Preface to the Third Edition

More than a decade has passed since the second edition of the *Encyclopedia of Molecular Pharmacology* was published. During this time, our knowledge in molecular pharmacology has increased and the way scientific information is presented and made accessible has changed. The third edition therefore puts an emphasis on essays, covering important aspects of molecular pharmacology and written by leading experts. We have removed short definitions from the encyclopedia, as they are now available from numerous internet resources. Similarly, the appendix, which listed drugs and drug targets, has been omitted. For systematic up-to-date information on established or potential drug targets such as receptors, channels, transporters, and enzymes, we now refer to the well-curated web-based databases provided by national and international pharmacological societies such as the Guide to Pharmacology (www.guidetopharmacology.org) or the biannually published *Concise Guide to Pharmacology* of the *British Journal of Pharmacology.*

It has again been a pleasure and a great learning experience to interact with the 400 authors of the encyclopedia, who have done a great job to briefly describe important topics of molecular pharmacology for a broad readership. We thank the new and old authors for their excellent work and many helpful and constructive suggestions, which went into the third edition. On the side of Springer Nature, we would like to thank Susanne Dathe and Andrew Spencer, for initiating and guiding the project, as well as Kate Emery, who tirelessly managed the project for the last two years. Finally, our special thanks go to Svea Hümmer, who provided excellent and invaluable assistance during all stages of this project.

Preface to the Second Edition

The first edition of the *Encyclopedic Reference of Molecular Pharmacology* was well received by its readers, thanks to the excellent work done by the authors, of whom most have contributed to the second edition as well. The basic structure of the Encyclopedia has remained unchanged. It is primarily based on essays, which have been updated, and their number has been increased to 225 to include many new exciting areas. These essays cover important drugs and drug targets, but also general principles of pharmacology as well as cellular processes and pathological situations which are relevant for drug action. In addition, there are about xy key words linked to the essays. The Encyclopedia is complemented by an Appendix, which has been greatly enlarged, listing more than 700 drugs and more than 4,000 proteins that act as receptors, membrane transport proteins, transcription factors, enzymes or adhesion molecules.

During the preparation, we greatly enjoyed the interaction with all our colleagues who contributed to this reference work. It has been a pleasure and an enriching experience to deal with so many facets of pharmacology. We are very thankful to the contributing authors for the careful updating of their essays, and, in particular, we would like to express our gratitude to the more than xy new authors who have written excellent essays on novel topics. Finally, we would like to thank Dr. Michaela Bilic and Simone Giesler from Springer for their enthusiasm throughout the project and their constant support.

Preface to the First Edition

The era of pharmacology, the science concerned with the understanding of drug action, began only about 150 years ago when Rudolf Buchheim established the first pharmacological laboratory in Dorpat (now, Tartu, Estonia). Since then, pharmacology has always been a lively discipline with "open borders", reaching out not only to other life sciences such as physiology, biochemistry, cell biology and clinical medicine, but also to chemistry and physics. In a rather successful initial phase, pharmacologists devoted their time to describing drug actions either at the single organ level or on an entire organism. Over the last few decades, however, research has focused on the molecular mechanisms by which drugs exert their effects. Here, cultured cells or even cell-free systems have served as models. As a consequence, our knowledge of the molecular basis of drug actions has increased enormously. The aim of *Encyclopedic Reference of Molecular Pharmacology* is to cover this rapidly developing field.

The reductionist approach described above has made it increasingly important to relate the molecular processes underlying drug actions to the drug effect on the level of an organ or whole organism. Only this integrated view will allow the full understanding and prediction of drug actions, and enable a rational approach to drug development. On the molecular or even atomic level, new disciplines such as bioinformatics and structural biology have evolved. They have gained major importance within the field but are particularly relevant for the rational development and design of new drugs. Finally, the availability of the complete genome sequence of an increasing number of species provides a basis for systematic, genome-wide pharmacological research aimed at the identification of new drug targets and individualised drug treatment (pharmacogenomics and pharmacogenetics). All these aspects are considered in this encyclopedia.

The main goal of the *Encyclopedia* is to provide up-to-date information on the molecular mechanisms of drug action. Leading experts in the field have provided 159 essays, which form the core structure of this publication.

Most of the essays describe groups of drugs and drug targets, with the emphasis not only on already exploited drug targets, but also on potential drug targets as well. Several essays deal with the more general principles of pharmacology, such as drug tolerance, drug addiction or drug metabolism. Others portray important cellular processes or pathological situations and describe how they can be influenced by drugs. The essays are complemented by more than 1600 keywords, for which links are provided. By looking up the

keywords or titles of essays highlighted in each essay, the reader can obtain further information on the subject. The alphabetical order of entries makes the Encyclopedia very easy to use and helps the reader to search successfully. In addition, the names of authors are listed alphabetically, together with the title of their essay, to allow a search by author name.

Apart from very few exceptions, the entries in the main text do not contain drug names in their titles. Instead, drugs that are commonly used all over the world are listed in the Appendix. Also included in the Appendix are four extensive sections that contain tables listing proteins such as receptors, transporters or ion channels, which are of particular interest as drug targets or modulators of drug action.

The *Encyclopedia* provides valuable information for readers with different expectations and backgrounds (from scientists, students and lecturers to informed lay-people) and fills the gap between pharmacology textbooks and specialized reviews.

All the contributing authors as well as the editors have taken great care to provide up-to-date information. However, inconsistencies or errors may remain, for which we assume full responsibility. We welcome comments, suggestions or corrections and look forward to a stimulating dialog with the readers of the *Encyclopedic Reference of Molecular Pharmacology* whether their comments concern the content of an individual entry or the entire concept.

We are indebted to our colleagues for their excellent contributions. It has been a great experience, both personally and scientifically, to interact with and learn from the 200 plus contributing authors. We would also like to thank Ms. Hana Deuchert and Ms. Katharina Schmalfeld for their excellent and invaluable secretarial assistance during all the stages of this project. Within Springer-Verlag, we are grateful to Dr. Thomas Mager for suggesting the project and to Frank Krabbes for his technical expertise. Finally, we would like to express our gratitude to Dr. Claudia Lange for successfully managing the project and for her encouraging support. It has been a pleasure to work with her.

Walter Rosenthal

List of Topics

Khurram Aamir	Unfolded Protein Response
Engi Abd el-Hady Algharably	Antihypertensive Drugs Blood Pressure Control
Amy N. Abell	MAP Kinase Cascades
K. Ravi Acharya	ACE Inhibitors
Ian M. Adcock	Glucocorticoids
Luis G. Aguayo	Glycine Receptors
Eike Ahlers	Psychostimulants
Sahana Aiyer	Protease-Activated Receptors (PARs)
Klaus Aktories	Bacterial Toxins Small GTPases
Paul L. R. Andrews	Emesis
Ion-George Anghelescu	Antidepressant Drugs Psychostimulants
Lucio Annunziato	Na^+/Ca^{2+} Exchangers
Stefano Aringhieri	Atypical Antipsychotics
Hildur Arnardottir	Pro-resolving Mediators
Aditya Arya	Unfolded Protein Response
Kamyar Asadipooya	Advanced Glycation End-Proteins
Joanna N. Assadourian	Aptamers
Qadeer Aziz	ATP-Dependent K^+ Channels
Magnus Bäck	Pro-resolving Mediators
Michael Bader	Renin–Angiotensin–Aldosterone System
Clifford J. Bailey	Glucose-Lowering Drugs Other than Insulin
Annabelle Ballesta	Circadian Rhythms
Philip J. Barter	Lipid-Lowering Drugs
Daniel E. Bassi	Proprotein Convertases
Holger Bastians	Cell Cycle Regulation
Michael Bauer	Sepsis
Antoni Bayes-Genis	Neprilysin Inhibitors
Andreas Beck	Non-selective Cation Channels
Sandra Beer-Hammer	Phospholipid Kinases
Jürgen Behrens	Cadherins/Catenins
Eric Beitz	Aquaporins
Nishanth Belugali Nataraj	Growth Factors

(continued)

Fabrizio Benedetti	Placebo Effect
Caroline Benn	Physiology and Treatment of Hyperuricemia and Gout
Richard L. Bennett	Epigenetics
Lokesh Kumar Bhatt	Atherosclerosis
M. Biel	HCN Channels
Andree Blaukat	Tyrosine Kinases
Matthias Blüher	Adipokines
Hans H. Bock	Low-Density Lipoprotein Receptor Gene Family
Mario Boehm	Pulmonary Arterial Hypertension
William Bourguet	Retinoids
Derek P. Brazil	Bone Morphogenetic Proteins
Annamaria Brioli	Cancer Immunotherapy Immune Checkpoint Blockade
Andrew J. Brown	Oxysterols
Hayley Burm	Ghrelin, Physiological Roles and Clinical Relevance of
Geoffrey Burnstock	Purinergic System
Sarah Byberg	Ghrelin, Physiological Roles and Clinical Relevance of
Giorgio Caratti	Transcriptional Regulation
Marco Carli	Atypical Antipsychotics
Ingolf Cascorbi	Drug Interactions
Thomas K. H. Chang	Nuclear Receptor Regulation of Hepatic Cytochrome P450 Enzymes
Sharmistha Chatterjee	Wnt Signaling
Guang Chen	Mood Stabilizers
C. Yan Cheng	Blood-Testis Barrier
Paola Chiodelli	Fibroblast Growth Factors
Chia-Lin Chuang	Amylin
A. J. Clark	Adrenomedullin/Intermedin
Niamh Coleman	DNA Damage Response
Stefano Comai	Melatonin
Deirdre R. Coombe	Heparin and Related Drugs
Rafael Coveñas	Neurokinin/Tachykinin Receptors
Dermot Cox	Integrins as Drug Targets: Is There a Future?
Thomas R. Cox	Extracellular Matrix (ECM)
James J. Crawford	Hippo Pathway
Tobias K. Dallenga	Tuberculosis
Paul J. Davis	Anti-integrins
Margherita De Rosa	Cephalosporins
Mireille Delhase	NF-κB, Molecular Target
Hector F. DeLuca	Vitamin D
Carmen W. Dessauer	Adenylyl Cyclases
Jan M. Deussing	Corticotropin-Releasing Hormone System
Vincenzo Di Marzo	Endocannabinoids
Dobromir Dobrev	Antiarrhythmic Drugs
Q. Ping Dou	Deubiquitylating Enzymes
Michael Dreher	Bronchial Asthma Chronic Obstructive Pulmonary Disease
Evgeniya V. Efimova	Trace Amine-Associated Receptors

(continued)

Franciska Erdő	Blood-Brain Barrier
Konstantinos Evangelou	Senescence
Pius S. Fasinu	Anticoagulants
S. Fenske	HCN Channels
Natalia C. Fernández	Histamine Receptors
Rebecca Flessner	Na^+/H^+ Exchangers
Veit Flockerzi	Non-selective Cation Channels TRP Channels
Jean-Marie Frère	β-Lactam Antibiotics
Lloyd D. Fricker	Proteasome Inhibitors
Andreas Friebe	Nitric Oxide
Robert Friis	Autophagy
Raul R. Gainetdinov	Dopamine System Trace Amine-Associated Receptors
Michael L. Garelja	Calcitonin Family Receptors
Bobin George Abraham	Janus Kinase
Pierre Germain	Retinoids
Noyel Ghosh	Wnt Signaling
Gabriella Gobbi	Melatonin
Jens P. Goetze	C-Type Natriuretic Peptide and Its Receptors
Muslum Gok	Cholinesterases
Maricel Gomez-Soler	Eph Receptors and Ephrins
Tao Gong	Inflammasome
Vassilis G. Gorgoulis	Senescence
Markus Grube	ABC Transporters
Tilman Grune	Antioxidants
Renata Grzywa	Viral Proteases
Thomas Gudermann	Contraceptives
Silke Haerteis	Acid-Sensing Ion Channels Epithelial Na^+ Channel
V. Hammelmann	HCN Channels
Bruce D. Hammock	Soluble Epoxide Hydrolase
Xu Han	Protease-Activated Receptors (PARs)
Mitchell T. Harberson	Bremelanotide
D. Grahame Hardie	AMP-Activated Protein Kinase
Debbie L. Hay	Amylin Calcitonin Family Receptors
Andrew C. Hedman	Adaptor Proteins
Jordi Heijman	Antiarrhythmic Drugs
Lutz Hein	α-Adrenergic System Heart Failure
Anke Heisig	Bacterial Resistance to Antibiotics
Peter Heisig	Bacterial Resistance to Antibiotics
Claus W. Heizmann	Ca^{2+}-Binding Proteins S100 Proteins
Peter Herrlich	Transcriptional Regulation
Heiko Herwald	Kinins
Isabella Heuser	Antidepressant Drugs
Staffan Hildebrand	Gene Therapy Vectors
Jennifer W. Hill	Bremelanotide
Andreas Hochhaus	Cancer Immunotherapy Immune Checkpoint Blockade

(continued)

Franz Hofmann	Smooth Muscle Tone Regulation Voltage-Dependent Ca^{2+} Channels
Jeffrey K. Holden	Hippo Pathway
Birgitte Holst	Ghrelin, Physiological Roles and Clinical Relevance of
Helmut Holtmann	Cytokines
Richard Horuk	Chemokine Receptors
Daniel Hoyer	Serotoninergic System
Norbert Hübner	Gene Expression Analysis and Next-Generation Sequencing
Christine Huppertz	Anti-obesity Drugs Interleukin-17 Interleukin-23
Andrea Huwiler	Inflammation
Jeeda Ismail	Protease-Activated Receptors (PARs)
Kenneth A. Jacobson	Adenosine Receptors
Gabriele Jedlitschky	ABC Transporters
Thomas J. Jentsch	Cl^- Channels and Cl^-/H^+ Exchangers
Fan Jiang	NADPH Oxidase
Ralf Jockers	Melatonin
Jayde J. Johnson	Protein Phosphatases
Hans-Georg Joost	Appetite Control Diabetes Mellitus Insulin Receptor
Nataliia Katolikova	Dopamine System
Nestor Kamdem	SAR-by-NMR
Simranjeet Kaur	Cell Cycle Regulation
Stephan Kellenberger	Acid-Sensing Ion Channels Epithelial Na^+ Channel
Terry P. Kenakin	Drug–Receptor Interaction
Joshua L. Kennedy	Interleukin-5
Tabassum Khan	DNA Gyrase Inhibitors
Sarah Kim	Bone Metabolism
Andrés J. P. Klein Szanto	Proprotein Convertases
André Kleinridders	Appetite Control Insulin Receptor
Lars-Oliver Klotz	Antioxidants
Enno Klussmann	A-Kinase Anchoring Proteins (AKAPs)
Klaus-Peter Knobeloch	Ubiquitin/Proteasome
Doris Koesling	Guanylyl Cyclase
Michael Kracht	Cytokines
Susan Kralisch	Adipokines
Gerd Krause	Endothelins Molecular Modelling
Reinhold Kreutz	Antihypertensive Drugs Blood Pressure Control
Nagomi Kurebayashi	Ryanodine Receptor
Stephanie A. Kustos	Anticoagulants
Koichiro Kuwahara	Atrial and Brain Natriuretic Peptides
G. Ladds	Adrenomedullin/Intermedin
Laurence Lanfumey	Neurosteroids

(continued)

Michael Lanzer	Antiprotozoal Drugs
Gladys O. Latunde-Dada	Ferroptosis
Lorraine Lau	Antithyroid Drugs
Brian K. Law	Cyclin-Dependent Kinases as Therapeutic Targets
Mary E. Law	Cyclin-Dependent Kinases as Therapeutic Targets
Xin Li	Deubiquitylating Enzymes
Yiwen Li	ATP-Dependent K^+ Channels
Jonathan D. Licht	Epigenetics
Filip Liebsch	Alzheimer's Disease
Eric L. Lindberg	Gene Expression Analysis and Next-Generation Sequencing
Stuart A. Lipton	Protein S-Nitrosylation
Amanda Littlewood-Evans	Interleukin-23
Anatoli N. Lopatin	Inward Rectifier Potassium Channels
Achim Lother	Heart Failure
Maja Lozic	Oxytocin Vasopressin
Margaret B. Lucitt	Interleukin-1 (IL-1)
Mike Ludwig	Oxytocin Vasopressin
Marie-Gabrielle Ludwig	Proton-Sensing GPCRs
Eugenie Macfarlane	Bone Metabolism
Rodrigo Machado-Vieira	Mood Stabilizers
Fernando Macian	NFAT Family of Transcription Factors
Antonello Mai	Sirtuins
Albane le Maire	Retinoids
Husseini K. Manji	Mood Stabilizers
Pekka T. Männistö	Catechol-*O*-Methyltransferase
Anna Marabotti	Cephalosporins
Peter D. Mark	C-Type Natriuretic Peptide and Its Receptors
Christian Martin	Bronchial Asthma Chronic Obstructive Pulmonary Disease
Petra May	Low-Density Lipoprotein Receptor Gene Family
Thomas Meyer	JAK-STAT Pathway PIAS Proteins
Dagmar Meyer zu Heringdorf	Lysophosphatidic Acid Lysophospholipids Sphingosine-1-Phosphate
Martin C. Michel	Neuropeptide Y
Alexandra A. Miller	Aptamers
Pasquale Molinaro	Na^+/Ca^{2+} Exchangers
Federico Monczor	Histamine Receptors
Cesare Montecucco	Botulinum Neurotoxins
Greg B. G. Moorhead	14-3-3 Proteins Protein Phosphatases
Gustavo Moraga-Cid	Glycine Receptors
João Nuno Moreira	Hematopoietic Growth Factors
Shaker A. Mousa	Anti-integrins
Judith M. Müller	Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor
Barbara Mulloy	Heparin and Related Drugs

About the Editors

Stefan Offermanns After finishing medical studies, Stefan Offermanns did postdoctoral work at the Free University Berlin and the California Institute of Technology. From 2000 to 2009, he held the Chair of Pharmacology at the University of Heidelberg. Since 2008 he has been Director at the Max Planck Institute for Heart and Lung Research and Professor at the Goethe University, Frankfurt. He has combined basic science with clinically oriented research to study the role of various cellular signaling mechanisms in the cardiovascular and metabolic systems as well as in cancer.

