tuberculosis* strains that are resistant to at least two of the first-line drugs. In countries of Central Asia, Russia, and East Europe, over 25% of new tuberculosis cases are multi-drug- or extensively drug-resistant (WHO 2020). Unrecognized or late diagnosis of multi-drug-resistant tuberculosis often leads to treatment failures. Treatment success rates in those patients are as low as 54%.

The Agent

Firstly discovered by Robert Koch in 1882 as causative agent of tuberculosis, *Mycobacterium tuberculosis* has subsequently been characterized as an aerobic and slow-growing mycobacterium and member of the Actinobacteria family. As facultative intracellular pathogen, it can survive and grow within host macrophages. Researchers estimate that humans acquired tuberculosis during evolution around 6000–9000 years ago since evidence of the disease has been found in human remains of the Neolithic era and in Egyptian mummies (Hershkovitz et al. 2008; Zink et al. 2003). Animal species crossed the species barrier to ruminants upon domestication in Neolithic times. *Mycobacterium tuberculosis* is a Gram-positive bacterium due to a thin peptidoglycan layer between an inner and an outer membrane. The hydrophobic cell wall and outer membrane, consisting of mycolic acids and wax esters, classify mycobacteria as acid-fast. *Mycobacterium tuberculosis* can be visualized using Ziehl-Neelsen's carbol fuchsin staining and remain stained after de-staining by acids and alcohol due to their thick and waxy lipid layers. This

acid-fast stain still represents the most commonly used method for detection of *Mycobacterium tuberculosis* in patient samples such as sputa and monitoring treatment success. Although *Mycobacterium tuberculosis* has an inner and outer membrane with a peptidoglycan cell wall layer in between, it phylogenetically belongs to the Actinobacteria.

The Control

After inhalation of contagious aerosol droplets coughed out by an active tuberculosis patient, *Mycobacterium tuberculosis* enters the upper respiratory tract and encounters pulmonary surfactant and deposits on the lung epithelial barrier, where it can become decorated by surfactant protein A and other humoral factors such as the complement component C3b. Alveolar macrophages, patrolling the alveolar surface, phagocytose opsonized mycobacteria and carry them into deeper lung tissues, thereby initiating the primary infectious focus. Within macrophages, *Mycobacterium tuberculosis* grows, eventually leading to necrotic host cell death and the release of a multiplicity of the initial bacterial inoculum. Concomitantly, additional immune cells become attracted to the site of infection through both danger signals of the dying/dead host cell and chemokine release induced by microbe-associated molecular patterns of *Mycobacterium tuberculosis* in epithelial cells and macrophages. Among the first infiltrating cells are myeloid-derived innate immune cells, such as neutrophilic granulocytes, monocytes, and macrophages, which can serve as host cells for *Mycobacterium tuberculosis*. Failure of these cells to kill the mycobacteria in a process termed early clearance can lead to primary tuberculosis as seen in small children, causing miliary tuberculosis and meningitis with high mortality rates. However, concomitant priming of CD4 and CD8 T cells in the draining lymph nodes causes onset of acquired immunity and production of interferon gamma and tumor necrosis factor alpha. These cytokines activate macrophages to unfold their microbicidal armamentarium rendering them capable to control mycobacterial growth, leading to latent infection in more than 90% of the infected. Histologically, this stage is characterized by the formation of a highly organized multicellular structure called the granuloma. The granuloma consists of a necrotic and lipid-rich core, most probably representing debris of former host cells, in which extracellular mycobacteria are located. The necrotic core is surrounded by multiple layers of immune cell populations (from inside to outside): (1) infected macrophages, foam cells, and giant cells; (2) uninfected macrophages, few neutrophils, and dendritic cells; (3) few natural killer cells and T and B cells (Ramakrishnan 2012). The structure is enclosed by a fibrous cuff consisting of collagen. With the help of antigen-specific T helper 1 cells secreting interferon-γ, host macrophages rather succumb to programmed apoptotic than necrotic cell death. Upon establishment of a hypoxic and nutrient-poor environment within the granuloma, *Mycobacterium tuberculosis* enters a non-replicating, metabolically inactive, dormant state, resulting in immune-controlled latent infection in absence of clinical symptoms (Gengenbacher and Kaufmann 2012). This latency can last for decades and in most cases infection can go unrecognized. However, the granuloma harboring dormant mycobacteria bears the risk of reactivation, primarily through immunocompromising conditions, which can lead to reactivation in 5–10% of all latently infected individuals at least once in their lifetime.

The Exacerbation

The exact immunological, cellular, and molecular mechanisms underlying the event when a granuloma is not able to restrain mycobacterial infection, reactivation, proliferation, and disease exacerbation anymore are still unknown. Genetic as well as environmental factors seem to play important roles in disease progression. Immunocompromising conditions resulting from, e.g., HIV coinfection, immunosuppressive therapies (cancer, autoimmune disease, organ transplantation), type 2 diabetes, age-associated immune senescence, smoking, malnutrition, or iron overload can disrupt maintenance of an intact granuloma structure and cause reactivation of dormant *Mycobacterium tuberculosis*. Mycobacterial proliferation kicks off inflammation, attracting immune cells such as neutrophils, monocytes, and macrophages from the bloodstream to the site of infection. Neutrophils are highly specialized, toxic innate immune cells equipped with

an armamentarium of many different damaging effector molecules. However, after uptake of *Mycobacterium tuberculosis*, neutrophils quickly succumb to a necrotic cell death, which is dependent on one of the toxic mechanisms exhibited by neutrophils, namely, the generation of reactive oxygen species (Corleis et al. 2012). Thus, with the help of several virulence factors, *Mycobacterium tuberculosis* turns the neutrophil's own killing machinery against itself. Necrotic cell death of neutrophils releases other highly tissue-damaging molecules, such as matrix metalloproteinases that degrade the extracellular matrix, reactive oxygen-generating enzymes, lipases, phosphatases, and membrane pore-forming proteins. Release of the cytokine interleukin 8 and neutrophil-derived, danger-associated molecules such as S100 alarmins attract further neutrophils. Neutrophil accumulation causes tissue damage and a massive influx of even more neutrophils, monocytes, and macrophages. Within macrophages that clean up infected and necrotic neutrophils, *Mycobacterium tuberculosis* can grow, before it eventually also induces necrotic cell death in these cells (Dallenga et al. 2017). These patho-dynamics result in establishment of a vicious circle of necrotic host cell death interspersed with periods of mycobacterial replication, lung tissue destruction, and, ultimately, coughing up of infectious particles for disease transmission (Dallenga and Schaible 2016).

Pharmacological Intervention

Classical Treatment

Classical treatment with antibiotics that have been shown to be effective against mycobacteria usually cures drug-susceptible tuberculosis after 2–6 months of treatment. The WHO recommends an intensive treatment phase of 2 months with daily administration of the four antibiotics rifampicin, isoniazid, pyrazinamide, and ethambutol followed by a continuation phase for 4 months with rifampicin and isoniazid (WHO 2020). However, many patients enter treatment only after prolonged periods of disease before being diagnosed. The chronic infectious process can have already led to severe lung tissue destruction and long-term sequelae, such as cavities and impaired lung function. Antibiotic treatment is only targeting the bacterium, which usually also leads to quick reduction of inflammation. Some patients however, although diagnosed as cured and sputum negative for *Mycobacterium tuberculosis*, do not show improvement of lung function and resolution of inflammation. Other patients show no reduction in mycobacterial burden over months of treatment. Those are often mis-diagnosed for susceptible tuberculosis but are infected with multi-drug- or extensively drug-resistant tuberculosis.

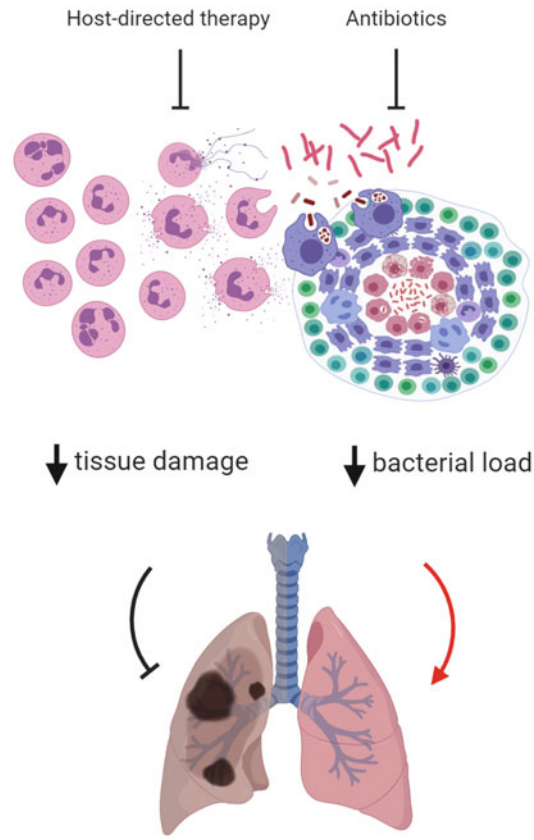
Multi-drug- and Extensively Drug-Resistant Tuberculosis

Successful treatment of multi-drug- or extensively drug-resistant tuberculosis displays a big challenge worldwide. Tuberculosis is considered multi-drug-resistant when the infecting mycobacterial strain is resistant to at least two of the abovementioned first-line drugs, usually to rifampicin and isoniazid. Additional resistances against two second-line drugs, including an injectable one, such as amikacin, define extensively drug-resistant tuberculosis. *Mycobacterium tuberculosis* has been shown to quickly acquire resistances even to newly developed and last resort antibiotics (Hoffmann et al. 2016). Combinations of second- and third-line antibiotics such as moxifloxacin, ethionamide, and rifabutin over a time course of 24 months are used to treat multi-drug- and extensively drug-resistant tuberculosis. However treatment success rates of multi-drug- and extensively drug-resistant tuberculosis are as low as 54% and 30%, respectively (WHO 2020). Moreover, second- and third-line drugs, especially upon long-term usage, display severe side effects such as irreversible hearing loss, burning sensation in the extremities, peripheral neuropathy, renal and liver toxicity, depression, and psychosis (Torun et al. 2005). Suffering from these side effects together with the prolonged period of treatment often causes patients to stop taking their medicines. Reduced patient compliance and withdrawal from the anti-tuberculosis regimen contribute to development of extensively or even totally drug-resistant *Mycobacterium tuberculosis* strains that are considered to be almost untreatable (Parida et al. 2015). The threat of increasing cases of multi-drug- and extensively drug-resistant

tuberculosis cases together with the occurrence of long-term sequelae, lung tissue scaring and cavitation, and impaired lung function requires alternative therapies adjunct to and supporting antibiotic treatment, which only targets the infectious agent.

Host-Directed Therapy

Host-directed therapies that target host immune mechanisms represent such supplemental strategies. Host cell necrosis, exacerbated inflammation, and lung tissue destruction characterize active tuberculosis, causing strong coughing and release of contagious aerosols and even blood. Interestingly, *Mycobacterium tuberculosis* produces a molecule, sulfolipid-1, that actively stimulates the lung-innervating neurons to induce coughing (Ruhl et al. 2020). Among others, this immunopathological condition is thought to be driven by the massive influx of neutrophils to the site of mycobacterial infection, which has been observed in histological examinations of the lungs of active tuberculosis patients (Dallenga et al. 2018). Indeed, increased numbers of infiltrating neutrophils exacerbate tuberculosis but generally also other severe respiratory diseases like influenza virus and SARS-CoV-2 infections (Camp and Jonsson 2017; Kimmey et al. 2015; Laforge et al. 2020). Interfering with neutrophil-mediated pathomechanisms, such as attraction, release of attractants and toxic effectors, and induction of necrotic cell death may represent a promising strategy to ameliorate severe forms of active tuberculosis, mitigate tissue destruction, and reduce long-term sequelae during antibiotic treatment. For instance, when neutrophils were depleted or their attraction to the site of infection was interfered with in experimental mouse models of tuberculosis, bacterial burden, pathology, and death rates were reduced (Vilaplana et al. 2013; Yeremeev et al. 2015). As mentioned above, neutrophils infected with *Mycobacterium tuberculosis* quickly succumb to a necrotic cell death. When this necrotic cell death was prevented by inhibition of one of the enzymes that produces reactive oxygen species, namely, myeloperoxidase, macrophages subsequently engulfing *Mycobacterium tuberculosis*-infected neutrophils were able to control mycobacterial growth (Dallenga et al. 2017). In this *in vitro* study with human cells, release of tissue-damaging molecules was prevented, while simultaneously other immune cells controlled mycobacterial proliferation. Biomarkers, defining disease stage and pathological sequelae, can help to stratify tuberculosis patients for individualized host-directed therapies targeting specific disease-associated mechanisms. Neutrophil-targeting host-directed therapies could be directed by the presence of enhanced neutrophil-associated mRNA signatures or mediators such as interleukin 8, S100, or prostaglandins. In the future, severe tuberculosis patients may benefit from tailored biomarker-educated host-directed therapies in support of antibiotic treatment (Fig. 1).



Tuberculosis, Fig. 1 Adjunct host-directed therapy in tuberculosis. Combined antibiotics and host-directed therapies, e.g., targeting neutrophils, reduce both lung tissue destruction and bacterial burden, resulting in improved disease outcomes and long-term sequelae. (Created with BioRender.com)

Definition

Protein tyrosine kinases (PTKs) are enzymes (EC 2.7.1.112) that catalyze the transfer of the γ-phosphate group of ATP to tyrosine residues of protein substrates. The activity of PTKs is controlled in a complex manner by posttranslational modifications and by inter- and intramolecular complex formations.

Basic Characteristics

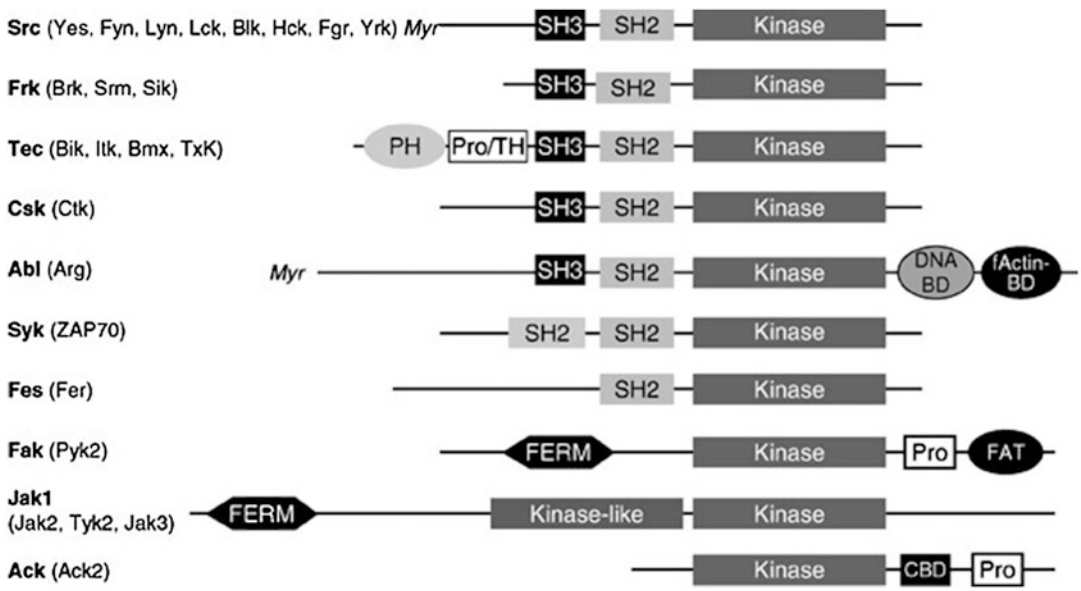
PTKs have been implicated in the regulation of a variety of biological processes such as cell proliferation, migration, differentiation, and survival. They have been demonstrated to play significant roles in the development of many disease states, including immunodeficiency, ► atherosclerosis, psoriasis, osteoporosis, diabetes, inflammatory diseases, and cancer. Currently, PTK inhibitors are clinically used for the treatment of specific hematological cancers and inflammatory diseases, such as rheumatoid arthritis.

PTKs can be subdivided into two large families, receptor tyrosine kinases (RTKs) and nonreceptor tyrosine kinases. The human genome encodes for a total of 90 tyrosine kinases of which 32 are nonreceptor PTKs that can be placed in ten subfamilies (Fig. 1). All nonreceptor PTKs share a common kinase domain and usually contain several additional domains that mediate interactions with protein-binding partners, membrane lipids, or DNA (Table 1). These interactions may affect cellular localization and the activation status of the kinase or attract substrate proteins for phosphorylation reactions.

c-Src

c-Src was the first cellular homologue of a viral oncoprotein (v-Src from the Rous sarcoma virus) that was discovered. It is involved in mitogenic signaling from many types of transmembrane receptors and has been implicated in a variety of cancers. c-Src and the Src-like kinases Fyn and Yes are expressed in most tissues and are at least partially redundant in their function. Hck, Fgr, and Blk are primarily found in hematopoietic cells, whereas Lyn and Lck are also expressed in neuronal cells.

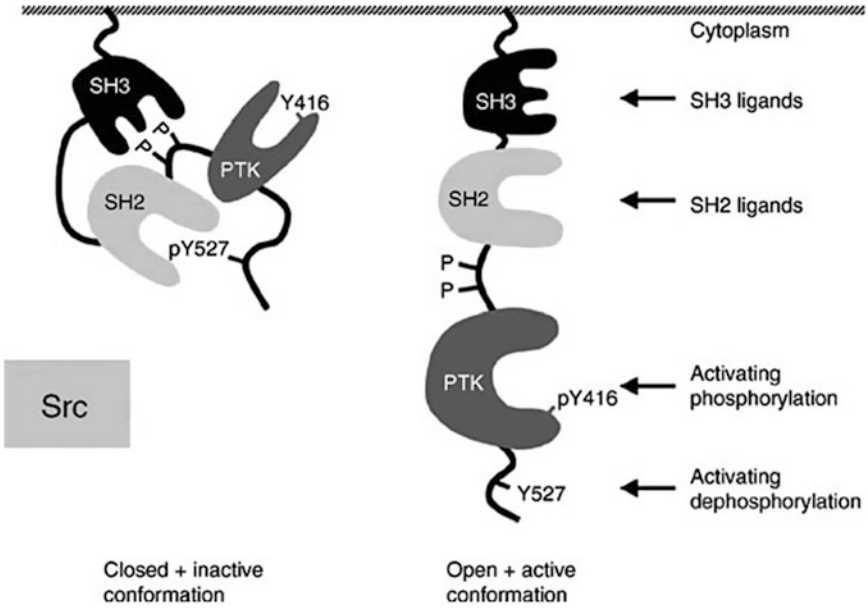
The inactive, closed conformation of Src is maintained by intramolecular interactions of the SH2 and SH3 domains (Fig. 2). The N-terminal SH3 domain binds to a proline-rich sequence in the linker region between the SH2 and the kinase domain. In addition, the SH2 domain binds to a phosphorylated tyrosine residue (Y527 in chicken, Y530 in human) in the C-terminal part of the protein. The kinase executing this phosphorylation is called Csk (C-terminal c-Src kinase) and is member of a distinct PTK family (Fig. 1). Both intracellular interactions together repress Src kinase activity by blocking access to the active site. Src can be activated by



Tyrosine Kinases, Fig. 1 Tyrosine kinases

Tyrosine Kinases, Table 1 Tyrosine kinases

Domain		Function
CBD	Cdc42-binding domain	Binding to the small G protein Cdc42
DNA-BD	DNA-binding domain	Binding to DNA
fActin-BD	f-actin-binding domain	Binding to F-actin
FAT	Focal adhesion targeting domain	Binding to focal adhesion complexes
FERM	4.1/ezrin/radixin/moesin domain	Binding to cytoplasmic regions of transmembrane proteins
Myr	Myristoylation site	Tethering to membranes
PH	Pleckstrin homology domain	Binding to membrane phospholipids, such as phosphoinositides
Pro	Prolin-rich sequences	Binding to SH 3 domains
PTB	Phosphotyrosine binding domain	Binding to phosphorylated tyrosine residues
SH1	Src homology 1 domain, kinase domain	Kinase activity
SH2	Src homology 2 domain	Binding to phosphorylated tyrosine residues
SH3	Src homology 3 domain	Binding to prolin-rich sequences
TH	Tec homology domain	SH3-binding prolin-rich sequences and Zn^{2+}-binding motif



Tyrosine Kinases, Fig. 2 Activation mechanism of Src

dephosphorylation of the inhibitory tyrosine residue and by intermolecular interactions with SH2 and SH3 binding partners. A variety of cytosolic and receptor-type protein tyrosine phosphatases (PTPs), such as PTPα, PTP1B, and SHP-1/2, has been shown to dephosphorylate pY527 and subsequently activate c-Src. Among the SH2 ligands that can activate Src are autophosphorylated RTKs (e.g., epidermal growth factor (EGF) and platelet-derived growth factor (PDGF) receptors) and nonreceptor PTKs (e.g., Fak and Pyk2) as well as tyrosine phosphorylated adaptor proteins (e.g., Shc). For full activation of Src a trans-autophosphorylation of a conserved tyrosine

residue in the activation loop (Y416) has to occur. This model is supported by the elevated Src activity in transformed cells with increased PTP activity; a Src mutant with truncated C-terminus lacking the inhibitory phosphotyrosine residue that has been found in human colorectal cancers and is constitutively activated, and v-Src, which in addition to several point mutations lacks a large part of the C-terminal domain, have transforming potential.

Among the substrates of Src are other nonreceptor PTKs (e.g., Fak, Syk, and Tec kinases), RTKs (e.g., EGF and PDGF receptors), phospholipase Cγ (PLCγ), PI3-kinase, phosphatases (e.g., SHP-2 and PP2A), and adaptor (e.g., Shc and Cbl) as well as focal adhesion proteins (e.g., paxillin, p130 ^{Cas}, and tensin). Src-mediated phosphorylation either modulates enzymatic activity of target proteins or creates docking sites for SH2 or PTB domain-containing proteins promoting the assembly of multimeric protein complexes that function in cellular signaling.

Given its involvement in many receptor-mediated signaling pathways, Src was thought to be an important regulator of cell proliferation, migration, and adhesion. However, the most striking phenotype of c-Src-deficient mice is an osteopetrosis suggesting a role for c-Src in bone remodeling and a compensation by alternative Src family members in other organs. Indeed, combined deletion of c-Src, Yes, and Fyn in mice results in a lethal phenotype.

c-Abl

c-Abl was first identified as the cellular homologue of the transforming gene product of the Abelson murine leukemia virus (v-Abl) and found to encode a nonreceptor PTK. Mammalian c-Abl is expressed ubiquitously and in most cells is primarily localized in the nucleus where it has a role in DNA damage-induced apoptosis.

c-Abl is activated by ionizing radiation in a manner dependent on phosphorylation by ATM (ataxia telangiectasia-mutated), a nuclear protein serine/threonine kinase. c-Abl kinase activity in G0 and G1 phase of the cell cycle is repressed by binding of Rb (retinoblastoma protein) to the activation loop, which is released during S-phase when Rb becomes hyperphosphorylated by cyclin-dependent kinases. Furthermore, c-Abl is negatively controlled by intramolecular SH3 domain interactions and by SH3-binding proteins, such as Pag/MSP23 (human proliferation-associated gene/macrophage 23-kD stress protein). More recently, a role of intramolecular binding of the N-terminal myristoyl residue to a corresponding pocket in the so-called C-lobe of the kinase has been described.

Nuclear substrates of c-Abl include DNA-PK (DNA-dependent protein kinase, an enzyme critical for DNA repair), Rad51 (a homologue of bacterial RecA involved in recombination/repair by catalyzing strand exchange between homologous DNAs), the tyrosine phosphatase SHPTP1, and the p85 subunit of PI3-kinase, negatively regulating their respective activity. In contrast, c-Abl activates JNK (c-Jun N-terminal kinase) and p38 mitogen-activated protein kinases (MAPKs). c-Abl also functions in the cytoplasm, where it is involved in PDGF-induced motility responses and cell adhesion.

In chronic myelogenous leukemia (CML) as well as in a subset of acute lymphoblastic leukemia (ALL), Bcr-Abl, a fusion protein of c-Abl and the breakpoint cluster region (Bcr), is expressed in the cytosol of leukemic cells. This fusion protein forms homo-oligomeric complexes that display elevated kinase activity and is the causative molecular abnormality in CML and certain ALL. The transforming effect of Bcr-Abl is mediated by numerous downstream signaling pathways, including ▶ protein kinase C (PKC), Ras-Raf-ERK MAPK, JAK-STAT, and PI3-kinase pathways.

Fak

Fak (focal adhesion kinase) is expressed in most tissues and is evolutionary conserved across species. It is activated by integrin clustering and by stimulation of several G protein-coupled receptors and RTKs. Fak is associated with focal adhesions and regulates cell spreading and migration. The kinase is essential for embryonic development since the homozygote Fak knockout is embryonic lethal. Pyk2 (proline-rich tyrosine kinase 2), the second member of the Fak kinase family, has a more restricted expression pattern (primarily

neuronal and hematopoietic cells) and does not localize to focal adhesions.

An early step in Fak activation is the autophosphorylation of a tyrosine residue (Y397) proximal to the kinase domain. Phosphorylated Y397 is a high affinity ligand for the SH2 domain of Src, thereby recruiting Src kinases and stimulating their catalytic activity. In a second step, several other tyrosine residues in Fak are phosphorylated, either by Fak itself or by recruited Src. As a consequence, Fak kinase activity is further increased or docking sites for SH2 domain-containing proteins are created, e.g., for Grb2-Sos complexes that link Fak to the Ras-Raf-► MAPK cascade. N-terminal sequences containing the FERM domain anchor Fak to integrins or RTKs, and the C-terminal FAT domain mediates binding to cellular focal adhesions. Among the substrates of the Fak/Scr complex are the adaptor proteins paxillin and p130 ^{Cas} and the focal adhesion-associated protein tensin that bind to C-terminal sequences of Fak and, after their phosphorylation, promote the assembly of signaling complexes at discrete sites within cells.

Fak kinases could be modulators of some aspects of human cancers and may also contribute to the development of vascular diseases involving hyperproliferation and migration of vascular smooth muscle cells.

Jak

Jak1 and 2 were identified, among others, by PCR using degenerate oligonucleotides spanning the conserved kinase domain of Src and therefore initially named Jak, for "Just another kinase." When full-length clones were isolated, it was recognized that they differ markedly from other PTKs by the presence of an additional (pseudo)-kinase domain of unknown function. To denote this unique feature, they were renamed as "Janus kinases" in reference to the ancient two-faced Roman god. Jak1, Jak2, and Tyk2 are ubiquitously expressed, whereas Jak3 is predominantly found in hematopoietic cells. Jak family PTKs mediate signaling downstream of a wide array of receptors, but the most commonly known family associated with Jak activation are cytokine receptors. In response to ligand stimulation, cytokine receptors oligomerize, and subsequently recruited or constitutively bound Jak kinases are activated and phosphorylate the receptors. Some of the receptors' phosphotyrosine residues subsequently bind to SH2 domains of STATs (signal transducers and activators of transcription), which are then phosphorylated by Jaks on a C-terminal tyrosine residue. This leads to STAT oligomerization through a reciprocal interaction between SH2 domains and phosphotyrosines. Dimeric STATs translocate to the nucleus where they initiate transcription of target genes. Alternatively, STATs can be activated by Src kinases that are recruited to Jak-phosphorylated cytokine receptors via their SH2 domain. Jak kinase signaling is negatively regulated by PTPs and by SOCS (suppressors of cytokine signaling) proteins that inhibit Jaks by binding to the activation loop and by targeting the kinases for protein degradation.

STAT 3 and 5 are overexpressed and/or overactivated in several human malignancies, such as breast, non-small cell lung cancer, and head and neck cancer. An aberrant activation of Jak kinases by fusion with the TEL transcription factor and subsequent constitutive dimerization has been observed in T-cell acute lymphocytic leukemia.

Tec

Tec family kinases participate in signal transduction in response to many types of extracellular stimuli that are transmitted by growth factor receptors, cytokine receptors, G protein-coupled receptors, integrins, and, most importantly, B-cell receptors. Tec kinases are involved in the regulation of growth, differentiation, apoptosis, and cell motility. They are primarily found in hematopoietic lineages, but some family members (Btk, Etk/Bmx) also have a broader expression pattern. The defining feature of Tec family kinases is the presence of a PH domain at their N-terminus. The PH domain has a broad binding capacity ranging from lipid products of PI3-kinases, heterotrimeric G protein subunits ($\beta\gamma$ as well as $G\alpha_q$ and $G\alpha_{12}$), and PKC isoforms (βI and δ) to STATs, and other PTKs, like Fak. These interactions may either be involved in Tec activation (phospholipids and G proteins) or recruit potential substrates of Tec kinases (PKC and STATs).

The current understanding of the activation of Tec kinases fits into a two-step model. In the first step an intramolecular interaction between the SH3 domain and a proline-rich region in the TH domain is disrupted by binding of the PH domain to phosphoinositides, G protein subunits, or the FERM domain of Fak. These interactions lead to conformational changes of Tec and translocation to the cytoplasmic membrane where, in a second step, Src kinases phosphorylate a conserved tyrosine residue in the catalytic domain thereby increasing Tec kinase activity. Autophosphorylation of a tyrosine residue in the SH3 domain further prevents the inhibitory intramolecular interaction resulting in a robust Tec kinase activation.

Among the substrates and downstream effectors of Tec kinases are PLCγ2 and PKCβI resulting in a sustained calcium influx and activation of MAPKs. The interaction with the GDP/GTP exchange factor Vav can potentially activate Rac/Cdc42/Rho pathways, which can modulate actin cytoskeleton dynamics and lead to JNK and p38 MAPK activation potentially inducing apoptosis. Paradoxically, Tec kinases may also trigger antiapoptotic signals by stimulating PI3-kinase and Akt and promote proliferation by activating STATs.

Naturally occurring mutations of Bruton's tyrosine kinase (Btk) were identified in human immunodeficiency diseases and X-linked agammaglobulinemia, where a lack of mature circulating B cells and immunoglobulins is observed, supporting a central role for Btk in B-cell biology. In contrast, the knockout of Itk results in a lack of mature T cells and defects in T-cell receptor signaling. Furthermore, Btk and Etk/Bmx are able to complement a weakly oncogenic Src in transformation of hepatocytes and fibroblasts suggesting their participation in anchorage-independent growth and development of cancer.

Syk

The PTKs Syk and ZAP-70 are early intermediates in the transduction of signals from immune receptors, including the B- and T-cell receptors for antigen, activating natural killer-cell receptors, the mast cell and basophil receptor for IgE, and the widely distributed receptors for the Fc portion of IgG. Immune receptors control checkpoints in lymphocyte development and serve to integrate the responses of innate and acquired immunity.

The current model proposes that upon engagement of immune receptors Src-family kinases are recruited that phosphorylate tyrosine residues in specific regions of the receptors, the immunoreceptor tyrosine-based activation motifs (ITAMs). These phosphotyrosines serve as docking sites for the SH2 domains of Syk and ZAP-70 that subsequently autophosphorylate and generate binding sites for SH2 domain containing proteins, like PLCγ, Vav, and the adaptor protein Cbl. Furthermore, Syk and ZAP-70 phosphorylate a number of cytosolic and transmembrane linker proteins, such as SLP-76 (SH2-containing leukocyte protein of 76 kD), LAT (transmembrane linker for activation of T cells), TRIMM (T-cell receptor-interacting molecule), and SIT (SHP2-interacting transmembrane adaptor protein) that function as scaffolds to localize and assemble signaling complexes. Syk has also been implicated in the activation of Btk. In addition to be a major player in immune receptor signaling, Syk has a role in the "inside-out" integrin activation signal that is necessary for fibrinogen binding and subsequent aggregation of platelets during hemostasis.

Drugs

PTKs have been shown to play significant roles in the development of many disease states, including immunodeficiency, atherosclerosis, psoriasis, osteoporosis, diabetes, inflammatory diseases, and cancer. Therefore, development of PTK inhibitors has been in the focus of many pharmaceutical companies. While the majority of these inhibitors are directed against RTKs, the poster child for targeted therapies in oncology is imatinib (*Glivec* ™, *Gleevec* ™) that potently inhibits the activity of the nonreceptor PTK c-Abl. Imatinib is a phenylamino-pyrimidine that competes for binding of ATP to the catalytic domain and stabilizes an inactive conformation of the kinase domain preventing activation of c-Abl. In CML as well as in a subset of ALL Bcr-Abl fusion proteins with elevated kinase activity are the causative molecular abnormalities. In clinical trials

with Bcr-Abl-positive CML patients, once-daily oral doses of imatinib led to impressive overall response rates (ORR) of >90% with a well-manageable adverse event profile resulting in the approval by the US Food and Drug Administration (FDA) in May 2001.

However, as with most anticancer treatments, resistance to imatinib therapy was observed in patients that were either irresponsive from the beginning or relapsed after initial successful treatment. Key mechanisms for this resistance are Bcr-Abl gene amplifications and mutations in the kinase domain that reduce the affinity for imatinib. Second-generation, orally available c-Abl inhibitors, such as nilotinib (*Tasigna* ™), dasatinib (*Sprycel* ™), or bosutinib (*Bosulif* ™), are more potent against Bcr-Abl and active against several imatinib resistance conferring mutations. An exception is the T351I variant that is targeted by third-generation Bcr-Abl inhibitors, like ponatinib (*Iclusig* ™). A typical consequence of broader activity against kinase domain mutants is the less stringent selectivity profile of these inhibitors, and indeed, many of the imatinib followers bind to off-target kinases, such as Src, Btk, PDGF receptor, c-Kit, or VEGF receptor 2, which on one hand may increase their therapeutic potential in CML and other cancer types but on the other hand could also involve safety liabilities. Asciminib that is still in clinical development has a completely different mechanism of action: this compound targets the myristate pocket of Bcr-Abl and is therefore active against all known kinase domain mutations that confer resistance to imatinib.

Meanwhile, imatinib is also approved for the treatment of gastrointestinal stroma tumors (GIST), dermatofibrosarcoma protuberans (DFSP), myelodysplastic/myeloproliferative diseases (MDS/MPD), aggressive systemic mastocytosis (ASM), and hypereosinophilic syndrome/chronic eosinophilic leukemia (HES/CEL). The clinical activity of imatinib in GIST is based on its ability to inhibit the RTK c-Kit, which is frequently mutated in this disease. Other indications, such as DFSP, HES/CEL, and a certain proportion of CML, involve aberrant PDGF receptor signaling that is blocked by imatinib.

Since Btk is a key component of B-cell receptor signaling and has an important role in regulating proliferation and survival of B cells, Btk inhibitors have been explored to treat B-cell malignancies, such as chronic lymphocytic leukemia (CLL), mantle cell lymphoma (MCL), Waldenström macroglobulinemia (WM), marginal zone lymphoma (MZL), and diffuse large B-cell lymphoma (DLBCL). Ibrutinib (*Imbruvica* ™) is an irreversible inhibitor of Btk covalently binding to cysteine 481 and was the first drug against this PTK approved by the FDA in 2013 for the treatment of MCL based on impressive ORRs of 68–72%. Meanwhile, it is also used for the treatment of CLL, WM, and MZL. While ibrutinib is already relatively selective, only inhibiting EGF receptor, Itk, Her2, and Jak3 at 11–32-fold higher concentrations than Btk and the clinical adverse event profile is considered as manageable, more selective inhibitors like acalabrutinib (*Calquence* ™) and zanubrutinib (*Brukinsa* ™) are in development and have received first approvals in MCL based on further improved ORRs of >80%. The promise of higher kinase inhibitor selectivity is a better safety profile requiring less dose reductions and allowing more sustained target inhibition, potentially resulting in improved clinical activity.

General concerns about the irreversible mode of action and first reports about acquired resistance to ibrutinib and other covalent Btk inhibitors through C481S mutations triggered the development of reversible, ATP-competitive Btk inhibitors, like LOXO-305 and ARQ 531, that have shown encouraging signs of clinical activity in patients with refractory B-cell malignancies in phase I studies.

Finally, Btk inhibitors may have potential outside of oncology in diseases like rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and multiple sclerosis. There are several clinical studies ongoing, for instance, exploring the highly selective and presumably safer Btk inhibitors evobrutinib and tolebrutinib in these non-oncology indications.

Jak family PTKs are essential for the signaling cascade downstream of type I and II cytokine receptors, and Jak-dependent cytokines are major contributors to immunopathology. The first Jak inhibitor that gained approval by the FDA in 2011 was ruxolitinib (*Jakavi* ™) for

the treatment of myelofibrosis that is associated with an activating mutation in Jak2. Meanwhile, the Jak2/Flt3/Ret inhibitor fedratinib (*Inrebic* ™) is licensed for the same indication. Despite concerns about the safety profile of kinase inhibitors and the potential implications for the treatment of non-life-threatening diseases, several Jak inhibitors, including the Jak1-selective compound upadacitinib (*Rinvoq* ™) and the pan-Jak inhibitors tofacitinib (*Xeljanz* ™) and baricitinib (*Olumiant* ™), have been approved for the treatment of RA and are clinically explored in other inflammatory diseases.

Experimental drugs against nonreceptor PTKs with therapeutic potential are Tyk2, Syk, and Fak inhibitors. Deucravacitinib is an orally available, selective Tyk2 inhibitor stabilizing the pseudokinase domain of this PTK and has shown preliminary evidence of clinical activity in SLE and psoriasis. Mixed clinical results have been reported about compounds targeting Syk and Fak. While the Syk inhibitor prodrug fostamatinib (*Tavalisse* ™) has shown limited clinical activity in RA, it has been approved for the treatment of chronic immune thrombocytopenia (ITP) by the FDA in 2018. The Fak inhibitor defactinib is still explored for the treatment of solid cancers, and future basic research and clinical studies will show whether these and other inhibitors of nonreceptor PTKs may be as successful drugs as imatinib or ibrutinib for the treatment of cancer or the management of certain chronic immunological diseases.

Definition

Protein modification by the covalent attachment of ubiquitin chains serves as a signal to mark proteins for the degradation by a multicatalytic proteinase complex called the proteasome. Thus, the ubiquitin proteasome system (UPS) controls the stability of proteins in a regulated manner affecting multiple essential cellular processes. In addition, dependent on the mode of linkage, ubiquitin regulates protein-protein interaction, endocytosis, replication, and the formation of signaling complexes in a proteasome-independent fashion. Besides phosphorylation ubiquitination represents the most important posttranslational regulatory mechanism in biology.

Basic Mechanisms

Ubiquitin Conjugation

Ubiquitin is a highly conserved 8.5 kDa polypeptide, which was first described in 1974. The discovery that the ubiquitin proteasome system serves as a general mechanism to target proteins for destruction by the proteasome was awarded with the Nobel Prize for Chemistry in 2004.

Upon cleavage from a precursor, ubiquitin becomes covalently attached to the ε-amino group of lysine (K) residues in specific target proteins by the consecutive activity of a set of E1, E2, and E3 enzymes. First an ubiquitin-activating enzyme (E1) is charged with ubiquitin. This is accomplished by using ATP to form a high-energy bond at the C-terminus of ubiquitin. Subsequently this linkage is attacked by the sulfhydryl group of the active site cystein present in the catalytic domain of the E1 enzyme resulting in a thioester formed between the E1 and ubiquitin. Ubiquitin can now be transferred from the E1 to the catalytic core of a second class of enzymes termed ubiquitin-conjugating enzymes (E2). The E1 is released and can now charge additional ubiquitin residues. Ubiquitin bound to E2 can finally be transferred to target protein substrates, a step which is catalyzed by E3 ligases (Song and Luo 2019). As ubiquitin itself contains several lysine

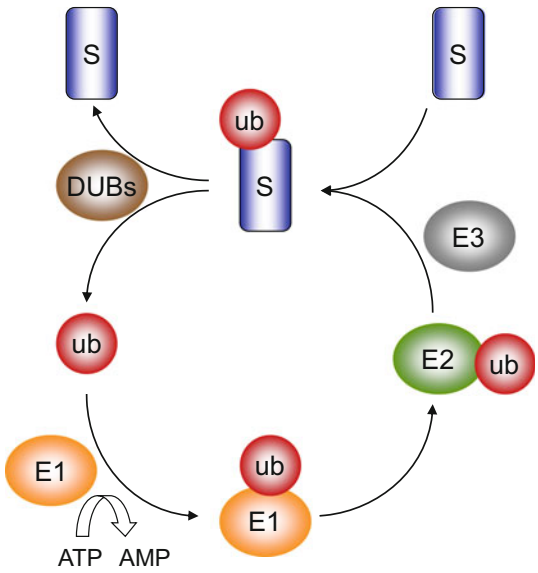
https://doi.org/10.1007/978-3-030-57401-7

residues, which can serve as targets for the linkage of additional ubiquitin molecules, variable chains of ubiquitin can be attached. Like most posttranslational modification mechanisms, ubiquitin conjugation is a reversible process. Analogous to the activity of phosphatases in protein phosphorylation, deubiquitinating enzymes (DUBs) counteract ubiquitin modification by cleaving the molecule from modified substrates (Clague et al. 2019). The hierarchical order of E1, E2, and E3 activity correlates with an increase in enzymatic specificity which ensures selective ubiquitin modification of distinct target proteins. While only 2 E1 enzymes and around 50 E2 enzymes have been described, more than 700 E3s are encoded in the human genome. The large group of E3 enzymes is mainly responsible to exert specificity in terms of substrate recognition. The existence of more than 90 different DUBs in humans adds further complexity to the system (Fig. 1). In addition to the canonical form of ubiquitination via E1, E2, E3, phosphoribosylated ubiquitin can be linked to serine residues of distinct substrates catalyzed by enzymes of the SidE family. Furthermore, ubiquitin chains can be attached to the N-terminal methionine by the linear ubiquitin chain assembly complex (LUBAC). Complexity is further enhanced as ubiquitin itself can be acetylated on lysine or phosphorylated on serine, threonine, or tyrosine residues. All these variations determine the consequences for the modified protein (Swatek and Komander 2016).



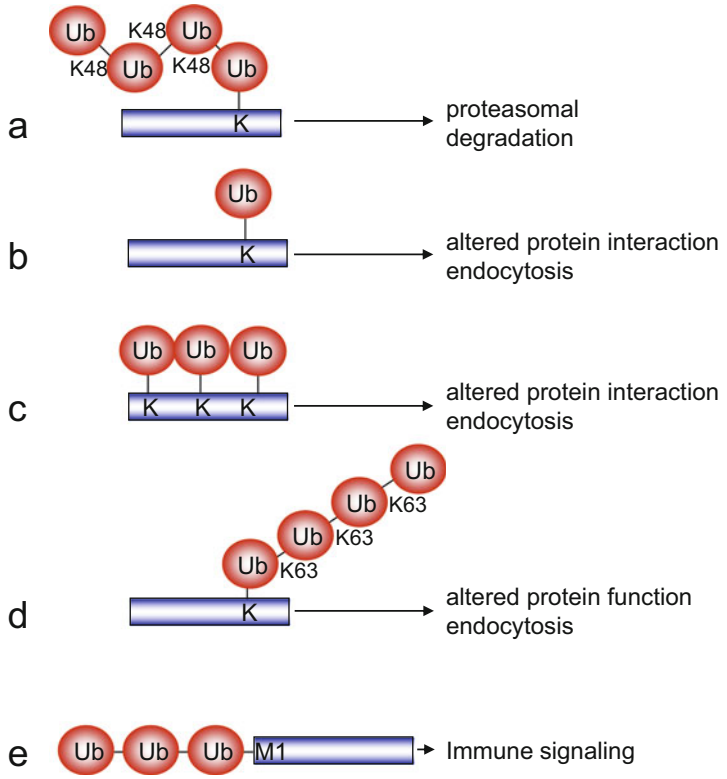
Ubiquitin/Proteasome, Fig. 1 Ubiquitin conjugation cycle. Ubiquitin (Ub) is ligated to target substrates (S) by the consecutive activity of ubiquitin-activating enzymes (E1), ubiquitin-conjugating enzymes (E2), and ubiquitin ligases (E3). Deubiquitinating enzymes (DUBs) mediate deconjugation of ubiquitin bound to substrates

Ubiquitin Modification as a Signal for Proteasomal Degradation

Single ubiquitin residues can be connected to one (monoubiquitination) or multiple lysine residues (multi-monoubiquitination) of the target protein. As different lysines within ubiquitin can serve as sites for the addition of further ubiquitin molecules, variable chains of ubiquitin can be connected to the substrate (polyubiquitination). The best-characterized lysines used for ubiquitin chain prolongation are K48 and K63, but also linkages via K6, K11, K27, and K29 and K33 are of relevance. The fate of ubiquitin-labeled proteins depends on the mode of linkage that is formed and has complex consequences (Akutsu et al. 2016). Some classical examples are depicted in Fig. 2.

K48-linked polyubiquitin serves as a signal for proteolytic degradation by the 26S proteasome, a multisubunit complex composed of a core protease termed 20S proteasome and a 19S regulatory particle (PA700), attached at either one or both ends. The 19S regulatory particle can further be dissected into two substructures, a lid and a base. The base harbors six homologous ATPases. The 20S proteasome consists of four heptameric rings (α1, β1, β2, α2) that form a cylindric, barrel-shaped structure harboring three distinct catalytic domains in the β-subunits orientated toward the internal side. These different catalytic subunits were shown to encompass chymotrypsin-like, trypsin-like, and peptidyl-hydrolase-like activity.

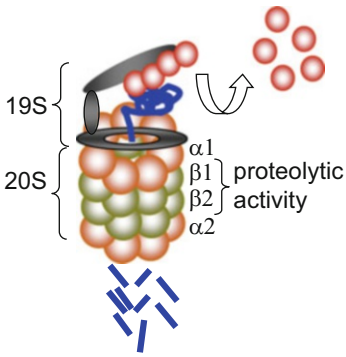
Recognition of ubiquitin-conjugated proteins, detachment of the ubiquitin chains, and unfolding is accomplished by the regulatory 19S subunit. From there the polypeptide is translocated in the



Ubiquitin/Proteasome, Fig. 2 Functional consequences of ubiquitin linkage. Substrates (blue bars) are linked via lysine residues (K) to ubiquitin or ubiquitin chains. (**a**) Attachment of chains connected via lysines in position 48 of ubiquitin (K48) targets substrates for proteasomal degradation. In contrast modification of one (**b**) or multiple (**c**) lysines by a single ubiquitin molecule mediates novel protein interactions or initiates endocytosis. Conjugation of K63-linked polyubiquitin (**d**) alters protein function and can also serve as a signal for endocytosis. (**e**) In linear ubiquitination, ubiquitin chains are linked to the terminal methionine (M1) which plays a major role in immune signaling

lumen of the 20S core proteasome and degraded by the proteolytic activity of the β-subunits (Fig. 3). The pore can be occluded by peptides from the α-subunits, and PA700 functions as a gatekeeper by removing these occlusions. The process of 26S proteasome-catalyzed proteolysis is energy dependent, i.e., depends on ATP hydrolysis.

The modular structure allows adaptation to different physiological demands by the exchange of subunit components in either the regulatory or proteolytic part of the proteasome. IFN-γ, for example, can modify the composition of the proteasome by mediating the exchange of the regulatory complex and replacement of proteolytic subunits. Proteolytic activities in this so-called immunoproteasome are altered in a way that generation of antigenic peptides suitable to be loaded to MHC class I proteins is favored. Thus, the ubiquitin proteasome system exerts an essential function in antigen presentation, necessary for appropriate immune defense against pathogens (Murata et al. 2018).



Ubiquitin/Proteasome, Fig. 3 Structure of the proteasome. Proteasomes form a barrel-like structure and are composed of a 20S core particle and the 19S regulatory subunit located at one or both ends. Two heptameric β-rings (green), which contain the proteolytic domains, are attached to the outer α-rings (orange). Substrates (blue) are recognized by the regulatory particle, unfolded, and upon detachment of ubiquitin chains (red) degraded in the lumen of the 20S core proteasome

The UPS also plays a major role in protein quality control where it is tightly connected and intertwined with autophagy (Pohl and Dikic

2019). In a process known as endoplasmic associated degradation (ERAD), misfolded proteins, which are formed in the endoplasmatic reticulum, are translocated back to the cytoplasm and degraded by the proteasome.

The ubiquitin-mediated degradation of certain proteins is also one of the key mechanisms underlying cellular growth control. Thus, the half-life of critical regulatory proteins of the cell cycle like p53, cyclins, and cyclin-dependent kinases (CDKs) are directly controlled by the ubiquitin system. Furthermore, cell cycle progression depends on a coordinated network of ubiquitin-mediated proteolysis of these factors. Key regulators of cell cycle checkpoints and cyclin degradation are the anaphase-promoting complex (APC) and the Skp1/Cul1/F-box protein complex (SCF) both acting as ubiquitin ligases.

APC is active from mid-M phase (anaphase) to the end of G1 phase and required for disconnecting sister chromatids and exit from M-Phase to G1. The complex mediates the ubiquitination of securin and cyclin B. Degradation of these proteins, which block mitotic progression, promotes anaphase onset and exit from mitosis.

The SCF ubiquitylates proteins from late G1 to early M phase. This complex consists of a core together with different so-called F-box proteins, which are responsible for the substrate recognition. Typically interaction of F-box proteins with their substrate involves sites of phosphorylation, so-called phosphodegrons. Thus, a highly coordinated and specific degradation of different cell cycle regulators in distinct activation stages can be achieved, and it is not surprising that E3 enzymes acting within this context are frequently deregulated in cancer (Senft et al. 2018).

Proteasomal degradation also plays an essential role in the activation of cellular signaling pathways. A prototype for this is the control of NF-κB signaling, which has a pivotal role in inflammatory responses. Upon stimulation the inhibitory IκBα protein is phosphorylated and thereby becomes a target substrate for K48 polyubiquitination. Proteasomal degradation of IκBα releases the transcription factor NF-κB, which subsequently translocates to the nucleus and activates specific target genes.

Non-proteolytic Functions of Ubiquitin Conjugation

In contrast to the proteasome-mediated degradation of proteins linked to K48-polyubiquitin chains, monoubiquitin, multi-monoubiquitin, or K63 linkage of ubiquitin chains is often not a signal for proteasomal degradation, but controls molecular mechanisms like protein activity and interaction, DNA repair, and inflammation. Monoubiquitination and multi-monoubiquitination are crucial events in signal termination. Upon ligand binding surface receptors like receptor tyrosine kinases or G-protein-coupled receptors are hereby marked for endocytosis and degraded via the endosomal/lysosomal pathway. Another example for non-proteolytic functions is the modification of proliferative cell nuclear antigen (PCNA), a DNA processivity factor. While K63-linked polyubiquitin modification results in error-free DNA repair, monoubiquitination of PCNA recruits an error-prone translesion polymerase (Masuda and Masutani 2019).

Ubiquitin modification of substrates can be sensed by proteins, which serve as "ubiquitin receptors." These proteins harbor domains capable of ubiquitin binding and help to translate the signal into the proper physiological response by forming signaling complexes or activating downstream effectors. So far more than 15 different ubiquitin recognition motifs have been identified.

Ubiquitin-Like Proteins

Proteins can also be modified by so-called ubiquitin-like modifiers (UBLs). These proteins have structural similarity to ubiquitin and are linked to substrates in a similar way. Like ubiquitin UBLs are conjugated by the consecutive action of E1, E2, and E3 ligases and sometimes use the same enzymes mediating

ubiquitin linkage. Prominent examples for UBLs are SUMO, NEDD8, FAT10, or interferon-stimulated gene 15 (ISG15), which have been shown to affect multiple cellular functions like protein localization, cell cycle progression, DNA repair, and immune function (Hochstrasser 2009).

Disease Associated with Perturbations of the Ubiquitin System

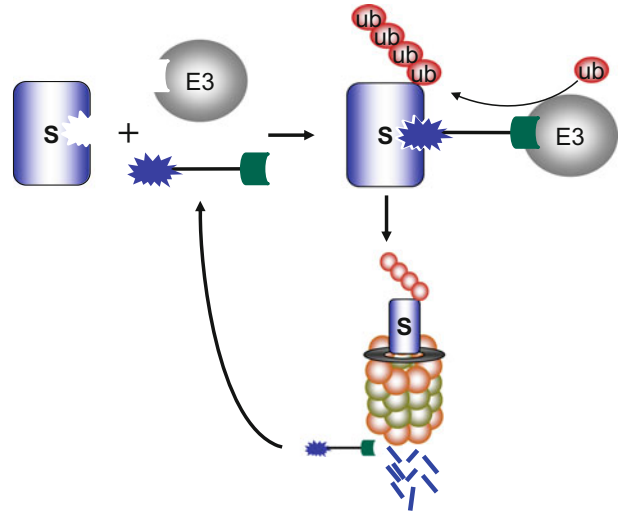
In concordance with the central role of ubiquitin modification in multiple cellular functions, perturbations of this system are associated with a variety of diseases, and only a small selection can be presented here. Defects in the control of cell cycle regulators or genome integrity by components of the ubiquitin system are connected to cancer progression, and many E3 ligases were originally identified as oncogenes (Wang et al. 2017). As the ubiquitin proteasome pathway is a main route for protein clearance, it is not surprising that in proteinopathies (disease caused by aggregate-prone proteins) like sporadic Parkinson or Huntington disease, proteasome activity is reduced. Autosomal recessive loss of function of the E3 ligase parkin is the molecular base for one of the most common forms of familial Parkinson disease. In concert with the kinase PINK1, Parkin plays a major role in the elimination of damaged mitochondria. PINK1, which is normally rapidly degraded, is stabilized upon mitochondrial damage and activates parkin involving parkin and ubiquitin phosphorylation. In its activated form, parkin then assembles ubiquitin chains on numerous proteins on the outer mitochondrial membrane, leading to the recruitment of ubiquitin-binding autophagy receptors and clearance of the damaged mitochondria. Disturbed function of this mitophagy is one etiology of Parkinson disease (Harper et al. 2018).

In cystic fibrosis a point mutation of the cystic fibrosis transmembrane regulator (CFTR) prevents transport of this molecule to the cell surface. Instead this otherwise functional molecule is degraded by the ERAD-ubiquitin proteasome pathway.

Pharmacological Intervention

Pharmacologic Targeting of Components of Ubiquitin and Ubiquitin-Like Modification Systems

Proteasomal inhibition represents a meanwhile established strategy in cancer treatment. Bortezomib (PS-341, Velcade™) was the first proteasome inhibitor to be brought into clinical use for the treatment of refractory and relapsed multiple myeloma, a proliferative disease of plasma cells. Bortezomib inhibits an active site in a proteasome subunit and remarkably shows selective cytotoxicity to certain cancer cells. Later on, second-generation inhibitors of the proteasome were developed which include carfilzomib, ixazomib, oprozomib, delanzomib, and marizomib. In clinical trials these small molecules also showed activity in tumors resistant to bortezomib. Although the precise mechanisms of the effect of proteasome inhibition against cancer are not entirely clear, studies uncovered a general promotion of apoptosis in malignant cells due to destabilization and stabilization of key players in this pathway (Manasanch and Orlowski 2017). The success of proteasome inhibition boosted various approaches to more specifically target distinct components of the UPS to reduce side effects and overcome resistance. An example for such a more specific pharmacological approach is to prevent ubiquitin-mediated degradation of the tumor suppressor p53, which is mediated by the E3 ligase MDM2. Inhibition of MDM2 ligase activity by a family of closely related 7-nitro-5-deazaflavin compounds (HLI98) was shown to stabilize p53. Protein interaction between MDM2 and p53 was effectively prevented by nutlins, a class of *cis*-imidazoline compounds, which exhibited strong antitumor effects in mice. Within the same molecular context, inhibitors were developed for USP7, a DUB that counteracts MDM2 autoubiquitination. Inhibition of USP7 enhances ubiquitination of MDM2 and thus promotes its proteasomal degradation. As a consequence p53 is stabilized and beneficial effects were detected in preclinical tumor models. To



Ubiquitin/Proteasome, Fig. 4 Principle of targeted protein degradation by PROTACS and related molecules. To selectively degrade a particular substrate protein (S), a bispecific adapter molecule (PROTAC) is designed which links the substrate to an E3 ligase-mediating ubiquitin conjugation. This marks the protein for proteasomal degradation, while the adapter is released and can enter a new recruitment cycle

block protein modification by ubiquitin or ubiquitin-like proteins, inhibitors for various E1 activating enzymes were developed. MLN7243 is the first ubiquitin E1 inhibitor to enter a clinical trial for cancer therapy, and also the NEDD8 E1 (NAE1) inhibitor pevonedistat (MLN4924) is currently in clinical trials for the treatment of various types of cancer (Yin et al. 2019). For pharmacologic modulation, the class of ubiquitin- or UBL-deconjugating enzymes (DUBs) represent attractive target structures. As being proteases, DUBs fall under a category of proteins already proven to be druggable, and biochemical assays can relatively easily be developed and adapted to high-throughput format. The large numbers of DUBs with their various functions allow more selective intervention strategies, and small molecules with proven activity were already developed. Many DUB inhibitors addressing severe diseases in oncology, inflammation, and neurodegeneration showed promising effects in preclinical studies or entered clinical trials (Harrigan et al. 2018).

Pharmacologic Exploitation of the Ubiquitin Proteasome System for Targeted Degradation of Proteins

Targeted degradation of proteins is a pharmacologic strategy which gained tremendous interest in recent years and offers great chances for the development of novel therapeutic applications. The approach hijacks the endogenous ubiquitin/proteasome degradation machinery to selectively destroy target proteins associated with pathological conditions. As depicted in Fig. 4, a chemical adapter molecule is constructed which on the one side harbors a specific binding entity for the target protein, while another element in the molecule mediates attachment to an endogenous E3 ligase. Thereby, these so-called proteolysis-targeted chimeras (PROTACs) recruit the target protein to the ubiquitin conjugation machinery, where decoration with ubiquitin chains marks it for proteasomal degradation. In an ideal scenario, the chemical linker leaves the proteasome in its active form and can recruit the next target protein. A single small-molecule ligase modulator can therefore drive the destruction of many molecules of a target protein reminiscent of a catalytic mechanism. In contrast to classical pharmacological approaches where the small molecule needs to block a particular functional domain of a protein, PROTACS offer the conceptual advantage that in principle any protein can be addressed. Even disease-associated proteins previously thought not to be pharmacologically accessible can in

principle be attacked by PROTAC-mediated degradation. These undruggable proteins still constitute the vast majority within the proteome and include transcription factors, adapter proteins, proteins with scaffolding function, aberrant proteins, etc. As the chemical moiety which links the substrate to the ligase only needs to bind the substrate anywhere rather than block a particular enzymatic core, ATP-binding site or whatsoever more options for the compound selection exist.

Synonyms

Endoplasmic reticulum stress; Misfolded proteins

Definition

The endoplasmic reticulum (ER) is the vital organelle in all eukaryotes, first explored by Porter and his colleagues in 1945 in mice fibroblast (Porter et al. 1945). ER is the complicated tubular meshwork, which controls calcium (Ca^{2+}) homeostasis and serves as a main site for the synthesis of 33–35% of all cellular proteins. Moreover, it is also responsible for folding of transmembrane and secreted proteins that comprise one-third of all the synthesized proteins in the cell (Oakes and Papa 2015). Appropriate folding of proteins is a critical step in preserving its functions, as any abnormality may lead to cellular stress and even causes death, called ER stress (ERS). Various endogenous and exogenous factors interrupt protein folding which causes

accumulation of unfolded proteins in ER lumen, resulting in exaggerating unfolded protein response (UPR).