Professor Walter Rosenthal is an MD and molecular pharmacologist. He is recognized as a specialist in signal transduction (G-proteins, G-protein-coupled receptors, and anchoring proteins). In 1996, he became founding Director of the Leibniz Institute of Molecular Pharmacology (FMP) in Berlin, and in 1998, he was appointed Full Professor at the Charité-Universitätsmedizin Berlin. He headed the FMP for 12 years before serving as Chair of the Board and Scientific Director of the Max Delbrück Center for Molecular Medicine in Berlin-Buch (2009–2015). Since 2014 he has been President of Friedrich Schiller University Jena.

ABC Transporters

Markus Grube and Gabriele Jedlitschky
Department of Pharmacology, Center of Drug Absorption and Transport, University Medicine Greifswald, Greifswald, Germany

Synonyms

ABC proteins; ATP binding cassette proteins

Definition

The ABC transporters represent one of the largest families of transmembrane proteins in most organisms including plants, bacteria, and eukaryotic cells. They perform numerous key physiological processes directly coupled with the hydrolysis of ATP. From the pharmacological point of view, ABC transporters are of special interest because of their relevance in transmembrane transport of various drugs, thereby modifying intracellular concentrations and hence effects of these compounds. Furthermore, they represent potential target structures to interfere with (patho-)physiological processes in which they are involved.

Basic Characteristics

ATP-binding cassette (ABC) proteins are present in plants, bacteria, and eukaryotic organisms including mammalians. In humans the ABC gene superfamily comprises about 50 members, which are organized in 7 subfamilies called ABCA to ABCG on the basis of their domain organization and phylogenetic similarities. Besides the systematic gene nomenclature alternative names for the proteins are widely used, which are based on the first functional description such as P-glycoprotein for ABCB1 (which are also used for the proteins in this article). ABC proteins are involved in various physiological processes including the transport of lipids such as cholesterol (e.g., ABCA1, ABCG1/5/8) or fatty acids (ABCD1/2), presentation of peptides by MHC class I molecules (ABCB2/ABCB3, which are better known as transporter associated

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

with antigen processing (TAP)), or regulation of ion channels. For example, the regulatory subunit of the K_{ATP} channel of the pancreatic beta-cells and target structure of the antidiabetic sulfonylureas SUR1 is encoded by the ABCC8 gene, and ABCC7 encodes an important chloride channel (cystic fibrosis transmembrane conductance regulator, CFTR) in epithelial cells of the lung and pancreas. In addition, some ABC transporters are important components of physiological barriers like the intestinal epithelium or the blood-brain barrier and in excreting organs as the liver and kidney. Here, they are acting as efflux pumps protecting the organism against endogenous metabolites as well as environmental toxins including several pharmacological important drugs. Some of these transporters, namely, ABCB1 (P-glycoprotein, P-gp, MDR1), ABCG2 (breast cancer resistance protein, BCRP), and several members of the multidrug resistance protein (MRP) family (ABCC1-C6; ABCC10-ABCC12), are of high pharmacological relevance, because they have been identified as one underlying mechanism of a cancer-related phenotype called multidrug resistance (MDR) (Chen et al. 2016; Gottesman and Ling 2006; Slot et al. 2011). This phenomenon is characterized by the resistance of cancer cells against anticancer drugs caused by reduced intracellular drug concentrations. Furthermore, these transporters can affect pharmacokinetic parameters of various drugs in general (Chan et al. 2004).

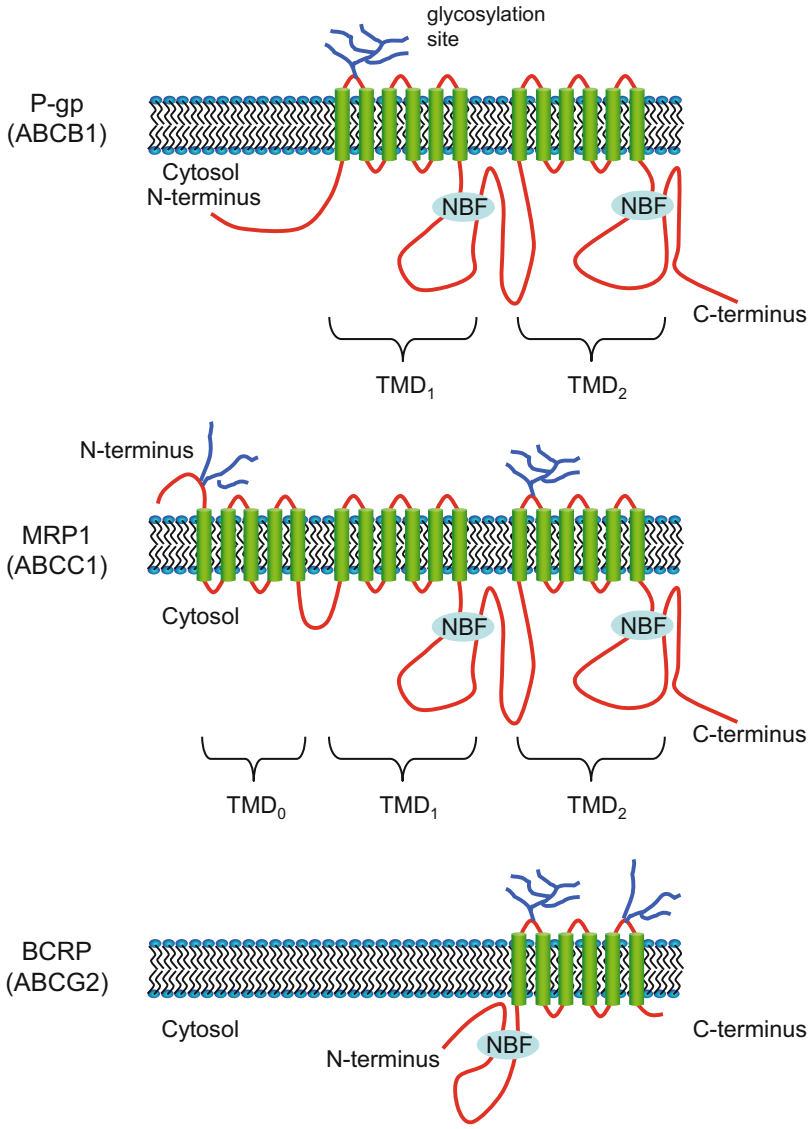
Topology and Structure

Most ABC transporters, especially those located in the plasma membrane, are phosphorylated and glycosylated transmembrane proteins of different molecular weights (e.g., P-gp/ABCB1, 170 kDa; BCRP/ABCG2, 72 kDa). In general, active ABC transporters consist of two nucleotide-binding folds (NBF) and two transmembrane domains (TMD, each consisting of six α-helices), which can be localized on a single polypeptide (full transporter, e.g., P-gp) or formed by dimerization of a so-called half transporter (e.g., BCRP). This core structure can be modified by additional TMDs (e.g., MRP1/ABCC1) (Fig. 1). The NBFs contain the highly conserved Walker A and B consensus motifs as well as the LSGGQ signature motif, which is unique for ABC transporters and catalyzes the ATP hydrolysis – a prerequisite for substrate binding and transport against a substrate gradient. For further details on structure and mechanism of ABC transporters, see Beis (2015).

Tissue Distribution and Localization

Although initially detected in cancer cell lines, ABC transporters show a wide tissue distribution. Several drug transporting ABC proteins are highly expressed in physiological barriers such as the luminal membrane of enterocytes, the endothelial cells of the blood-brain barrier, or the maternal facing (apical) membrane of the placental syncytiotrophoblast. In all of these organs, they protect sensible tissues like the brain or the growing fetus against potentially toxic compounds. In addition, ABC transporters are highly abundant in the kidney and liver (Fig. 2). In hepatocytes they are involved in the elimination of many endogenous and exogenous compounds and therefore expressed in both the canalicular and sinusoidal membranes. The canalicular expression is a prerequisite for biliary elimination. For example, the bile salt export pump (BSEP/ABCB11) transports bile salts, MRP2 (ABCC2) is involved in the elimination of organic anions like bilirubin glucuronides or glutathione conjugates, MDR3 (ABCB4) is essential for secretion of phospholipids, and P-gp (ABCB1) eliminates a number of drugs into bile. Other ABC transporters like MRP3 (ABCC3) and MRP4 (ABCC4) are located at the sinusoidal membrane of hepatocytes. They transport xenobiotics and several conjugates back into the blood and are of special relevance under pathophysiological conditions. For example, hepatic expression of both transporters is induced during cholestasis, thereby protecting the hepatocytes against toxic bile acid concentrations by transport into the blood followed by increased renal elimination (Keppler 2011; Slot et al. 2011).

ABC transporters are also expressed in other organs like the heart, lung, pancreas, or blood cells. Here, they may be important for both physiological processes and local drug concentrations. In this context it is noteworthy that many of these transporters not only eliminate xenobiotic and

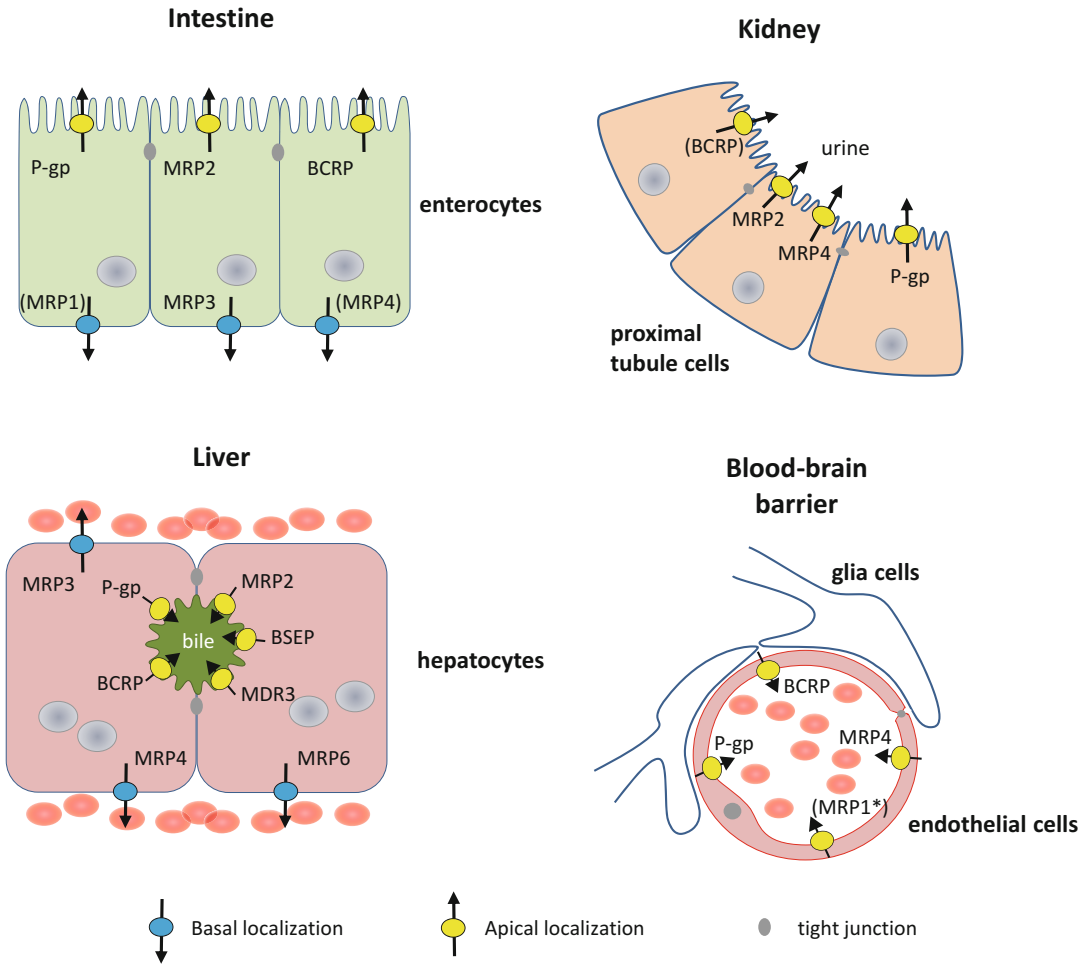


ABC Transporters, Fig. 1 Predicted membrane topologies of P-gp (ABCB1), MRP1 (ABCC1), and BCRP (ABCG2), exemplifying full (P-gp and MRP1) and half (BCRP) transporters, as described in the main text (NBF, nucleotide-binding fold; TMD, transmembrane domain; scheme modified according to Borst and Elferink 2002)

toxic compounds from the cell but export also physiological important metabolites. Finally, the intracellular localization of ABC transporters is not restricted to the plasma membrane, but they have been also detected in intracellular structures. For example, ABCD1/2 is localized in peroxisomes and ABCB2/3 in the endoplasmic reticulum. For further reading, see Borst and Elferink (2002).

Physiological and Pathophysiological Aspects

Based on their physiological function, it is not surprising that genetic variants affecting expression and function of ABC proteins have been identified as the underlying mechanisms for several diseases. For example, loss-of-function mutations in the gene encoding the cholesterol transporter ABCA1 have been associated with the Tangier disease (patients show a severe reduction of high-density lipoprotein, HDL), and genetic variants of ABCA7 have been identified as risk factors for Alzheimer's disease (Aikawa et al. 2018). Cystic fibrosis is caused by genetic defects in the CFTR (ABCC7) gene, and certain polymorphisms in the SUR1 (ABCC8) gene are risk factors for the development of diabetes. In



ABC Transporters, Fig. 2 ABC transporter expression and localization in pharmacokinetically important tissues, such as the intestine, liver, kidney, and brain microvascular endothelial cells forming the blood-brain barrier. Details on localization and function of the depicted transporters are given in the main text (∗the localization of MPR1 at the blood-brain barrier is still unclear)

view of physiological processes, also several MRPs are of interest. The block of biliary elimination of bilirubin glucuronides caused by the absence of MRP2 (ABCC2) from the canalicular membrane leads to the Dubin-Johnson syndrome. Genetic defects of MRP6 (ABCC6) cause the ectopic mineralization disorder pseudoxanthoma elasticum (characterized by fragmentation and mineralization of elastic fibers) probably through a diminished hepatocellular export of ATP, which is extracellularly rapidly converted into AMP and the mineralization inhibitor pyrophosphate (Jansen et al. 2013).

MRP4 (ABCC4), which is expressed in many tissues and cancer cells, transports not only xenobiotics like nucleotide-based anticancer drugs but also endogenous signaling molecules such as cyclic nucleotides and has been established as an independent regulator of especially cAMP levels in several cell types including vascular smooth muscle cells and platelets (Belleville-Rolland et al. 2016). Genetic variations of MRP8 (ABCC11) determine the human cerumen type (wet or dry ear wax) and presence of underarm osmidrosis but are also involved in therapy resistance in breast cancer (Ishikawa et al. 2013).

Based on their pathophysiological roles, ABC proteins represent drug targets of established and potential novel drugs. For example, the widely used antidiabetic sulfonylureas and glinides inhibit the regulatory subunit SUR1 (ABCC8) of the ATP-sensitive potassium channels (K_{ATP}), thereby inducing the insulin secretion. Drugs such as ivacaftor have been developed, which can at least partially restore the function of CFTR (ABCC7) in certain genetic defects and thus treat cystic fibrosis (Berical et al. 2019). Moreover, in order to treat this disease, several approaches have already been evaluated to replace the defective ABCC7 by gene therapy. Other physiological relevant transporters like MRP4 may also represent novel targets, e.g., to regulate platelet function (Belleville-Rolland et al. 2016).

Drugs

From the pharmacological point of view, ABC transporters represent drug targets (pharmacodynamics relevance, see above) and – even more important – affect the bioavailability of other compounds including various drugs (pharmacokinetic relevance).

Drug Transport

The pharmacokinetic relevance of ABC transporters becomes evident because of their high expression at physiological barriers and excretion organs like the intestine, blood-brain barrier, liver, and kidney. Substrates of these transporters, especially for P-gp, BCRP, and several MRPs, are intensively eliminated into the bile and the urine or transported back to the intestine, thereby limiting oral bioavailability. In this context, it is not surprising that ABC transporters are involved in drug-drug interactions in analogy to metabolizing enzymes. Besides inhibition and in turn enhanced bioavailability after coadministration of transporter substrates or inhibitors, ABC transporters can also be induced by certain mechanisms leading to a reduced bioavailability of their substrates. For example, similar to the P450 enzyme CYP3A4, the promoter of ABCB1 (P-gp) contains a transcription factor binding site for the pregnane X receptor (PXR). PXR, which is expressed in high abundance in the liver and intestine, functions as a xenosensor detecting potential toxic compounds. Its activation leads to an enhanced expression of metabolizing enzyme (e.g., CYP3A4) and ABC transporters (mainly P-gp), thereby protecting the organisms. Of note, not only drugs like rifampicin, barbiturates, or carbamazepine but also apparently harmless compounds like St. John's wort (active compound hyperforin) can activate PXR and in turn upregulate transporter expression. Besides PXR, binding sites for other nuclear receptors like the constitutive androstane receptor (CAR), the farnesoid X receptor (FXR), the steroid and xenobiotic receptor (SXR), or the peroxisome proliferator-activated receptor (PPAR) have also been described for ABC transporters.

Besides pharmacokinetic important organs, ABC transporters are expressed in drug target structures, thereby affecting local drug concentrations. Many anticancer drugs are ABC transporter substrates, and tumor cells often show an enhanced transporter expression resulting in a multidrug resistance phenotype, an unsolved problem in chemotherapy. Inhibitors of ABC transporters, especially P-gp, have been developed as chemosensitizers to overcome resistance, but so far clinical trials revealed only limited or no benefits. The problem of limited drug availability at its target site is not restricted to cancer therapy. As already mentioned, drug transporting ABC transporters like P-gp and BCRP are also expressed at the blood-brain barrier, thereby limiting the access of drugs to the brain. While this is useful for drugs like loperamide, a morphine-based drug against diarrhea, it is a problem for central acting drugs like antipsychotics. A list of pharmacological relevant ABC transporters and their substrates is given in Table 1.

In pharmacotherapy, a different response of patients to a certain drug is often observed. A part of this interindividual variability can be attributed to pharmacokinetic differences of the substances in the different patients. Besides the abovementioned drug-drug interaction on transporter level, genetic variability of ABC

ABC Transporters, Table 1 Substrates of ABC transporters involved in multidrug resistance and drug transport according to (Keppler 2011; Ishikawa et al. 2013; Lund et al. 2017; Mao and Unadkat 2015; Slot et al. 2011; Zhou et al. 2008)

ABC transporter	Transporter substrates
P-gp (ABCB1)	**Endogenous substrates:** steroids, lipids, bilirubin, bile acids **Drugs:** anticancer drugs (e.g., docetaxel, doxorubicin, etoposide, erlotinib, imatinib, irinotecan, paclitaxel, topotecan, vinblastine); antibiotic and virostatic drugs (e.g., abacavir, clarithromycin, elvitegravir, erythromycin, indinavir, levofloxacin, maraviroc, nelfinavir, ritonavir, sofosbuvir); immunomodulatory drugs (e.g., cyclosporin A, everolimus, methylprednisolone, sirolimus, tacrolimus); cardiovascular drugs (e.g., apixaban, atorvastatin, dabigatran etexilate, digoxin, simvastatin, talinolol, ticagrelor); and others (e.g., canagliflozin, cimetidine, domperidone, fexofenadine, glibenclamide, ivermectin, lansoprazole, loperamide, morphine, oxcarbamazepine, ondansetron, saxagliptin)
MRP1 (ABCC1)	**Endogenous substrates:** cysteinyl leukotrienes (LTC4, LTD4); reduced (in co-transport) and oxidized glutathione (GSH, GSSG); glutathione, glucuronate, and some sulfate conjugates of endogenous lipophilic compounds such as steroids (e.g., estradiol 17β-glucuronide); folic acid; sphingosine 1-phosphate; and others **Drugs (resistance profile):** many cytostatic drugs (e.g., methotrexate, anthracyclines, vinca alkaloids, etoposide, cyclophosphamide, paclitaxel; transport often GSH-dependent), colchicine; HIV protease inhibitors (e.g., indinavir ritonavir); some antibiotics (e.g., ciprofloxacin); and others
MRP2 (ABCC2)	**Endogenous substrates:** bilirubin glucuronides, cysteinyl leukotrienes, estradiol 17β-glucuronide, estrone-3-sulfate, dianionic conjugated bile salts, and others **Drugs:** glutathione, glucuronate, and sulfate conjugates of drugs; statins (e.g., pravastatin); HIV protease inhibitors (e.g., indinavir, ritonavir); antibiotics (ampicillin, azithromycin, ceftriaxone); resistance to cytostatic drugs (e.g., irinotecan, cisplatin, anthracyclines, vinca alkaloids, methotrexate, mitoxantrone); valsartan; and others
MRP3 (ABCC3)	**Endogenous substrates:** estradiol-17β-glucuronide, LTC4, bile salts (e.g., cholylglycine), bilirubin glucuronides, dehydroepiandrosterone-3-sulfate (DHEAS), and others **Drugs:** methotrexate, clopidogrel metabolites, acetaminophen glucuronide, phytoestrogen conjugates, and others
MRP4 (ABCC4)	**Endogenous substrates:** cyclic nucleotides (cAMP, cGMP), urate, estradiol-17β-glucuronide, DHEAS, bile acids (+GSH), folate, LTC4, LTB4 (+GSH), prostanoids (PGE1/2, TXB2), sphingosine 1-phosphate, and others **Drugs:** nucleoside-based antiviral drugs (e.g., adefovir, zidovudine, acyclovir, ganciclovir); some HIV protease inhibitors (e.g., nelfinavir, tenofovir); resistance to purine-based anticancer drugs (e.g., 6-mercaptopurine, 6-thioguanine), methotrexate; statins, furosemide, hydrochlorothiazide, olmesartan, and others
MRP5 (ABCC5)	**Endogenous substrates:** cyclic nucleotides (cGMP, cAMP, cCMP), folate, glutamate conjugates, and others **Drugs:** nucleoside-based antiviral drugs (e.g., adefovir), methotrexate and several other anticancer drugs (resistance to cladribine, cladarabin, gemcitabine, cytarabine, 5-FU, 6-mercaptopurine, thioguanine), and others
MRP8 (ABCC11)	**Endogenous substrates:** cyclic nucleotides (cAMP, cGMP), estradiol-17β-glucuronide, DHEAS, LTC4, folate, GSH-conjugated sulfanylalkanols (odorant precursors), and others **Drugs:** fluoropyrimidine-based anticancer drugs, eribulin, tenofovir, and others
BCRP (ABCG2)	**Endogenous substrates:** flavonoids, porphyrins, folate, sulfate conjugates (e.g., estrone-3-sulfate) **Drugs:** anticancer drugs (e.g., topotecan, irinotecan, SN-38, methotrexate, imatinib, mitoxantrone); antibiotics/anti-retrovirals (e.g., zidovudine, lamivudine, sulfasalazine, nitrofurantoin); prazosin, pantoprazole, rosuvastatin, and others

transporter is also involved. Besides genetic loss-of-function variants leading to the abovementioned inherited diseases, several more common polymorphisms have been identified in ABC transporter genes. Some of these variants have been associated with a reduced transporter

expression or function (Bruhn and Cascorbi 2014; Wolking et al. 2015). For example, an amino acid exchange in the BCRP transporter (rs2231142, 421C>A, Q141K) leads to reduced transporter function and in turn causes enhanced plasma levels of certain drugs (e.g., statins). In the case of MRP2, a polymorphism (rs717620, -24C>T) in the promoter region of the ABCC2 gene has been identified. This variant is associated with a reduced transporter expression and in turn pharmacokinetic differences of some MRP2 substrates in the respective patients. Interestingly, the relevance of genetic variation within the ABCB1 (P-gp) gene is still less clear. Even if ABCB1/P-gp is probably the best characterized transporter in this field and various synonymous and nonsynonymous polymorphisms as well as deletions and insertions have been identified, the clinical relevance of these polymorphisms is still unclear.

Taken together, ABC transporters represent a large family of proteins affecting the pharmacokinetic parameters of various drugs. Here, P-gp is currently the best characterized member, and it may also be one of the most important ABC transporters with regard to drug transport. However, ABC transporters act in a coordinated fashion with other detoxification systems like P450 enzymes and uptake transporters. In particular, P-gp and CYP3A4 are closely intertwined in terms of regulation and function. Thus, further reviews have to address the combined action of various systems.

Synonyms

Angiotensin-1 converting enzyme inhibitors

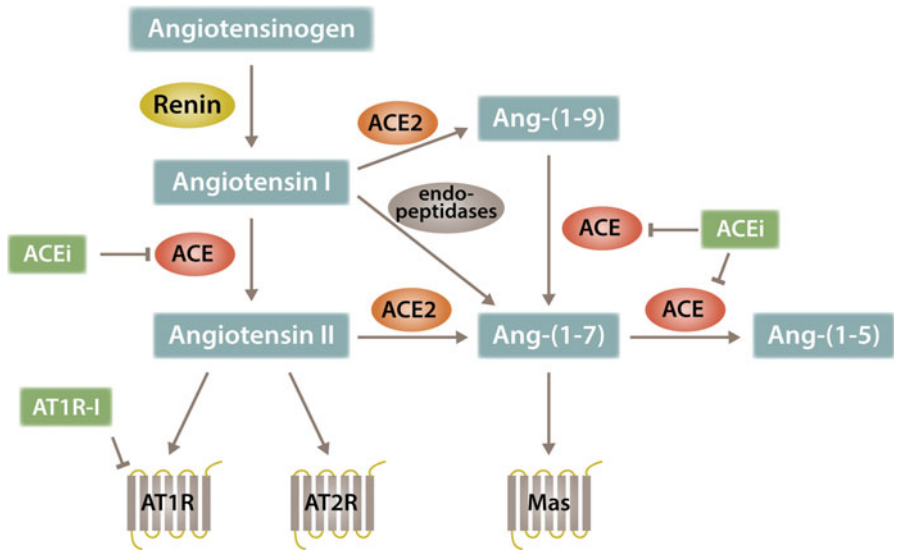
Angiotensin-1 Converting Enzyme (ACE)

Angiotensin-1 converting enzyme (ACE, EC 3.4.15.1, also known as peptidyl dipeptidase) is a key zinc metallopeptidase in cardiovascular regulation that acts against angiotensin peptides (Ang I, Ang II), as well as other vasoactive peptides, including kinins (e.g., bradykinin), substance P, and the acetylated tetrapeptide Ac-SDKP. Becasue of its promiscuity as an enzyme, ACE and its peptide substrates and products affect many physiologic processes, including blood pressure control, hematopoiesis, reproduction, renal development, renal function, and the immune response (for reviews see Acharya et al. 2003; Bernstein et al. 2012; Arendse et al. 2019).

ACE is a critical component of the renin-angiotensin aldosterone system (RAAS) (Fig. 1), which controls blood pressure and strongly influences the function of the heart and the kidneys, as well as the walls of blood vessels. For these reasons, drugs that target the RAAS, such as ACE inhibitors, are among the most important therapeutic agents available today for the treatment of hypertension, heart failure, coronary artery disease, renal insufficiency, and general atherosclerosis.

Mechanism of Action of ACE Inhibitors

ACE inhibitors competitively inhibit the enzymatic activity of ACE with K_i values between



ACE Inhibitors, Fig. 1 An overview of the renin-angiotensin-aldosterone system (RAAS). A complex pathway of peptides converted to active hormones by peptidases and key receptors provide a number of targets for therapeutic intervention. AT2R, angiotensin type 2 receptor; AT1R, angiotensin type 1 receptor; Mas, Mas receptor for Ang 1–7; ACE, angiotensin-converting enzyme; ACE2, angiotensin-converting enzyme 2; ACEi, ACE inhibitor; AT1R-I, angiotensin type 1 receptor blocker

10^{-10} and 10^{-11}. ACE cleaves a wide range of pairs of amino acids from the carboxy-terminal end of a plethora of peptide substrates. The conversion of Ang I to Ang II and the degradation of bradykinin to inactive fragments are considered the most important functions of ACE. Ang II (a powerful vasoconstrictor) primarily circulates in the blood and causes the muscles surrounding the blood vessels to contract, thereby narrowing the vessels. This increases the pressure within the vessels, causing an increase in blood pressure (known as hypertension). Ang II also stimulates the release of the hormone aldosterone from the adrenal glands, which in turn signals the kidneys to retain salt and water, which further raises blood pressure. Furthermore, Ang II acts as a growth factor that stimulates thickening of the blood vessel walls, aggravating the process of atherosclerosis, or hardening of the arteries. Drugs acting on ACE and the RAAS reduce blood pressure, improve the function of the heart, and slow down the progression of atherosclerosis and kidney disease. However, Ang II is not the only peptide metabolized by ACE.

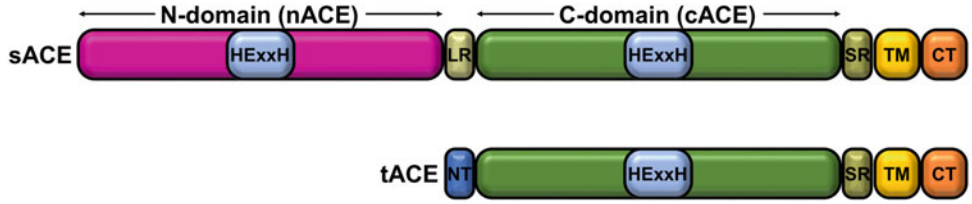
ACE also acts on other peptide hormones, notably bradykinin, which has the opposite effect of Ang II and acts as a vasodilator. ACE inhibition results in reduced levels of Ang II (therefore, less vasoconstriction) but increased levels of bradykinin (therefore, more vasodilatation). These effects together cause a greater reduction in blood pressure than Ang II alone. Bradykinin also has anti-inflammatory effects, all of which explains why ACE inhibitors have a different therapeutic profile than drugs that only block the Ang II receptor. Ang I in the blood is formed from angiotensinogen, a protein produced by the liver and released into the blood. Ang II is formed from Ang I in the blood by ACE. Current clinically available ACE inhibitors are nonpeptide analogues of Ang I that reduce (inhibit) the enzymatic activity ACE by decreasing the production of Ang II. As a result, blood vessels enlarge or dilate, and blood pressure is reduced. This lower blood pressure makes it easier for the heart to pump blood and can improve the function of a failing heart. In addition, the progression of kidney disease due to high blood pressure or diabetes is slowed.

Molecular Properties of ACE

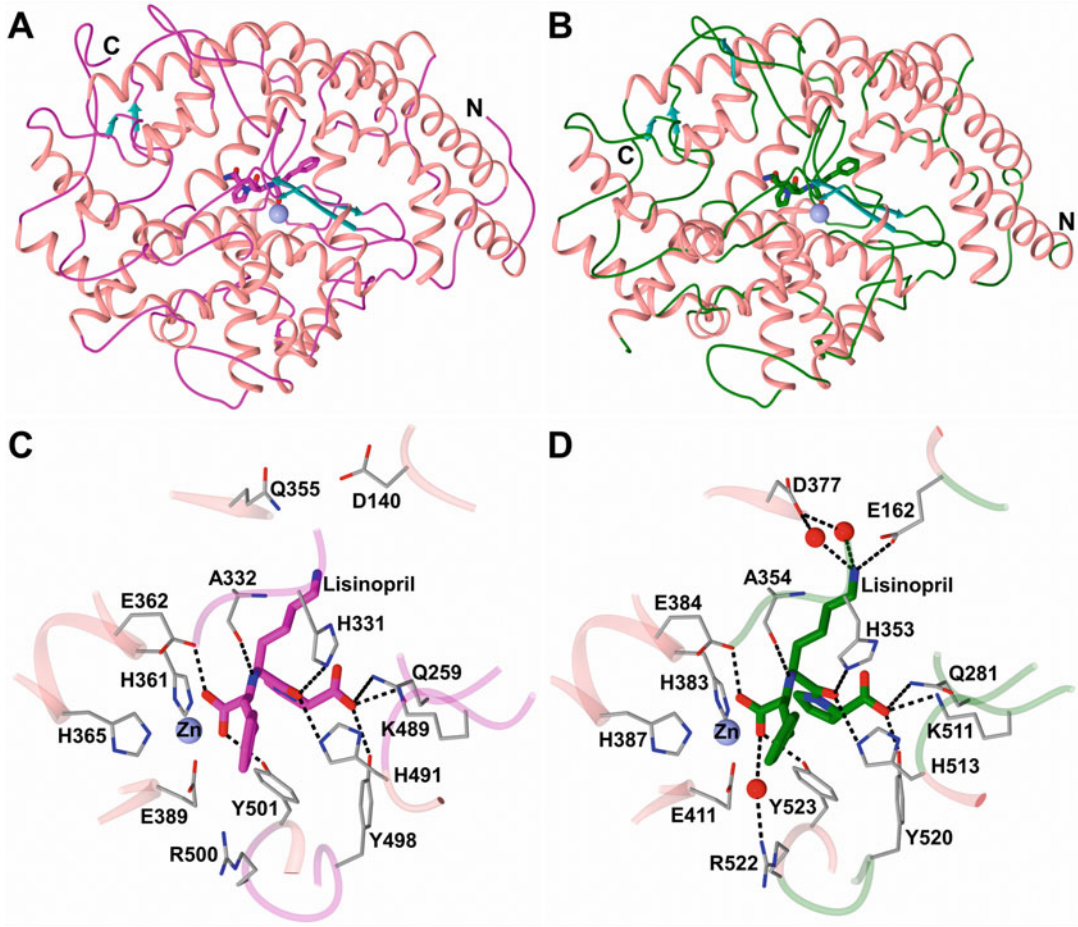
Human ACE is a type I transmembrane protein comprised of 1306 amino acids when processed to its mature form. A sequence of 22 hydrophobic amino acids located near the carboxy terminus of the protein serves as the transmembrane domain that anchors ACE to the cell surface. This creates a 28-residue cytosolic domain and a 1277-residue glycosylated extracellular domain. ACE is member of a large family of proteins that undergo cleavage with release of their ectodomain as a soluble form of the protein. This solubilization or shedding is a controlled process that can be upregulated by protein kinase C activation and other mechanisms, resulting in the release of ACE into the systemic circulation.