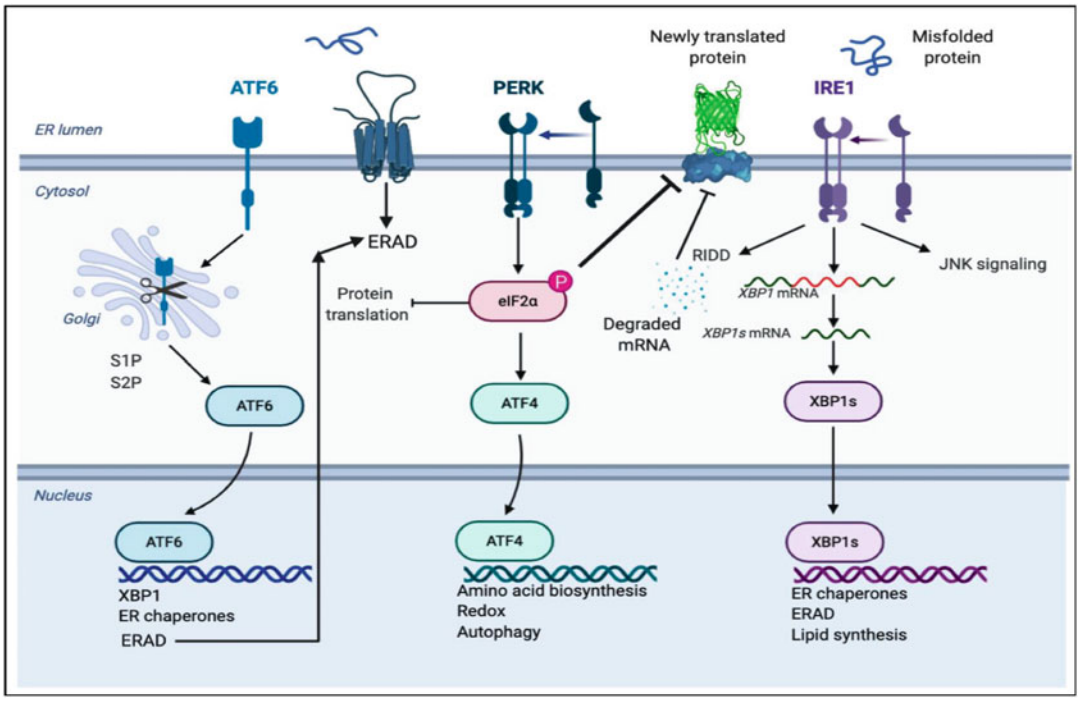
Basic Characteristics of UPR Pathway

The UPR is a highly conserved ER adaptive pathway designed to respond against misfolding of protein in the ER. This pathway consists of three transmembrane stress sensors, namely, inositol-requiring enzyme 1 alpha (IRE1α), PKR-like ER kinase (PERK), and activating transcription factor 6 (ATF6). During normal physiological conditions, the internal domains of these sensors are inactive via binding with molecular chaperons comprising binding immunoglobulin protein (BiP), also termed as glucose-regulated protein 78 (GRP78) and heat shock protein A5 (HSPA5). Despite outstanding affinity of BiP for unfolded proteins, BiP detaches from ER stress sensors during luminal accumulation of misfolded proteins to activate downstream signaling pathway (Pincus et al. 2010). Mechanistically, accumulated misfolded protein within ER lumen ignites heat shock protein to activate transcription of genes responsible for encoding cytosolic BiP to refold unstable proteins. However, during pathological conditions such as inflammation, neurodegenerative disorder, diabetes mellitus (DM), and cardiovascular disease (CVD), ERS leads to activation of UPR to counterbalance the cellular damage. Furthermore, hydrophobic and basic residues of unfolded proteins directly attach with distinct binding site on IRE1α to induce UPR (Grootjans et al. 2016).

Consequently, upregulated UPR accelerates transcriptional factors and related gene expression to attenuate ERS by repressing synthesis of proteins and activates ER-associated degradation (ERAD) of incomplete folded proteins, thereby elevating synthesis of molecular chaperones to expedite protein folding. The UPR within ER lumen accomplished these compensatory responses via stress sensors by four distinctive approaches. The primary goal of these stress sensors is to preserve proteostasis by rapidly mitigating mRNA translation through PERK-mediated phosphorylation of α-subunit in eukaryotic by translating initiation factor 2 (elF2α), which blocks protein and thus restricts limited amount of protein entry inside the ER. Second, entry of newly synthesized proteins into the ER is reduced by deterioration of ER membrane-bound mRNAs via IRE1-α-dependent decay (RIDD) (Scheuner et al. 2001). Third, elimination of misfolded protein from the ER is mediated by enhancing transcription of ERAD and autophagy like proteins. Lastly, protein folding capacity of ER is increased by the specific genes that mediate its expansion through augmentation of lipid synthesis and biogenesis (Oakes and Papa 2015). Nevertheless, when these compensatory responses are unable to cope with pathological state, the UPR shifts to pro-apoptotic mode as terminal UPR and leads to cellular damage (Grootjans et al. 2016).

Characteristics of IRE1α Signaling

IRE1α is the transmembrane protein consisting of two domains: an endoribonuclease (RNase) domain and a serine/threonine kinase domain. After detaching from BiP, IRE1α undergoes dimerization to induce RNase activity to generate non-conservative splicing of mRNA that encrypts X-box binding protein 1 (XBP1). The resultant translational shift produces a transcriptional inducer, termed as spliced XBP1 (XBP1s), which translocates inside the nucleus to initiate synthesis of GRP78, GRP94, and XBP1, to enhance ER size and facilitate protein folding. Moreover, IRE1α is also responsible for the activation of RIDD which degrades ER membrane-bound mRNAs to limit the quantity of protein which enters inside the ER as shown in Fig. 1. Conversely, during persistent ERS, the compensatory role of IRE1α is impaired, while PERK signaling becomes dominated. Chronic ERS causes activation of cytosolic RNase domain of IRE1α after oligomerization, which leads to non-specific cleavage of apoptosis inhibitory microRNAs (other than RNA of XBP1), thus fans the flame of apoptosis. In summary, during sustained



Unfolded Protein Response, Fig. 1 The accumulation of misfolded proteins within ER lumen stimulates three branches of UPR. After dissociation from BiP, ATF6α translocates to Golgi complex and processed by S1P and S2P to generate p50 cytosolic fragment. P50 fragment serves as transcriptional factor that enhances ER capacity of protein folding. PKR-like ER kinase (PERK) phosphorylates elf2α to halt ribosomal assembly and allow cells to manage temporary ERS. Upon separation from BiP, IRE1α non-covalently splices intron to produce XBP1s mRNA, which encodes proteins to facilitate protein folding capacity of ER

ERS, IRE1α switches to aggravate inflammation and necrosis rather than being adaptive (Amen et al. 2019).

Characteristics of PERK Signaling

The second arm of UPR is PERK which is a local ER transmembrane protein that plays a crucial role during ERS. Moreover, it has been well-established that lipid components in the ER membrane are also capable for the induction of PERK signaling during ERS (Volmer et al. 2013). The primary role of PERK pathway is to suppress synthesis of protein and implicates attenuating eIF2α-mediated translational activities within the ER. During ERS, PERK separates from BiP and undergoes oligomerization to phosphorylate eIF2α, a main substrate for PERK. Phosphorylated eIF2α further blocks eIF2-ternary complex (eIF2-TC) development and thus temporarily mitigates global mRNA translation to facilitate management of transient ERS, although, within ER-stressed cells, translation of majority of mRNA is suppressed by translational activity of some mRNA species which are beneficial during the phase. Importantly, mRNA transcribes activating transcription factor 4 (ATF4) as presented in Fig. 1, which is a critical moderator in UPR and involves transactivation of genes responsible for developing resistance to oxidative stress (OS), metabolism of amino acids, and autophagy (Lei et al. 2017).

Conversely, prolonged translational blockade is not favorable for the survival of cell. Therefore, ATF4 enables protein phosphatase 1 regulatory subunit 15A (PPP1R15A) expression, which encrypts growth arrest and DNA damage-

inducible protein (GADD34). GADD34 directly dephosphorylates elF2α to resume mRNA translation. On the other hand, ATF4 also stimulates transcriptional events leading to the synthesis of C/EBP homologous protein (CHOP), which is implicated in ERS-mediated programed cell death. In order to facilitate cells in the management of ERS, various mechanisms are directed to depress CHOP transcription including PERK-dependent microRNA 211 (miR-211), which suppresses CHOP via methylation of histone. Furthermore, CHOP synthesis is also inhibited by toll-like receptor (TLR) pathway through protein phosphatase 2A (PP2A), which facilitated dephosphorylation of serine residue of elF2Bε subunit (Woo et al. 2012). In fact, strong stimulation of PERK enhances constant level of CHOP; hence, only persistent ERS can switch UPR to pro-apoptotic mode. Based on previous studies, both ATF4 and CHOP during constant ERS functions act as heterodimer to initiate apoptosis by enhancing synthesis of protein, leading to the generation of misfolded protein and cell death (Grootjans et al. 2016).

Characteristics of ATF6 Signaling

ATF6 is a transmembrane transcriptional factor bearing cytosolic N-terminal and ER luminal C-terminal domains that stimulates transcriptional processes, which enable ER to sense ERS. ATF6 signaling pathway comprises of two isoforms, namely, ATF6α and ATF6β. Signal transduction of ATF6 is similar to IRE1α and PERK; however, autophosphorylation and oligomerization are absent. During ERS, N-terminal of ATF6 dissociates from BiP to reallocate itself in Golgi complex (Fig. 1), where it undergoes proteolysis via Golgi resident site 1 protease (S1P) and site 2 protease (S2P) to generate p50 cytosolic fragment that translocates to the nucleus (Amen et al. 2019). The p50 fragment mediates expression of CHOP, GRP78, GRP94, and protein disulfide isomerase (PDI) to promote expansion and protein folding capacity of ER along with stimulation of ERAD pathway (Han et al. 2013).

Therapeutic Approach to Modulate UPR

The lethal connection between deregulated UPR and development of chronic human disorders accelerated researcher to explore small molecules, which modulate UPR signaling during pathological conditions. Previously published findings revealed involvement of UPR signaling pathways in the development of metabolic disorders, cancer, obesity, neurodegenerative diseases, and immune-related disorders (Lebeaupin et al. 2018). Our understanding regarding molecular mechanisms mediating UPR is clearly understood, and the implication of UPR proteins in various disease conditions has been established. Therefore, robust therapeutic approach is needed that enhances the delivery of potential medicaments, mediating through the targeted UPR signaling for the beneficial clinical outcomes.

IRE1α RNase Inhibitors

RNase poses difficult therapeutic targets; direct inhibitors of IRE1α RNase were explored through florescent hairpin RNA, human recombinant protein, and luciferase assays. The chemical structure of all renowned RNase domain inhibitors possesses central aromatic aldehyde with an adjacent hydroxyl group, called hydroxyl-aryl-aldehydes (HAAs). Various HAAs including STF-083010 have been investigated based on their structure activity relationship (SAR), but their in vivo therapeutic potential is still under investigation. Mechanistically, these inhibitors work in a non-competitive fashion by impairing catalytic cleavage, while XBP1 mRNA may modulate and bind to IRE1α (Zhao et al. 2018). However, still further research is needed to explore exact mechanism of impairing catalytic activity.

Allosteric IRE1α Kinase Modulators

Kinases comprise well-defined drug-binding sites. Wang et al. (2012) investigated kinase inhibitors due to their ability to maintain inactive state of IRE1α with subsequent inhibition of RNase,

Unfolded Protein Response, Table 1 Small molecule inhibitors targeting arms of UPR signaling

Class	Disease	Experimental model	Pharmacological action	Reference
IRE1 inhibitors				
STF-083010	Multiple myeloma	MCF-7 xenograft	Inhibition of tumor growth	[12]
KIRA6	Type 1 diabetes	Akita diabetic mouse model	Improved hyperglycemia	[13]
AMG18	Non-obese diabetes	Non-obese diabetic mice	Protect beta cells with enhanced insulin secretion	[14]
PERK inhibitors				
GSK2606414	Prion disease	Tg37 transgenic mice	Neuroprotection with improved behavioral and cognitive function	[15]
GSK2656157	Neonatal diabetes mellitus	Mouse and human islets	Improved hyperglycemia	[15]
elf2α phosphatase blockers

	Renal injury	C57B/6J mice	Preserved renal functions	[21]

using allosteric effect in an in vitro study (Wang et al. 2012). Importantly, they expanded biaryl urea motif after replacing central structure to synthesize KIRA6 (Table 1). Similarly, Amgen and their colleagues explored another kinase inhibitor named AMG18; both the compounds have similar binding affinities that block IRE1α RNase via the same mechanism. Binding of inhibitor mobilizes Cα-helix of IRE1α which causes disruption of contact between dimers and thus diverts the state of equilibrium toward silenced monomeric form of IRE1α (Feldman et al. 2016). Other IRE1α kinase inhibitors may lead to activation of IRE1α such as type I kinase blockers that competitively attach with ATP, and kinase-inhibitor complex undergoes a conformational change similar to active ATP state. Only in vitro findings revealed that these inhibitors stimulate IRE1α signaling, but still there is a dearth in understanding the abovementioned mechanisms via preclinical studies using animal models.

Inhibitors of PERK Signaling

The first reported and extensively investigated PERK inhibitors are GSK2606414 and GSK2656157 as enlisted in Table 1, which are highly potent and well characterized on pharmacokinetic (PK) platforms compatible for in vivo

studies. These inhibitors possess a central structure, indoline, and competitively attached with cytosolic kinase domain of PERK within ATP binding cleft, leading to modification of Cα-helix. This molecular modification accounts for their potent inhibitory effect and selectivity for kinases. Another novel group of PERK inhibitor with structural alterations and distinct binding chemistry was discovered. These agents after binding at the ATP cleavage of PERK cause rearrangement of catalytic moiety and maintain inactive state of PERK. However, AMG44 and AMG52 have similar potential of kinase inhibition but are less potent than GSK2606414 and GSK2656157. Based on pharmacodynamic (PD) study, it attributes to kinase selectivity; AMG52 and AMG44 are favored to explore pharmacology of PERK signaling. In future, long-term investigation with additional selective entities is required (Hetz et al. 2019).

elf2α Phosphatase Blockers

The primary compound, which served as an investigational tool to analyze elf2α phosphatase, is salubrinal (Table 1). Studies based on its mechanism demonstrated prevention of dephosphorylation of elf2α during ERS. More specifically, salubrinal non-selectively blocks protein phosphatase 1 (PP1) holoenzyme phosphatase complexes that regulate P-elf2α as negative feedback during integrated stress response (ISR), facilitated through GADD34 controlling subunits (Colla et al. 2012). In search of selective inhibition of elf2α phosphatases, identification of α-adrenergic agonist guanabenz (Table 1) showed selective blockade of GADD34. This finding motivated further efforts to identify another potent and selective inhibitor named sephin1, lacking α-adrenergic effects as shown in Table 1. However, direct binding of guanabenz and sephin1 with GADD34-PP1 has been disapproved recently. Therefore, extensive molecular study is required to further dissect role of sephin1 and guanabenz to reveal pharmacological basis of their mechanism of action (Crespillo-Casado et al. 2018).

ATF4 Inhibitors or elf2B Activator

Table 1 presented selective ISR or ISRIB inhibitor of ATF4 which was discovered after phenotypic screening by Sidrauski et al. (2013) that effectively depress translational modification of ATF4 reporter during ERS (Sidrauski et al. 2013). Binding of ISRIB to lipophilic cleft at the junction of elf2B β and δ-subunits derives equilibrium dissemination of subunits toward dense population of accumulated decamer complex with highest catalytic activity. The enhanced catalytic potential of elf2B mediated by ISRIB recruits elf2-TC and hampers ATF4 translation. Notably, ISRIB is only limited to elevate catalytic activity of non-sequestered (P-elf2α sequestered elf2B) elf2B, and efficacy of ISRIB during stress is dependent on relative expression of P-elf2α to restricted amount of elf2B. Due to poor physicochemical characteristics, ISRIB is insoluble and poses difficulty in formulation. Moreover, recently it has been reported that ISRIB is effective only during moderate ISR stimulation. Conversely, 2BAct was discovered as new elf2B activator, equipped with excellent pharmacokinetic and physicochemical attributes compatible for oral administration and can be mixed in regular chow diet for long-term in vivo investigations (Wong et al. 2019).

ATF6 Modulators

Small molecule inhibitors and activators targeting ATF6α have been explored using in vitro ERS responsive luciferase reporter assay. Ceapins selectively inhibit ATF6α activation. SAR analysis highlighted pyrazole amide motif enhanced ten-fold increase in the potency of the compound. Presumably, ceapins inhibit translocation of ATF6α from the ER to the Golgi complex by interrupting with coat protein complex II (COPII) facilitated transportation, thereby sequestering ATF6α from S1P and S2P (Gallagher et al. 2016). Similarly, ATF6 activators have been exposed such as 147 (Table 1) and 263 compounds that selectively activate ATF6α signaling pathway. Activated compound 147 modulates ER

local PDI to provoke ATF6α stimulation, while mechanism of 263 remains to be elucidated (Hetz et al. 2019).

Future Prospective

The utilization of small molecules that modulate specific domains of UPR signaling during ERS has confirmed UPR implication in the pathogenesis of several diseases with underlined mechanisms. The understanding of UPR signaling with various in-depth insight paves the way for potential and promising outcomes in the management of multiple human disorders. However, due to broader indications and critical nature of UPR pathways, there are many unanswered questions need to be addressed. Side effects related to these small molecules can be tested in non-human primates and rodents, prior to their investigations at preclinical level. Importantly, comparison between pharmacological inhibition and preclinical investigations using genetic deletion of UPR components is very difficult, as genetic deletion provides permanent inhibition, whereas inhibition via inhibitor occurs in troughs and peaks. One important question needs answer: how the intensity of inhibition is required over the time to achieve beneficial therapeutic outcome with minimum toxic effects? It has been shown that high therapeutic dose with subsequent target inhibition is well tolerated in mice over the months of treatment, while long-term management with on/off treatment cycles needs to be established in future. In addition, future investigations warrant acute vs. chronic elucidation of UPR signal transduction in various disease conditions, to implement unbound strategies and interventions needed in clinical aspects.

Overall, UPR domain plays pivotal role and displayed rapid advancement in drug discovery and development process of small molecules. Modulation of UPR signaling and its core branches provides an opportunity to dissect molecular mechanisms for the expansion of therapeutics in a wider range of ERS-related disorders.

Vasopressin

Maja Lozic and Mike Ludwig
Centre for Discovery Brain Sciences, University of Edinburgh, Edinburgh, UK

Synonyms

Antidiuretic hormone (ADH); Arginine vasopressin; Argipressin

Definition

Vasopressin is a nonapeptide synthesized in the hypothalamus and secreted from the posterior pituitary gland. It plays a major role in the maintenance of hydromineral balance in the body, exerting antidiuretic action on collecting ducts of the kidney. It is also a very potent vasoconstrictor, acting on arterioles and increasing peripheral vascular resistance. As a neuropeptide, vasopressin regulates affiliative and aggressive behaviors and the response to stress.

Several pathological conditions are directly connected either to malfunction of vasopressin secretion or to the resistance of target tissues to vasopressin action.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is characterized by an increased secretion of vasopressin, independent of plasma osmolality, which causes excessive water reabsorption and dilutional hyponatremia. SIADH can be of central origin, when the production of vasopressin in the hypothalamus is affected by an underlying neurological condition or brain injury, but it can also be drug-induced (by selective serotonin-reuptake inhibitors, thiazide diuretics, anticonvulsants) or may even occur as a clinical manifestation of some hormone-producing malignant tumors (e.g., small-cell lung cancer).

Lack of vasopressin due to impaired synthesis, transport, or release leads to the development of central diabetes insipidus, a rare disorder caused by pathological changes in the hypothalamus or/and pituitary gland. In contrast, nephrogenic diabetes insipidus reflects unresponsiveness of the kidneys to water-conserving vasopressin action. Despite their etiological differences, both forms of diabetes insipidus have a similar clinical presentation, comprising polydipsia, polyuria, dehydration, and hypernatremia.

Basic Characteristics

Vasopressin is a cyclic nonapeptide containing an N-terminal cyclic ring core comprising six amino

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

acid residues stabilized with a disulfide bridge between residues 1 and 6 and a flexible C-terminal three-residue amidated tail. Structurally, it is very similar to oxytocin, differing from it in only two amino acid residues, in positions 3 and 8.

The vasopressin gene comprises three exons and two introns. In mammals, it is located on the same chromosome as the gene encoding oxytocin, separated by just a few kilobases of sequence and transcribed in the opposite direction to that of oxytocin. It is assumed that the genes for vasopressin and oxytocin descend from the single gene present in Archaemetazoa, the common ancestor of both invertebrates and vertebrates, that was duplicated during evolutionary development.

Vasopressin is synthesized as a pre-prohormone consisting of a signal peptide, the hormone vasopressin itself, the binding protein neurophysin, and the glycosylated peptide copeptin. Due to its stoichiometric generation and stability, copeptin measured in plasma is shown to reliably represent vasopressin release (Christ-Crain 2019). The major site of synthesis is the magnocellular neuroendocrine neurons of the hypothalamic supraoptic and paraventricular nucleus. In the cell bodies of these neurons, the preprohormone is packed into large dense-core vesicles. These vesicles are then transported along the axons to the posterior pituitary gland (de Bree 2000). During axonal transport, the preprohormone is cleaved by proteolytic enzymes, yielding vasopressin that is then stored in vesicles in the posterior pituitary, awaiting osmotic or non-osmotic stimuli that trigger its release (Brown et al. 2013).

Recently, it was shown that some magnocellular neurons axon collaterals project to many sites in the brain, including medial and lateral preoptic area, suprachiasmatic nucleus, lateral habenula, amygdala, locus coeruleus, and arcuate nucleus. These axon collaterals have been implicated in the modulation of different behaviors. As well as containing magnocellular vasopressin neurons, the paraventricular nucleus contains smaller (parvocellular) vasopressin neuroendocrine neurons. Some of these project to the median eminence to regulate ACTH secretion from the anterior pituitary gland; others project centrally and to the spinal cord and are involved in a variety of functions, including cardiovascular regulation and thermoregulation and pain. Vasopressin is also expressed in neurons of the suprachiasmatic nucleus that regulate circadian rhythms and in diverse other populations, including in the olfactory bulbs and retina (Wacker and Ludwig 2019).

Vasopressin secretion from the posterior pituitary increases linearly with plasma osmotic pressure. In short, the magnocellular vasopressin cells are directly osmoreceptive; they express stretch-sensitive ion channels that cause them to be depolarized in response to volume shrinkage that accompanies a rise in extracellular osmotic pressure; they also express specific sodium receptors. In addition, other osmoreceptive neurons in the anterior hypothalamus also sense changes in extracellular osmolality and contribute to stimulation of vasopressin secretion when osmolality rises.

On the other hand, hypotension and hypovolemia are non-osmotic triggers that can increase the secretion of vasopressin. Afferent nerve fibers from cardiopulmonary (volume) baroreceptors located in the atria and pulmonary vasculature synapse within the nucleus of the solitary tract, which interact with neurons of the ventrolateral medulla, including noradrenergic neurons of the A1 cell group. Neurons in both the NTS and in the ventrolateral medulla project directly to the magnocellular neurons of the SON and PVN, and vasopressin neurons in particular receive a strong projection from A1 neurons. Increases in plasma volume normally inhibit the secretion of vasopressin; conversely, under conditions that lead to hypovolemia or a decrease in central venous pressure, atrial pressure and the atrial receptor firing rate decrease, inducing the release of vasopressin from the pituitary gland.

Activation of angiotensin II receptors in the hypothalamus, stress, pain, nausea, and vomiting, as well as some pharmacologically active substances such as nicotine, tricyclic antidepressants, certain antineoplastic drugs, and apomorphine, may also cause the release of vasopressin.

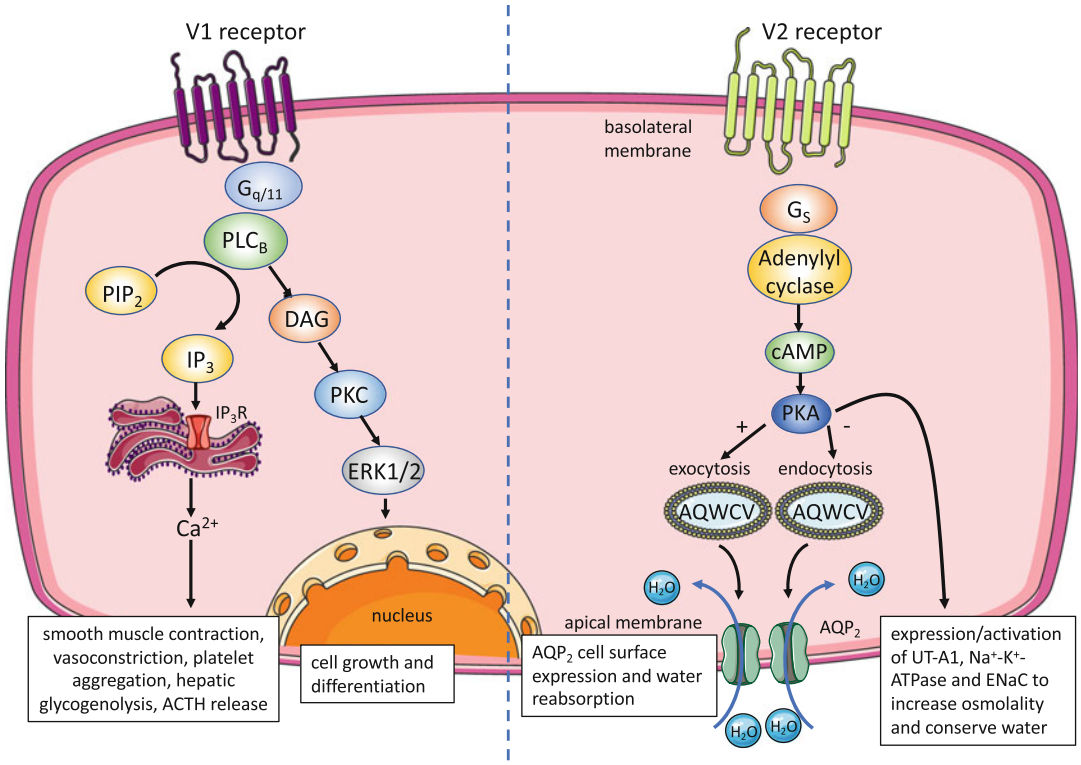
The secretion of vasopressin is inhibited by ethanol, atrial natriuretic peptide, dynorphin, low doses of morphine, dopamine receptor antagonists

(fluphenazine, haloperidol, or promethazine), and anticonvulsive drugs (phenytoin, carbamazepine).

Vasopressin Receptor Activation

Vasopressin elicits its numerous physiological and pharmacological effects through three types of transmembrane, rhodopsin-β adrenergic (type A) G protein-coupled receptors, namely, V1a, V1b, and V2 receptors (Fig. 1). Since the sequence homology between oxytocin and vasopressin receptors is approximately 80% (this high sequence conservation of receptors is especially noticeable in extracellular binding domains), vasopressin may also act as a ligand for oxytocin receptor (Manning et al. 2012).

Vasopressin binding to V1a and V1b receptors activates the Gq-(phospholipase C) PLC- (inositol-3-phosphate) IP_3 pathway (Koshimizu et al. 2012). Once activated, this pathway further leads to mobilization of intracellular Ca^{2+} and activation of protein kinase C (PKC). PKC and Ca^{2+}/calmodulin-activated protein kinases phosphorylate cell-type specific proteins, eventually leading to cellular responses, including vasoconstriction, glycogenolysis, platelet aggregation, ACTH release, and growth responses in smooth muscle cells. Activation of V1 receptors also mobilizes phospholipases A and D (PLA and PLD), which



Vasopressin, Fig. 1 Vasopressin V1 receptor (left side) and V2 receptor (ride side) signalling cascades. Binding to the V1 receptor (V1a and V1b) stimulates membrane-bound phospholipase (PLC_B) via stimulation of a G-coupled protein (G_{q11}), which in turn results in inositol triphosphate (IP_3) formation and mobilization of intracellular Ca^{2+}. A separate phosphorylation cascade occurs via diacylglycerol (DAG). DAG activates protein kinase C (PKC) and ERK1/2 pathway. The binding of vasopressin to the V2 vasopressin receptor stimulates a G_s-coupled protein that activates adenylyl cyclase, in turn causing production of cAMP to activate protein kinase A (PKA). This pathway increases in aquaporin 2 (AQP2) channel formation and apical membrane insertion by increasing the exocytosis of aquaporin water channel-containing vesicles (AQMCV) and inhibiting endocytosis of the vesicles

results in the production of arachidonic acid. Arachidonic acid provides a substrate for eicosanoid synthesis by the cyclooxygenase and lipoxygenase pathways. These locally produced prostaglandins, leukotrienes, and thromboxanes may further activate whole array of signalling pathways.

V1a receptors are present throughout the body. They can be found in vascular and gastrointestinal smooth muscle cells, liver, renal medulla, platelets, myometrium, iris, and various brain regions. V1b receptors are located in the anterior pituitary, kidneys, pancreas, adrenal medulla, and brain.

The V2 receptor activates the Gs protein and adenylate cyclase signalling pathway. Adenylate cyclase converts ATP to cyclic adenosine monophosphate (cAMP), a key signalling molecule in this pathway. In addition, stimulation of V2 receptors also leads to activation of the ERK1/2 MAP kinase pathway, although the exact physiological or pathophysiological importance of V2-regulated MAP kinase pathways needs to be further elucidated.

V2 receptors are most abundant in basolateral membranes of the collecting tubule cells in kidneys. They can also be found on the thick ascending limb of the loop of Henle and in endothelial cells.

Vasopressin Effects

Antidiuretic Action

Acting on V2 receptors, vasopressin increases the permeability to water of the collecting duct cells in the kidney, allowing water reabsorption and excretion of concentrated urine, i.e., antidiuresis. This occurs through the insertion of water channels, aquaporin-2 (AQP2), into the apical membrane of the collecting duct epithelial cells. Consequently, water moves out of the nephron, increasing the amount of water reabsorbed from the forming urine back into the bloodstream. Vasopressin increases transcription of the aquaporin-2 gene, increasing the number of aquaporin-2 molecules in collecting duct cells. Vasopressin also increases the permeability of the inner medullary portion of the collecting duct to urea, allowing increased reabsorption of urea into the medullary interstitium. Finally, vasopressin stimulates sodium and chloride reabsorption in the thick ascending limb of the loop of Henle. This antidiuretic action is crucial for osmoregulation, and defects in vasopressin production, secretion, or action result in diabetes insipidus, characterized by excessive thirst and frequent passing of large volumes of dilute urine.