There are two isoforms of human ACE: in somatic tissues, it exists as a glycoprotein composed of a mature single large polypeptide chain of 1277 amino acids (sACE), corresponding to the extracellular domain of the full-length membrane protein. sACE is localized on the plasma membrane of endothelial and absorptive epithelial and neuroepithelial cells (Soubrier et al. 1988). The approximate concentration of sACE in human plasma is between 36 and 288 ng/ml (260–2076 pM), which is ~200-fold molar excess compared with Ang I. However, sACE has limited impact on tissue Ang-II levels, which might be more dependent on the local conversion of Ang-I to Ang-II by endothelial ACE in direct proximity to type I angiotensin II receptor (AT1R). sACE consists of two homologous catalytically active centers on each N and C domain, known as nACE and cACE (Soubrier et al. 1988) (Fig. 2). In germinal cells, ACE is synthesized as a lower molecular mass form and is thought to play a role in sperm maturation and the binding of sperm to the oviduct epithelium. Testis ACE (tACE, 701 amino acids long) is identical to cACE, except for a unique 36-residue sequence constituting its amino terminus.

Our understanding of the function of ACE has been aided by detailed molecular structures, based on high-resolution crystal structures of cACE and nACE with a clinical ACE inhibitor such as lisinopril (Fig. 3, Natesh et al. 2003; Corradi



ACE Inhibitors, Fig. 2 Schematic representation of the domain structure of sACE and tACE. *LR* linker region, *NT* N-terminus, *SR* stalk region, *TM* transmembrane region, *CT* C-terminus, *HExxH* Zinc binding histidine and catalytic glutamate conserved motif



ACE Inhibitors, Fig. 3 Structures of nACE (PDB2C6N) and cACE (PDB1O86) in complex with lisinopril. Zinc ions and water molecules are depicted as lilac and red spheres, respectively, with helices and β-strands colored in rose and dark cyan, respectively. Lisinopril and loop regions are colored magenta for nACE and dark green for cACE

et al. 2006). The catalytic site with the zinc ion is buried deep inside the groove of the molecule. It contains the conserved HEXXH zinc binding motif, formed by two histidine residues that coordinate the zinc ion together with a conserved glutamate residue. Two functionally important chloride ion binding sites, two with cACE and one with nACE, have also been identified.

Both nACE and cACE possess distinct but overlapping substrate specificity and physiologic functions, differences in chloride dependence, and distinct glycosylation patterns. Both domains catalyze the degradation of bradykinin with similar efficiencies. Knockout mouse models for these domains show similar bradykinin plasma levels as wild-type mice (Bernstein et al. 2011), suggesting that bradykinin cleavage by one domain can effectively compensate for the absence of the other domain. In contrast, cACE is the primary site for Ang-II formation and is essential and sufficient for controlling blood pressure in vivo (Fuchs et al., 2008; Bernstein et al. 2011). On the other hand, nACE is the primary site for the clearance of the tetrapeptide Ac-SDKP, a potent anti-inflammatory and antifibrotic peptide. nACE is thermally more stable than cACE, more resistant to proteolysis under denaturing conditions, and is less dependent on chloride activation as compared to cACE.

Design of First-Generation ACE Inhibitors

In 1977 Cushman et al. first described the synthesis of a series of potent inhibitors of ACE designed on the basis of an assumed mechanistic homology with carboxypeptidase A (Cushman et al. 1977). This ushered in a generation of drugs including captopril, lisinopril and enalapril, many of which are still used today in the clinic. Remarkably, these inhibitors were developed without the benefit of any detailed chemical, kinetic, or structural information on human ACE.

There are currently over 20 ACE inhibitors available which belong to three different chemical classes: thiolate compounds such as captopril; carboxylate compounds, such as enalapril; and phosphinate zinc binding group compounds, such as fosinopril (Fig. 4). The thiolate compounds exert more undesired, but also desired effects, since they additionally interact with endogenous sulfhydryl groups. Carboxylate group compounds are in general more potent than captopril. The phosphinate compounds are usually characterized by the longest duration of action.

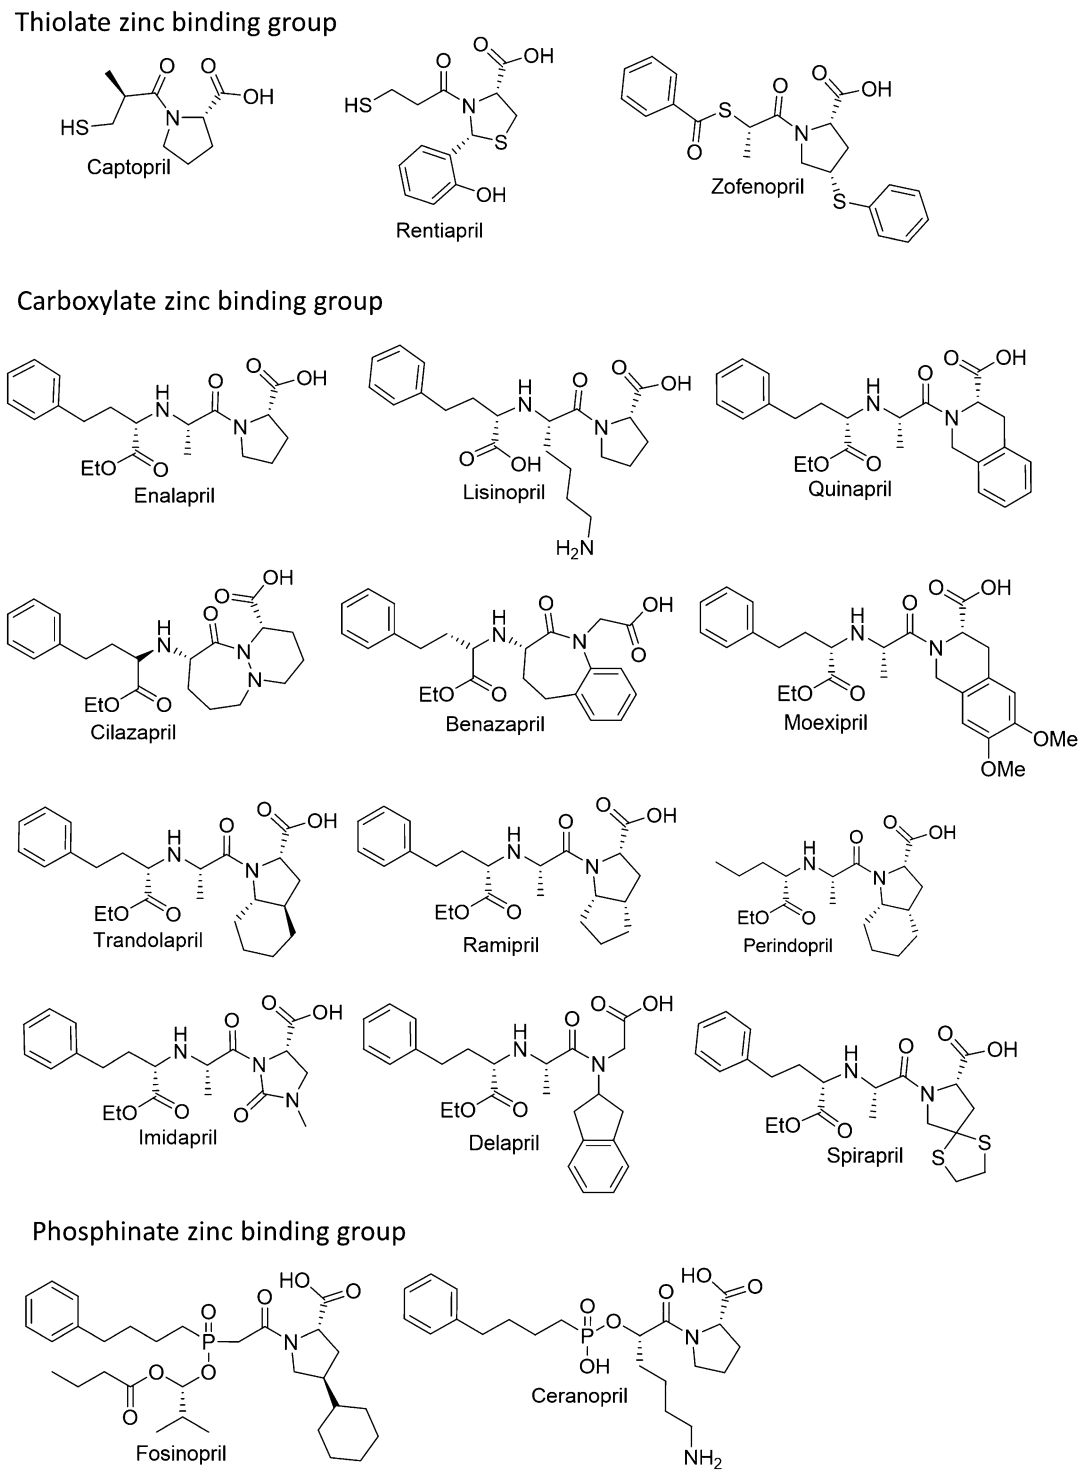
The majority of these ACE inhibitors are prodrugs which improve their oral bioavailability, but need to be converted to active compounds in the liver, kidneys, and/or intestinal tract. In effect, converting enzyme inhibitors have quite different kinetic profiles with regard to half-life, onset and duration of action, or tissue penetration. However, in general, ACE inhibitors at the doses currently used in the clinic are safe drugs with good glucose tolerance.

Adverse Effects of Present ACE Inhibitors

ACE inhibitors are commonly prescribed because they seldom cause adverse effects. Despite the success of ACE inhibitors, many patients (~20–25%) are unable to tolerate long-term treatment with current-generation ACE inhibitors because of undesired side effects. These side effects may include:

- Dry cough
- Skin rash
- Increased blood potassium levels (hyperkalemia)
- Dizziness from blood pressure decreasing too much
- Headaches
- Loss of taste

In rare cases, particularly in certain populations, ACE inhibitors can cause issues in the throat and tongue to swell (this is called angioedema) which is potentially life threatening. It is now widely accepted that these effects are caused by increased bradykinin or substance P and stimulation of the vagal fibres. Additionally, ACE inhibitors can result in lower aldosterone



ACE Inhibitors, Fig. 4 ACE inhibitors. The structures of 17 approved ACE inhibitors categorized according to their respective zinc binding groups

levels which lead to hyperkalemia in patients with poor kidney function. ACE inhibitors containing sulfhydryl groups, such as captopril, have been linked to rash, neutropenia, and nephrotic syndrome and these effects have been associated with renal insufficiency.

Chronic use of ACE inhibitors can lead to ACE inhibitor escape, where Ang-II is not reduced to normal levels. The hydrolysis of Ang-I by chymase is a possible mechanism for ACE inhibitor escape. Studies in rodents have shown that chronic ACE inhibitor treatment caused a marked increase in chymase activity in the left ventricle mediated by the bradykinin receptor (Wei et al. 2010).

Thus, some of these limitations of ACE inhibitors involving the wide substrate specificity of ACE and the ability of other enzymes to metabolize Ang II have necessitated the design of a next-generation ACE inhibitor that is specific for the cACE catalytic site of the enzyme.

ACE Inhibitors: Clinical Implications

Essential Hypertension

Essential or primary hypertension is a type of elevated blood pressure that does not have an identifiable cause, but is usually associated with poor diet, obesity, genetic factors, smoking, and lack of exercise. The first-choice drugs for the treatment of hypertension are ACE inhibitors or Ang II receptor blockers (ARBs), thiazide or thiazide-like diuretics, and calcium channel blockers. ACE inhibitors as initial therapy alone, or in combination with thiazide diuretics, were recommended in the landmark ALLHAT study (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group. The Antihypertensive and Lipid Lowering Therapy in Heart Attack Trial 2002). However, there were no differences between ACE inhibitor (lisinopril), diuretics (chlorthalidone), and calcium channel blockers (amlodipine) in the primary endpoint of combined fatal coronary heart disease or nonfatal or fatal myocardial infarction. In other trials (HOPE and EUROPA), ACE inhibitors ramipril and perindopril produced better outcomes than placebo in patients at increased cardiovascular risk. ACE inhibitor and ARBs have a cardioprotective effect independent of blood pressure lowering in patients at high risk for a cardiovascular event, however the attained blood pressure, not the drug used, is of primary importance in such patients.

Congestive Heart Failure and Myocardial Infarction

Several large randomized trials have shown that ACE inhibitors reduce mortality in patients with congestive heart failure (CHF). The reduction in mortality has been seen in patients with asymptomatic left ventricular dysfunction, and mainly results from a reduction in the progression of CHF, although the incidence of myocardial infarction (MI) and sudden death may also decrease. While ACE inhibitors improve the outcome in patients with systolic dysfunction, a lot of patients with hypertension develop CHF because of diastolic dysfunction related to left ventricular hypertrophy. ACE inhibitors reverse left ventricular hypertrophy in hypertensive patients, but have not been shown to reduce adverse outcomes in patients with heart failure and preserved ejection fraction.

Changes in the shape, size, and function of the heart due to cardiac injury (cardiac or ventricular remodeling) following MI is attenuated with ACE inhibitor treatment. A number of large clinical trials have demonstrated that ACE inhibitors reduce short- and long-term mortality, prevent onset of heart failure, and reduce the risk of stroke following MI. Trials such as SAVE, AIRE, and TRACE showed a 20% reduction in mortality in high-risk patients with left ventricular dysfunction or heart failure after MI. Moreover, ACE inhibitor or ARB treatment after acute MI is linked to long-term survival, regardless of underlying renal function (Evans et al. 2016).

Diabetic Nephropathy

The burden of diabetes has increased dramatically over the last three decades and the number of adults living with diabetes is projected to rise from 463 million (2019) to 700 million (2045) (https://diabetesatlas.org/en/). Over time,

diabetes can damage the blood vessels, heart, eyes, kidneys, and nerves and it is one of the leading causes of kidney disease. One of the reasons ACE inhibitors are so effective in the treatment of diabetes is their inhibition of bradykinin metabolism. Bradykinin acts as a vasodilator generating signals that lead to increased production of nitric oxide. Additionally, bradykinin increases insulin sensitivity, most notably during insulin resistance (Henrikson and Jacob 2003). ACE inhibitors also regulate the production of the vasoconstrictor Ang II and high blood pressure (more specifically, increased glomerular capillary pressure) that contribute to the acceleration of the complications associated with diabetic nephropathy. Finally, there is evidence for a local RAAS that directly affects the pancreas and can lead to decreased insulin secretion by regulating islet perfusion (Stump et al. 2006).

ACE Inhibitors and Cancer

The RAAS also plays a critical role in cancer biology and affects tumor growth and metastasis. Angiotensin II has an antiapoptotic role that involves AT1R/phosphatidylinositol 3-kinase/Akt activation and the suppression of caspase-9 and -3 activation. Ang II also reduces cell adhesion and invasion via Ang II interaction with the AT1 receptor, and this effect may be due to reduced expression of integrins. However, there have been conflicting results from epidemiological studies assessing whether ACE inhibitors and ARBs have protective effects against cancer risk. The response to ACE inhibitor and ARB therapy might depend on tumor type or stage, as studies have shown that specific cancer types, such as renal cell carcinoma, hepatocellular carcinoma, certain lung cancers, and pancreatic cancer, are more responsive to inhibition of the RAAS than others (Rosenthal and Gavras 2019). Furthermore, the high ACE activity DD genotype is associated with increased susceptibility to develop certain cancers. ACE inhibitors and ARBs have also been suggested to prevent cardiotoxicity and improve patient outcomes in different cancers when administered as coadjuvants with chemotherapy.

ACE Inhibitors as Modulators of Atherosclerosis

ACE inhibitors play an important role in the regulation of oxidative stress. Ang II stimulates NADPH oxidase in the vascular wall resulting in the production of superoxide anion leading to smooth muscle cell hypertrophy. ACE inhibitors enhance nitric oxide activity and limit the formation of hydrogen peroxide which is involved in smooth muscle cell proliferation and this retards the progression of carotid artery thickening. The benefits of the ACE inhibitor ramipril on the thickness of the carotid artery, administered with or without antioxidant vitamin E, were investigated in the SECURE clinical trial (Lonn et al. 2001). The progression of atherosclerosis was significantly less in the ramipril treated patients, but there was no significant decrease in progression rates in the vitamin E group. In the randomized Quinapril Ischemic Event Trial (QUIET, Cashin-Hemphill et al. 1999), there was no overall benefit of quinapril on coronary angiography-measured progression of atherosclerosis. This outcome could be due to the dosage or that almost 20% of the patients were simultaneously taking lipid-lowering drugs. ACE inhibitors should be considered in appropriate patients to slow atherosclerosis or prevent its development.

New Generation of Domain-Specific ACE Inhibitors

Until the molecular cloning of the ACE gene, expression of the full-length protein and nACE and cACE in isolation, ACE was assumed to comprise a polypeptide chain with a single active site and this was the basis for the design of all currently used ACE inhibitors. Animal studies using transgenic mice that express ACE with inactivated nACE or cACE have provided valuable insights regarding the in vivo functions and synergy of these structurally similar but nonidentical substrate binding sites (Fuchs et al. 2008). We now know that nACE and cACE play distinct physiological roles (with minor differences in potency and pharmacokinetic properties). Concomitantly, domain-selective ACE inhibitors as a single drug, or in combination with other inhibitors or receptor blockers, offer the promise of safer

and more effective treatment for hypertension and cardiovascular disease.