Osmoreception

Magnocellular vasopressin neurons in the hypothalamus are the "command" neurons that regulate antidiuresis, and the rate of spike discharge increases as extracellular osmolality increases. As a result, vasopressin concentrations in the plasma are proportional to the plasma osmotic pressure above a threshold, known as the "set point," for osmoregulated vasopressin secretion. The set point can vary in different physiological circumstances: for example, in pregnancy the set point is lowered; as a result, more water is retained, allowing for an expansion of plasma volume, and this is accompanied by a lower plasma sodium concentration (Leng et al. 2012).

Cardiovascular Function

Vasopressin is implicated in the maintenance of cardiovascular homeostasis both through its peripheral and central actions. Acting as a vasoactive peptide in periphery, vasopressin controls vascular tone through direct activation of V1a receptors, modulation of ATP-sensitive K^+ channels (KATP), modulation of endothelial nitric oxide system, and potentiation of other vasoactive substances, like noradrenaline or angiotensin II.

Centrally, vasopressin modulates autonomic control of cardiovascular system. Paraventricular parvocellular neurons containing vasopressin project to the intermediolateral column of the spinal cord, regulating renal sympathetic activity, diuresis, and vascular tone. Also, vasopressin modulates baroreceptor reflex sensitivity through area postrema and nucleus of the solitary tract.

Behavioral Effects

Vasopressin does not cross the blood-brain barrier in appreciable amounts, so the central actions of

the hormone reflect the central release, including that from the dendrites of the magnocellular neurons (Ludwig and Leng 2006). Vasopressin has effects on social behavior that seem to complement oxytocin effects; in male prairie voles, vasopressin enhances the expression of aggression toward other males – behavior that seems analogous to territorial behavior designed to protect a mate from access by other males or to defend a nest (Donaldson and Young 2008). The brain vasopressin system also mediates anxiogenic effects (Neumann and Landgraf 2012).

Drugs

Agonists

Vasopressin (synthetic 8-L-arginine vasopressin) is clinically registered for use as a replacement therapy in the treatment of central diabetes insipidus. Due to its short half-life and non-selectivity for V2 receptor, it has been generally replaced by its synthetic analogue desmopressin.

The propensity of vasopressin to cause contraction of smooth muscles in blood vessels and gastrointestinal tract has been used in the management of esophageal variceal bleeding and postoperative ileus and to reduce the possibility of intraoperative bleeding in patients with portal hypertension. Furthermore, vasopressin can be used as a second-line agent during cardiopulmonary resuscitation (CPR) in adults.

Vasopressin increases peripheral vascular resistance and consequently arterial blood pressure, and this can be important for restoring blood pressure in hypovolemic shock and septic shock. Patients with vasodilatory shock are reported to have inappropriately low plasma levels of vasopressin and to be particularly sensitive to the pressor actions of vasopressin. Therefore, vasopressin is indicated for the treatment of hypotension in patients with vasodilatory shock that does not properly respond to therapy with catecholamines and fluids.

The majority of vasopressin side effects are the result of V1a activation, and they include gastrointestinal disturbances due to increased gastrointestinal motility, such as nausea, cramps, and urgency to defecate. Vasopressin can aggravate symptoms of coronary artery disease, cause arrhythmia, and decrease cardiac output. Peripheral vasoconstriction and even gangrene may occur after application of high doses of vasopressin. The most prominent V2 receptor-mediated side effect of vasopressin is water intoxication.

Desmopressin (dDAVP) is a synthetic, long-acting analogue of vasopressin, modified by deamination of cysteine-1 and substitution of L-arginine-8 with D-arginine. Apart from having a longer half-life (~158 min) and duration of action (6–24 h) in comparison to vasopressin, desmopressin is more potent antidiuretic agent, with fewer pressor effects due to higher selectivity for V2 receptor. In fact, desmopressin is 10 times more efficient as an antidiuretic agent than vasopressin, with 1500 times less pronounced ability to induce vasoconstriction. These characteristics make desmopressin the drug of choice in the treatment of central diabetes insipidus (desmopressin is not effective in the treatment of nephrogenic diabetes insipidus and can even be used as a diagnostic method to distinguish between two forms of diabetes insipidus).

In addition, desmopressin is used for primary nocturnal enuresis in both children and adults and enuresis in multiple sclerosis, as well as in idiopathic enuresis. It can also be applied to the management of polyuria and polydipsia occurring after surgical procedures. By activating extrarenal V2 receptors, desmopressin stimulates secretion of procoagulant factor VIII and von Willebrand factor from vascular endothelium into circulation and can therefore be applied to the treatment of mild to moderate hemophilia and von Willebrand disease. The most common side effects of desmopressin include hyponatremia, seizures that may develop as a consequence of hyponatremia, headache, nausea, decreased urinary output, and facial flushing.

Terlipressin is an analogue of vasopressin that shows affinity toward V1a receptors located in the splanchnic smooth muscle cells. Inducing splanchnic vasoconstriction, terlipressin increases renal blood flow, has beneficial effects on hepatorenal syndrome, and also reduces portal pressure and reduces the risk of portal

hypertensive bleeding. Like vasopressin, it is used in the management of variceal bleeding.

Antagonists

Despite various attempts to develop both peptide and non-peptide vasopressin receptor antagonists, to this day only two non-peptide antagonists have been approved for use by regulatory agencies in Europe, Canada, and the USA. These antagonists are called "vaptans" and "aquaretics," the latter due to the tendency of these agents to increase free water excretion in kidneys with no change in sodium or potassium reabsorption.

Conivaptan is a non-selective V1a/V2 receptor antagonist, available only for parenteral (intravenous) administration. It is extensively protein bound, with a half-life between 6 h and 10 h, and is metabolized by the hepatic CYP3A4 system, with minimal excretion by the kidney. It is used in the treatment of hyponatremia in SIADH and in the treatment of hospitalized patients with euvolemic or hypervolemic hyponatremia.

Tolvaptan is a highly selective V2 receptor antagonist with pharmacokinetic properties comparable to those of conivaptan. Like conivaptan, it can be used in patients with SIADH who show signs of hyponatremia and in hypervolemic and euvolemic hyponatremia.

The most dangerous adverse effects of vaptans result from the rapid correction of hyponatremia, with osmotic demyelinating syndrome potentially having fatal consequences. Others include liver damage, polyuria with dehydration, xerostomia, hypotension and dizziness, headaches, gastrointestinal disturbances, and hypokalemia.

Definition

Viral proteases are proteins encoded by the genome of some viruses that exhibit catalytic activity leading to the hydrolysis of peptide bonds at specific sites within the polypeptide chain. The activity of viral proteases is crucial for a successful completion of the virus replication cycle.

Basic Characteristics

Proteases (peptidases, proteinases) compose a large class of enzymes that catalyze the cleavage of the peptide bond (mainly via the hydrolytic mechanism). Although proteases can be found in all living organisms, they are also encoded by genomes of many viruses. The catalytic activity of proteases is crucial for many biological processes such as protein processing and catabolism, coagulation of blood, immune response, cell signaling, or apoptosis. The enzymatic reaction of proteases is executed by the nucleophilic attack of the catalytic residue (such as serine, cysteine, or threonine) or a water molecule on the carbonyl carbon of the cleaved peptide bond of the substrate. The nucleophile is activated by the neighboring amino acid residue (mainly histidine) or metal ion (e.g., zinc) present in the active center. The structure of the active center as well as specific substrate-oriented binding sites located on the surface of the enzyme allows the hydrolyzed peptide bond to achieve an optimal orientation in close proximity of the enzyme catalytic machinery for the reaction to take place. Considering the catalytic type, proteases can be classified into six groups: serine, threonine, cysteine, aspartic, glutamic, and metalloproteases. The cleavage of the peptide bond can also be catalyzed by the asparagine peptide lyases, i.e., enzymes which break peptide bond utilizing the mechanism of elimination reaction rather than hydrolysis. Additionally, the classification of proteases can be based on other characteristics such as the protein fold (describing topology of the tertiary structure with one of the most common being chymotrypsin-like fold with the characteristic two-β-barrel motif) and the organization of the catalytic center (e.g., catalytic dyad or triad, including not only the number and type of amino acids in the active center but also their order in the amino acid sequence which are the basis of the MEROPS classification system of proteolytic enzymes) (Rawlings et al. 2018) (Fig. 1).

Viruses compose a highly diverse group of infectious agents that invade all types of cellular life forms. The viral replication cycle is possible only intracellularly and is, at least partially, dependent on the host-cell biosynthetic and energetic pathways. Viral genomes are very diverse in terms of their content and organization. The genetic material that has a form of single- or double-stranded RNA or DNA includes at least one open reading frame translated into polyprotein. Proteins encoded by the viral genome are broadly described as structural and/or nonstructural. The first group includes proteins forming capsid and in many cases other proteins involved in the formation of the viral particle such as envelope-building proteins. On the other hand, the nonstructural proteins are important for virus replication, playing regulatory or catalytic functions. The most common enzymes encoded by the viral genomes are polymerases, helicases, and proteases (Mesters et al. 2006). Interestingly, some viruses of the *Filoviridae*, *Paramyxoviridae*, or *Pneumoviridae* families do not show protease activity in their genetic material and are fully dependent on the host proteolytic enzymes (e.g., furin, cathepsins). Still, some viruses code in their genomes two or even more proteolytic activities. The viral proteases constitute a highly diverse group of enzymes that belongs for the most part of cases to cysteine (e.g., severe acute respiratory syndrome coronavirus, SARS-CoV) and serine (e.g., Zika virus, ZIKV) catalytic types. The representatives of other types such as metallo (e.g., variola viruses, VARV), aspartyl (e.g., human immunodeficiency viruses, HIV), glutamyl (e.g., strawberry mottle virus, SMoV) proteases, or asparagine peptide lyases (e.g., poliovirus, PV) are also known (Table 1). Based on the structure organization, the viral proteolytic enzymes are mainly described as chymotrypsin-, papain-, or pepsin-like. Considering the biological characteristics of viral

proteases in terms of their substrate specificity, biological activity and function, as well as mechanism of regulation, great differences are observed between viral families. The most common function of viral proteases is the hydrolytic cleavage of viral polyprotein leading to the formation of structural and nonstructural viral proteins and their further processing and maturation. The activity of some viral proteases is also important for proper capsid assembly and maturation that is crucial for the release of new functional virions. The viral proteases can acquire control over cellular processes which allows the virus to shift the biosynthetic machinery of the cell into multiplication of the virus particles. The activity of these enzymes might be regulated by various mechanisms including the presence of a cofactor (e.g., flavivirus protease-cofactor complex, NS2B/NS3), dimerization (HIV protease, HIV PR), membrane association (e.g., coronavirus papain-like protease, PL^{pro}), or self-inhibition (e.g., Chikungunya virus capsid protein, CHIKV CP) (Rawlings et al. 2018).

Drugs

Aspartyl Proteases

HIV-1 Protease

Although HIV-1 was discovered nearly 40 years ago, it is still causing serious health problems worldwide. In 2018 alone, approximately 1.7 million new cases were identified accounting for about 37.9 million people living with HIV around the world. The hydrolase encoded by the HIV-1 is an aspartic protease with a characteristic Asp-Thr-Gly catalytic triad. This enzyme is able to hydrolyze several peptide bonds located in the Gag and Gag-Pro-Pol precursors (Swanstrom and Wills 1997). This activity is required for viral polyprotein processing crucial for the maturation of virus particles. Thus HIV-1 protease has become an attractive molecular target for the anti-HIV-1 agent development.

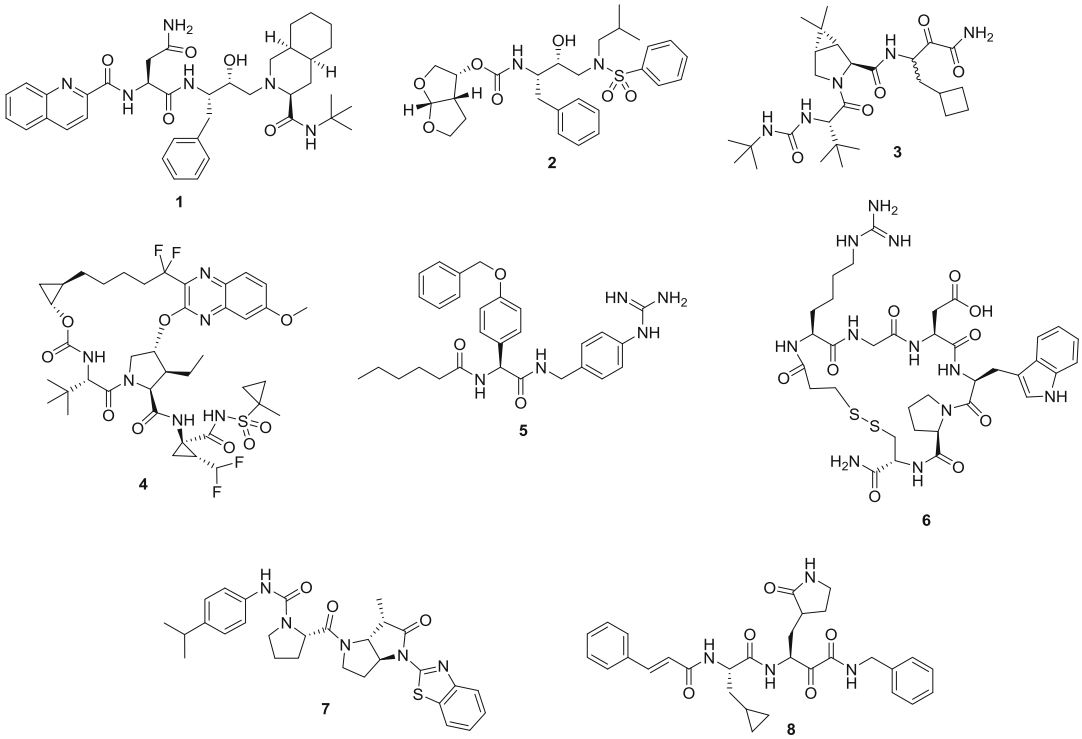
The catalytically active HIV-1 protease functions as a homodimer of which each monomer donates the catalytic residue (Asp25/Asp25′).

Viral Proteases, Table 1 The representatives of the human-infecting viruses expressing proteolytically active proteins (Mesters et al. 2006)

Family	Representative	Protease name	Catalytic type	Catalytic center
Adenoviridae	Human adenovirus C	Adenain (L3)	Cysteine	His-Asp-Cys
Astroviridae	Human astrovirus	Human astrovirus protease ($HAstV^{pro}$)	Serine	His-Asp-Ser
Caliciviridae	Norwalk virus	Calicivirin ($3CL^{pro}$, NS6)	Cysteine	His-Glu-Cys
Coronaviridae	Severe acute respiratory syndrome coronavirus	SARS-CoV papain-like peptidase (SARS-CoV PL^{pro})	Cysteine	Cys-His-Asp
		SARS-CoV picornain 3CLpro (SARS-CoV M^{pro})	Cysteine	His-Cys
Flaviviridae	Hepatitis C virus	HCV peptidase 2 (NS2)	Cysteine	His-Glu-Cys
		Hepacivirin (NS3/NS4A)	Serine	His-Asp-Ser
Herpesviridae	Herpes simplex virus	Assemblin (VP24)	Serine	His-Ser-His
Matonaviridae	Rubella virus	Rubella virus peptidase	Cysteine	Cys-His
Orthomyxoviridae	Influenza A virus	Influenza A PA peptidase	Serine	Ser
Picornaviridae	Poliovirus	Picornavirus capsid VP0-type self-cleaving protein	Asparagine lyase	Asn
		Enterovirus picornain 2A	Cysteine	His-Asp-Cys
		Poliovirus-type picornain 3C ($PV\ 3C^{pro}$)	Cysteine	His-Glu-Cys
Poxviridae	Variola virus	Pox virus metallopeptidase (G1L)	Metallo	Zn
		Vaccinia virus I7L processing peptidase	Cysteine	His-Asp-Cys
Retroviridae	Human immunodeficiency virus 1	HIV-1 retropepsin	Aspartic	Asp-Asp
Togaviridae	Chikungunya virus	Sindbis virus-type nsP2 peptidase	Cysteine	Cys-His
		Togavirin, capsid protease (CP)	Serine	His-Asp-Ser

The substrate binding site is located in a long cleft between both subunits. The HIV-1 protease contains the structural motif of two interlocking loops similar to eukaryotic aspartic proteinases (Lapatto et al. 1989). As for the general substrate specificity of HIV-1 protease, the P1 position is usually occupied by the hydrophobic residues, and the P2 position is commonly occupied by amino acids with branched side chains. The P1′ residue is proline or an amino acid with an aromatic side chain. This structural substrate recognition pattern is quite frequently disturbed. For example, in the p2-NC (p2-nucleocapsid protein) cleavage site, methionine residues are present at P1 and P1' positions.

Saquinavir (**1**, Fig. 2) – the first HIV-1 protease inhibitor – was approved by FDA in 1995. Since then extensive research brought to the drug market several HIV-1 protease inhibitors (PIs) of which nine are currently used in highly active antiretroviral therapy (HAART). In general, the HIV-1 protease inhibitors can be divided into two



Viral Proteases, Fig. 2 Selected inhibitors targeting various viral proteases

groups. The first-generation inhibitors were peptide-based transition state analogs containing hydroxyethylene or hydroxyethylamine function which bind into the enzyme catalytic site. Further studies resulted in a second generation of inhibitors such as lopinavir, atazanavir, tipranavir, and most recently approved HIV-1 protease inhibitor – darunavir. The biggest challenge in the development of HIV-1 protease inhibitors is the design of compounds active also against drug-resistant virus strains. One of the strategies used to fulfil such requirements is to design PIs able to form an extensive hydrogen-bonding interaction network with the backbone atoms located within the HIV-1 protease active site (Ghosh et al. 2016).

Serine Proteases

Hepatitis C Protease

It has been estimated that 71 million people live with chronic hepatitis C virus (HCV) infection worldwide. Although hepatitis C occurs globally, multiple strains or genotypes of various regional distribution have been distinguished. While many patients remain asymptomatic, chronically infected patients have a high chance of developing liver cirrhosis. In 2016 approximately 399,000 people died from hepatitis C-related liver diseases which is a serious consideration around the world. Fortunately, the available antiviral drugs can cure approximately 95% patients with hepatitis C infection.

One of the effective anti-HCV therapies relies on the inhibition of viral serine protease essential for replication. This bifunctional nonstructural protein 3 (NS3/4A) is composed of a functional element (NS3) and its cofactor (NS4A). Interestingly, it has two separate functional activities: serine protease activity and NTPase/RNA helicase activity, both of which located in a single peptide chain and both indispensable for viral polyprotein processing, RNA replication, and new virions formation (Morikawa et al. 2011).

The active site of NS3/4A protease domain is made up by the classical serine protease catalytic triad (His, Asp, and Ser) and represents a chymotrypsin-like fold. This enzyme also contains a zinc binding motif which stabilizes the enzyme structure. The preferably recognized substrate sequence motif is Asp/Glu-X-X-X-X-Cys/Thr↓Ser/Ala-X-X-X (scissile peptide bond is marked by an arrow).

Both the NS3 protein and its cofactor contain α-helical fragments that reassure the membrane association of the complex required for the viral genome replication. Firstly, the *cis* cleavage at the NS3-cofactor junction site is catalyzed and subsequently the polyprotein sequence is processed. The host-cell proteases (e.g., furin, signal peptidase) and other viral proteases can be involved in this process. For example, the NS3/NS4A is not the only protease involved in the HCV replication cycle, and the second proteolytic activity associated with the cysteine protease NS2 responsible for the cleavage between NS2 and NS3 is necessary. The biological role of NS3/NS4A goes beyond the processing of viral polyprotein. Since NS3/4A protease is able to destroy several important cellular proteins such as mitochondrial antiviral signaling protein (MAVS), T-cell protein tyrosine phosphatase (TC-PTP), and TIR domain-containing adaptor inducing IFN-β (TRIF), it blocks the innate immune pathways and modulates the growth factor signaling pathways, thus significantly influencing the persistence and pathogenesis of HCV infection (Morikawa et al. 2011).

In 2003, the NS3/4A protease inhibitor (BILN-2061) was shown to be effective for HCV treatment in a clinical proof-of-concept study. Three years later telaprevir (VX-950) and boceprevir (SCH-503034) were reported to show high potency and effectivity as NS3/4A inhibitors in HCV infections. These two inhibitors form a covalent but reversible bond with the catalytic serine residue located in the NS3 protease active site. In 2011 the FDA approved both drugs for the treatment of HCV infection in combination with PEG-IFN-α and ribavirin. A new generation of non-covalent reversible inhibitors of NS3/4A protease have recently been approved for the HCV treatment including simeprevir, paritaprevir, grazoprevir, glecaprevir, and voxilaprevir (**4**) which are used in combination with other drugs (USA) as well as vaniprevir and asunaprevir (approved in Japan). Although these therapies show a great promise, they are out of reach for many patients due to their high cost. The discovery of NS3/4A protease inhibitor-resistant strains of HCV highlights the need for further studies in this area (Sarrazin et al. 2012; Manns et al. 2017).

Despite the fact that almost all human-infecting viruses carry the information of the protease in their genetic material, until now only HIV-1 and HCV viral proteases have been used as drug targets in clinical practice. We believe that since many research groups have already developed a number of inhibitors active against viral proteases, the breakthrough discoveries in this area are expected in the years to come.

Flavivirus Protease

To the *Flaviviridae* family (*Flavivirus* genus) belong viruses responsible for the development of life-threatening diseases and human mortality such as West Nile virus (WNV), dengue virus (DENV), yellow fever virus (YF), tick-borne encephalitis (TBE), Japanese encephalitis virus (JEV), St Louis encephalitis (SLE), Murray Valley encephalitis (MVE), or Zika virus (ZIKV). These viruses express serine protease – flavivirin (NS2B-3, NS2B/NS3 endopeptidase). The NS3 protease complexed with the NS2B cofactor is responsible for the cleavage of virus polyprotein leading to the generation of the N-terminal nonstructural proteins (NS2B, NS3, NS4A, and NS5) and participates in the processing of the C-terminal regions of the capsid proteins.

NS2B/NS3 is a trypsin-like serine protease with a classic canonical catalytic triad (His, Asp, and Ser). The active NS2B/NS3 protease possesses a chymotrypsin-like fold with two barrels. NS2B cofactor takes part in forming the substrate binding site and directly interacts with the protease substrate: it forms one strand of the N-terminal and two strands of the C-terminal barrels. The NS2B/NS3 flavivirus peptidases recognize basic amino acid residues at the P1 and P2 positions (Lys or Arg, respectively) and small amino acid

residue side chains (Gly, Ala, Ser, Thr) at P1′ (Luo et al. 2015).

The structure of already known potent inhibitors of NS2B/NS3 protease encompasses combination of basic peptides containing a C-terminal electrophilic warhead such as an aldehyde, boronic acid, amide, or phosphonate ester which interact with the catalytic serine residue. Their application as potential drugs is limited by their poor pharmacokinetic properties resulting from their high molecular weight and pronounced polarity of highly basic amino acid side chains. The structure-activity relationships studies focused on the development of DENV and WNV protease inhibitors have not yet delivered any compounds useful for clinical application. Recently Klain et al. developed a new class of dengue and West Nile virus protease inhibitors displaying a submicromolar activity. These compounds are decarboxylated peptides containing a C-terminal 4-guanidinobenzylamino group which is responsible for interacting with S1 pocket of the protease. The most potent inhibitor obtained in these studies (**5**) showed a EC_{50} value of 0.5 μM in cell-based assays with no relevant cytotoxicity (Kühl et al. 2020).

Alphavirus Protease

Alphaviruses similarly to flaviruses are mostly transmitted via bite of an infected mosquito, while replication occurs alternately in a vertebrate host and a hematophagous arthropod. To the alphavirus genus belong among others O'nyongnyong (ONNV), Sindbis (SINV), Semliki Forest (SFV), Venezuelan equine encephalitis (VEEV), Ross River (RRV), and Chikungunya (CHIKV) viruses. The characteristic feature of all alphaviruses is a multifunctional capsid protein (CP) which is crucial for the viral life cycle. Two domains can be distinguished in the structure of capsid protein: unstructured RNA binding N-terminal segment (residues 1–118) and the C-terminal globular protease domain with a typical serine-histidine-aspartic acid catalytic triad (residues 119–267) (Baron 1996). CP protease has a chymotrypsin-like fold, however; viral CP protease has two β-strands instead of the C-terminal α-helix present in chymotrypsin. Such unique structure allows for bending the protein chain in a way that the catalytic center gets access to the substrate cleavage site. After autoproteolytic cleavage, the side chain of tryptophan residue remains bound in a hydrophobic S1 pocket of CP protease, and newly generated C-terminal carboxyl group forms a hydrogen bond network with the catalytic site of the enzyme consequently blocking its trans-proteolytic activity. Hence, alphaviral capsid protein undergoes a single proteolytic event before maturation leading to its assembly into the virus capsid shell forming a nucleocapsid core via encapsidation of viral genomic RNA. The interaction of CP protease with the virus envelope glycoproteins is important for the budding process (Owen and Kuhn 1997).

The site of autoproteolytic cleavage (Glu-Gly-X-Glu-X-Trp↓Ser) is highly conserved among all known alphaviruses. Since it has been shown that the proteolytic cleavage is critical for the life cycle of alphaviruses, inhibitors targeting the CP protease are considered potential anti-alphavirus agents. Recently structure-based drug retargeting studies have identified eptifibatide acetate (**6**), P1,P4-Di (adenosine-5′) tetraphosphate, and paromomycin sulfate as potent CHIKV capsid protease inhibitors. These compounds showed half-maximal effective concentrations (EC_{50}) of 4.01 μM, 10.66 μM, and 22.91 μM, respectively. This report was the first to demonstrate that alphavirus CP protease could be successfully blocked by inhibitors opening a way for the development of novel antiviral drugs (Fatma et al. 2020).

Herpesvirus Protease

Herpesviruses are responsible for several medical disorders including cold sores (herpes simplex virus, HSV-1), genital herpes (HSV-2), chicken pox (varicella-zoster virus, VZV), pneumonitis (human cytomegalovirus, CMV), or Kaposi's sarcoma (Kaposi's sarcoma-associated herpes virus, KSHV). The role of the herpesvirus protease is crucial for a successful capsid assembly and packing the viral DNA molecule. Herpesvirus protease is a part of a complex protein scaffold enveloped by the premature viral capsid. After the protease is self-released, it subsequently degrades the protein scaffold leading to its collapse forming space for

the viral DNA molecule. The herpesvirus protease is essential for the production of fully infectious virions; thus the inhibition of its proteolytic activity could potentially prevent the spread of the virus inside infected cells (Holwerda 1997). The core of the protease is composed of a central barrel formed by seven antiparallel β-strands. The catalytic unit located within the active site is serine and two histidine residues which all together form an uncanonical catalytic triad on the surface of the β-barrel. The substrate recognition pattern is similar for all known herpesvirus proteases: the S1 binding pocket accepts small side chains amino acids such as alanine, the P2 position is usually occupied by a hydrophilic side chain, while small aliphatic amino acids such as valine or leucine are preferred as the P3 residues. Although numerous studies reported the development of many herpesvirus protease inhibitors, none, even highly potent inhibitors which are active in enzymatic tests, significantly suppress the replication of the virus in cell-based assays. One of the most active inhibitors of the herpesvirus protease is *trans*-lactams (**7**) (Skoreński and Sieńczyk 2014).

Cysteine Proteases

Coronavirus Protease

In 2003, China saw an outbreak of an unknown disease which spread worldwide. The observed symptoms of atypical pneumonia, named severe acute respiratory syndrome (SARS), resulted in more than 8,000 infections with approximately 800 deaths in 29 countries (Drosten et al. 2003). Later, it was discovered that the infectious agent responsible for this pandemic was a previously unknown coronavirus, named SARS-CoV. Almost 17 years later in December 2019, a new similar to SARS disease surfaced. Further studies showed that the new disease was triggered by a new coronavirus whose genome displayed a 96% and 79.6% sequence identity to a bat coronavirus and to SARS, respectively. This novel virus was named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and the resulting pneumonia and associated symptoms caused by the coronavirus became to be called disease 2019 (COVID-19) (Zhu et al. 2020; Zhou et al. 2020).

SARS viruses encode two proteases which are tightly involved in the virus replication cycle. One of them is a papain-like protease (NSP3), while the other is a chymotrypsin-like protease (3CL-like protease, main protease, M^{pro}). SARS M^{pro} occurs in three quaternary structures: an inactive monomer, active homodimer, and active octamer (Graziano et al. 2006). The catalytic dyad is formed by cysteine and histidine residues. The high protein sequence similarity between main proteases of SARS-CoV and SARS-CoV-2 was observed, and inhibitors active against SARS-CoV M^{pro} were also found active against SARS-CoV-2 M^{pro}. A majority of M^{pro} inhibitors are peptide-based molecules mimicking part of the substrate with a lactam ring (a rigid isostere of glutamine) at P1 position and C-terminal reactive electrophilic warhead such as α-ketoamide (**8**), boronic acid, α-halocarbonyl, acrylamide, sulfonyl chloride, aldehyde, or isatine (Dömling and Gao 2020; Dai et al. 2020). Recently Wang et al. showed that some of the already known inhibitors such as boceprevir GC-376 and calpain inhibitors II and XII were able to suppress SARS-CoV-2 replication in cell culture studies (EC_{50} ranging from 0.49 to 3.37 μM) (Ma et al. 2020).

In addition to M^{pro}, NSP3 protease of SARS-CoV is considered an attractive drug target since, besides its polyprotein processing function, it participates in the attenuation of the host innate immune responses via stripping ubiquitin and ISG15 (interferon-stimulated gene 15) from the host-cell proteins. A wide range of compounds able to form a covalent bond with the enzyme active site has been described including epoxyketones, α-halo-ketones, alkynes, aldehydes, trifluoromethyl ketones, activated esters, and vinyl sulfones (Báez-Santos et al. 2015).

Although cysteine proteases are a protease type abundant in viruses, they do not compose structurally homogenous group as several different types of the catalytic center organization and composition as well as backbone fold have been described (Table 1). One of the well-known representatives of this group is 3C/3C-like peptidases ($3C^{pro}$/$3CL^{pro}$), which are proteases mainly found in *Coronaviridae*, *Caliciviridae*, and *Picornaviridae* families, but 3C or 3C-like

proteases are also conserved among members of *Pisoniviricetes* and *Stelpaviricetes* classes of viruses. The His-Cys dyad (e.g., SARS-CoV $3CL^{pro}$ or M^{pro}, EC 3.4.22.69) or His-Glu/Asp-Cys triad (e.g., PV $3C^{pro}$, EC 3.4.22.28) can be responsible for the enzymatic activity of 3C-like peptidase, while the sequence cleavage preference can be generally described as Gln-Gly (P1-P1′; Schechter and Berger nomenclature) (Schechter and Berger 1967). The 3C peptidases are catalytically active in the monomeric form; however, $3CL^{pro}$ requires a homodimerization in order to become catalytically active (e.g., SARS-CoV $3CL^{pro}$). After autocatalytic cleavage out, the protease subsequently releases other viral proteins from the polyprotein. Various processes of the virus replication cycle are reported to be dependent on the $3C^{pro}/3CL^{pro}$ activity including stimulation of viral RNA synthesis (via direct interaction with protease or its precursors), inhibition of the host-cell transcription and protein synthesis (by degradation of cellular proteins but also disruption of the nucleus-cytoplasm macromolecules trafficking), immune system suppression, or even initiation of apoptosis (Sun et al. 2016).

Apart from 3C proteinase, the *Picornaviridae* family members encode other cysteine proteases, namely, Leader (Lpro) and A2 (A2pro) but also asparagine peptide lyases (picornavirus capsid VP0-type self-cleaving protein). The biological function of these enzymes is not as broad as $3C^{pro}$ and is limited to few processes such as degradation of initiation factors for translation of host cell or immune response modulation, whereas the asparagine lyases catalyze autolytic cleavage of the capsid protein.

Vitamin D

Lori A. Plum and Hector F. DeLuca
Department of Biochemistry, University of WI-Madison, Madison, WI, USA

Synonyms

$1,25(OH)_2D_3$; Calcidiol; Calciol; Calcitriol

Definition

Whether vitamin D is absorbed from the intestine or is derived from the epidermis, it is clear that the liver is the first stop for vitamin D where it is 25-hydroxylated to what is clearly recognized as the major circulating form of vitamin D (Jones et al. 2017) (Fig. 1). The enzyme found largely if not exclusively in the liver is Cyp2r1 that carries out this hydroxylation. However, it is also clear in *Cyp2r1* KO mice some 25-hydroxylation of vitamin D occurs. Although several possibilities have been suggested, the source of the remaining 25 hydroxylation remains undetermined.

At physiologic concentrations of between 10 and 100 ng/mL, $25OHD_3$ does not function directly but must be further hydroxylated on carbon one to $1,25(OH)_2D_3$, the final active form of vitamin D before function. It is $1,25(OH)_2D_3$ that binds to the nuclear receptor programming cells to carry out the well-known functions of vitamin D in the intestine, bone, and other tissues.

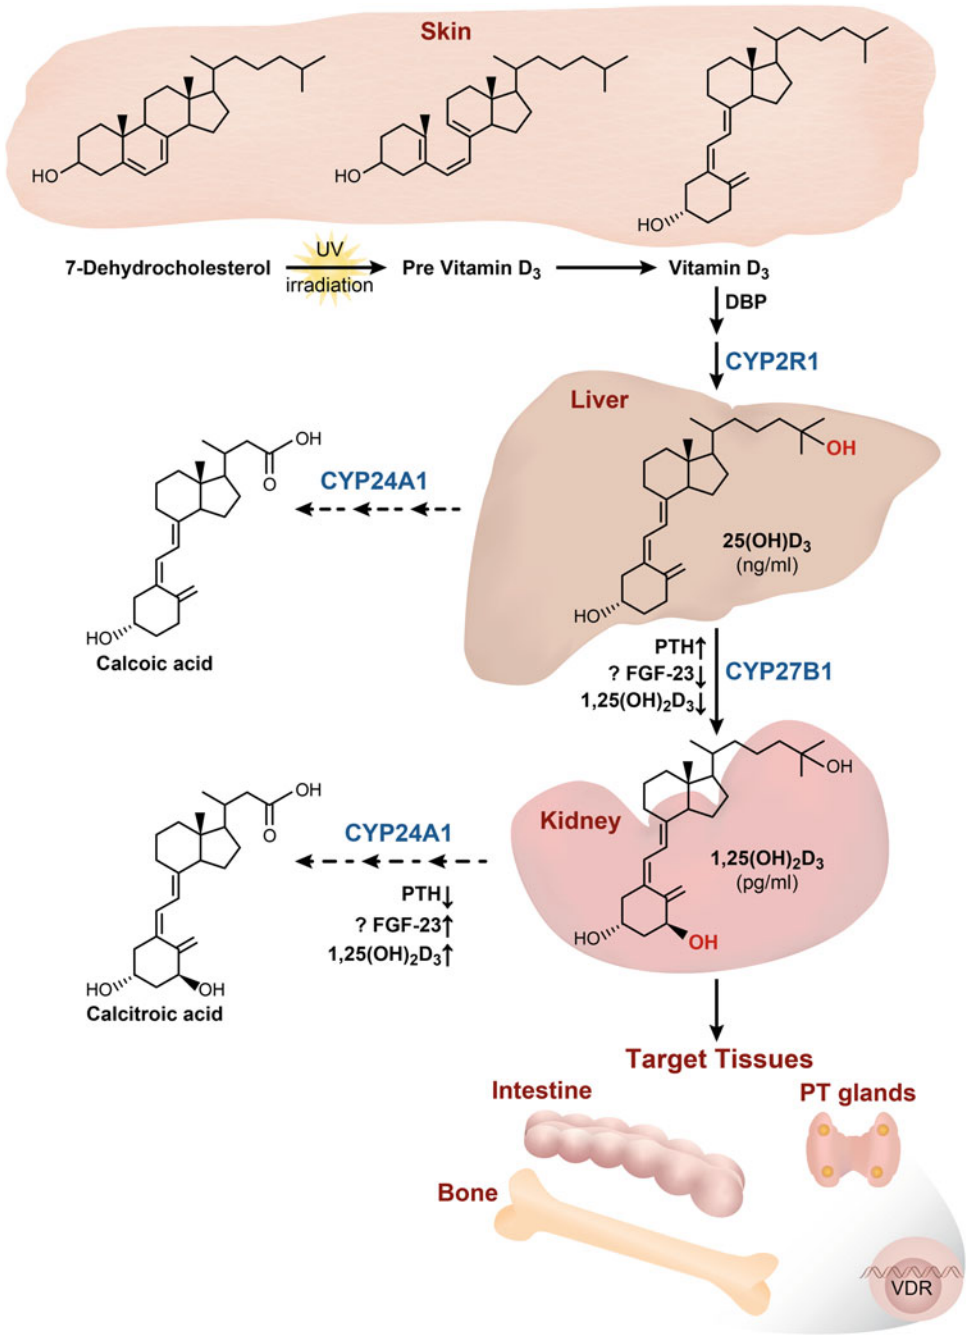
The CYP24A1 enzyme further converts these compounds ultimately to calcitroic acid and calcioic acid (Kaufmann et al. 2019). The CYP24A1 pathway represents the inactivation and elimination pathway of vitamin D metabolism. As described below, the conversion of $25OHD_3$ to $1,25(OH)_2D_3$ or to $24,25(OH)_2D_3$ is tightly regulated by parathyroid hormone and $1,25(OH)_2D_3$ itself and perhaps FGF-23.

Endocrine-derived $1,25(OH)_2D_3$ travels to target tissues. Once inside the target cells, $1,25(OH)_2D_3$ binds the vitamin D receptor. This complex interacts with DNA to alter the expression of a range of genes involved in calcium and phosphorus homeostasis as well as the genes encoding the metabolic enzymes responsible for the production and destruction of $25(OH)D_3$ and $1,25(OH)_2D_3$. More detailed aspects of vitamin D metabolism will be discussed below.

Mechanism of Action

In Vivo Production of Vitamin D

Before the introduction of synthetic vitamin D and/or the fortification of foods by UV irradiation



Vitamin D, Fig. 1 Functional metabolism of vitamin D_3

following the discovery of Steenbock and others, the major source of vitamin D was by sunlight exposure with the exception of some usage of fish liver oils (DeLuca 2014). Sunlight exposure remains the dominant source of vitamin D. However, the exact amount of vitamin D that results from sunlight has been the subject of many papers and disagreement (Holick 2007). So many

factors such as season, distance from the equator, cloud cover, clothing, and skin pigmentation are involved. The angle at which sunlight strikes the skin is of paramount importance. For example, in the winter months of October–April in the northern hemisphere, little or no vitamin D is produced (Webb et al. 1988). A general useful concept is that a 10–20-min exposure of 1/8th body surface to mid-day summer sun will certainly provide an adequate amount of vitamin D (Holick 2007). Dermatologists discourage sun exposure over concern that UV light in excess is carcinogenic. However, a reasonable amount of sun light exposure would provide sufficient vitamin D with a minimum of cancer risk (Webb and Engelsen 2008). Oral intake of vitamin D can certainly be viewed as a great human invention that prevents and treats rickets, osteomalacia, and hypocalcemic tetany, but dermal production represents the true physiologic source of vitamin D.

A new development has been the discovery of how vitamin D produced in the epidermis by UV light is mobilized. Vitamin D binding protein (DBP) is required for this mobilization because *Dbp* -/- mice are unable to utilize vitamin D produced in epidermis by UV light (Duchow et al., 2019). Further, when small amounts of recombinant Dbp are injected in *Dbp* -/- mice, mobilization of vitamin D from skin proceeds. This discovery is supported by a clinical report that a DBP-deficient patient did not respond to UV treatment (Henderson et al. 2019). Thus, DBP now occupies an essential role in the function of vitamin D produced physiologically in the skin. It also focuses on the idea that the synthetic vitamin D in use throughout the world is a superb pharmaceutical solution to disease, but the true physiologic source of vitamin D is the skin produced by the sun's ultraviolet light. Further, vitamin D is not a vitamin since it can be produced in the body.

Metabolic Enzymes and Their Regulation

Enzymes involved in the production of the vitamin D hormone are the 25-hydroxylase (CYP2R1) and 1-hydroxylase (CYP27B1). CYP2R1 is likely the major enzyme that produces $25(OH)D_3$ from vitamin D (Jones et al. 2017). Although other enzymes have been purported to be responsible for 25 hydroxylation, i.e., CYP27A1, CYP2D25, CYP3A4, CYP2C11, and CYP2J1, their involvement is unlikely. Nevertheless, CYP2R1 is probably not the only 25-hydroxylase since mice devoid of Cyp2r1 still produce small amounts of 25OHD as do humans with mutations in the *CYP2R1* gene. So far regulation of CYP2R1 has not been reported. That it is not tightly regulated is suggested by the fact that high blood levels of $25(OH)D_3$ can be produced by providing higher and higher doses of vitamin D_3 (DeLuca et al. 2011). Thus it seems likely that high blood levels of $25(OH)D_3$ are responsible for vitamin D toxicity by acting as an analog of $1,25(OH)_2D_3$ activating genes responsible for calcium absorption and bone mobilization.

CYP27B1 is the sole enzyme responsible for production of $1,25(OH)_2D_3$ from $25(OH)D_3$. When this gene is knocked out or mutated in mice or humans, no $1,25(OH)_2D_3$ is detected. In contrast to the production of $25(OH)D_3$, $1,25(OH)_2D_3$ generation is very tightly regulated in the kidney, and the regulation has been defined at the physiologic level (DeLuca 2014). Meyer et al. (2019) have now mapped the DNA regions important for this regulation. Parathyroid hormone increases the expression of *CYP27B1*, while FGF-23 suppresses renal *CYP27B1*. Not surprisingly, there is a feedback mechanism, so when $1,25(OH)_2D_3$ levels are elevated, the 1-hydroxylase is suppressed. A recent report by Pike and colleagues confirms prior reports indicating the regulators of Cyp27b1 in kidney do not affect expression of Cyp27b1 in non-renal tissues (Meyer et al. 2019). Whether extra-renal production of $1,25(OH)_2D_3$ occurs under physiologic conditions is unclear.

Besides the negative feedback regulation of CYP27B1, control of $25(OH)D_3$ and $1,25(OH)_2D_3$ levels is mediated by another cytochrome P-450, CYP24A1. This enzyme oxidizes the side chains of both molecules, ultimately converting the native hormone to calcitroic acid. Jones and colleagues have also demonstrated $25(OH)D_3$ is converted to an analogous product, calcioic acid (Kaufmann et al. 2019). The discovery of loss-of-function mutations in the *CYP24A1* gene results in hypercalcemia

clearly demonstrates the essential degradation of $1,25(OH)_2D_3$ (Jones et al. 2017). Of great importance is the fact that some of the factors that upregulate CYP27B1 also downregulate CYP24A1 and vice versa, i.e., PTH suppresses and $1,25(OH)_2D_3$ increases CYP24A1 expression.

CYP3A4 is another enzyme that has been reported to contribute to the degradation of the $1,25(OH)_2D_3$ and $25(OH)D_3$. However, individuals with functioning CYP3A4 but with mutations in CYP24A1 still have elevated $1,25(OH)_2D_3$ levels. Only very potent CYP3A4 inducers, such as rifampicin, are able to treat those patients with mutations in CYP24A1 (Hawkes et al. 2017). Of some importance is a recent report of two unrelated human patients that presented with rickets and mutations in the *CYP3A4* gene which resulted in accelerated oxidative removal of $1,25(OH)_2D_3$ while having normal CYP24A1 activity (Roizen et al. 2018).

Conjugation with glucuronides and sulfates in the liver is another proposed catabolic pathway for $25(OH)D_3$ and $1,25(OH)_2D_3$. Conjugates of $25(OH)D_3$ and of $1,25(OH)_2D_3$ have been identified, such as $25OHD_3$-3-*O*-sulfate, $25OHD_3$-3-*O*-glucuronide, and 1,25-glucuronide (Tuckey et al. 2019). It is unclear whether these conjugates play any role except as excretory forms. It has been suggested that they represent enterohepatic circulation, but conclusive evidence supporting this suggestion has not appeared.

Other Metabolites

Lithocholic Acid

Lithocholic acid (LCA) was first identified as a ligand for the nuclear vitamin D receptor nearly 20 years ago. The vitamin D receptor was proposed to act as a bile acid sensor (Makishima et al. 2002). Because of the high concentrations necessary for binding to the VDR, it was proposed to complement the already established role of $1,25(OH)_2D_3$ in the intestine, namely, calcium and phosphate absorption. Subsequent to this finding, the DeLuca laboratory reported that LCA could in fact elevate serum calcium levels in vitamin D-deficient rats (Nehring et al. 2007). However, the concentrations required were nearly 1000X that of $1,25(OH)_2D_3$ calling into question the physiological relevance of this finding.

3-epi-25(OH)D_3 and 3-epi-1,25(OH)$_2D_3$

3-epi-$25(OH)D_3$ and 3-epi-$1,25(OH)_2D_3$ have been reported in human serum. Biologically, these compounds have little activity (Bailey et al. 2013). Whether or not these compounds are generated endogenously or are present as contaminants in the vitamin D preparations remains an important question. Even if 3-epimerization is a bonafide in vivo occurrence, the fact that 3-epimerization markedly reduced biologic activity argues for its lack of importance, except as a possible degradation pathway.

25,26(OH)$_2D_3$ and 1,25,26(OH)$_3D_3$

25,26-Dihydroxy vitamin D_3 was discovered as a metabolite of vitamin D in 1970 (DeLuca et al. 1970). Several laboratories have reported the presence of the 26-hydroxylated forms of $25(OH)D_3$ and $1,25(OH)_2D_3$. In 2001, Endres and DeLuca reported that a contaminant in the ^{3}H-$1,25(OH)_2D_3$ preparation was responsible for the generation of $1,25,26(OH)_3D_3$ in rat (Endres and DeLuca 2001). Thus, it is not clear whether $25,26(OH)_2D_3$ or $1,25,26(OH)_3D_3$ are endogenous metabolites of vitamin D or result from contaminants in the vitamin D preparations. In any case, their biological activities are lower than their respective non-26 hydroxylated counterparts.

24,25(OH)$_2D_3$

$24,25(OH)_2D_3$ is the first product formed when $25(OH)D_3$ is acted on by CYP24A1. This metabolite has recently been proposed to function in the repair of bone fractures, which is a continuation of suggestions made previously (DeLuca 2014). The evidence presented is not convincing, and previous extensive examination of the idea that $24,25(OH)_2D_3$ has bone anabolic activity was quite thoroughly disproved. Overall, it is clear that 24-hydroxylation is the product of CYP24A1 activity and plays a key role in the inactivation of the potent vitamin D metabolites, especially $1,25(OH)_2D_3$ (Masuda et al. 2005).

Clinical Uses

(a) The first clinical area to benefit from the discovery of the vitamin endocrine system is **vitamin D dependent rickets type 1A**. This disorder was discovered by Andreas Prader (Prader et al. 1961) and shown to be an autosomal recessive dysfunction of the *CYP27B1* gene. Before discovery of the vitamin D pathway, clinicians successfully treated this disorder with high doses of vitamin D. This practice generates high blood levels of 25OHD. At serum concentrations of >250 ng/ml, 25OHD acts as an analog of $1\alpha25(OH)_2D$, activating VDR, restoring serum calcium and phosphorus to normal levels, and healing rickets. Current practice is to treat this defect with Ca and 0.5–1.0μg $1,25(OH)_2D_3$ per day (Jones et al. 2017).

(b) **Vitamin D dependent rickets type II** was discovered by Brooks, Balsan, and colleagues and later by extensive recording of several kindreds by Malloy and Feldman (2010). In this disorder high blood levels of $1,25(OH)_2D$ are found with severe rickets. The mutations found are in the vitamin D receptor gene (Malloy and Feldman 2010). In cases where the defect is an early termination codon so no VDR receptor is produced, the only treatment available is the I.V. infusion of calcium (Malloy and Feldman 2010). In other defects where the VDR affinity for $1,25OHD_3$ is altered but still present, high doses of $1,25(OH)_2D$ are more or less effective.

(c) Perhaps the greatest use of the vitamin D metabolites has been in **chronic renal failure patients on dialysis**. In this disorder one of the problems is destruction of the major if not exclusive source (kidney) of $1,25(OH)_2D$ resulting in poor calcium absorption, failure of mineralization, and high levels of parathyroid hormone causing marked bone resorption. Either $1,25(OH)D_3$ or $1OHD_2$ and analogs such as 19-nor-$1,25(OH)_2D_3$ and 22-oxa-$1,25(OH)_2D_3$ have been successfully used to suppress parathyroid hormone production and secretion. $1,25(OH)_2D_3$ with its receptor suppressing the parathyroid gene directly through a VDR binding site on the parathyroid gene. Although oral $1,25(OH)_2D_3$ was initially used for this disorder, on first pass through the intestine, it markedly increases calcium absorption causing unwanted hypercalcemia. This practice was replaced by I.V. $1,25(OH)_2D_3$ which in turn was replaced by less calcemic analogs, i.e., 19-nor-$1,25(OH)D_2$ and $1OHD_2$. Because of cost restriction in the "Bundling" reimbursement for dialysis therapeutics in the USA, "least cost alternative" has resulted in return to low cost $1,25(OH)_2D_3$ for control of secondary hyperparathyroidism without regard to potential hypercalcemia. Nevertheless, 1-hydroxylated vitamin Ds are an important if not essential treatment for renal osteodystrophy.

(d) Another clear application for the 1-hydroxylated vitamin D is **hypoparathyroidism** brought about either by surgery or a genetic circumstance (Gafni and Collins 2019). These patients must be provided with a high calcium intake and a 1-hydroxylated vitamin D to facilitate absorption of calcium. Recall that without parathyroid hormone, the CYP27B1 remains silent in the face of hypocalcemia and little or no $1,25(OH)_2D_3$ is produced. Although parathyroid hormone replacement might be used, its short lifetime, expense, and required intravenous treatment make this approach not practical. Since bone calcium mobilization in vivo by $1,25(OH)_2D_3$ requires PTH, treatment must rely on intestinal calcium absorption.

(e) **Osteoporosis** is another disease area where various vitamin D compounds have been effectively utilized (Cianferotti et al. 2015). It has been especially useful in countries where calcium intake is less than 1 g per day. Although occasional reports that $1,25(OH)_2D_3$ fails to improve either bone density or reduce fractures in post-menopausal women have appeared, these studies are largely flawed by using doses of $1,25(OH)_2D_3$ of 0.25μg/day or less when an estimate of normal production of $1,25(OH)_2D_3$ per day is of the order of 1–2μg/day. In all other studies, impressive increases in bone mass and a reduction of fracture rates

have been achieved with $1,25(OH)_2D_3$, $1\alpha OHD_3$, or ED-71.

(f) **Failed application of 1-hydroxylated vitamin Ds**

One of the most troublesome applications of vitamin D has been in the autoimmune disease multiple sclerosis (MS). This is based largely on the relationship of low sunlight areas with high incidence of the disease (DeLuca and Plum 2017). Animal models of the disease, i.e., experimental autoimmune encephalomyelitis (EAE), have been used to determine if vitamin D plays a role in this disease. The administration of $1,25(OH)_2D_3$ does suppress EAE, but the animals develop hypercalcemia. Clearly hypercalcemia and not vitamin D is responsible for the suppression of EAE. Unfortunately, clinical trials on human MS with high dose vitamin D were initiated resulting in hypercalcemia without benefit to the patient (Hausler and Weber 2019). Quite unexpected is the finding that vitamin D deficiency suppresses EAE as shown in two independent laboratories (DeLuca and Plum 2017). Thus, support for the clinical use of vitamin D in the treatment or prevention of MS is absent. Upon examination of the role of light suppression, a narrow band of ultraviolet light at 313 nm (NBUV) was found effective in suppressing EAE either not altering or slightly increasing serum $25OHD_3$ levels. In a follow-up study, Irving et al. used mice that are unable to synthesize the precursor of vitamin D, i.e., 7-dehydrocholesterol (Irving et al. 2019). These knockout mice responded to the NBUV to the same extent as the wild-type littermates clearly demonstrating that the NBUV suppresses EAE independent of vitamin D. It is not clear what compound mediates the NBUV effect but is under investigation.

(g) **Other possible clinical connections**

A number of investigations have been conducted because of the appearance of the VDR in cells of the immune system (Lang and Aspinall 2017). In particular are the reports that $1,25(OH)_2D_3$ stimulates the synthesis of cathelicidin. Most of the studies carried out are in vitro using nonphysiological concentrations of $1,25(OH)_2D_3$ of at least 10^{-8} M. To our knowledge no report of a well-controlled in vivo effect of vitamin D on suppression of an infectious disease has appeared. An attempt to find an effect of vitamin D on infection of mice by listeria was without success (Baisa et al. 2019). Vitamin D-deficient mice and vitamin D-sufficient mice were equal in their response to listeria infection. A role for vitamin D in immunity has not been found to date despite many suggestions.

The fact that the islet cells of the pancreas are laden with VDR suggests a possible role for vitamin D in type 1 diabetes, an autoimmune disease. Certainly vitamin D-deficient NOD mice develop diabetes more quickly than vitamin D-sufficient NOD mice (Zella et al. 2003). Further vitamin D compounds do suppress diabetes in NOD mice, but unfortunately hypercalcemia is a problem. Thus it is unclear what the role of the vitamin D receptor is in the islet cells and what relationship exists between vitamin D and the development of type 1 diabetes.

Certainly, vitamin D and its functional metabolites play a key if not essential role in calcium and phosphorus metabolism and in prevention of bone disease. It is also an essential element in the control of the parathyroid. So far evidence for a role for vitamin D compounds in immunity or in suppression of autoimmune disorders is lacking. Further the role of the vitamin D receptor in the islet cells of the pancreas and a relationship if any to type 1 diabetes remains unknown.

Vitamin K

Donatus Nohr
Institute of Nutritional Sciences (-140-),
University of Hohenheim, Stuttgart, Germany

Synonyms

Phylloquinones (vitamin K1), menaquinones-n (MK-n; vitamin K2), and menadione (vitamin K3, synthetic and intermediate between K1 and MK4). While phylloquinones are synthesized by plants, menaquinones are synthesized in small amounts by human intestinal microbiota using repeated 5-carbon units in the molecule side chain. n stands for the number of 5-carbon units. MK-4 can also be produced by animals (including humans) from phylloquinones and can be found in a number of organs (The Linus Pauling Institute 2014; Biesalski 2016).

Definition

Vitamin K belongs to the group of fat-soluble vitamins. The term "K" refers to its main actions in blood clotting, coagulation, in German named "**K**oagulation."

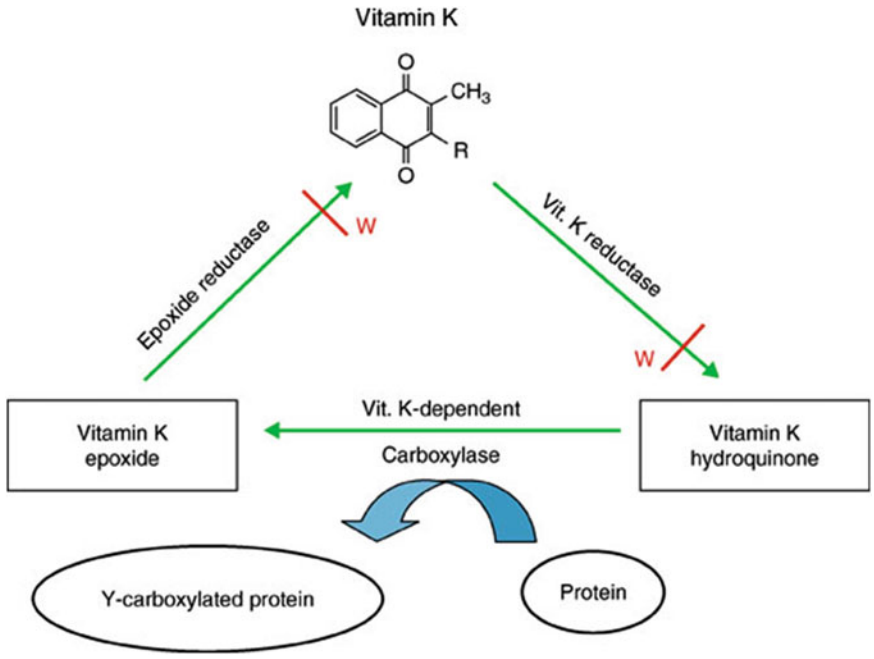
Mechanisms of Action

General Aspects

Although vitamin K is a fat-soluble vitamin, only little stores are found in the body which have to be refilled permanently via dietary input. The role of vitamin K derived from bacteria in the terminal ileum and the colon seems to play a minor role in human nutrition, as the concentration of biliary acids for the resorption of the fat-soluble vitamin K is very low here (Biesalski 2016; Wu et al. 2015). In addition, only diseases of the small intestine lead to a deficit in vitamin K concentration, which cannot be restored by K2 production of colonic bacteria. However, water-soluble vitamin Ks can be resorbed by the colonic mucosa. Maybe because of the little stores for vitamin K, the process of vitamin K-dependent carboxylation of proteins is part of a cycle with several steps during which vitamin K normally is regenerated (see Fig. 1) and thus can be used several times.

Influence on Cell Functions via Gas6

Growth arrest-specific gene 6 (Gas6) is a γ-carboxylated and thus vitamin K-dependent protein found throughout the nervous system and in the heart, lung, stomach, kidneys, and cartilage. It is regarded as a ligand for several families of receptor tyrosine kinases (RTKs). Gas6 plays a role in regulation of cell proliferation, differentiation, migration, and adhesion, release of pro-inflammatory cytokines, platelet aggregation, differentiation of NK cells, adipocyte development, phagocytosis, atherosclerosis, or cancer growth (The Linus Pauling Institute 2014; Wu et al. 2015). Also a role in the developing and the aging nervous system seems realistic (Ferland 2012). Gas6 is hypothesized to act via the Axl receptor with additional effects on adiposity and insulin resistance (Dihingia et al. 2017). However, there are no studies comparing the role of the carboxylated and undercarboxylated form of



Vitamin K, Fig. 1 The vitamin K cycle; w indicates where warfarin or other vitamin K antagonists inhibit the cycle

Gas6 in glucose metabolism and inflammatory pathophysiology.

Coagulation

Binding calcium ions (Ca^{2+}) is a prerequisite for the activation of seven factors in the coagulation cascade that are dependent on vitamin K. The term cascade indicates that the factors involved depend from each other to become activated and to fulfill their special part to stop bleeding. Prothrombin (factor II) and factors VII, IX, and X play central roles in the coagulation cascade; protein Z seems to enhance the thrombin action via promoting its association with phospholipids in cell membranes. The proteins C and S act as anticoagulant proteins such providing an also vitamin K-dependent control and balance of the whole cascade. With both coagulant and anticoagulant factors present in the cascade in the liver, uncontrolled bleeding and/or clotting can well be prevented. On the other hand, liver damage or diseases can disturb this well-controlled cascade, e.g., via reduced clotting factors in the circulating blood resulting in uncontrolled bleeding (hemorrhage) (Olson 1999). One has to be cautious in patients using anticoagulants like phenprocoumon or in elderly persons with vitamin K deficiencies; however, a change in nutrition behavior actually is not recommended.