Based on what we now know, inhibitors of cACE will affect cardiovascular function similar to those of current-generation ACE inhibitors, but with improved side effect profiles largely due to decreased bradykinin levels. Moreover, we cannot rule out the possibility that cACE-selective inhibitors have a different therapeutic spectrum than current-generation inhibitors, all of which are essentially mixed nACE/cACE inhibitors. This, together with reduced side effects, will enable clear marked differentiation from current strategies.

RAAS inhibitors, for example ACE inhibitors, are among the few treatment options for slowing cardiovascular disease (CVD) end-organ damage, but the benefits seen with normal clinical doses of these drugs are modest. This has been ascribed, in part, to incomplete blockade of the RAAS. A novel approach to limiting CVD end-organ damage is increasing plasma levels of the acetylated tetrapeptide Ac-SDKP, a thymosin β4-derived tetrapeptide that reduces target-organ inflammation and fibrosis in relevant animal models. Ac-SDKP degradation is almost entirely dependent on hydrolysis by nACE, and current ACE inhibitors lead to a fivefold increase in plasma Ac-SDKP levels. It has been shown that inactivation of nACE significantly reduces bleomycin-induced lung fibrosis, implicating Ac-SDKP in the mechanism of protection. This represents a strong case for the use of nACE-selective ACE inhibitors for increasing tolerance to bleomycin in cancer therapy and treatment of fibrosing lung diseases (Li et al. 2010). Highly selective nACE inhibitors will substantially increase Ac-SDKP levels, providing cardio- and reno-protective effects, without leading to excessive RAAS inhibition. AnnACE-selective inhibitor will leave the cACE active site free to metabolize angiotensin and bradykinin peptides and will therefore not induce hypotension, hyperkalemia, and renal impairment that are observed with excessive RAAS inhibition.

There are currently no domain-selective ACE inhibitors commercially available. However, several domain-specific residues within the active site of each domain have been identified that are important for conferring domain selectivity. A number of experimental compounds with up to 3–4 orders of magnitude selectivity for one domain over the other have been identified (Dive et al. 1999; Watermeyer et al. 2008, 2010; Kröger et al. 2009; Douglas et al. 2014). In particular, a cACE-selective ACE inhibitor, lisinopril-tryptophan (Lis-W) reduces blood pressure and Ang II levels similarly to a conventional ACE inhibitor without increasing bradykinin levels in a hypertensive mouse model (Burger et al. 2014). Moreover, nACE-selective phosphinic-based inhibitors RXP407 (Dive et al. 1999) and 33RE (Douglas et al. 2014), and cACE inhibitors RXPA380 (Georgiadis et al. 2004) and carboxylate and ketone derivatives have proved to be invaluable in elucidating the molecular basis of the selectivity of nACE and cACE. The phosphinic peptides RXP407 and RXPA380 are good starting points for further development, but are not suitable for use as pharmacological lead compounds due to their poor pharmacokinetic profiles. These compounds (delivered as a single IV dose in rats) are rapidly cleared, unchanged, via renal excretion, probably because of their highly polar nature. Compounds with similar pharmacological profiles, but substantially improved PK properties, are required to deliver the benefits of a domain-selective ACE inhibitor.

Dual ACE/NEP or Vasopeptidase Inhibitors

Maximal suppression of the RAAS by ACE inhibitors and ARBs does not always lead to adequate reduction in blood pressure, and thus extensive efforts have gone into developing vasopeptidase inhibitors that target multiple structurally related peptidases within the different vasoactive systems controlling blood pressure and cardiovascular function. The natriuretic peptide system is an important peptide hormone system that influences blood pressure, fluid and electrolyte homeostasis, renal function, and cardiovascular function. Natriuretic peptides (NPs) comprise atrial, brain, and C-type natriuretic peptides (ANP, BNP, and CNP, respectively), which principally mediate natriuretic, diuretic, vasorelaxant, and antimitogenic responses largely directed to reduce blood

pressure and maintain fluid volume homeostasis (reviewed by Pandey (2005)). With the discovery and elucidation of the actions of NEP and its inhibitors, both the similarities and differences between the RAAS and the NP system have become clearer. The greater efficacy of dual ACE and NEP inhibitor therapy was initially confirmed in animal models of heart failure and cardiomyopathy, followed by the development of orally active molecules that inhibited both ACE and NEP, i.e., dual inhibitors (Fournie-Zaluski et al. 1994). The structural similarity between ACE, NEP, and endothelin converting enzyme (ECE-1) and their overlapping substrate specificity enabled the development of single molecules that target two or even three of these enzymes. Remarkably, the design of current-generation ACE inhibitors as well as vasopeptidase inhibitors that have entered clinical trials to date has been achieved with limited knowledge of the sequences and three-dimensional structures of the enzymes. Early dual inhibitors were designed rationally based on specific ACE and NEP inhibitors. Combining a P1′ benzyl group, known to be important for NEP inhibition, with a P2′ proline group, as seen in the first ACE inhibitors such as captopril, led to a series of potent mercaptoacyl dipeptides with dual inhibitory activity. Further structure–activity relationships (SAR) to optimize for in vivo activity led to conformationally restricted dipeptide mimetics and, eventually, to the development of omapatrilat. The dual ACE/NEP inhibitors were the first vasopeptidase inhibitors to enter clinical trials. They were developed to simultaneously block the ACE-mediated formation of the vasoconstrictor Ang II and the NEP-mediated degradation of vasodilator natriuretic peptides. Of the dual natriuretic peptides tested in the clinic, omapatrilat progressed the furthest but eventually failed to obtain approval after large stage III clinical trials due to an increased risk of vasodilator-mediated adverse effects. In the OVERTURE (Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events) trial, comparison of omapatrilat with enalapril in 5,770 patients with heart failure failed to show any superiority of omapatrilat in the primary endpoint (all cause mortality or hospitalization for heart failure) (Packer et al. 2002). Moreover, angioedema, which can obstruct the upper airways, occurred more frequently with omapatrilat (0.8%) than with enalapril (0.5%). In order to obtain a clearer understanding of the frequency of this complication, and, in particular, to compare omapatrilat with an ACE inhibitor, enalapril, the OCTAVE (Omapatrilat Cardiovascular Treatment vs. Enalapril) trial was conducted in 25,302 hypertensive subjects. As expected, omapatrilat was superior to enalapril in reducing blood pressure. However, the incidence of angioedema was again significantly higher and more severe in the subjects treated with omapatrilat (2.17%) than in those receiving lisinopril (0.68%). Based on observations of increased angioedema in the OCTAVE trial, efforts to gain approval for omapatrilat, and further clinical research on the entire class of vasopeptidase inhibitors were halted.

Despite decades of research on structure–function relationships on peptidases that metabolize vasoactive peptides, in preclinical models of cardiovascular diseases, and in clinical research, significant uncertainties remain regarding the physiology and pathophysiology of vasoactive peptide systems and their effect on cardiovascular function and diseases. It may be unnecessary to leave both nACE and NEP free to degrade bradykinin and other vasodilatory peptides. Since ACE is the primary bradykinin-metabolizing enzyme, nACE may compensate sufficiently for cACE in preventing the buildup of dangerous levels of bradykinin. Consequently, dual cACE–selective/NEP inhibitors are likely to offer a promising alternative for the treatment of hypertension and cardiovascular disease by potentiating natriuretic peptide levels in addition to blocking Ang II formation. Important insights from the crystal structures of cACE and NEP in complex with different inhibitors (Sharma et al. 2020) pave the way for the development of new leads with similar efficacy to omapatrilat, but with improved side effect profiles.

Acid-Sensing Ion Channels

Silke Haerteis[1] and Stephan Kellenberger[2]
[1]Institute for Molecular and Cellular Anatomy, University of Regensburg, Regensburg, Germany
[2]Department of Biomedical Sciences, University of Lausanne, Lausanne, Switzerland

Definition

Acid-sensing ion channels (ASICs) are non-voltage-gated sodium channels transiently activated by extracellular protons, selective for sodium, and belong to the epithelial sodium channel (ENaC)/degenerin (DEG) family of ion channels. The members of this ion channel superfamily share a similar topology with short intracellular amino and carboxy termini and two membrane-spanning domains connected by a large extracellular domain. The ASIC ion channel group consists of four genes encoding at least six ASIC subunits including 1a, 1b, 2a, 2b, 3, and 4.

Basic Characteristics

Channel family, structural organization and function

Channel Family

The ENaC/DEG superfamily of cation channels encompasses more than 60 members including the ASICs (Wemmie et al. 2006, 2013; Kellenberger and Schild 2015, 2002; Stockand et al. 2008). ASICs have been cloned in the mid-1990s based on sequence homology to ENaC and DEGs. Extracellular acidification opens ASICs only transiently, because of rapid desensitization, indicating that ASICs can exist in the three functional states closed, open, and desensitized (Waldmann et al. 1997; Carattino 2011; Kellenberger and Schild 2015) (Fig. 1c). ASICs are expressed in all vertebrates and responsible for acid-evoked currents in many neurons of the nervous system.

Structural Organization

The ASIC group consists of four ASIC genes resulting in six isoforms in rodents, termed ASIC1a, ASIC1b, ASIC2a, ASIC2b, ASIC3 and ASIC4 with a length of 500 to 560 amino acids (Kellenberger and Schild 2015). The members of ENaC/DEG superfamily share the same topology characterized by a large extracellular domain (~370 amino acids), short intracellular amino and carboxy termini (~35 to 90 amino acids), and two transmembrane regions (~20 amino acids). Individual ASIC subunits assemble to form homo- or heterotrimeric channels, except for ASIC2b and ASIC4. ASIC2b is not functional as homomeric channel, but forms functional

heteromeric channels together with other ASIC subunits. So far, no role for ASIC4 in homo- or heteromeric channels has been observed. In 2007, Jasti et al. described the first crystal structure of one of the ASIC proteins, the chicken ASIC1a channel (Jasti et al. 2007) which shares 90% sequence identity with human ASIC1a. This structure showed that the channel is formed by three subunits. The shape of the single subunit was compared to that of a hand, and sub-domains were named accordingly (Fig. 1a). Subsequently, structures obtained from chicken ASIC1a representing likely the closed and the toxin-opened conformation were published (Baconguis et al. 2014; Yoder et al. 2018).

Basic Functional Properties

ASICs are transiently activated by a rapid drop in extracellular pH (Fig. 1b). Protons are the main physiological activators of ASICs. As mentioned above, ASICs exist in three different functional states termed closed, open, and desensitized (Fig. 1c). The transient peak current lasts hundreds of milliseconds and is terminated by desensitization. In ASIC3 and some heteromeric ASICs, the desensitization is not complete and allows a small sustained current. Return to physiological pH 7.4 brings the channel into the closed state, allowing subsequent activation by protons. The molecular details of the activation of ASICs are currently not completely understood. Several studies indicate that protonation events close to

The subdomains are color-coded in one subunit and labeled. (**b**) Typical ASIC1a current trace, obtained with two-electrode voltage-clamp to −60 mV of a *Xenopus* oocytes expressing ASIC1a. The extracellular pH was changed as indicated on the top of the Fig. (**c**) Kinetic scheme of ASIC function. Upon a pH change from 7.4 to 5.0, the channels pass from the closed to the open and then into the desensitized state. (**d**) pH – current response curve of ASIC1a. The normalized current amplitude is plotted as a function of the pH

the thumb (the "acidic pocket"), in the palm, and in the extracellular pore entry contribute to pore opening (see Kellenberger and Schild 2015).

ASIC1a opens at pH 7.0 and reaches its half-maximal activation (pH_{50}) at pH 6.2–6.6 (Fig. 1d). The pH_{50} values of other ASICs are 5.9–6.3 (ASIC1b), 4.0–4.9 (ASIC2a), and 6.4–6.7 (ASIC3) (Waldmann et al. 1999; Wemmie et al. 2013; Kellenberger and Schild 2015). Many endogenous and exogenous compounds were shown to modulate ASIC function (reviewed in Wemmie et al. 2013; Kellenberger and Schild 2015), as discussed below.

Physiological Roles

ASICs are expressed in all vertebrates; even organisms with rudimentary nervous system have been shown to express at least one of the ASICs. ASICs contribute to acid-evoked currents in many neurons of both the central and peripheral nervous systems (CNS and PNS). ASIC1a, ASIC2a, and ASIC2b are expressed throughout the CNS and PNS (Wemmie et al. 2013; Kellenberger and Schild 2015). In the CNS, ASIC1a, ASIC2a, and ASIC2b show their highest expression in the hippocampus, the cortex, the cerebellum, the olfactory bulb, and the amygdala. ASIC1b and ASIC3 expression is restricted to the PNS (Wemmie et al. 2013). ASIC3 is most abundant in dorsal root ganglia. So far, ASIC4 has not been found in the PNS and shows a more dispersed expression compared to other ASICs in the CNS (rev. in Kellenberger and Schild 2015; Wemmie et al. 2013).

Local pH changes affect the function of almost any protein, including ion channels, and influence therefore many cellular processes. The release of the content of the synaptic vesicles that are acidic leads to a rapid lowering of the pH in the synaptic cleft. Tissue acidification occurs in situations such as inflammation or ischemia (rev. in Boscardin et al. 2016).

The activation of ASICs allows Na^+ entry into neurons, inducing depolarization of the neuronal membrane, generating action potentials, and, thus, exciting the neurons. The physiological and pathological roles of ASICs, demonstrated with mouse models deficient of specific ASIC isoforms or with pharmacological approaches using small molecule inhibitors or ASIC-specific toxins, include fear conditioning and anxiety, retinal function, neurodegeneration after ischemic stroke, synaptic plasticity, learning, and memory (Wemmie et al. 2013; Kellenberger and Schild 2015). In addition, studies with mice and rats showed evidence for a role of ASICs in the PNS (mostly ASIC3) and of ASICs of the CNS (mostly ASIC1a) in the sensation of different forms of pain. ASICs also have been proposed to play a role in mechanosensation. While such a role has been demonstrated on the level of the animal, it has so far not been possible to directly show activation of ASICs by mechanical stimuli in cell systems, suggesting that ASICs are part of a mechanotransduction complex that may not be intact in dissociated cells (rev. in Wemmie et al. 2013 and Kellenberger and Schild 2015).

ASIC Regulators

Ions and Polyamines

The activity of ASICs can be modulated by both divalent and trivalent metal ions, including Ni^{2+}, Cu^{2+}, Ca^{2+}, and Zn^{2+} ions (rev. in Wemmie et al. 2013; Kellenberger and Schild 2015). Ca^{2+} functions as allosteric modulator of ASIC pH dependence, likely by competing with protons for binding sites, and as a channel blocker (Paukert et al. 2004; Babini et al. 2002).

Depending on the ASIC type of channel, Zn^{2+} can potentiate or inhibit the channel. Zn^{2+} has been reported to potentiate proton-induced currents mediated by homomeric ASIC2a and heteromeric ASIC2a-containing channels at micromolar concentrations. In contrast, ASIC1a, ASIC1b, and ASIC3 are inhibited by Zn^{2+}; nanomolar concentrations inhibit homomeric ASIC1a channels, whereas ASIC1b and ASIC3 are only inhibited by micromolar concentrations of Zn^{2+} (rev. in Wemmie et al. 2013; Kellenberger and Schild 2015; Baron and Lingueglia 2015).

The endogenous polyamine spermine modulates proton-evoked ASIC1- and ASIC1a/ASIC2a-mediated currents (Babini et al. 2002; Baron and Lingueglia 2015).

Neuropeptides

FANaC, a member of the ENaC/DEG ion channel family, is activated by the neuropeptide FMRFamide (Phe-Met-Arg-Phe amide). FMRFamide has also been shown to modulate the function of ASIC1 and ASIC3 by potentiating their responses to acidification. The action on ASICs of FMRFamide and related neuropeptides involves amino acid residues in the palm and a linker between the palm and the thumb (Vick and Askwith 2015; Bargeton et al. 2019). FMRFamide and related neuropeptides increase ASIC activity in several ways, including an acidic shift of the pH dependence of desensitization, a slowing of the current decay, and the generation of a sustained current (Fig. 2).

Proteases

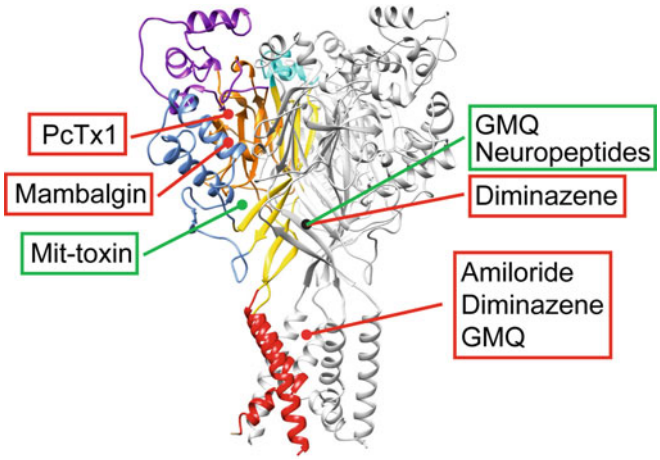
Channel regulation by different types of proteases (mainly serine proteases) is a topic that has been intensively described for the ENaC. There is also evidence for proteolytic regulation of ASICs. The serine proteases trypsin and matriptase led to an acidic shift of the pH dependence of the peak current of ASIC1a, but not ASIC1b. Furthermore, proteolytic cleavage of ASIC1a, but not ASIC2a, by tissue kallikrein was reported (Su et al. 2011). The relevant protease cleavage sites involved in this process are located in the finger domain of ASIC1a for trypsin and matriptase (Vukicevic et al. 2006; Clark et al. 2010), similar to the cleavage sites in α and γENaC. This points to a regulatory role of the finger domain for ASIC activity.