Bone Mineralization

In bone, several proteins have been described, which are vitamin K-dependent, osteocalcin (bone Gla protein), matrix Gla protein (MGP), Gla-rich protein (GRP; also named Ucma), protein S, and Gas6. Osteocalcin is synthetized by osteoclasts, regulated by the active form of vitamin D, calcitriol. Its capacity to bind calcium needs a vitamin K-dependent γ-carboxylation of three glutamic acid residues. The calcium-binding capacity of osteocalcin indicates its role in synthesis and regulation of bone matrix. Protein S, a coagulant, is also vitamin K dependent in its synthesis by osteoclasts; its role in bone metabolism is still unclear. However, children with reduced protein S levels express enhanced blood clotting and a reduced bone density. MGP has been found in several supportive tissues (bone, cartilage) and in soft tissues including smooth muscle cells in blood vessels. MGP prevents soft tissues (blood vessels) as well as cartilage from calcification (inhibited Ca uptake), while on the other hand, it facilitates bone development and growth (Ca uptake in osteoblasts). Additionally, MGP inhibits bone morphogenic protein2/4 (Wasilewski et al. 2019). Rat studies with warfarin (vitamin K antagonist; see Fig. 1) led to prominent deformations of the skeleton of fetuses as well as newborns including excessive mineralization of growth plates and nasal cartilage and stunted growth. Comparable effects were seen in humans after a therapy with vitamin K antagonists during pregnancy. The so-called warfarin embryopathy includes hypercalcification of the growth plates (chondrodysplasia punctata), a nasal hypoplasia, and disturbances in the growth of facial and hollow bones. The major role of GRP seems to be the Ca regulation in extracellular matrix as an inhibitor of ectopic calcification.

Clinical Use (Including Side Effects)

Vitamin K Deficiency

There are clear-cut differences in deficiencies concerning infants, especially newborns, and adults. Deficiencies of vitamin K are really seldom in healthy adults, because the supply through daily food is (more than) enough, because vitamin K is repeatedly recycled and therefore only a small loss appears, and – although not really accepted – because of the K2 production by intestinal bacteria (see above). On the other hand, those people with severe liver diseases or fat malabsorption or taking vitamin K antagonist anticoagulants have a risk of vitamin K deficiency (cf Schek 2017a). Also, menopausal women are at risk. Symptoms are impaired blood clotting as revealed by routine tests measuring clotting time, unusual bleeding after smaller wounding, nose bleeding, heavy menstrual bleeding, or a great susceptibility to hematoma.

The picture is different concerning infants during the first days of life, especially for those being breastfed (Biesalski 2016). Coagulation-related (vitamin K-dependent) plasma proteins develop

slowly during pregnancy resulting in markedly reduced levels after birth. In addition, human milk is a nutrient low in vitamin K content; the newborns' intestine almost totally lacks menaquinone-synthesizing bacteria, and the vitamin K cycle might not yet be established. Vitamin K supplementation during pregnancy seems not to improve the infant's situation; only VK levels in maternal plasma were enhanced (Shahrook et al. 2018). These deficiencies can lead in healthy newborns to uncontrolled, in worst cases, lethal, intracranial bleedings. Due to that risk, in most countries newborns are supplied with phylloquinones direct postnatally, normally by 1×1 mg injections or by bottle feeding 3×2 mg direct postnatally, between day 3 and 10 and between weeks 4 and 5 (Deutsche Gesellschaft für Neonatologie und Pädiatrische Intensivmedizin 2021).

Osteoporosis

This illness is mainly characterized by an age-related bone loss. The detection of osteocalcin in bone – produced by osteoblasts – was the starting point for a series of studies on the role of vitamin K-dependent proteins in bone development and maintenance and on possible supplementation therapies (see "bone mineralization"). While various studies found a positive correlation between vitamin K status (or intake) and the risk of several fracture types (hip, vertebral, non-vertebral) in several populations, others did not (cf Palermo et al. 2017). Therefore, further prospective studies or clinical trials are needed.

Osteocalcin has been found to be a reliable marker of bone formation, and vitamin K is necessary for the carboxylation of this protein. Therefore, the degree of carboxylation of osteocalcin is a reliable marker for the respective vitamin status (Biesalski 2016). Blood levels of undercarboxylated osteocalcin were found to be higher in postmenopausal women and markedly higher in women over 70. Studies with elderly women resulted in a positive correlation of the blood level of undercarboxylated osteocalcin and the risk of bone fractures. Interestingly, also a correlation of undercarboxylated osteocalcin with the vitamin D nutritional status was described, and a co-supplementation with Ca and vitamin D seems to provide better results in terms of bone mineral density. In addition, K1 may be more effective than MK4 and MK7 (Palermo et al. 2017).

Studies on the effects of an (even long-time) application of vitamin K-antagonistic anticoagulants like warfarin gave no clear-cut results concerning bone density or a changed risk for bone fractures. While negative effects were shown in animal models, in patients with atrial fibrillation or venous thromboembolism, no effect was found in a study with postmenopausal women (cf Palermo et al. 2017).

Supplementation of women >65 years with vitamin MK-7 from Nattō (200μg/day for 3 years) resulted in decreased reduction of bone mineral density (BMD) in the femur, but not in the hip; one over 36 months (180μg/day) had equal results, while 360μg/day for 12 months showed no effects (cf Schek 2017b).

Atherosclerosis

Vitamin K might play a role to counteract the Ca paradox, a loss of BMD on one side together with enhanced arterial calcification in postmenopausal women as well as older men and most prominent in patients with chronic kidney disease on the other side. Vitamin K carboxylates osteocalcin and MGP resulting in more Ca uptake in osteoblasts and reduced uptake in vascular smooth muscle cells, respectively (Wasilewski et al. 2019). However, the role of various fractions of MGP at different vascular sites is further under discussion (Barrett et al. 2018).

Safety and Toxicity

As studies with high supplementation dosages exemplarily show, there is no known toxicity for phylloquinone (K1) or menaquinone (K2) (Biesalski 2016). Therefore no tolerable upper intake level is given by the European Food Safety Authority (EFSA 2021). This is not true for

Vitamin K, Table 1 Vitamin K content of selected nutrients in alphabetic order[a]#

[a]The adequate intake level (AI) in the USA given by the FNB of the Institute of Medicine in 2001 is 120 µg/day and 90 µg/day for men and women older than 19 years. respectively. In Germany. 70 µg/day for men and 60 µg/day for women <51 years and 80 µg/day and 65 µg/day older than 51 years. 4 µg/day for sucklings <4 months. 10 µg/day 4–12 months. and finally in 3-year steps 50 µg/day for children <15 years are proposed by the German Nutrition Society (DGE) (DGE 2021)

menadione (vitamin K3) that can interfere with glutathione, a natural antioxidant, resulting in oxidative stress and cell membrane damage. Injections of menadione in infants led to jaundice and hemolytic anemia and therefore should not be used for the treatment of vitamin K deficiency.

People using warfarin should try to consume the recommended daily intake of vitamin K very regularly to avoid interferences with their anticoagulant dosage adjusted by the physician. Interestingly, high doses of vitamins A and E seem to antagonize vitamin K, vitamin A interfering with vitamin K absorption and vitamin E inhibiting vitamin K-dependent carboxylase enzymes (Biesalski 2016).

Until 1993 the adequate intake of phylloquinone (there is none given for K2) is set to 1µg/KG BW/day by the EFSA (EFSA 2021).

An idea about the concentration of vitamin K in food sources is shown in Table 1 (Schek 2017a). Interestingly, there are great differences between different sources of such data (e.g., 2, 15) which makes it difficult to find out the real values.

Voltage-Dependent Ca^{2+} Channels

Franz Hofmann
Institut für Pharmakologie und Toxikologie, Technische Universität München, München, Germany

Synonyms

High voltage-activated (HVA) calcium channels; Low voltage-activated (LVA) calcium channels

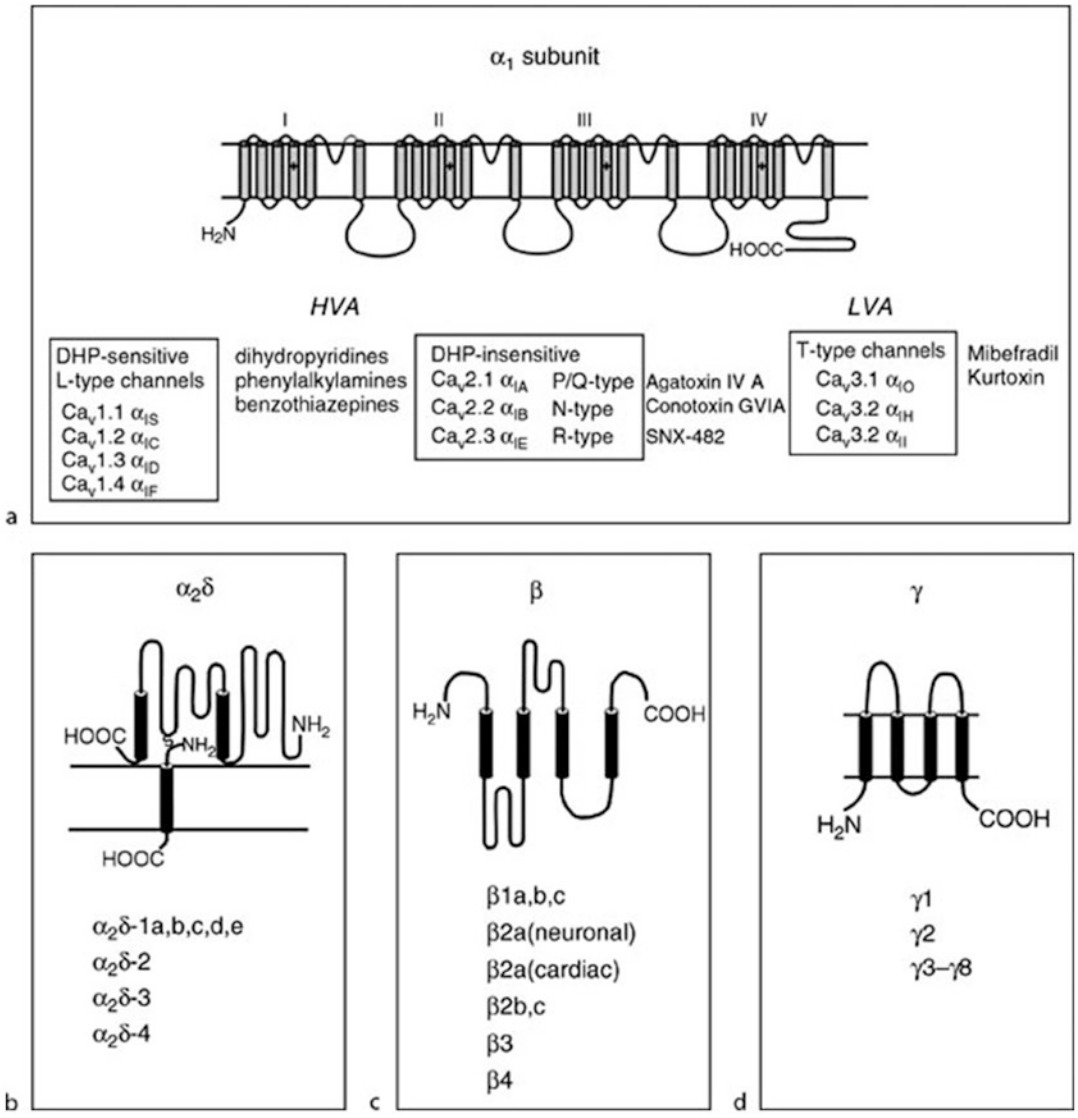
Definition

Voltage-dependent Ca^{2+} channels are a family of multi-subunit complexes of five proteins responding to membrane depolarization with channel opening allowing the influx of calcium into a cell. Voltage-dependent calcium channels are subdivided into three subfamilies: the HVA DHP-sensitive L-type calcium channels, the HVA DHP-insensitive calcium channels and the LVA T-type calcium channels (Hofmann et al. 2014).

Basic Characteristics

Voltage-activated calcium channels regulate the intracellular calcium concentration and contribute thereby to calcium signaling in numerous cell types. These channels are widely distributed in the animal kingdom and are an essential part of many excitable and non-excitable mammalian cell signaling pathways. Electrophysiological studies characterized different calcium currents identified as L-, N-, P-, Q-, R- and T-type current (Catterall et al. 2019; Hofmann et al. 2014). The opening of these channels is primarily triggered by depolarization of the membrane potential, but is also modulated by a wide variety of hormones, protein kinases, protein phosphatases, toxins and drugs. Site-directed mutagenesis has identified sites on these channels, which interact specifically with other proteins, inhibitors and ions.

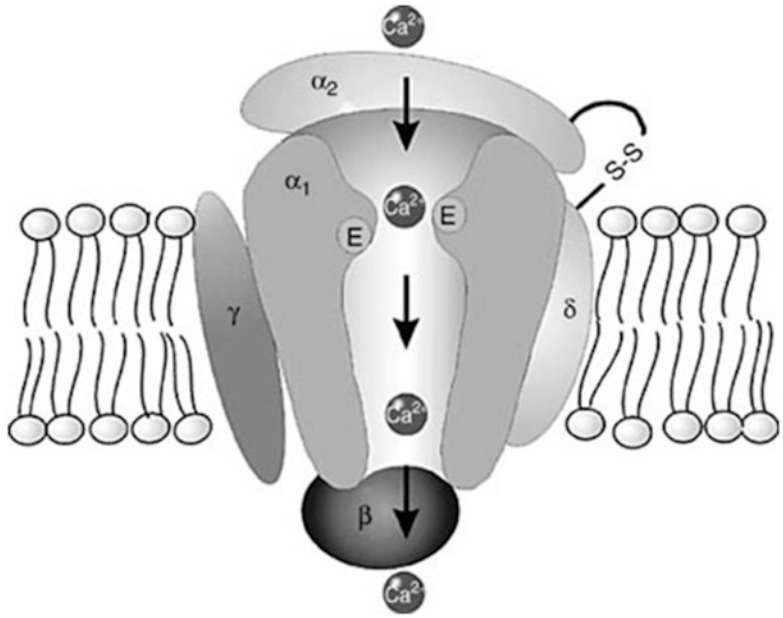
HVA calcium channels are biochemically heterooligomeric complexes of five proteins encoded by four gene families (Fig. 1): The α_1 subunits of ~190–250 kDa contain the voltage-sensor, the selectivity filter, the ion-conducting pore, the binding sites for most calcium channel blockers, and the interaction sites for heterotrimeric GTP-binding protein subunits and other proteins. Seven α_1 genes have been identified (Fig. 1). Four genes ($Ca_v1.x$) encode L-type, dihydropyridine-sensitive channels. Three genes ($Ca_v2.x$) encode the dihydropyridine-insensitive neuronal N-, P-, Q-, R-current. These α_1 subunits are associated with four auxiliary proteins (Fig. 2). The $\alpha_2\delta$ subunits, disulfide-linked dimers, are transcribed from four different genes and are clipped posttranslational into the extracellular located α_2- and the transmembrane δ-protein. The intracellular located β subunit and the



Voltage-Dependent Ca^{2+} Channels, Fig. 1 Structure, identity and blockers of calcium channel subunits

transmembrane γ subunit are encoded by four and up to eight distinct genes, respectively. With the exception of the skeletal muscle calcium channel, a heterooligomer containing the $Ca_v1.1$ (α_{1S}), β1, $\alpha_2\delta$-1 and γ1 subunit, the exact composition of individual channels is not known. The identity of these complexes is further complicated by the existence of several splice variants for most genes that confer significant effects on the electrophysiological and/or pharmacological properties of the channels.

The exact subunit composition of the Low Voltage-activated (LVA) Ca^{2+} channels is unknown (Lacinova et al. 2000; Perez-Reyes 2003). Three α_1 subunits, $Ca_v3.x$, have been identified which induce large T-type current after expression in *Xenopus* oocytes and in HEK cells in the absence of additional subunits. The T-type



Voltage-Dependent Ca^{2+} Channels, Fig. 2 Subunit composition of a HVA calcium channel. The selectivity filter of the channel is created by four glutamates (E)

current can be affected by the $\alpha_2\delta$ and the γ6 subunit suggesting a maximal subunit composition of $\alpha_1/\alpha_2\delta./\gamma$.

Properties of the α_1 Subunits: Each α_1 subunit contains four repeats that are composed of six transmembrane helices and a pore region between helix S5 and S6. The selectivity filter of the channels is located in the pore region and calcium selectivity of the HVA channels is created by four glutamates (E) in each pore, whereas the LVA channels have glutamates in the pore of repeat I and II and aspartates (D) in that of repeat III and IV. Conformational changes of the protein allow the channel to occupy one of three states: the closed, open or inactivated state. The change in membrane potential is sensed by the S4 helices of each repeat which contain a number of positive charged amino acids. Movement of these helices induces opening of the channel pore. HVA channels are activated approximately at a membrane potential of −30 mV with a maximal activation around 0 mV, whereas the LVA channels activate at potentials around −60 mV and have a maximal inward current around −10 mV. The LVA channels activate and inactivate faster than the HVA channels. Inactivation of all channels is voltage-dependent and accelerated if the membrane is depolarized for prolonged time. Voltage-dependent inactivation may be mediated by sequences present in repeat I and II. Some of the HVA channels, especially the $Ca_v1.2$ channel, show calcium-dependent inactivation. Calcium flowing through the channel binds on the internal side to calmodulin, a calcium binding protein tethered to the carboxy terminal tail of the α_1 protein by an isoleucine/glutamine (IQ)-motive. The calcium–calmodulin complex induces a conformational change in the α_1 protein that leads to inactivation of the channel. The $Ca_v1.4$ and the LVA channels do not have this type of inactivation.

The intracellular loop between repeat II and III couples and signals to intracellular effectors. The II–III loop of the $Ca_v1.1$ protein couples directly with the ryanodine receptor 1 located at the sarcoplasmatic reticulum in the skeletal muscle triad. In contrast, the cardiac $Ca_v1.2$ channel is in close proximity but not in direct contact with the cardiac ryanodine receptor 2. This cardiac ryanodine receptor channel is activated by the calcium flowing through the open $Ca_v1.2$ channel. The II–III loops of the neuronal presynaptic

localized Ca $_v$2.1 and Ca $_v$2.2 channels interact directly with the SNARE complex of the neurotransmitter containing vesicles and facilitates together with the inflowing calcium fusion of the vesicle and plasma membrane resulting in opening of the vesicle. Similar interactions occur probably between the Ca $_v$1.2 II–III loop and insulin containing vesicles of the murine pancreatic islets.

Neurotransmitter receptors inhibit the neuronal Ca $_v$2.x channels by activation of G-proteins. The β/γ subunit of the heterotrimeric GTP-binding proteins binds to a QxxER sequence that is located at the I–II loop. Binding of the β/γ subunits confers the "reluctant phenotype" to these channels. This phenotype includes a reduced channel activation and current at normal depolarized membrane potentials. The I–II loop interacts also with the calcium channel β subunit with high affinity allowing transport of the α $_1$ protein from the Golgi to the membrane surface and a shift in the voltage-dependence of channel opening and closing.

Recent results show that the positive inotropy mediated by the cardiac beta-receptor includes cAMP-dependent phosphorylation of the β-2 subunit. This modification weakens the interaction between the β-2 subunit and the small GTPase rad. Rad inhibits the Cav1.2 current, if bound to the β2-subunit.

► Channel blockers: Distinct blockers have been identified for the various HVA calcium channels which are listed in Fig. 1. Dihydropyridines, phenylalkylamines and benzothiazepines block all Ca $_v$1.x L-type calcium channels. These compounds are used mainly to lower the blood pressure in hypertensive patients. In therapeutic concentrations, they block mainly the smooth muscle Ca $_v$1.2 channel. The dihydropyridines bind with high affinity to the inactivated state of the L-type channels. Binding requires amino acids on the IIIS5, IIIS6 and IVS6 helices. Mutation of Thr1061 in IIIS5 to tyrosine abolished completely the high affinity interaction of dihydropyridines with the Ca $_v$1.2 channel protein. The difference in the sensitivity between the cardiac and the smooth muscle L-type calcium channel is in part caused by the use of alternative exons (No. 8) coding for the IS6 helix (Welling et al. 1997). The phenylalkylamine and benzothiazepine binding sites contain amino acids present in the IIIS6 and IVS6 helices and the glutamates in the pore region of repeat III and IV. The latter two groups include compounds that block neuronal Ca $_v$2.x channels at similar concentrations as the Ca $_v$1.x channels.

The LVA α $_1$ subunits are blocked by moderate to low (10μM) concentrations of nickel and bind the channel blocker mibefradil and kurotoxin. Both compounds are not specific LVA channel blockers because they block also Ca $_v$1.x and Ca $_v$2.x channels at about tenfold higher concentration. Interestingly, the endogenous cannabinoid anandamide binds to LVA channels and stabilizes the inactivated state. This effect decreases T-type calcium current and neuronal firing activities.

The α $_2$δ subunit 1 and 2 bind gabapentin and pregabalin with high affinity. This interaction may be causally related to its antiepileptic and neuropathic pain alleviating property.

Localization of channels: The Ca $_v$1.1 channel is present in skeletal muscle at the triad. The Ca $_v$1.2 channel is widely distributed and represents the major L-type calcium channel in most tissues. In contrast, the Ca $_v$1.4 channel has been detected only in the retina, so far. The Ca $_v$1.3 (α $_{1D}$) channel is mainly found in neuroendocrine cells and the inner ear. The Ca $_v$2.1, Ca $_v$2.2 and Ca $_v$2.3 are mainly localized presynaptic. The Ca $_v$2.1 and Ca $_v$2.2 channels interact with the vesicular release machinery and regulate the release of neurotransmitters.

The LVA channels are expressed in a wide variety of tissues. In the cardiac sinus node and the thalamus, activation of LVA channels seems to be necessary to generate action potentials upon depolarizing the membrane.

Mutation and Deletion

Deletion of the Ca $_v$1.1 and Ca $_v$1.2 gene is not compatible with viable mouse pups (Moosmang et al. 2007; Muth et al. 2001). The Ca $_v$1.2 channel is absolutely required for the contraction of the developing mouse heart after embryonal day

14. Mutation of the human $Ca_v1.1$ gene is associated with hypokalemic periodic paralysis. Deletion of the $Ca_v1.3$ gene leads to viable pups that are deaf and have cardiac arrhythmia at rest. Mutation of the human $Ca_v1.4$ gene is associated with X-linked congenital stationary night blindness.

Mutation in the neuronal $Ca_v2.1$ channel is associated with familial hemiplegic migraine and episodic ataxia in humans. Deletion of the $Ca_v2.1$, $Ca_v2.2$ and $Ca_v2.3$ gene is compatible with life accompanied by a variety of central and peripheral defects.

Deletion of the $Ca_v3.1$ channel in thalamocortical relay neurons prevents absence epilepsy. Block of the neuronal LVA channels alleviates certain forms of epilepsy. Deletion of $Ca_v3.2$ leads to coronary artery constriction and focal myocardial fibrosis.

Deletion of the ß1 subunit is lethal, whereas deletion or mutation of the $\alpha_2\delta$-2, β3, β4, γ1 and γ2 genes is associated either with no or various neuronal phenotypes.

More recent analysis of tissue specific gene deletions showed that the $Ca_v1.2$ channel is involved in a wide variety of function including hippocampal learning, insulin secretion, intestine and bladder motility. Further analysis will be required to unravel the functional significance of voltage-dependent calcium channels for specific cellular functions.

Drugs

Numerous dihydropyridine calcium channel blockers have been introduced to treat hypertension and stable angina pectoris. Nifedipine, nitrendipine, nisoldipine, nilvadipine, nicardipine, amlodipine, felodipine, isradipine block preferentially the vascular, smooth muscle $Ca_v1.2$ calcium channel at therapeutic doses. Nimodipine that has a short half-life has been used to alleviate cerebral vasospasms after subarachnoidal bleeding. The phenylalkylamines verapamil and gallopamil and the benzothiazepine diltiazem have been used as antihypertensive drugs and to treat supraventricular tachyarrhythmia. Mibefradil – a compound thought to inhibit preferentially T-type channels – that blocks at low concentrations vascular $Ca_v1.2$ L-type channels in the mouse, has been used for a short period as an antihypertensive drug. It has been removed from the market due to intolerable interactions with other drugs.

Gabapentin and pregabalin are prescribed in certain epileptic diseases such as absence epilepsy and in neuropathic pain. Their therapeutic target for pain suppression is the $\alpha_2\delta$-1 subunit.

Voltage-Gated K^+ Channels

Olaf Pongs
Institute of Cellular Neurophysiology, CIPMM
University of Saarland, Homburg-Saar, Germany

Synonyms

Kv-channels

Definition

Voltage-gated potassium (Kv) channels are membrane-inserted protein complexes, which form potassium-selective pores that are gated by changes in the potential across the membrane. The potassium current flow through the open channel follows by the electrochemical gradient as defined by the Nernst equation. In general, Kv channels are localized in the plasma membrane.

Basic Characteristics

Functional Characteristics

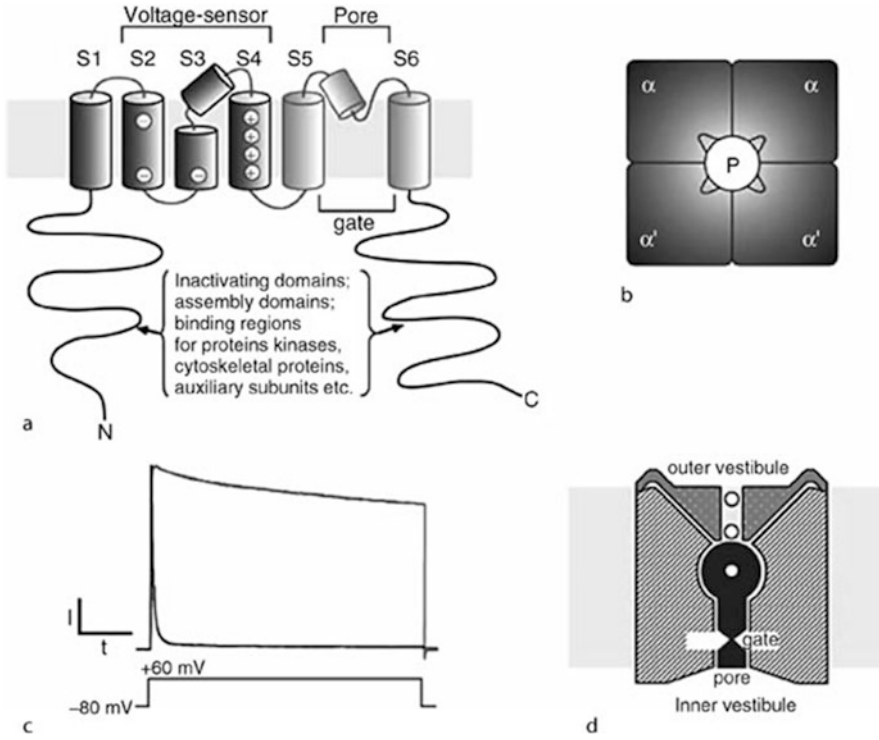
Kv channels may be important determinants of cellular activities correlated with changes in membrane potential. Examples range from neural signal transduction, action potential wave forms, action potential propagation, action potential frequency, pacemaking, and secretion to the regulation of cell volume and cell proliferation. In addition to changes in voltage, Kv-channel activities may be regulated by various physical and/or chemical stimuli. They include Na^+, Ca^{2+}, Mg^{2+}, ATP, O_2, pH, pressure, redox potential, phosphorylation/dephosphorylation, G protein binding, calmodulin binding, KChiP binding, interaction with cytoskeletal proteins, and more (Hille 2001). Once Kv channels have been activated, they catalyze a rapid passage of K^+ through the open pore along the electrochemical gradient as defined by the Nernst equation. Activated Kv-channels often tend to inactivate (Jan and Jan 1997). The kinetics of inactivation may occur in time ranges of ms to tens of seconds. The inactivation mechanism of Shaker-channels, which inactivate rapidly, has been thoroughly investigated. One mechanism utilizes an amino-terminal inactivating domain. This domain is able to bind to the open pore of Shaker-channels. Thereby, the pore becomes both occluded and locked in an open state. Upon repolarization, inactivated Kv-channels recover from inactivation. Inactivated Kv-channels are refractory to activation. In most circumstances, intracellular K^+ concentrations are higher than the extracellular ones, and the membrane potential is positive to the Nernst potential. Therefore, the direction of K^+ current flow through Kv-channels is mostly outward. But there are important exceptions, where either the membrane potential at which the Kv-channel opens is negative to the Nernst potential or the extracellular K^+ concentration is not very different from the intracellular one. For example, inactivated Kv-channels like HERG-channels (see above) may recover from inactivation at very negative membrane potentials. During recovery they pass through an open state permitting an inward flow of K^+ current. Depending on the particular conditions, hyperpolarizing Kv-channel activity may attenuate cellular excitability (e.g., the firing of action potentials) or they may balance depolarizing activities (e.g., clamp the membrane potential to a certain value to allow a steady inward flow of calcium ions). Frequently, repolarizing Kv-channel activity shifts the membrane potential into a hyperpolarizing direction.

Kv-channels are closed in the resting state. Upon depolarization of the cellular membrane potential, closed Kv-channels undergo a series of voltage-dependent activating steps until they reach an activated state from which they can open and close in a voltage-independent manner. HERG-channels represent a particularly interesting example of Kv-channel inactivation. HERG-channels have faster inactivation than activation kinetics, and they very rapidly recover from inactivation at negative membrane potentials. This behavior may result in a situation where most of the current carried by HERG-channels occurs during their recovery from inactivation at negative

potentials, that is, it represents an inward rather than outward current.