Protein Kinases

The activation of the tropomyosin-related kinase B (TrkB) has been shown to increase ASIC1a activity and its surface expression via the phosphatidylinositol 3-kinase (PI3-K)/protein kinase B (PKB or Akt) pathway. Moreover, the regulation of ASIC function by other protein kinases has been described in many studies (discussed in Wemmie et al. 2013; Kellenberger and Schild 2015).

Amphiphilic Substances

Bile acids have been shown to activate two members of the ENaC/DEG family of ion channels, the bile acid-sensitive ion channel (BASIC) and ENaC. It is conceivable that bile acids may play a role in ASIC regulation under physiological and pathophysiological conditions as increased ASIC activity in sensory neurons of the gastrointestinal tract may contribute to hyperalgesia and colonic hypersensitivity observed in patients with irritable bowel syndrome with increased bile acid concentrations in their gut. Indeed, it was reported that the function of ASIC1a heterologously expressed in *Xenopus laevis* oocytes is modulated by bile acids and also other amphiphilic substances like the detergent maltoside (Ilyaskin et al. 2017). In the presence of these bile acids, the whole-cell currents elicited by acidic pH were significantly



Acid-Sensing Ion Channels, Fig. 2 Sites of drug action. The figure shows the sites of action of toxins and small molecules that inhibit or modulate ASICs. Green lines mark positive modulation, while red lines indicate inhibition. Note that for mit-toxin, the interaction region with ASIC is larger than indicated and stretches over the whole thumb and up to the finger

increased. Molecular docking predicted binding of bile acids to the pore region near the DEG site (G433) in the open conformation of the channel.

Lipids

ASIC function can also be regulated by lipids, e.g., arachidonic acid (AA) (Kellenberger and Schild 2015). It has been proposed that AA acts directly on ASICs to increase channel activity. Recently it has been shown that AA together with the endogenous lipid lysophosphatidylcholine can activate ASIC3 in the absence of any extracellular acidification (Marra et al. 2016).

GMQ and Related Compounds

The synthetic compound 2-guanidine-4-methylquinazoline (GMQ) is an exogenous modulator of ASICs. GMQ has been described as first non-proton activator of ASICs that depends on extracellular Ca^{2+} and exclusively activates ASIC3 (Yu et al. 2010). Subsequent studies showed that GMQ affects the pH dependence of not only ASIC3 but also ASIC1a, ASIC1b, and ASIC2a, leading to activation of ASIC3, and a decrease of the H^+-activated current amplitude of other ASICs (Alijevic and Kellenberger 2012). Based on their structural similarity with GMQ, two natural polyamines, the arginine metabolite agmatine and its analog arcaine, have been proposed to be endogenous non-proton ligands for ASIC3. These two compounds lead to ASIC3 activation similar to GMQ however to a smaller extent. Agmatine also activated heteromeric ASIC3/ASIC1b channels, extending its potential physiological relevance (rev. in Kellenberger and Schild 2015; Baron and Lingueglia 2015).

Drugs

Toxins

Several peptide toxins have been identified that bind to ASICs with nano- or micromolar affinity and act as gating modifiers, inhibitors, or activators. The most important known ASIC toxins comprise psalmotoxin1 (PcTx1) from the venom of the spider *Psalmopoeus cambridgei*, Hi1a of the Australian funnel-web spider *Hadronyche infensa*, APETx2 of the sea anemone *Anthopleura elegantissima*, mambalgin of the black mamba (*Dendroaspis polylepis polylepis*), and mit-toxin of the Texas coral snake (*Micrurus tener tener*) (Baron and Lingueglia 2015; Chassagnon et al. 2017). These are peptide toxins composed of ≥40 amino acid residues. PcTx1 and Hi1a are structurally related, with Hi1a containing two tandem PcTx1-like sequences. From co-crystallization and mutagenesis studies, it is known that mit-toxin, PcTx1, and mambalgin bind to the thumb – acidic pocket region of ASIC1a (rev. in Kellenberger and Schild 2015; Baron and Lingueglia 2015). Mit-toxin activates ASIC1a, ASIC1b, and ASIC3 and potentiates ASIC2a opening by protons. PcTx1 inhibits mostly ASIC1a homomers, and mambalgin inhibits ASIC1a and ASIC1b homomers and ASIC1a-containing heteromers, while APETx2 inhibits ASIC3 homomers and ASIC3-containing heteromers. Except for APETx2, which inhibits besides ASICs also voltage-gated Na^+ channels (Peigneur et al. 2012; Blanchard et al. 2012), these toxins appear to be specific for ASICs. PcTx1 and mambalgin exert their inhibition by changing the pH dependence of ASICs. PcTx1 shifts the pH dependence of desensitization to more alkaline values, leading to desensitization of ASIC1a at physiological pH and preventing channel opening by subsequent acidification. Mambalgin shifts the pH dependence of activation to more acidic values, thereby leading to a smaller response to acidification. In contrast, the effects of Hi1a and APETx2 appear to be pH-independent. The ASIC toxins have been instrumental in defining some functional roles of ASICs in animal studies (Wemmie et al. 2013).

Small Molecule Inhibitors

Currently there are no ASIC-selective, high affinity small molecule inhibitors available. Amiloride and its derivative benzamil are pore blockers of ENaC/DEG channels. While amiloride inhibits ENaC with an IC_{50} of ~100 nM, its IC_{50} of ASIC peak currents is ≥10 μM, and it does not inhibit sustained ASIC currents. At concentrations ≥10 μM, amiloride also inhibits several transporters (Wemmie et al. 2013; Kellenberger

and Schild 2015). In spite of these limitations, amiloride has been used in experimental studies in humans. A-317567 inhibits the transient and sustained ASIC current fractions in dorsal root ganglion neurons with an IC_{50} of 2–10 μM and was shown to be more potent in treating pain than amiloride in animal models (rev. in Kellenberger and Schild 2015; Baron and Lingueglia 2015). Nafamostat mesylate is a synthetic protease inhibitor with potential use as anticoagulant or antitumor agent. It has been shown to inhibit ASIC currents, including the sustained current component of ASIC3, with IC_{50} values of 2–70 μM (rev. in Kellenberger and Schild 2015; Baron and Lingueglia 2015). The analysis of a number of anti-protozoal diarylamidines identified several compounds that inhibit ASICs with IC_{50} values of 0.3–40 μM. Among these, diminazene was further characterized in several studies and shown to inhibit ASICs in part by a pore block (Schmidt et al. 2017). Diminazene inhibits the related BASIC channel with similar affinity. Several nonsteroidal anti-inflammatory drugs (NSAIDs) were shown to inhibit ASICs, with IC_{50} values in the micromolar range, requiring thus much higher concentrations than clinically used. ASIC mRNA levels in sensory neurons are upregulated in inflammation. Interestingly, several NSAIDs, including aspirin, diclofenac, and ibuprofen, prevented this upregulation at therapeutic doses (Voilley et al. 2001). There have been several attempts in developing more specific and potent ASIC inhibitors, resulting in the identification of inhibitors with sub-micromolar affinities (reviewed in Kellenberger and Schild 2015; Baron and Lingueglia 2015; Rash 2017). However, so far, these compounds have not been further developed.

Adaptor Proteins

Andrew C. Hedman and David B. Sacks
Department of Laboratory Medicine, National Institutes of Health, Bethesda, MD, USA

Synonyms

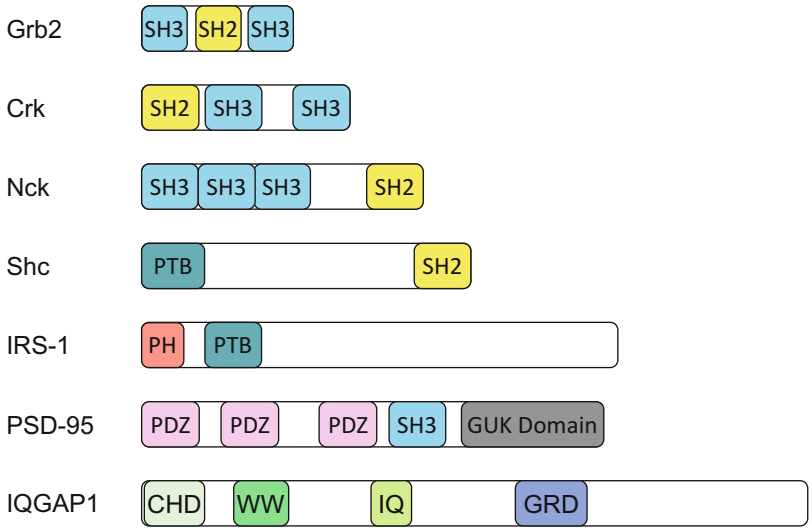
Anchoring protein; Docking protein; Scaffold

Definition

Adaptor proteins are multi-domain proteins (Fig. 1) that interact with components of signaling pathways. As a consequence of these interactions, adaptor proteins are able to regulate signaling events within the cell, providing spatiotemporal control and specificity and influencing how a cell responds to a particular stimulus.

Basic Mechanisms

Adaptor proteins function by simultaneously interacting with multiple components of a signaling pathway (Fig. 2). In order to be able to bind to more than one target protein at the same time, adaptor proteins contain at least two specific protein-protein interaction domains. These domains recognize specific motifs in the target proteins and can act



Adaptor Proteins, Fig. 1 Adaptor protein domains. A scheme of the domain structures of some well-characterized adaptor proteins is shown. Descriptions of domain characteristics are in main text except GUK domain, guanylate **kinase** domain; CHD, calponin homology domain; IQ, isoleucine/glutamine (IQ) domain; GRD, GAP-related domain. For clarity, not all domains contained within these proteins are shown

completely independently, like beads on a string, or interact with another domain within the same molecule. Such intramolecular interactions can regulate the ability of each domain to bind to its target (Pawson 2007).

Adaptor Protein Function

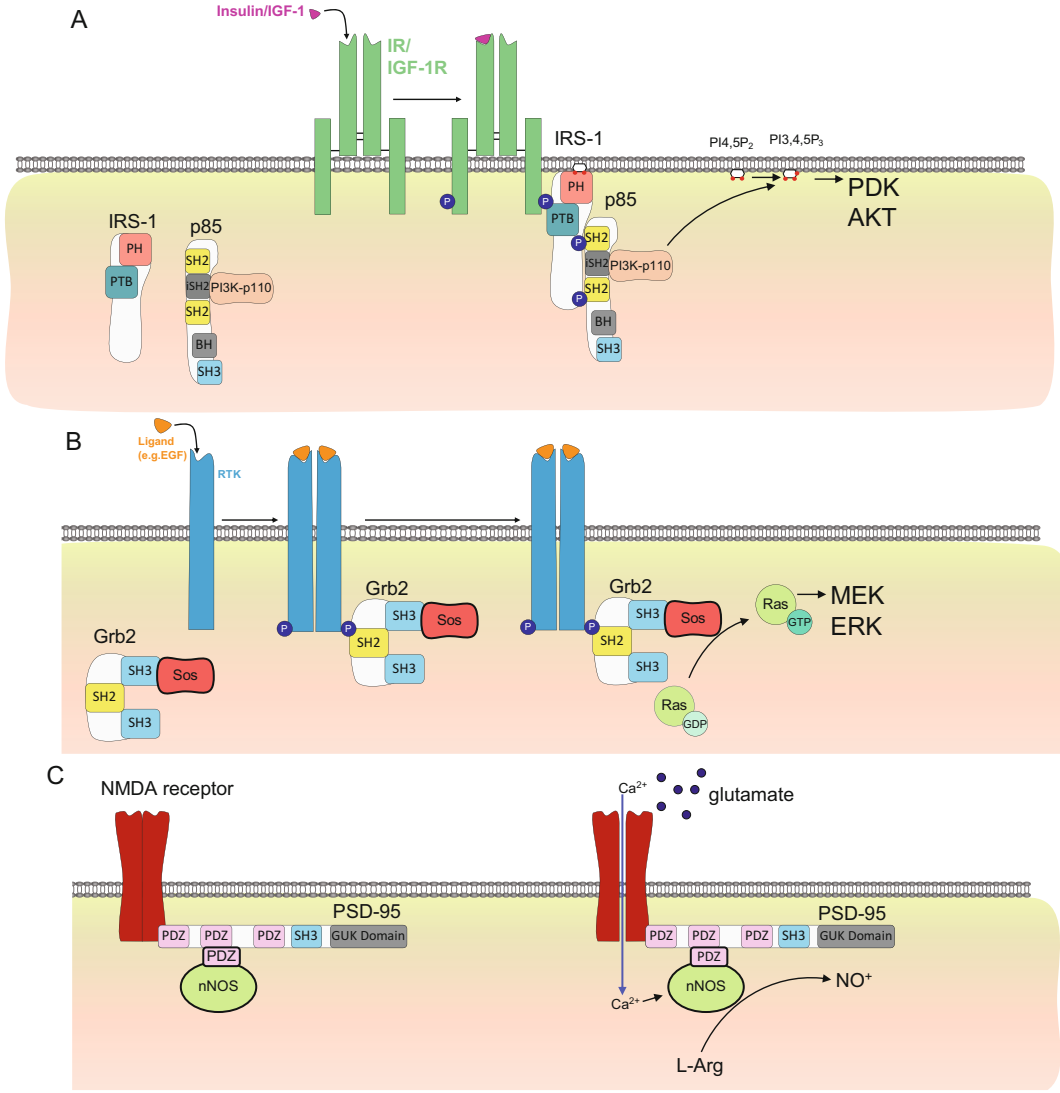
In their simplest form, adaptor proteins perform a straightforward function: the formation of multiprotein complexes. However, they often provide more than a static scaffold support for signaling components, instead enabling dynamic regulation to control propagation of pathways and networks. Consequently, adaptor proteins can act as signaling modules, directing propagation of the pathway, influencing downstream events, and even modifying the cellular response to a specific stimulus. Some of the different roles of adaptor proteins are described below. These functions are not mutually exclusive, and more than one of these roles can be performed by a particular adaptor protein at one time.

Assembly of Signaling Complexes

This is perhaps the simplest function provided by adaptor proteins and involves bringing together individual components of a pathway. These complexes promote propagation, and often amplification, of the signal. Examples of this are found in the **MAP kinase** pathway, where the adaptor proteins IQGAP1 and kinase suppressor of Ras-1 (KSR-1) bind to multiple **kinases**. Consequently, they enable efficient signaling from one **kinase** to the next (Brown and Sacks 2009; Langeberg and Scott 2015).

Spatial Regulation

Adaptor proteins can assemble the complexes in particular subcellular compartments. For example, following activation of a ligand-bound receptor, adaptor proteins can localize downstream signaling targets to the intracellular domains of the receptor (Fig. 2a, b), thereby facilitating propagation of the signal through the cell. Note that signaling events occur in all cell organelles and subcellular compartments and adaptor proteins appear to function throughout the cell. Through their ability to localize signaling targets to specific subcellular compartments, adaptor proteins not only facilitate signaling events but also influence how these signals are interpreted by the cell and consequently the cellular response. For example, in the **MAP kinase** pathway, signaling from the plasma membrane activates different signaling components to those activated when the signal originates from the Golgi (Brown and Sacks 2009).



Adaptor Proteins, Fig. 2 Examples of adaptor protein function. Selected examples of how adaptor proteins facilitate signaling are shown. (**a**) The insulin receptor contains an intrinsic tyrosine **kinase**. Following stimulation by insulin binding, the intracellular domains of the transmembrane receptor autophosphorylate (P) on key tyrosine residues. The adaptor protein IRS-1 contains a PH domain and PTB domain that recruit IRS-1 to the activated receptors. The receptor then catalyzes tyrosine phosphorylation of IRS-1 on its C-tail. These phosphorylated tyrosines are recognized by proteins containing **SH2** domains, such as the p85 regulatory subunit of phosphatidylinositol 3-**kinase** (PI3K). PI3K signaling can then generate lipid signals through the PDK-1 and AKT kinases to promote cell survival. (**b**) Analogous to the insulin receptor, many growth factor receptors contain an intrinsic tyrosine kinase that catalyzes receptor autophosphorylation. The **SH2** domain of the adaptor protein **Grb-2** associates with the phosphorylated tyrosine residues on the receptor, while the SH3 domain binds to the **Ras** activator **Sos**. Consequently, **Sos** is localized to the receptor at the plasma membrane where it activates the small GTPase **Ras**, which results in activation of the **mitogen-activated protein (MAP) kinase** cascade. By this mechanism, **Grb-2** facilitates the transduction of an extracellular stimulus to an intracellular signaling pathway. (**c**) The adaptor protein **PSD-95** associates through one of its three **PDZ** domains with the N-methyl-D-aspartic acid (NMDA) receptor. Another **PDZ** domain associates with a **PDZ** domain from neuronal nitric oxide synthase (nNOS). Through its interaction with **PSD-95**, nNOS is localized to the NMDA receptor. Stimulation of the NMDA receptor by glutamate induces an influx of calcium, which activates nNOS, resulting in the production of nitric oxide

Temporal Regulation

The duration of signaling influences how a cell responds to a particular stimulus. For example, brief activation of the **MAP kinase** cascade in the neuronal cell line, PC12, results in proliferation, while sustained **MAP kinase** signaling promotes differentiation of PC12 cells. Adaptor proteins are able to regulate the time course of signaling events and therefore the cellular outcome (Brown and Sacks 2009).

Activation of Signaling Components

The binding of an adaptor protein may activate the target molecule. An example of this is the adaptor protein insulin receptor substrate-1 (IRS-1), which is activated during insulin signaling. Following binding by insulin, the insulin receptor (which contains an intrinsic tyrosine kinase) catalyzes receptor autophosphorylation. The phosphotyrosine residues on the receptor are recognized by the PTB domain of IRS-1, and the activated receptor catalyzes phosphorylation of selected tyrosine residues on IRS-1 (Fig. 2a). A subset of these phosphorylated tyrosines act as docking sites for SH2 (see below) domains on p85, the regulatory subunit of phosphoinositide 3-**kinase (PI3K)**. As a consequence of the interaction between IRS-1 and p85, phosphoinositide 3-**kinase** is activated.

Inactivation of Kinases

A-kinase anchoring proteins (AKAP) are a well-studied class of adaptor proteins that regulate protein kinase A (PKA) signaling. PKA is activated in response to cyclic-adenosine monophosphate (cAMP). **AKAP**s provide spatiotemporal specificity for PKA activity by forming multi-protein complexes and localizing them to the appropriate subcellular compartment. These complexes contain kinases and phosphatases, as well as phosphodiesterases, which catalyze the hydrolysis of cAMP to AMP. Therefore **AKAPs** anchor both positive and negative regulators of PKA signaling (Langeberg and Scott 2015).

Sequestering Signaling Components

Specificity in signal transduction is also achieved by selective separation of signaling components. By associating with specific proteins and bringing them together, adaptor proteins can determine how the pathway propagates through the cell. This is important for **Ras** signaling, for example. **Ras**, which can be activated in response to numerous growth factors and signaling cues, regulates multiple pathways. Therefore, by sequestering specific proteins, adaptor proteins ensure that a particular stimulus activates only the appropriate pathway(s). Sequestration of proteins also enables adaptor proteins to negatively regulate signaling. An example of this can be found in T-cell activation. The adaptor protein, c-Cbl, sequesters the tyrosine **kinase**, Syk, preventing recruitment to IgE receptors. Consequently, T-cell activation is attenuated.

Domains

In order to bind to target proteins, adaptor proteins contain protein-protein interaction domains which recognize specific target motifs (Fig. 1). Through combinations of these domains, adaptor protein can interact with multiple target proteins, potentially forming large signaling complexes. While many different protein binding domains have been identified, adaptor proteins often utilize the well-characterized domains described below.

Src Homology 2 (SH2) and Src Homology 3 (SH3)

SH2 domains are common protein modules that recognize short motifs containing a tyrosine residue that has been phosphorylated by a tyrosine **kinase**. Other residues outside of this motif provide specificity to determine which **SH2** domain-containing protein associates with that particular site. **SH3** domains bind to polyproline motifs with the sequence PXXP. These two domains are often found independently in adaptor proteins such as **Src** homologous and collagen (Shc) and **PSD-95** (Fig. 1). However, the SH2/SH3 adaptors **Crk**, **Nck**, and **Grb-2** contain both **SH2** and **SH3** domains (Fig. 1). In these proteins, the **SH2** domain recognizes a binding motif in activated transmembrane receptors, while the **SH3** recognizes other signaling proteins, such as the **Ras** activator **Sos** (Fig. 2b). Consequently, these

proteins couple an activated receptor to signaling components downstream, thereby facilitating signal propagation.

Postsynaptic Density Protein/Drosophila Disk Large Tumor Suppressor/Zonula Occludens-1 Protein (PDZ)

PDZ domains bind to short peptide motifs at the C-terminal end of target proteins and are particularly important in spatial organization of receptors and ion channels. Many adaptor proteins contain multiple **PDZ** domains, which have important implications for their functions. By interacting with subunits from different receptors, adaptor proteins containing multiple **PDZ** domains can promote formation of homogenous receptor complexes. This clustering can be further enhanced through the ability of **PDZ** domains to self-associate, enabling oligomerization of the adaptor proteins. Conversely, individual **PDZ** domains can associate with different target proteins, enabling the formation of large heterogeneous complexes of proteins. Examples of **PDZ**-containing adaptor proteins include **PSD-95** (Fig. 1), **LIM kinase**, and membrane-associated guanylate kinases (MAGUKs) (Sugiura et al. 2011).

Phosphotyrosine Binding (PTB)

PTB domains recognize small peptides containing a phosphotyrosine, usually with the consensus sequence, NPXpY. Some **PTB**-containing proteins, such as Numb, are able to bind to the consensus peptide in the absence of phosphorylated tyrosine, suggesting phosphotyrosine is dispensable for the function of certain **PTB** domains. Hydrophobic residues N-terminal to the phosphotyrosine provide some specificity of target and distinction from **SH2** domains. **PTB** domains appear to be particularly important in docking proteins to activated receptors. Examples of **PTB**-containing proteins include Numb, IRS-1, and Shc (Fig. 1) (Wagner et al. 2013).

WW

WW domains (named after the one-letter abbreviation for the amino acid tryptophan) are small regions of around 30 residues, which, like **SH3** domains, bind to polyproline sequences. These sequences often contain the consensus sequence PPXY or PPLP. Examples of proteins that contain **WW** domains include the transcription coactivator YAP, Nedd4 E3 ubiquitin ligase, and IQGAP1 (Fig. 1).

Pleckstrin Homology (PH)

PH domains consist of about 120 amino acid residues. They do not interact with other proteins, but associate with specific phosphoinositides. Consequently, **PH** domains appear to be important for localizing target proteins to cellular membranes. Examples of **PH** domain-containing proteins include phospholipase C, IRS-1 (Fig. 1), and p120/RasGAP.

Regulation of Adaptor Proteins

The interactions between adaptor proteins and their targets are often regulated (see below). By these mechanisms, specific signals are able to control which adaptor proteins, and consequently which target proteins, are recruited to a particular signaling complex. Common methods of adaptor protein regulation are described here.

Phosphorylation

Phosphorylation is a common method of regulation. As described above, **SH2** domains bind to phosphorylated tyrosine residues. Conversely, phosphorylation of serines and threonines proximal to **SH3** and **PDZ** domains uncouples them from their target motifs. Therefore, modulation of protein **kinase** activity in cells regulates interactions between adaptor proteins and their target proteins.

Chemical Regulation

Cellular messengers, such as calcium, also regulate adaptor protein function. The adaptor protein IQGAP1 binds multiple members of the **MAP kinase** cascade, including B-Raf, MAPK/extracellular-regulated **kinase kinase** (MEK), and extracellular-regulated **kinase** (ERK). Binding of calcium to its effector, calmodulin, increases the association of calmodulin

with IQGAP1 and inhibits the interaction of IQGAP1 with B-Raf.

Intramolecular Interactions

Another way in which the function of adaptor proteins is regulated is through modulation of intramolecular interactions. Often one domain will bind to another domain in the same adaptor molecule, preventing further interactions with other proteins. An example of this is found in the adaptor protein, **Crk**. **Crk** contains an N-terminal **SH2** domain, followed by two **SH3** domains (Fig. 1). The **SH3** domains are separated by a linker region containing a tyrosine residue. When Crk is phosphorylated by a tyrosine **kinase**, such as Abl, the intrinsic **SH2** domain binds to the phosphotyrosine, attenuating **Crk** signaling activity (Kumar et al. 2014).

Conformational Changes

Changing the conformation of adaptor proteins can also alter their function. p130Cas, which is a target for **Src kinase**, serves as an example. The central region of p130Cas contains multiple **Src** phosphorylation sites that, when phosphorylated, promote the binding and recruitment of other targets proteins. Under resting conditions, these phosphorylation sites are hidden due to the folded conformation of p130Cas. When mechanical stress is applied to the cell, this central region is stretched exposing the **Src** phosphorylation sites. This alteration in conformation results in increased phosphorylation of p130Cas and recruitment of the adaptor protein **Crk**II, leading to activation of the Ras family GTPase, Rap1.

Pharmacological Intervention

Adaptor proteins are attractive targets for the design of new therapies for diseases in which signaling pathways are deregulated. For example, many cancers and inflammatory disorders display hyperactive **MAP kinase** signaling. This may be due to increased growth factor/cytokine stimulation or increased intracellular **kinase** activity. Adaptor proteins play well-established roles in controlling **MAP kinase** activation and so provide a potential target for novel therapies. For example, **Grb-2** has been the focus of research to identify compounds which target either its **SH2** or **SH3** domains. The importance of **Grb-2** in the activation of **Ras**, and therefore stimulation of the **MAP kinase** pathway, suggests that compounds that inhibit **Grb-2** function could potentially be useful in the treatment of many cancers.

At present no compounds targeting adaptor proteins have been approved for clinical use.

Therapies for treatment of diseases caused by hyperactive intracellular signaling may utilize inhibitors targeted against a specific **kinase**. However, this approach has several problems, such as inhibition of other nontarget **kinases** and inhibition of signaling events not related to the disease. Consequently, the use of **kinase** inhibitors is not always effective and often produces side effects. However, as described above, adaptor proteins provide specificity to signaling pathways. Therefore, disrupting adaptor protein function may allow more specific targeting of the aberrant cellular response which contributes to the disease, such as cell proliferation or cytokine production. By selectively interfering with adaptor interactions, these agents are likely to have fewer side effects and increased efficacy.

Adenosine Receptors

Kenneth A. Jacobson
Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, USA

Synonyms

A receptors; Ado receptors; P1 receptors

Definition

Extracellular adenosine acts through a class of G protein-coupled receptors (GPCRs), defined across mammalian species as A_1, A_{2A}, A_{2B}, and A_3ARs (adenosine receptors). Adenosine has a cytoprotective and allostatic role in the body, both in the periphery and in the central nervous system. Following binding of adenosine, or another naturally occurring agonist, the receptor interacts with heterotrimeric G proteins and β-arrestin to stimulate or inhibit downstream signaling cascades, or to induce receptor desensitization.

Basic Characteristics

The purine nucleoside adenosine, as a natural local modulator of cell action, increases the ratio of oxygen supply to demand, suppresses excessive inflammation, and promotes tissue protection against apoptosis or ischemic damage. ARs also have effects on proliferation and differentiation. Nearly every cell type in the body expresses one or more of these receptors, indicating the fundamental nature of adenosine as a cytoprotective mediator. A study of a mouse line in which all four ARs were knocked out indicated that ARs are not generally required for homeostasis of an animal, rather for allostasis (Xiao et al. 2019). In the cardiovascular system, ARs present on myocardial, vascular, and inflammatory cells respond to the stress of ischemia and other damaging conditions. Adenosine has been termed a "retaliatory" metabolite of ATP, in that its extracellular level rises in response to excessive energy demand in relation to the available energy supply, i.e., utilization of intracellular ATP. Adenosine aids in correcting this imbalance between energy supply and demand by causing vasodilation, increasing vascular integrity and angiogenesis, and counteracting the lethal effects of prolonged ischemia on cardiac myocytes. In the brain, activation of the presynaptic A_1AR suppresses the acute release of excitatory neurotransmitters and counteracts excitotoxicity by both presynaptic and postsynaptic mechanisms. However, in the aging brain, A_{2A}AR antagonists have cerebroprotective properties (Canas et al. 2018).

The affinity and selectivity of nucleosides as adenosine agonists has been extensively explored, resulting in thousands of selective agonists, of which many are useful in pharmacological studies (Müller and Jacobson 2011). Selected agonists of A_1, A_{2A}, and A_3 ARs are shown in Fig. 1. Highly selective antagonists of A_1, A_{2A}, A_{2B}, and A_3 ARs have been reported both as research tools and as experimental therapeutic agents (Fig. 2) (Chen et al. 2013; Jacobson et al. 2019). Caffeine and other naturally occurring alkylxanthines act as nonselective competitive antagonists of adenosine with respect to at least three of the four subtypes of the ARs. In fact, antagonism of ARs is the most likely mechanism of action of ingested caffeine. These simple xanthine antagonists are of micromolar affinity, but these lead molecules have been optimized for affinity and selectivity. Library screening has pointed the way for the identification of a variety of chemically novel lead structures that have been optimized by medicinal chemists for affinity and selectivity as adenosine antagonists.

Sources of Adenosine, Its Transport Mechanisms, and Metabolism

Adenosine production increases upon stress to an organ or tissue, and it acts locally in autocrine or paracrine fashion. It is not a classical neurotransmitter, but it can be formed from ATP, which is released from synaptic vesicles. Most cells in culture and in situ produce and release adenosine and ATP extracellularly. These endogenous purines released tend to influence the outcome of pharmacological studies and can cause misleading results if not properly controlled. Depending on stress factors present, the levels of extracellular adenosine in a given tissue or organ may vary widely, leading to highly variable basal levels of stimulation of the ARs by endogenous adenosine. The level of adenosine may be as low as ~20 nM in the resting brain and as high as 100 μM in severe ischemic conditions. The half-life of adenosine in the blood is short (~1 sec), and the peripheral administration of adenosine has no effect on the extracellular concentration of adenosine in the brain. Both neuronal and glial cell function are regulated by adenosine.

One source of extracellular adenosine may be from inside the cell, where it is present in millimolar concentrations. As a hydrophilic small molecule, adenosine does not diffuse freely through the intact plasma membrane; rather, it may pass through an equilibrative transporter such as the ENT1 nucleoside transporter, for which there are well-characterized inhibitors, e.g., 30–32 (Fig. 1b) (Pastor-Anglada and Pérez-Torras 2018). Approved drug dipyridamole (structure not shown) acts in part by inhibiting adenosine uptake through ENTs. Levels of extracellular adenosine may also rise as a result of the enzymatic hydrolysis of extracellular adenine nucleotides or cell lysis. Nucleotide precursors of adenosine, notably ATP and ADP, have their own extracellular signaling properties that are mediated by P2 receptors. Ectonucleotidases, which are also ubiquitously expressed on the cell surface, but with characteristic distribution patterns, cleave adenine nucleoside 5′-phosphate derivatives (including activators of P2X and P2Y nucleotide receptors) to eventually form adenosine. There are many classes of ectonucleotidases; however, the most relevant species in the family of ectonucleoside triphosphate dihydrolases (E-NTPDases) that act to breakdown P2 agonists are apyrase or NTPDase1 (also known as ENTPD1 and CD39, which converts ATP and ADP to AMP) and NTPDase2 (also known as ENTPD2, which converts ATP to ADP). A separate enzyme, ecto-5′-nucleotidase (CD73), converts AMP to adenosine. CD73 is characteristically found on the surface of astrocytes but not neurons.

Unlike classical neurotransmitters, adenosine does not have a rapid synaptic uptake system (as for the biogenic amines), and its chemical inactivation system is not as rapid as for the transmitter acetylcholine, for example. Adenosine may be metabolized and inactivated with respect to the ARs in a more general fashion by the widespread enzymes adenosine kinase (AK, to produce AMP intracellularly) and adenosine deaminase (AD, to produce inosine both extracellularly and intracellularly). Inosine can weakly activate ARs, depending on the subtype (Xiao et al. 2019).

Inhibition of the metabolism of extracellular adenosine or its uptake proteins is being explored for therapeutic purposes. AK inhibitors have been proposed for the treatment of pain and seizures; however, the promising clinical development of these efficacious compounds was discontinued due to toxicity (Jarvis 2019).

Adenosine Receptors, Fig. 1 (continued) for A_1 receptors (3–11) or A_{2A} receptors (12–17). (**b**) Nucleoside derivatives that are selective for A_{2B}AR alone (18) or mixed with A_{2A}AR (19) or A_3 receptors (20–24). Indirect modulators of AR signaling, either allosteric enhancers (PAMs) or enzyme/transporter inhibitors are shown (25–32). Inhibitors of CD73, which forms adenosine extracellularly, are omitted

Signaling Pathways Coupled to ARs and AR Regulation

The four mammalian ARs are members of the rhodopsin-like Class A family of GPCRs, which contain seven transmembrane helical domains (TMs). Characteristics of the four subtypes of the human ARs, length of their primary sequences, their chromosomal localization, and their signaling pathways are given in Table 1. The A_{2A}AR is considerably longer than the other three subtypes, due to its extended carboxy-terminal.

Two AR subtypes, A_1 and A_3, couple through the α-subunit of G_i to inhibit adenylate cyclase, while the other two subtypes, A_{2A} and A_{2B}, stimulate adenylate cyclase through G_s or G_{olf} (for A_{2A}). The A_{2B}AR is also coupled to the activation of PLC through G_q. Furthermore, each of these receptors may couple through the β,γ subunits of the G proteins to other effector systems, including ion channels and phospholipases. Levels of intracellular calcium increase upon stimulation of ARs, which interact with other second messenger systems. ARs have been found to couple to mitogen-activated protein kinases (MAPKs) in a variety of

All of the ARs are found in the CNS and in many peripheral tissues, including immune cells. The A1AR is found in the brain (cortex, cerebellum, hippocampus), dorsal horn of the spinal cord, eye, adrenal gland, heart (atrium), skeletal muscle, liver, kidney, adipose tissue, salivary glands, esophagus, colon, antrum, and testis. The A2AAR is found in spleen, thymus, leukocytes (both lymphocytes and granulocytes), and blood platelets. In the brain it is restricted to the striatum, nucleus accumbens, olfactory tubercle, and large striatal cholinergic interneurons. The A2BAR is found in intestines, brain, spinal cord, lung, epididymis, vas deferens, and pituitary. The message for A3 is found in the lung and liver and to a lesser degree in the brain, aorta, testes, and heart

circumstances, leading to effects on differentiation, proliferation, and cell death.