Structural Characteristics of Kv-Channels

Kv-channels are frequently heteromultimeric protein assemblies of pore-forming membrane-integrated α-subunits and of auxiliary subunits (Jan and Jan 1997; Pongs and Schwarz 2010). The first Kv-channel subunits were cloned from *Drosophila*. This work initiated the subsequent identification and cloning of many more Kv-channel genes constituting a superfamily of related proteins. The design of the proteins is structurally and functionally highly conserved (Jiang et al. 2003; Wang and MacKinnon 2017). Kv-channel α-subunits have cytoplasmic amino- and carboxy-termini, which



Voltage-Gated K^+ Channels, Fig. 1 Basic features of voltage-gated potassium channels. (**a**) Schematic drawing of the membrane topology of Kvα-subunits. Transmembrane segments are numbered S1–S6. The linker regions between segments S3/S4 and S5/S6 contain small α-helical regions marked as cylinders. Negative charges (−) in segments S2 and S3 and positive charges (+) in segment S4 contribute to the voltage-sensor of Kv-channels. Pore-forming residues are located within the S5/S6 linker region and segment S6. The gate that opens and closes Kv-channels is not exactly known. Amino acid residues of the S4/S5 linker region, segment S5, and segment S6 are directly and/or indirectly involved in the gating machinery. Brackets give examples for additional functions and properties associated with sequences and domains of the cytoplasmic amino- and/or carboxy-termini. (**b**) Assembly of four Kvα-subunits is needed to form functional Kv-channels with a central pore P. α and α′ indicate that assembly of homo- and heteromultimers is possible. (**c**) Typical examples of potassium outward currents (I) mediated by Kv-channels upon jumping from a holding potential of −80 mV to a test potential of +60 mV. Black trace: rapidly inactivating outward current; gray trace: noninactivating delayed-rectifier type current. Time-scale (t) is in ms. Upon repolarization from a depolarizing test potential to a hyperpolarizing holding potential an inward current or tail current can be observed that reflects the closure of open channels. (**d**) Schematic diagram of pore structure. A hypothetical sagittal section through the pore is shown. The pore has an outer vestibule, a selectivity filter (dotted gray) in the upper third of the membrane, an aqueous cavity, a gate (black), and an inner water-filled vestibule. Potassium ions are drawn approximately to scale as white circles

frame a membrane-spanning core domain. The core domain consists of six hydrophobic membrane-spanning segments S1 to S6. Segments S5 and S6 are linked by the so-called P-loop. This P-loop enters and exits the plasma membrane from the extracellular face. Figure 1a shows a cartoon of the most likely membrane topology of Kv-channel α-subunits. Four subunits are necessary to form a functional channel. Homo- as well as heterotetrameric assembly of Kv-channels is possible (Fig. 1b). Kv-channels can be expressed in vitro in heterologous expression systems (Fig. 1c). The relative ease to in vitro mutate Kv-channel cDNAs and to express Kv-channel cDNAs heterologously in the *Xenopus* oocyte or tissue culture expression systems has produced a detailed understanding of many basic features concerning Kv-channel activity. The results showed that the voltage-sensing apparatus of Kv-channels is mainly formed by amino acids residing in segments S2 to S4. Most notably is the occurrence of a repeat sequence $(R/KXX)n_{=3-5}$ in segment S4, lining up several positive charges in the membrane electric field. The charges apparently move in the electric field when the Kv-channels become activated, giving rise to a gating current across the membrane. Gating currents are observed during the voltage-dependent activation of Kv-channels.

Amino acid residues residing in the S5–P–S6 region are engaged in forming the pore, most notably a highly conserved P-loop sequence TVGY/FGD/N, which has been dubbed the K-channel signature sequence. This sequence forms part of the selectivity filter of the Kv-channel pore. Crystal structures of several Kv channels provide detailed high-resolution images of the pore of a K-channel with its surrounding transmembrane helices (Jiang et al. 2003; Wang and MacKinnon 2017; Whicher and MacKinnon 2019; Sun and MacKinnon 2020). K-channel pore structures are apparently highly conserved (Lu et al. 2001; Gonzáles et al. 2012). Hallmarks of the pore structure are an outer vestibule with a relatively flat surface. Beneath, in the upper-third of the membrane, lies a narrow selectivity filter. This is followed by a central aqueous cavity narrowing into the internal mouth of the pore (Fig. 1d). Kv-channels, during voltage-dependent activation and opening, undergo marked conformational changes. In the resting state, a "gate" closes the pore. Upon activation, the gate opens. Amino acid residues in the carboxy-terminal half of the S6 region apparently play a pivotal role for the structure and function of the Kv-channel gate. Other Kv channel domains, for example, the S4-S5 linker region, which links gate and voltage sensor, participate in channel gating via allosteric mechanisms. Furthermore, intracellular domains may also participate in the regulation of gating. Thus, gating involves considerable structural rearrangements typically seen in allosteric proteins (Wang and MacKinnon 2017; Whicher and MacKinnon 2019; Sun and MacKinnon 2020; Long et al. 2005; Barros et al. 2019). In addition, cytoplasmic domains play important roles in Kv-channel function (Wang and MacKinnon 2017). Many of these functions are related to subunits assembly, channel trafficking to and from the plasma membrane, and interactions with cytoskeletal components (Fig. 1a). A tetramerization (T) domain for subunit assembly has been well defined in Shaker-channels, where it is localized in the amino-terminus. Other Kv-channels (e.g., eag, HERG, KvLQT1) have comparable domains within the cytoplasmic carboxy-terminus. ER retention and retrieval signals have been found in the cytoplasmic amino- or carboxy-termini. Thus, channelopathies may be associated with defects in ion channel function as well as with defects in ion channel folding, trafficking, and membrane localization/retention (Curran and Mohler 2015). Also, cytoplasmic Kv-channel domains may contain recognition

Voltage-Gated K^+ Channels, Table 1 Auxiliary subunits and their reported interactions with Kvα-subunits

Auxiliary subunit	Kvα-subunits
Kvβ1, Kvβ2, Kvβ3	Kv1-family, Shaker
MIRP2	Kv3.4
KChIPs (KChIP1,2,3,4)	Kv4.1, Kv4.2, Kv4.3

	HERG, Kv3.4, Kv4.3
sloβ1–sloβ4	BK(slo)α-subunits

sequences for a variety of serin/threonine and/or tyrosine protein kinases, which contributes to additional structural and functional diversity (Vacher and Trimmer 2011). Finally, motifs have been characterized that interact with a variety of cytoskeletal components. For example, the conserved carboxy-terminal amino-acid motif TDV is recognized by MAGUK(PSD)-proteins of the post- and presynaptic densities and KvLQT1 contains a functionally important C-terminal domain for calmodulin binding (Yi et al. 2001; Sun and MacKinnon 2017).

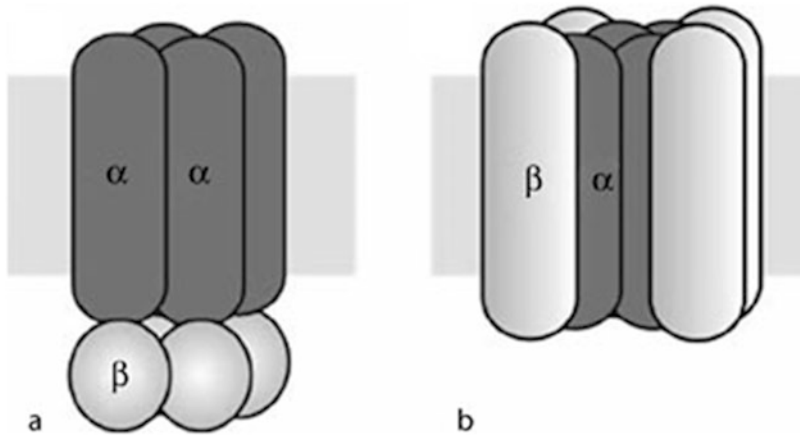
Auxiliary Subunits

Kvα-subunits may coassemble with auxiliary subunits (see Table 1) (Pongs and Schwarz 2010). Auxiliary subunits (e.g., Kvβ-subunits) may bind to cytoplasmic regions of the Kvα-subunits extending the reach of the membrane-integrated core channel into the cytoplasm (Fig. 2a). A particularly interesting group is the KChIP-family. KChIP stands for K-channel interacting protein. The proteins are small Ca^{2+}-binding proteins being related to the superfamily of neuronal calcium sensors. They are tightly associated with somato-dendritic rapidly inactivating Kv-channels (Kv4.1, Kv4.2, Kv4.3). Alternatively, the auxiliary subunits may be membrane integrated proteins like Kvα-subunits (Fig. 2b). Examples are members of the KCNE-family of auxiliary subunits that may assemble with a great variety of Kv-channels including KCNQ-channels, HERG-channels, and Shaker-related Kv-channels.

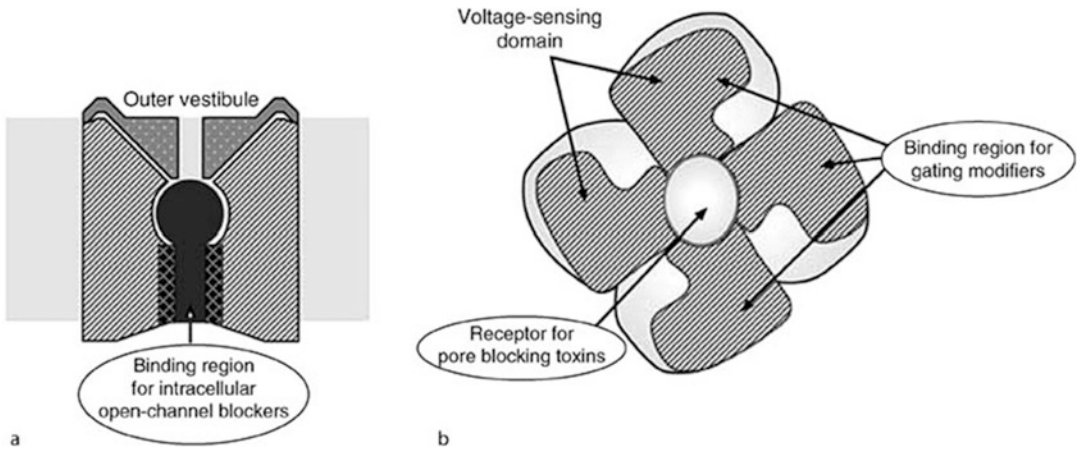
Functional activities of auxiliary subunits may include chaperone activities during assembly, for example, Kvβ-subunits have been shown to exert a chaperone function for the assembly of Shaker α-subunits or the recognition of ER-retention signals as discussed for KChIPs. Notably, auxiliary subunits may modulate the biophysical and pharmacological properties of Kv-channels. Certain Kvβ (Kvβ1.1 and Kvβ3.1) confer a rapid-inactivation behavior to otherwise noninactivating Kv-channels. Association of KCNE1 with KvLQT1 leads to a significant slowing of Kv-channel activation, a depolarizing shift in the voltage dependence of activation and a change in drug sensitivity (e.g., for mefenamide). On the other hand, association of KCNE3 with KvLQT1 leads to voltage-insensitive channels.

Drugs

In the animal kingdom, a great number of toxins from snakes to scorpions, insects, spiders, and sea anemones that block various Kv-channels with



Voltage-Gated K^+ Channels, Fig. 2 Schematic drawing of voltage-gated potassium channels as heteromultimeric assemblies of pore-forming Kvα-subunits and auxiliary subunits. (**a**) Assembly of Shaker-type Kv-channels with cytoplasmic subunits, for example, Kvβ-subunits and KChIPs. (**b**) Assembly of Kv-channels with membrane-integrated auxiliary subunits, for example, MinK and MirPs. Membrane is shaded gray



Voltage-Gated K^+ Channels, Fig. 3 Schematic drawing of Kv-channel binding sites for toxins and drugs. (**a**) Side view of a cut-open Kv-channel. Intracellular open-channel blockers may bind to the inner vestibule of Kv-channels (hatched) formed by segment S6. (**b**) View of a Kv-channel from the top. Pore-blocking toxins bind to receptor sites formed by the Kv-channel pore and the outer vestibule. Gating modifiers have binding sites outside of the pore (striped) and interfere with the voltage-sensing machinery

nano- to picomolar affinities have been identified. Two kinds of block may be discerned in general. The toxin may bind to the outer vestibule of the Kv-channel pore and thereby occlude the pore (Fig. 3a). In this case, the binding of one toxin per channel may suffice to block channel activity. Alternatively, the toxin may interfere with the voltage-sensing machinery and modify Kv-channel gating. The voltage-sensing machinery is located in the periphery of the pore. As each subunit appears to have its own voltage-sensing apparatus, gating-modifying toxins may have four binding sites per Kv-channel (Fig. 3b). Characteristically, gating-modifying toxins induce a positive shift in the current–voltage relationship of Kv-channels and accelerate channel deactivation (closing of the open channel).

Many nonpeptidergic compounds are known to block Kv-channels. Where the mechanism of block is known, it is related to pore occlusion. Most frequently, nonpeptidergic drugs block the pore by interacting with amino acid residues located in the carboxy-terminal part of segment S6 (Fig. 3a). This part is particularly hydrophobic in the pore of HERG-channels (Wang and MacKinnon 2017). Apparently, it distinguishes HERG-channels from other Kv-channels and renders HERG-channels exceptionally sensitive to block by many pharmaceuticals. Since HERG-channels make an important contribution to cardiac action potential repolarization, HERG-channel block may be frequently responsible for cardiac side effects of drugs associated

Voltage-Gated K^+ Channels, Table 2 Kv-channel genes associated with heritable diseases

Gene	Trivial name	Kv-channel type	Disease
KCNA 1	Kv1.1	Shaker-family	EA
KCNA5	Kv1.5	Shaker-family	LQT
KCNB1	Kv2.1	Delayed rectifier	EIEE
KCNH 2	HERG	IKr-channel	SB, LQT
KCNE 1	MinK	Auxiliary subunit	LQT
KCNE 2	MirP1	Auxiliary subunit	LQT
KCNE 4	MirP2	Auxiliary subunit	Myopathy
KCNQ 1	KvLQT1	Delayed rectifier	LQT/JLN
KCNQ 2	–	M-channel	EIEE
KCNQ 3	–	M-channel	EIEE
KCNQ 4	–	M-channel	DFNB2

EA, episodic ataxia; EIEE, early infantile epileptic encephalopathy; LQT, long QT syndrome; SB, sinus bradycardia; JLN, Jervell–Lange Nielsen syndrome; DFNB2, deafness syndrome

with cardiac arrhythmia. Tetraethylammonium, 4-aminopyridine, and quinidine are unspecific drugs blocking Kv-channels by binding to the inner entrance of the pore. TEA may also bind to the outer entrance of Kv-channel pores.

Mutations in Human Kv-Genes Associated with Hereditary Channelopathies

Mutations in human Kv-channel genes have been detected that are associated with hereditary diseases ranging from heart arrhythmia (long QT-syndrome) and deafness to epilepsy and ataxia (see Table 2). Typically, many Kv-channel related channelopathies are correlated with a mutant phenotype that is episodic in nature and appears as a dominant hereditary trait.

Outlook

Solving crystal structures of several Kv channels represents a major breakthrough in our understanding of Kv-channel structure and function, including association of mutant Kv channels with life-threatening cardiac arrhythmias. This knowledge provides a promising basis for development of suitable drugs and personal treatment strategies.

Wnt Signaling

Noyel Ghosh, Sharmistha Chatterjee and Parames C. Sil
Division of Molecular Medicine, Bose Institute, Kolkata, India

Definition

The *Wnt*s are a group of 19 genes essentially coding for glycoproteins which have been highly conserved along the evolutionary lineage from the coelenterates to modern *Homo sapiens*. "Wnt" is a portmanteau of *Drosophila* wingless (*Wg*) and mouse *integrated-1* (*Int-1*) which stands for *wingless-related integration site.* Wnt proteins interact with serpentine Frizzled (Fzd) receptor and a wide array of co-receptors in order to execute expression of target genes regulating cellular polarity, cell motility, proliferation, cell fate determination, differentiation, as well as stem cell activity.

Basic Mechanism

Insight into Posttranslational Modification of Wnts

All of the Wnt proteins share a signal sequence required for successful secretion, and nearly 23 Cys residue-invariant patterns in their primary structure, some of which are crucial for folding into a proper secondary structure through intramolecular

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

disulfide bond formation. With a number of potential N-glycosylation and fatty acylation sites, nearly all Wnts undergo huge posttranslational processing except *Drosophila*-ortholog WntD. Appending palmitoleate (C16:1) or myristoleate (C14:1) on conserved Ser residues is unique to Wnts among other secretory proteins. In addition, another selective modification including glycosylphophatidylinositol (GPI) anchor attachment to Wnt1 and Wnt3A and tyrosine sulfation on Wnt5A and Wnt11, etc. ensures "just right" Wnt signaling to be achieved.

Glycosylation of Wnts

Glycosylation might aid in proper exocytosis and extracellular spread of Wnts; yet, the role of glycosylation in Wnt secretion and function is still elusive (Ghosh et al. 2019). Interestingly, heparan sulfur proteoglycan is implicated in extracellular Wnt transportation, but its role in Wnt secretion is unclear. Wnt1 and Wnt5 are reported to bear, respectively, one and two of N-glycosylations; yet, WntD remains persistently unglycosylated. Though site-directed mutagenesis of Wnt1 and Wnt5 glycosylation sites has impaired their proper secretion to certain extents, it does not affect their activity notably. Similarly, studies showing no major change in secretion and signal transduction activity in mutant *Drosophila* Wnt wingless (*Wg*), devoid of all N-glycosylation, also postulate glycosylation to be dispensable for Wnts secretion and action.

Fatty Acylation of Wnts

Unlike glycosylation, lipidation of Wnts seems to be vital from both structural and biochemical viewpoints (Nile and Hannoush 2016). In 2003, the first report of fatty acylation at the conserved Cys77 of murine Wnt3A was documented through an experiment using radioactive ^{3}H-labelled palmitic acid (C16:0). Discovery of corresponding palmitoylated-Cys residues of Drosophila Wg and Wnt8, soon established palmitoylation to be a conserved feature across all Wnts. Afterwards, a second lipidation of murine Wnt3A was reported at Ser209 by mass spectroscopy. Indeed, the crystal structure of *Xenopus* Wnt8 in association with Cys-rich domain (CRD) of murine Frizzled 8 (Fzd8) receptor revealed the second corresponding palmitoylation at Ser187. However, the importance of Cys-acylation is quite debatable. Reports suggest that mutation of Ser209 to Ala results in retention of Wnt3A in ER; whereas, mutation of Cys77 to Ala renders Wnt3A with little to no activity without harming its secretion. Contrastingly, crystal structures have revealed that Cys77 of Wnt3A (equivalent to Cys55 in *Xenopus* Wnt8) itself engages within a disulfide bond and thus is unlikely to be acylated. In support, a biochemical experiment with non-radioactive alkyne palmitate (Alk-C16) in association with click chemistry has been performed where the presence of palmitoylation only at Ser224 and Ser209 of Wnt1 and Wnt3A, respectively, was noticed with unacylated Cys77.

Other than palmitate, fatty acids with the length of 13- to 16-carbon atoms can be acylated at Ser209 of Wnt3A through ester linkage. In contrast to S-palmitoylation of other secretory proteins which involves a high turnover of palmitate, Wnt3A doesn't undergo cycles of acylation and deacylation intracellularly. Perhaps stable O-linked acylation (ester bond), in place of labile thioester bond, has been selected to provide a greater time window for extracellular activities with endured activity.

Porcupine (PORCN), an ER-resident multi-pass membrane-bound O-acyltransferase (MBOAT)-superfamily protein, acts to lipidate Wnts. PORCN acylates Ser- and Thr-residues but doesn't modify Cys-residues on Wnts. Loss of PORCN activity abrogates Wnt secretion entirely. PORCN competently catalyzes 14- and 16-carbon fatty acylation on conserved Ser residues, whereas catalysis of 13- and 18-carbon fatty acylation was reported to be less preferable. However, PORCN has been reported to be selective for cis-Δ9-unsaturated fatty acyl Co-A over the saturated ones. Recently, it has been discovered that PORCN itself gets acylated at Cys187 in order to get regulated. Human PORCN, deficit in Cys187 palmitoylation, acylates Wnts to a slightly higher degree illustrating negative regulation of Wnt lipidation by PORCN acylation.

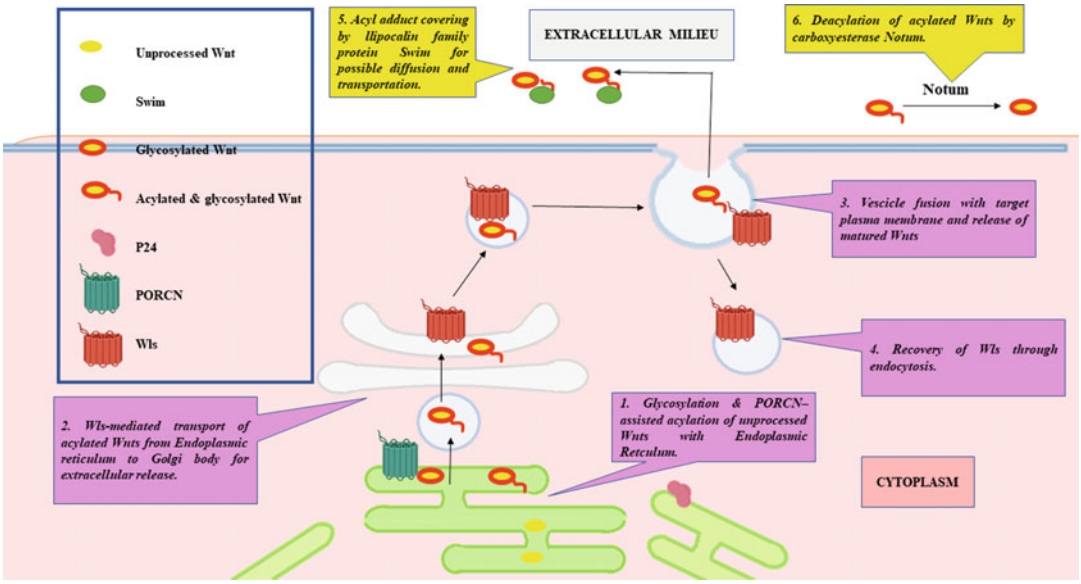
Beyond just facilitating interaction with the cellular membrane and increasing protein

hydrophobicity, fatty acylation of Wnts has other crucial jobs too. Predominantly, it eases the interaction of Wnts with its cognate Fzd receptors as unsaturated fatty acylation on Wnts enhances affinity toward the CRD of Fzd receptors. In addition, acylation might facilitate the occurrence of Wnts in active monomeric forms. Also, lipidation might enhance the interaction of Wnts with chaperones such as Wntless (Wls). Apart from that, Notum, which identifies only cis-unsaturated fatty acid adducts on Wnts, enables Wnts to be deacylated in the extracellular matrix and to be recycled.

Insight into Secretion of Wnt Proteins

Steps involving Wnt secretion seem to be controversial till date (Langton et al. 2016). However, researchers propose that an ER-resident multipass transmembrane protein Wls or evenness interrupted (Evi), to be vital for Wnt secretion in *Drosophila* (see Fig. 1). This protein corresponds to *C. elegans* Mig-14 and mouse GPR177. Other than WntD which remains unacylated, the rest of the Wnts require Wls/Evi for their secretion. However, knocking down Wls expression doesn't affect the secretion of other morphogens such as sonic hedgehog; hence, it is reported to be dedicated toward Wnt proteins only. X-ray crystal structure depicts that Wls/Evi possesses lipid-binding β-barrel in its tertiary structure which interacts with Wnts through their acylated residues. In addition to Wls/Evi, p24 performs as another cargo protein in the early Wnt secretory pathway; however, unlike Wls/Evi it appears to be optional for intracellular transport of Wnts.

Regarding Wls-assisted Wnt secretion, the simplest route is the Wls/Evi-assisted direct transport of Wnts from trans-Golgi network (TGN) to plasma membrane; yet, endosomal trafficking of Wnts in association with Wls has also been suggested. Moreover, it has been also reported that before being secreted, Wnts might undergo endocytosis along with Wls/Evi enabling Wls/Evi recycling and endosomal attachment of



Wnt Signaling, Fig. 1 Schematic representation of post-translational modification and secretion of Wnt proteins. Once translated, Wnt proteins undergo N-liked glycosylation and PORCN-mediated acylation in the endoplasmic reticulum (ER). From ER they move to the Golgi body for further modification through vesicular transport where p24 seems to be functional along with other vesicle-associated transport proteins. From the Golgi body up to the release from secretory cell occurs through vesicular transport where Wls is essential. For ongoing secretion, recycling of Wls is essential. On the other hand, once secreted, insoluble lipoprotein chiefly uses lipophorin/lipocalin family protein Swim as a shield to become soluble and eligible for transport. Otherwise, matured Wnts encounters carboxylesterase Notum in order to be deacylated in extracellular space

lipoprotein molecules for extracellular diffusion after secretion. Much complex pre-secretion transportation might take place in polarized epithelial cells. For example, in Madin-Darby canine kidney cells, different glycosylation appears to probe Wnt3A secretion basally yet Wnt11 secretion apically. Therefore, the route of Wnt secretion seems to be determined depending on the type of the secretory cells and the Wnt protein to be secreted.

An adequate pool of Wls/Evi must be maintained in order to sustain successful Wnt signaling. Thus, AP-2 and clathrin-dependent endocytosis of Wls/Evi is essential followed by retromer-mediated transport of Wls/Evi back to TGN. Lack of retromer complex results in termination of Wnt signal transduction cascade due to lysosomal degradation of Wls/Evi. Wls/Evi turnover does not depend upon classical SNX-BAR retromer-forming nexins such SNX1-2 and SNX5-6, rather SNX3-retromer complex, which retrieves Wls/Evi from early endosome through vesicular budding, seems to be the key role player. Very recently, it has been shown that Wls/Evi also backtracks from Golgi to ER through ARF-mediated COPI-coated vesicles. An ER signal at the C-terminal end of the Wls and an ER-Golgi intermediate cargo protein ERGIC2 assist in this retrograde transport.

Insight into Transportation of Secreted Extracellular Wnts

Once emitted, Wnts mostly function as a morphogen, producing a gradient and acting upon the receptor cells. Since entirely processed Wnts are unlikely to be soluble, it is essential to mask Wnts' fatty acyl adducts in order to diffuse and translocate from secretory cells to the receiving ones. Herein, a handful of subcellular structures are involved to keep Wnts soluble extracellularly (Hausmann et al. 2007). Wnts have been proposed to be shielded by lipoprotein particles (structures composed of outer phospholipid monolayer surrounding the central hydrophobic core of triglyceride and other lipids). Lipoproteins are known to stabilize through apolipoprotein insertion. In *Drosophila* imaginal disc, apolipoprotein lipophorin has been reported to engage with Wg, and knockdown of lipophorin with siRNA treatment has been shown to cut the long-range diffusion of Wg. In *Drosophila* lipophorin expression occurs in fat bodies rather than imaginal disc, which postulates the loading of Wg within lipoproteins either extracellularly or endosomally before the secretion of Wg. Besides, mammalian Wnt3A has been also reported to be incorporated in lipoprotein particles in vitro.

Other than lipoprotein particles, exosomes are known to contribute to Wnt solubility. Plasma membrane-derived micro-vesicular bodies fuse together outside the cell to form exosomes where Wnts' palmitoylated adducts are reported to be inserted within the lipid bilayer. In vitro supernatant describes the presence of Wg as well as Wnt3A-incorporated exosomes to be active. Moreover, researches have produced evidence that both Wg and Wls bear exosomes at *Drosophila* neuromuscular junction. Additionally, inhibiting expression of exosome-associated protein such RAb11, SNARE recognition protein Ykt6, has been reported to decrease Wg gradient formation, which explains the importance of exosome-mediated transportation of Wnt proteins.

Also, swim, a protein of lipocalin family, has shown to increase Wnts' solubility directly by interacting with them. Swim-knock down can deteriorate Wg long-range impact but remains passive to regulate Wg short-range gradient. Similarly, a serum glycoprotein afamin recently has been noted to keep Wnts soluble and active which dictates its great practical implications. Apart from short-range transportation, the existence of Wnt signaling has been also reported on axin-based extension of cells known as cytonemes. In zebrafish during neural plate formation, Wnt8 was shown to elicit signals at distantly located cells via cytonemes. Therefore, depending on cell types and their behavior, both close and long-range diffusion of Wnts are evident.

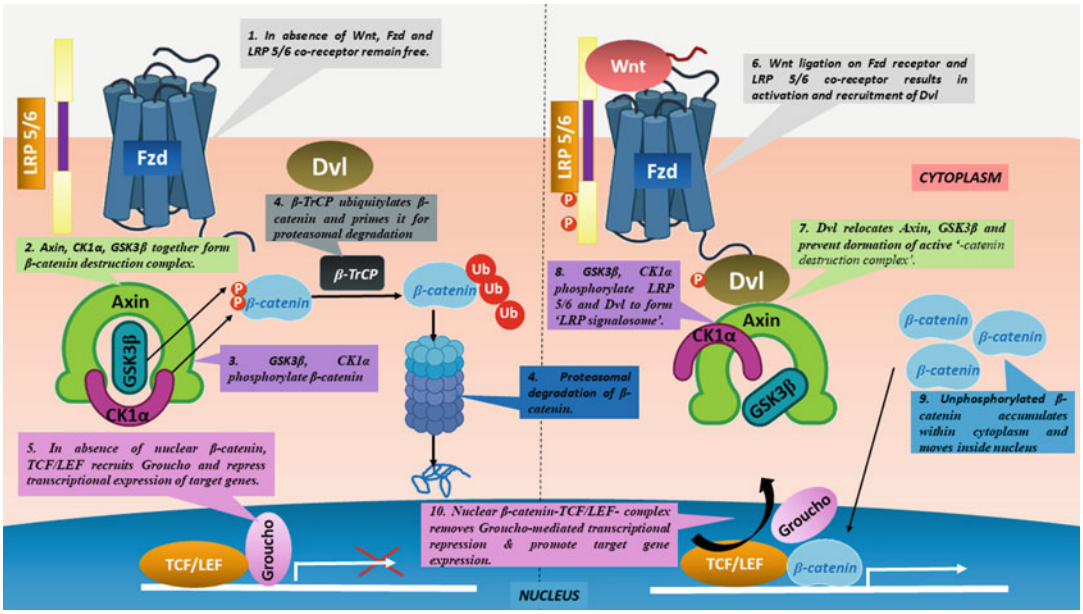
Insight into Wnt Signaling

Secreted Wnts also interact with a number of transmembrane receptors which subsequently drive the signaling towards a specific fate in a particular cellular context. Among many, Fzd is the widespread high-affinity Wnt receptor that, in

association with other co-receptors, channelizes downstream signaling into distinct branches. Co-receptors which take part in Wnt signaling include low-density lipoprotein receptor-related protein 5/6 (LRP5/6), ROR, RYK, PTK7, MUSK, etc. Depending on the type of receptor-co-receptor interaction and downstream participation of transcriptional co-activator β-catenin, broadly Wnt signaling cascade can be categorized into two types, β-catenin-dependent canonical pathway, and β-catenin-independent noncanonical pathway.

Canonical Wnt Signaling

Fzd is a group of serpentine receptors having 10 homologs in humans, all of which carry N-terminal extracellular Cys-rich domain (CRD) for ligand interaction. A three-dimensional structure of *Xenopus* Fzd8 together with mouse Wnt8 has confirmed that the palmitoylated N-terminal domain, termed as, of Wnt8 projects into a groove of Fzd8. Also, the C-terminal index finger domain of Wnt8 has shown to engage certain variable amino acids within Fzd8 CRD which possibly provides Wnt-Fzd interaction specificity. Canonical pathway is triggered when ligands such as Wnt1, Wnt3A, Wnt8, etc. (Fig. 2) (Niehrs 2012) form a ternary complex with Fzd and co-receptor LRP5/6. In absence of ligand binding, downstream "β-catenin destruction complex" (a constitute of scaffold protein Axin, adenomatous polyposis coli or APC, glycogen synthase kinase 3β or GSK-3β, and casein kinase1α or CK1α) remains active. N-terminal phosphorylation by CK1α at Ser45 followed by GSK3β-mediated phosphorylation at Ser33, Ser37, and Thr41 render β-catenin targeted by beta-transducin-repeat–containing protein (β-TrCP), a substrate recognition subunit of multimeric Skp1-Cullin-F-box (SCF) RING-type E3 ubiquitin ligase (Gao et al. 2014). Subsequently, $SCF^{\beta\text{-}TrCP}$ targets β-catenin for proteasomal degradation by adding poly-ubiquitin chain on its Lys19 and Lys49. Thus, lowered cytosolic β-catenin concentration



Wnt Signaling, Fig. 2 Schematic representation of canonical Wnt signaling pathway. Absence of Wnt ligands keeps receptor Fzd and co-receptor LRP 5/6 inactive. Cytosolic Axin, GSK3β, and CK1α together form "β-catenin destruction complex" which phosphorylates cytosolic β-catenin and aid its β-TrCp-driven ubiquitination and proteasomal degradation. But, Wnt ligation on Fzd-LRP activates Dvl which relocates Axin from "β-catenin destruction complex" and LRP-signalosome formation. Unphosphorylated β-catenins gather and enter the nucleus where they interact with TCF/LEF to wave Groucho-mediated target gene repression

prevents their nuclear gathering and, thus, represses target gene expression through repressive T-cell factor/lymphoid enhancer factor (TCF/LEF) complex and further Groucho-mediated histone deacetylase recruitment, whereas the presence of Wnt recruits disheveled (Dvl) to Fzd intracellular domain which in turn relocates Axin and GSK3β to the plasma membrane (PM). At this point Dvl itself oligomerizes inducing Wnt-Fzd complex to be internalized via endocytosis. Dvl induces type-I phosphatidylinositol-4-phosphate-5-kinase catalyzed production of phosphatidylinositol 4,5-bisphosphate (PIP_2). PIP_2 seems to be crucial for sequential phosphorylation of LRP6 intracellular domain at Ser1490, Thr1493, and Thr1479 by GSK3β, CK1α, and CK1γ, respectively. Phosphorylated PPPSP motif on LRP6 acts as the docking site for more Axin which ends up forming LRP signalosome at PM involving Fzd, LRP5/6, Axin, GSK3β, and CK1α. As a result, piled up cytosolic unphosphorylated β-catenins translocate in the nucleus where they interact with TCF/LEF in order to promote Groucho displacement and recruitment of transcription activators such as p300-CREB binding protein, BCL-9, Brahma related gene1, and Pygo, letting the downstream targeted gene expression.

Noncanonical Wnt Pathway

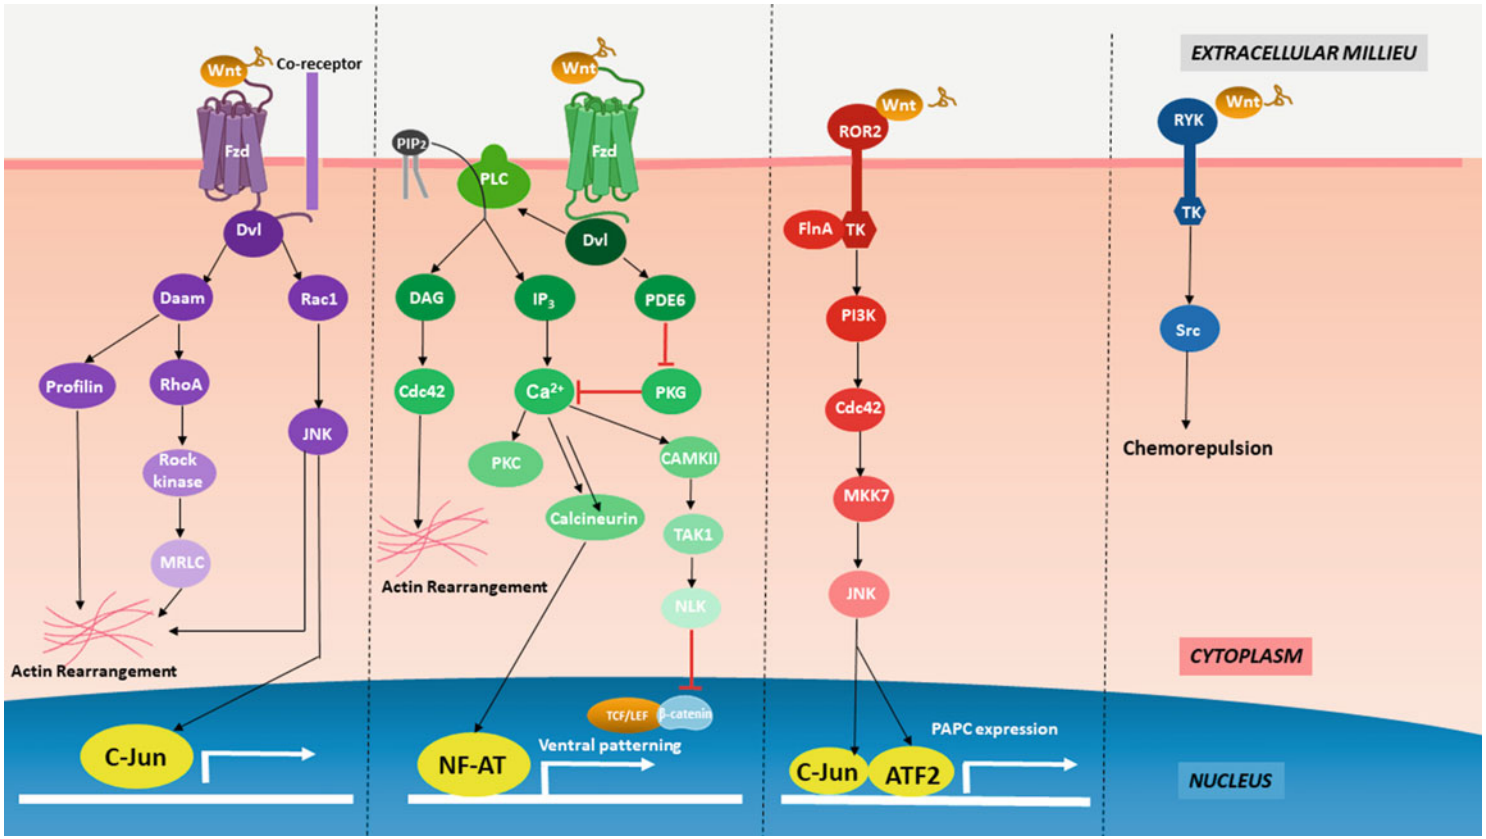
The noncanonical pathway is triggered by ligands like Wnt5A, Wnt11, etc. Among a vast array of noncanonical pathways, two categories are best understood, namely, planar cell polarity (PCP) pathway and Wnt/Ca^{2+} pathway (Niehrs 2012).

PCP signaling actuates when Wnt ligand bind with Fzd receptor along with cognate co-receptors other than LRPs. Binding initiates Dvl1 recruitment at Fzd and further stabilization by PCP factor Diego. Dvl1 in turn activates small G-protein RhoA and Rac1, parallelly activating two different pathways. In this scenario, regulation of such small GTPases occurs through the communication of Dvl with partitioning defective 6 (PAR6), Dvl-associating protein with a high frequency of Leu residues (DAPLE), DVL-associated activator of morphogenesis 1 (DAAM1), etc. RhoA in turn activates Rho kinase leading to the actin rearrangement, whereas Rac1 promotes transcriptional activation of c-Jun N-terminal kinase (JNK) in order to activate target transcription factors such as activating transcription factor 2 (ARF2) inducing target gene expression. PCP signaling is essential during embryogenic morphogenesis such as cellular movement in gastrulation, neural tube closure, and movement of stereocilia in the inner ear.

In Wnt/Ca^{2+} pathway, Wnt triggers Fzd-assisted activation of heterotrimeric G-protein which concomitantly induces phospholipase C (PLC)-mediated formation of diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP_3) (De 2011). Later IP_3-exterted Ca^{2+} influx results in activation of Ca^{2+} and calmodulin-dependent kinase II (CAMKII), calcineurin, phosphatase CNC, and protein kinase C (PKC). Wnt-Fzd also upregulates cGMP-specific phosphodiesterase PDE6, thus depleting cellular cGMP and inactivating protein kinase G (PKG), thereby leading to an increase in the cellular concentration of Ca^{2+}. Activated PKC further upregulates nuclear factors associated with T-cell (NFAT) promoting ventral patterning in *Xenopus*. In *Xenopus* Wnt5A-Ca^{2+}-CaMKII signaling can uplift TAK1-NLK kinases, which counteracts canonical Wnt signaling.

Depending on various receptor-co-receptor combinations, other than the aforementioned two principal pathways, there are also different modes of noncanonical Wnt signaling pathways. Some of them are discussed next (Fig. 3).

ROR1 and ROR2 are single-pass integral membrane receptor with intracellular tyrosine kinase domain and extracellular N-terminal CRD. Wnt5A binding with Fzd and ROR2 co-receptor induces ROR2 homodimerization and formation of subsequent ternary complex. Activated receptor recruits Dvl, Axin, and GSK3 which in turn incorporate actin-binding protein filamin A to activate JNK leading to fibroblast cytoskeletal rearrangement, polarization, and filopodia extension. Molecular and phenotypical resemblance of Wnt-ROR signaling with PCP signaling does not implicate their obvious overlapping. ROR1-ROR2 mutant cells were capable of JNK signaling, while mice carrying such mutation phenotypically differ from the mice mutant



Wnt Signaling, Fig. 3 Schematic representation of important noncanonical Wnt signaling pathways. Wnt5 and Wnt11 initiate noncanonical Wnt signaling pathway when they ligate with cognate Fzd receptors along with co-receptors other than LRPs. Ligand-receptor interaction activates downstream Dvl which through a number of pathways activates transcriptional co-activators ultimately expressing proteins involved in cytoskeletal rearrangement to encourage cell polarity, cell motility, morphogenesis, etc.

for Vang like-2 (a PCP pathway component). During *Xenopus* gastrulation, ROR2-Wnt5A complex activates PI3K-Cdc42-MKK7-JNK pathway leading to ATF2 and c-Jun induction and paraxial protocadherin (PAPC) expression (Semenov et al. 2007).

RYK (*Drosophila* homolog derailed) is another single-pass transmembrane co-receptor that is implicated in all three major areas of Wnt signaling through neural fate determination and providing axonal guidance in the central nervous system. RYK possesses an inactive kinase domain and is kinase-dead. Like others it also acts by Dvl recruitment probably through hiring additional Src kinase. γ-Secretase is known to cleave the intracellular domain of RYK which allows cleaved RYK to translocate in the nucleus leading to the transcriptional modification of target genes. E3 ubiquitin ligase Mind bomb1 targets RYK for proteasomal degradation which, in turn, is known to accelerate B-catenin stabilization.

Besides, PTK7 (known as off-track in *Drosophila*) is another class of single-pass transmembrane co-receptor that has been implicated only in PCP signaling through Dvl interaction. Its incomplete intracellular kinase domain seems to be kinase-dead. However, like other PCP activators, it appears to be a negative regulator of β-catenin stabilization.

Another co-receptor that acts through PCP signaling pathway is MUSK. Binding of Wnt11 to the extracellular CRD of MUSK specially at neuromuscular junction where it restricts postsynaptic acetylcholine receptors to the center of long muscle cells. Additionally, in human myocytes Wnt4, Wnt11, and Wnt9A ligation at Fzd-LRP4 lead to MUSK dimerization and concomitant phosphorylation leading to clustering of acetylcholine receptor.

Extracellular Wnt Regulation

Wnt Antagonists

Once secreted Wnt encounters with a wide variety of regulatory molecules that involves secreted as well as secreted soluble antagonists and agonists. Among them Wnt interacts with secreted extracellular inhibitors such as Wnt-inhibitory factor-1 (Wif-1), Dickkopf (Dkk), secreted Fzd-related proteins (sFRPs), bone-related SOST/scleostin, etc. Moreover, Wnt interacts with membrane-bound antagonists such as glypicans, APC down-regulated-1 (APCDD-1), Tiki1/Tiki2, etc. Dkk is a group of secreted glycoproteins with 255–350 amino acid residues. Functioning as a decoy receptor, Dkk recruits a single-pass transmembrane protein Kremen that after binding results in endocytosis of LRP5/6, diminishing canonical Wnt signaling.

Unlike Dkk, Wif-1 directly impedes Wnt signaling by sequestering Wnt ligands. Wif-1 contains one WIF domain and five epidermal growth factor (EGF)-like domains. Structural study of Wif-1 reveals 1,2-dipalmitoylphosphatidyl choline to be integral component of WIF domain. Exchange of Wif-1-linked diacyl lipid with Wnt-bound palmitoyl moiety seems to seize Wnt signaling predominantly. Besides, heparan sulfate (HS)-binding domain of EGF-like domain I-IV proposes the role of HS in co-localizing Wif-1 and Wnts together.

On other hand, sFRPs are known to harbor N-terminal CRD similar to Fzd receptors. Thus, it can be easily suggested that sFPRs dampen Wnt signal by competing with Fzd receptors for Wnt ligation.

Additionally, transmembrane Tiki1/Tiki2 acts catalytically to dampen Wnt signaling. Quantitative mass spectroscopy and protein sequencing have revealed Tiki2 functions as a protease and promote the removal of the last eight amino acid residues from the N-terminal end of the post-translationally processed mature Wnt3A and prevent their further ligation at Fzd receptor (Langton et al. 2016).

Wnt-YAP/TAZ Interplay

Two transcriptional regulators of Hippo pathway, namely, yes-associated protein/taffazin (YAP/TAZ), are reported to regulate Wnt-β-catenin pathway at the level of β-catenin destruction complex. In absence of Wnts, cytosolic YAP/TAZ forms a part of β-catenin destruction complex and thus in association with Axin1 appoint β-TrCP and sequester β-catenin for proteosomal degradation. However, Wnt ligation promotes

their displacement from Axin and further β-catenin stabilization in order to promote increased canonical Wnt signaling.

Modulation by R-spondin (RSPO)

RSPO is a group of secreted proteins all of which share common structural similarities and harbor two furin domains essential for β-catenin-mediated signaling, whereas their thrombospondin type-I domains engage in PCP signaling. High-affinity receptor syndecan binds RSPO2 and RSPO3 thrombospondin domain and enhances PCP signaling. The binding of RSPOs stimulates clathrin-assisted RSPO-receptor endocytosis by possible flocking of Wnt-receptor and Dvl.

Another class of furin-interacting RSPO receptors which drive β-catenin stabilization is known as leucine-rich repeat-containing G protein–4/5/6 (LGR 4/5/6) (Fig. 4). They are explicit markers of stem-cell renewal in intestinal epithelia. In both cases, RSPO seems to uplift Wnt signaling by downregulating membrane-bound E3 ubiquitin ligase Znrf3/Rnf43. In absence of RSPO, Znrf3/Rnf43 ubiquitylates Fzd receptors and targets a portion of it to be degraded. In presence of RSPOs, the RSPO-LGR complex assembles in a complex with Znrf3/Rnf43, causing their internalization and greater clustering of Fzd receptors on the plasma membrane to upregulate the entire Wnt Signaling (Ghosh et al. 2019).

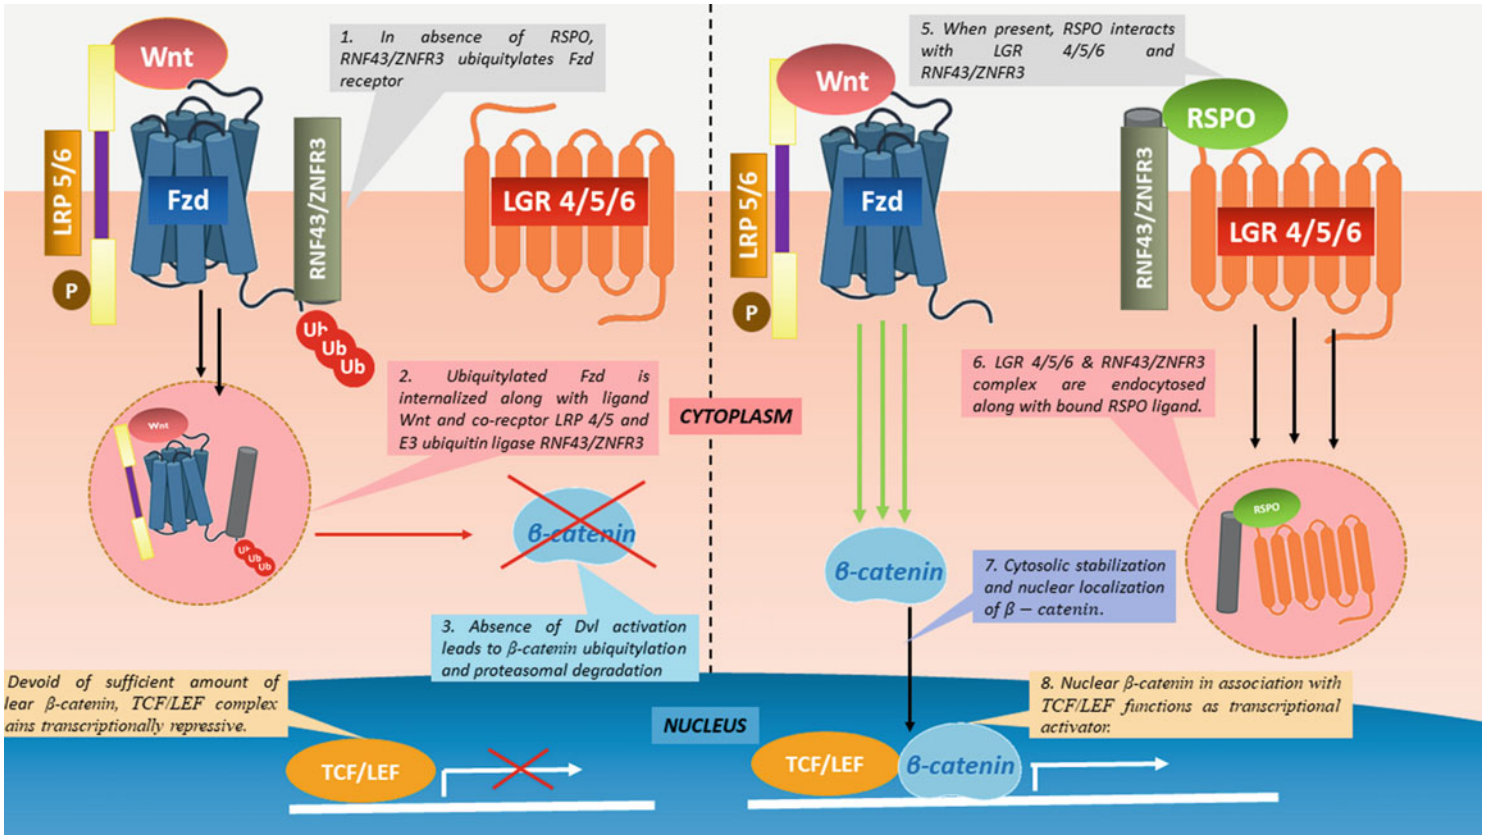
Decarboxylation of Acylated Wnts by Notum

Once secreted, acylated Wnts also act as the substrate for Notum, imposing another level of regulation on Wnt signaling (Nile and Hannoush 2016). Molecular labeling experiments and mass spectroscopic data have revealed that Notum instead functions as the carboxylesterase by hydrolyzing carboxyester linkage connecting the palmitoleate residue at Ser209 on Wnt3A. Besides, Notum forms an oxidized cluster of Wnts inhibiting the over signaling pathway. Surface plasmon resonance study of human Notum (hNotum) has been noted to interact with the glycose-aminoglycan of GPC3, and in addition, loss of dally and dlp from the outer surface of *Drosophila* imaginal disc has shown to reduce Wnt signals too; both of these findings state that glypicans tether Notum to the cell surface through their sulfated glycan moieties and seems to stimulate Wnt deacylation. Instead of modulating Wnt secretion, deacylation of Wnts has been suggested to downregulate Wnt signaling enzymatically, whereas interrupting Wnt3A-Fzd8 interaction via sequestering fatty acyl adducts seems to inhibit Wnt signaling non-catalytically. Such findings prove the activity of Notum to be entirely extracellular. Crystal structure study of both *Drosophila* and human Notum defines the presence of a conserved α/β-hydrolase fold where the catalytic triad incorporates Ser 232, Asp340, and His389. X-ray crystallographic data of enzymatically dead hNotum, complexed with palmitoleated and myristoleated human Wnt7A, illustrates that both of the substrates acquire the active site of the enzyme by entering the hydrophobic pocket of Notum through a comparatively flexible opening. At the active site, the carbonyl carbon of the fatty acyl moiety has been depicted to be placed at about 3.3 A^0 distance from the catalytic Ser232 ensuring enough place to accommodate hydroxyl nucleophilic attack. During catalysis, the interaction of palmitoleate- or myristoleate-peptide derived from acylated Wnts, with Ile291, Phe319, and P320 at the base of enzyme's hydrophobic pocket further stabilizes substrates for successful catalysis. The binding pocket of hNotum was shown to accommodate saturated fatty acid up to the length of C8-C10, beyond which the hydrocarbon tail of the fatty acid must be kinked in order to avoid steric hindrances. Therefore, Notum has been considered to show selectivity towards cis-unsaturated fatty acid explaining why Notum prefers diacylation of Wnts' palmitoleate and myristoleate residues over palmitate and myristate residues, respectively.

Drugs

Owing to the diversity of Wnt signaling, several components of Wnt signaling can be targeted for therapeutic intervention (see Table 1) (Nusse and Clevers 2017).

Wnt antagonist SOST can be targeted in several bone disorders; indeed, anti-SOST



Wnt Signaling, Fig. 4 Schematic representation of Wnt signaling pathway in presence of RSPO ligands. In absence of RSPO ligands, E3 ubiquitin ligase single-pass RNF43/ZNFR3 ubiquitylates Fzd receptor both in absence and presence of Wnt ligation. Resultant ubiquitylated Fzd receptors are targeted for cellular internalization which renders cytosolic "β-catenin destruction complex" active and β-catenin targeted for proteasomal degradation. However, RSPO ligation to receptor LGR tethers RNF43/ZNFR3 in order to promote endocytosis of RSPO-LGR-RNF43/ZNFR3 complex which deactivates "β-catenin destruction complex" and encourages β-catenin nuclear gathering for subsequent target gene transcription

Wnt Signaling, Table 1 Drugs modulating Wnt signaling pathway

Name of the drug	Phase of clinical or subclinical trial and trial number	Disease associated	Target molecule	Effect on overall Wnt signaling	Mode of action
ETC-159	Trial phase I (NCT02521844)	Solid tumor treatment	PORCN	Inhibitory	Prevents PORCN-mediated acylation of Wnt proteins
IWP-2	Preclinical –	Metastatic colorectal cancer, Notch-mutant head and neck carcinoma treatment			
LGK974	Trial phase I/II (NCT02278133 NCT02649530)	–			
CGX1321	Clinical trial phase I (NCT026759462)	Metastatic solid tumor treatment	Wnts	Inhibitory	Prevents Wnt functionality
Foxy-5	Clinical trial phase I (NCT02020291 NCT02655952)	Metastatic breast cancer, prostate cancer having lowered Wnt5A expression, and colorectal cancer			Mimics activity of Wnt5A
Ipafricept	Clinical trial phase I (NCT02069145 NCT02092363 NCT02050178)	Metastatic hepatocellular carcinoma, ovarian cancer, and stage IV pancreatic ductal adenocarcinoma			Acts as decoy receptor of Wnts through competition with Fzd receptors
OSTA101	Clinical trial phase I (NCT01469975)	Synovial sarcoma	Fzd10	Inhibitor	Yttrium90 labeled anti-Fzd10 monoclonal antibody
Vantictumab	Clinical trial phase I (NCT01973309 NCT02005315 NCT01957007)	Metastatic breast cancer, pancreatic ductal adenocarcinoma, and non-small cell lung cancer	Fzds		Humanized antibody against Fzd1, Fzd2, Fzd5, Fzd7 and Fzd8
SB-216763	–	–	GSK3 inhibitor	Activator	–
G007-LK, G244-LM	Preclinical trial phase	Colorectal cancer	Tankyrase inhibitor	Inhibitor	Prevents GSK degradation and stabilizes β-catenin
L807mts	Preclinical trial phase	Alzheimer's Disease	GSK3 inhibitor	Activator	Inhibits GSK3 by changing its catalytic site conformation
LY2090314	Preclinical trial phase	Melanoma	GSK3 inhibitor	Activator	Inhibits GSK3-mediated phosphorylation and stabilizes β-catenin
OMP121R10	Clinical trial phase I (NCT02482441)	RSPO3 positive metastatic colorectal carcinoma	RSPOs	Inhibitory	Monoclonal anti-RSPO3 antibody
Cirmtuzumab	Clinical trial phase I (NCT02222688)	Chronic lymphoid leukemia	ROR1	Inhibitory	Humanized monoclonal anti-ROR1 antibody

(continued)

Wnt Signaling, Table 1 (continued)

Name of the drug	Phase of clinical or subclinical trial and trial number	Disease associated	Target molecule	Effect on overall Wnt signaling	Mode of action
DKN01	Clinical trial phase I (NCT01457417 NCT02013154 NCT02375880)	Relapsed lung cancer, esophageal cancer, advanced biliary cancer with gemcitabine and cisplatin combination therapy	Dkk	Inhibitory	Humanized monoclonal anti-Dkk1 antibody
BHQ880	Clinical trial phase I (NCT00741377)	Multiple melanomas with zoledrinic acid combination therapy			Humanized anti-Dkk1 Ig-G1 monoclonal antibody
PRI-724	Clinical trial phase Ia (NCT01302405 NCT01764477 NCT01606579) Clinical trial phase II (NCT02413853)	Locally advanced solid tumor, pancreatic cancer with gemcitabine combination therapy, and advanced myeloid malignancy. Combinatorial therapy with bevacizumab in myeloid malignancy	CBP and β-catenin	Inhibitory	Blocks β-catenin and CBP
CWP232291	Clinical trial phase Ia/Ib (NCT0398462)	Acute myeloid leukemia, myelodysplastic syndrome	APC and TCF1	Inhibitory	Targets Sam68 through APC interaction and alternative splicing of TCF1
IWR1	Preclinical trial phase	–	Tankyrases	Inhibitory	Prevents tankyrase1 and 2 mediated PARsylation
XAV939	Preclinical trial phase	–	Tankyrase	Inhibitory	Tankyrase inhibitor
JW55	Preclinical trial phase	–	Tankyrase	Inhibitory	Same as above
NVP-PNKS656	Preclinical trial phase	–	Tankyrase	Inhibitory	Same as above
PKF115-584	Preclinical trial phase	–	β-catenin/LEF complex	Inhibitory	β-catenin/LEF inhibitor
NSC668036	Preclinical trial phase	–	Dvl	Inhibitory	Inhibits interaction of Dvl with Fzd receptor by blocking Dvl-PDZ domain
NCB-0846	Preclinical trial phase	–	Tankyrase	Inhibitory	Tankyrase inhibitor
ICG001	Preclinical trial phase	–	CBP	Inhibitory	CBP inhibitor
PKF118-310	Preclinical trial phase	–	β-catenin/TCF1 complex	Inhibitory	β-catenin/TCF1 inhibitor

monoclonal antibody romosozumab has yielded encouraging results in clinical trials. Being the central scaffold protein, Axin can be targeted widely. Tankyrases, a group of poly-ADP-ribopolymerase, ubiquitylases Axin; thus, small-molecule tankyrase inhibitors such as IWR, XAV939 etc., can be used in several types of cancer with upregulated β-catenin expression.

Another way of Wnt inhibition can be achieved by inhibiting PORCN. IWP, LGK974 etc., functions as PORCN inhibitors and thereby block Wnt acylation and subsequent secretion. Diseases with uplifted Wnt signaling can be treated by targeting Fzd receptors. Hence, monoclonal antibody OMP-18R5 has been shown to inhibit tumor formations in several xenograft studies.

Recently, soluble Wnt protein agonists have been shown to activate Wnt signaling in vivo. In addition, a number of small-molecule compounds such as Bio, L807mts, CHIR, etc. dampen GSK3 activity and thus result in target gene expression. Such drugs can be useful in treating several neurogenerative disorders involving Alzheimer's disease.

The effect of GSK3 inhibitors can be mediated by targeting the expression of gene REST which acts as the repressor of neuronal gene expression during embryonic development and seems to be protective in Alzheimer's disease.

Conclusively, we are closing in now to a point of Wnt signaling where the importance of this signaling pathway for understanding several pathological conditions is coming into focus. The efforts for finding all the interferences with Wnt signaling are yet to bloom, but there are promising ways out which hopefully will replicate soon into reality.