Cross talk occurs between ARs and other receptors. For example, an otherwise subthreshold concentration of acetylcholine, as might be present in the Alzheimer's brain, still produces a strong calcium signal when the A_1 AR is costimulated. Cross talk occurs with the striatal dopamine receptor system, in which a direct physical association (dimerization) occurs between A_{2A} and D_2 dopamine receptors and between other subtypes (Canas et al. 2018). The A_1AR forms functional heterodimers with the $P2Y_1$ nucleotide receptor, which may be stimulated by $P2Y_1$ receptor agonists but is not blocked by $P2Y_1$ receptor antagonists.

Downregulation of ARs should be considered in pharmacological studies and in the development of agonists for therapeutic purposes. Responses of all four subtypes have been found to desensitize and downregulated the receptors. The most rapid downregulation in cells among the AR subtypes is generally seen with the A_3AR, but the action of A_3AR to reduce chronic neuropathic pain is maintained over days in rodent testing (Jacobson et al. 2019).

Selective Ligands and Indirect Modulators of Adenosine Signaling

The structure activity relationships (SAR) of numerous synthesized analogues of nucleosides, xanthine heterocycles, and nonxanthine heterocycles have been explored at the ARs (Figs. 1 and 2). Potent and selective AR antagonists have been prepared for all four subtypes (Müller and Jacobson 2011), and selective agonists are known for three subtypes (Jacobson et al. 2019). Thus, numerous pharmacological tools are available for in vitro and in vivo use (Table 2). Potent and selective A_{2B}AR agonists are yet to be reported, although several research groups have identified lead compounds.

Agonists

Medicinal chemists have extensively explored the SAR of adenosine derivatives as agonists of the ARs. Except for atypical adenosine agonists that are pyridine-3,5-dicarbonitrile derivatives, such as 10, 11, and 18, nearly all AR agonists have been purine nucleoside derivatives. In general, for the adenine moiety of adenosine, modifications at the N^6 position have led to selectivity for the A_1AR, and modifications at the 2 position, especially with ethers, secondary amines, and alkynes, have led to selectivity for the A_{2A}AR. Some N^6 derivatives are not selective for the A_1AR; for example, N^6-p-(2-aminophenyl)ethyladenosine (APNEA) and metrifudil (structures not shown) are relatively nonselective. 2-Chloroadenosine is a nonselective agonist that is subject to cellular uptake and nonreceptor-mediated effects. Commonly used A_1AR agonists that are N^6-cycloalkyl derivatives are the 2-chloro analogue CCPA 4 and Cl-ENBA 6, and recently reported MRS7469 5 has exceptionally high A_1AR selectivity. When using the human ARs, 5 and 6 are more highly A_1AR-selective than CCPA or its 2-H analogue CPA, although 6 is a mixture of diastereomers. The A_1AR agonist SPA 8 contains a sulfonate group, which tends to prevent passage across the blood–brain barrier. Nitro ester 7 was in unsuccessful clinical trials for glaucoma treatment.

The substitution at the 2 position may also lead to A_{2A}AR enhancing effects, which are further boosted with an uronamido substitution at the 5′ position of adenosine. When the 5′-N-alkyluronamide group alone is present, high affinity [at the A_{2A}AR but not selectivity] is typically observed, similar to the nonselective agonist NECA 2. By combination of this uronamide group with the appropriate 2 position substitution, selectivity may be achieved for the A_{2A}AR. For example, the 5′-N-ethyl derivatives CGS21680 13 and ATL-146e 14 are both selective in binding to the rat A_{2A}AR, but they are less selective at the human subtypes. CGS21680 crosses the blood–brain barrier to only a small degree. UK-432097 16, a drug originally proposed for COPD to be administered by inhalation, was cocrystallized with the human A_{2A}AR to obtain the first agonist-bound AR structure.

Several agonists are selective for the A_{2B}AR, known as the "low affinity" adenosine A_2 receptor. Nonadenosine ligand BAY 60–6583 is

selective for that subtype, but has variable reports of maximal efficacy, so it can be classified as a partial agonist. An adenosine derivative, the 2-(6-bromotryptophol) ether MRS3997 19, is a full agonist with mixed selectivity at A_{2A} and A_{2B}ARs.

The A_3 agonists Cl-IB-MECA 21 and its corresponding 2-H analogue IB-MECA 20 are widely used as selective agonists of the A_3AR, although even more selective agents are now known, including those in which the ribose-like ring has been conformationally locked in the receptor-preferring north conformation, such as MRS5698 22, MRS5841 23, and MRS5980 24 (Jacobson et al. 2019). MRS5841 contains a sulfonate group that prevents passage across biological barriers and has been used to distinguish peripheral and CNS A_3AR effects.

Antagonists

The classical AR antagonists are xanthines derivatives such as theophylline (33, 1,3- dimethylxanthine) and caffeine 34. The micromolar affinity of the naturally occurring antagonists has been greatly exceeded with the introduction of selective antagonists, even reaching subnanomolar affinity. For example, the A_1AR-selective antagonists DPCPX 39, KW3902 40, and PSB-36 41 are xanthine derivatives. The 8-cyclopentyl derivative DPCPX is highly A_1AR selective in the rat and less A_1AR selective among the human AR subtypes. DPCPX is an inverse agonist at the A_1AR, while the adenine derivatives are neutral antagonists. In general, modifications of the xanthine scaffold at the 8 position with aryl or cycloalkyl groups have led to selectivity for the A_1AR, although the water-soluble 8-sulfophenyl derivative SPT 36 is nonselective and xanthine amine congener (XAC, 35) is potent at all human ARs. Persistent problems in the use of xanthine derivatives as AR antagonists of the A_1AR are their low aqueous solubility and their interaction at the A_{2B}AR. Use of adenine derivatives, such as the inverse agonist WRC-0571 26 37, provides A_1AR-selective antagonists that have low affinity at the A_{2B}AR.

Modifications of xanthines at the 8 position with alkenes (specifically styryl groups) have led to selectivity for the A_{2A}AR. The 8-styrylxanthine derivatives KW6002 42, CSC 43, and MSX-2 44 and its prodrug derivatives 45 and 46 are moderately potent A_{2A}AR antagonists (Müller and Jacobson 2011). Some 8-styrylxanthine derivatives, especially CSC, have been discovered to inhibit monoamine oxidase-B as well. High selectivity of xanthines at the A_1, A_{2A}, and A_{2B} (e.g., MRS1754 54, its p-$COCH_3$ analogue MRS1706 55, and PSB-603 57) ARs has been achieved. Few xanthines are selective for the A_3AR; however, A_3AR antagonist PSB-11 66 contains an elaborated xanthine ring system.

Over several decades, an enormous diversity of heterocyclic structures has been reported as AR antagonists (Table 2) (Müller and Jacobson 2011). For example, the nonselective triazoloquinoline antagonist CGS15943 (structure not shown), first

introduced in the early 1990s, has given rise to numerous derivative compounds, including A_{2A}AR-selective antagonists (a triazolotriazine 49 and pyrazolo-triazolo-pyrimidines 51a and 51b), Preladenant 51a, and several other A_{2A}AR-selective antagonists which have been in clinical trials for Parkinson's disease (Müller and Jacobson 2011). SCH-442416 51b displays >23,000-fold selectivity for the human A_{2A}AR (K_i 0.048 nM) in comparison to human A_1AR and IC_{50} > 10 μM at the A_{2B} and A_3 ARs. Also, elaboration of an adenine scaffold has provided A_1AR-selective antagonists (37, 38) and A_{2A}AR-selective antagonists (48, 50, and 53) (Müller and Jacobson 2011). AB928 60 is an experimental cancer immunotherapy drug that is a mixed antagonist at A_{2A} and A_{2B}ARs.

Although the simple xanthine antagonists have not provided suitable analogues with A_3AR selectivity, a cyclization of the xanthine nucleus, leading to imidazopurinones 65 and 66. For A_3AR, most of the successful leads have come from chemically diverse heterocycles. The dihydropyridine derivatives MRS1191 61, its more potent nitro analogue MRS1334 62, and other heterocyclic scaffolds such as pyridylquinazolines have led to potent, selective A_3AR antagonists. There is a marked species dependence of antagonist affinity at the A_3AR. It is to be noted that many heterocyclic nonnucleoside A_3AR antagonists are potent in the human but are weak at the rat and mouse A_3ARs. Nevertheless, MRS1191 has been used successfully in murine species. MRS1220 42 is very potent and selective at the human A_3AR but not at the rat or the mouse receptor, at which it is A_{2A}AR selective. Commonly used A_3AR antagonists must be treated with caution in non-primate species. In general, one must be cognizant of potential species differences for both AR agonists and antagonists. The pyridine derivative MRS1523 67 is a moderately selective A_3AR antagonist for both the rat and human homologues.

Variations in the relative efficacy of nucleosides, depending on structure, have been noted. This is especially pronounced for the A_3AR, at which changes on the adenine moiety (N^6 and 2 positions) and ribose moiety can either reduce efficacy to the point of pure antagonism (i.e., combination of 2-Cl and N^6-(3-iodobenzyl)) or guarantee a robust, nearly full activation of the A_3AR (i.e., 5′-uronamide) (Canas et al. 2018). Such nucleoside-derived A_3AR antagonists tend to have selectivity that is more general across species.

Radioligands

Radioligands commonly used for the ARs are nonselective agonist [^{3}H]NECA 2, A_1 agonist [^{3}H]CCPA 4, antagonist [^{3}H]DPCPX 39, A_{2A} agonist [^{3}H]CGS21680 13, antagonist [^{3}H]ZM241385 49, A_3 agonist [^{125}I]I-AB-MECA (the N^6-(4-amino-3-iodobenzyl) 2-H analogue of 20), and antagonist [^{3}H]PSB-11 66. Ligands for in vivo positron emission tomographic (PET) imaging of A_1 and A_{2A}ARs have been developed (Müller and Jacobson 2011). Potent fluorescent ligands have been reported for all four AR subtypes and have been used in chemical library screening to discover novel antagonists.

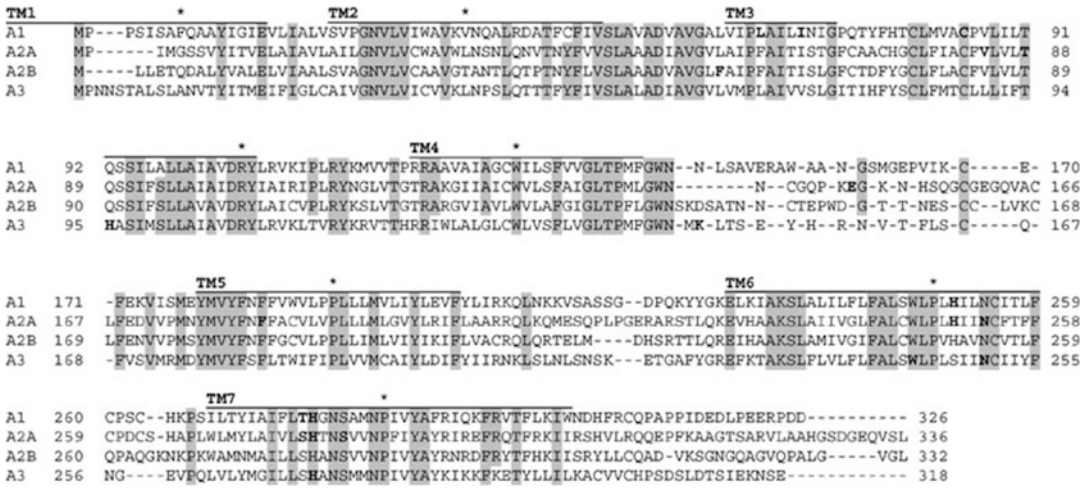
Allosteric modulation: In addition to AR agonists and antagonists that interact directly with the primary (orthosteric) site of the receptor, allosteric modulators of agonist action are also under consideration for disease treatment. Such modulators, either positive allosteric modulators (PAMs) or negative allosteric modulators (NAMs), might have advantages over the directly acting (orthosteric) receptor ligands. The action of the allosteric compounds would depend on the presence of a high local concentration of adenosine, which often occurs in response to a pathological condition (Chen et al. 2013). In some cases (dependent on tissue, receptor subtype, and other conditions), one would wish to boost the adenosine effect, and therefore, an allosteric enhancer would be useful. In other cases, the elevated adenosine may be detrimental, in which instance one would want to apply a negative modulator. Allosteric modulators have been explored and are under development for the A_1 and A_3 AR subtypes (Fig. 1b) (Jacobson et al. 2019).

Receptor Structures

Numerous A_{2A}AR structures and several A_1AR structures have been determined by X-ray crystallography and cryogenic electron microscopy (cryo-EM) (Jespers et al. 2018). Both antagonist and agonist ligands have been cocrystallized with the ARs for structure determination. Some structures include a G protein or G protein segment to simulate the active state of the receptor. The A_{2A}AR has become one of the most studied GPCRs, and it was used for the development of the technique by which stabilizing mutations are introduced strategically, in order to study the receptor using biophysical methods. Much of the current discovery of AR ligands uses structure-based approaches.

Receptor structures and computational modeling, including molecular dynamics (MD) simulation, have aided in the drug discovery process for ARs. Each of the ARs has been modeled effectively based on homology to the already reported A_{2A}AR or A_1AR structures (Table 1), and numerous theoretical models are now available. Molecular modeling of the ARs and ligand docking have provided insights into the putative binding sites of all of the subtypes, which has aided in the rational design of ligands (Müller and Jacobson 2011). For example, AZD4635 53 was discovered through an iterative process of biophysical mapping of the A_{2A}AR binding site determined in multiple X-ray structures. It is currently in clinical trials for treating solid tumors, either as a monotherapy or as a cotherapy with other agents for cancer immunotherapy.

Essential residues for the binding of ligand and activation of all four ARs have been defined through structure determination, site-directed mutagenesis, and modeling. Similar to other GPCRs having small molecular ligands, TMs 3, 5, 6, and 7 of the ARs are thought to be most closely associated with bound agonists and antagonists. An alignment of the primary sequences of the four human AR subtypes (Fig. 3) indicates a high degree of homology within the TMs. Key functional residues for ligand binding and activation have been identified. Extensive mutagenesis of the ARs had predicted, even before the X-ray structures were available, a putative, hydrophilic ribose-binding region spanning TMs 3 and 7. The putative adenine-binding region contains more hydrophobic residues, particularly in the vicinity



Adenosine Receptors, Fig. 3 An alignment of the primary sequences of the four human AR subtypes. Regions of conservation are highlighted. ∗ indicates the most conserved (X.50) residue in each TM region. Bold residues correspond to those which have a role in ligand recognition. The A_{2A} receptor is truncated in the carboxy-terminal region

of the N^6 substituent. The binding and activation steps of receptor action have been dissected using inactive and active-like structures, including strategic mutagenesis, computational methods, and other biophysical techniques such as NMR. The conformational dynamics of the activation of the A_3AR and other subtypes have been studied. The second extracellular loop (EL2) generally contacts the receptor ligands and is highly variable in sequence and contains a relatively high content of charged residues, in addition to sterically constraining disulfide bridges.

Drugs

Presently, only agonists adenosine and regadenoson and antagonist istradefylline are potent AR ligands that are approved for clinical use. Adenosine is used widely in the treatment of supraventricular tachycardia and in cardiac stress imaging to assess coronary artery disease (Jacobson et al. 2019). Other agonists and antagonists, and an allosteric modulator of the A_1 receptor T-62 25, have been in clinical trials for a variety of indications.

Selective AR agonists have been in or are being considered for clinical trials for cardiac arrhythmias and pain (A_1), cardiac imaging and inflammation (A_{2A}), hepatocellular carcinoma (HCC), non-alcoholic steatohepatitis (NASH), rheumatoid arthritis, psoriasis, and chronic neuropathic pain (A_3). Selective AR antagonists have been in or under consideration for clinical trials for kidney disorders (A_1); Parkinson's disease and cancer (A_{2A}); cancer, diabetes, and asthma (A_{2B}); and glaucoma (A_3). CD73 inhibitors, both small molecules and monoclonal antibodies, are in clinical trials for cancer immunotherapy.

Definition

Adenylyl cyclases (AC) comprise a family of enzymes that catalyze the synthesis of adenosine 3′:5′-monophosphate (cyclic AMP, cAMP) from adenosine 5′-triphosphate (ATP). The second messenger cAMP regulates effects in all eukaryotic cells, through the activation of cAMP-dependent protein kinase (PKA), cAMP-gated ion channels (CNGs), hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, exchange proteins activated by cAMP (Epacs), and Popeye domain containing (Popdc) proteins, in addition to the regulation of a subset of cAMP- and cGMP-degrading enzymes (PDEs, phosphodiesterases) (Fig. 1). Cellular levels of cAMP levels reflect the balance of activities of adenylyl cyclases (ACs: 5′-ATP to cAMP + PPi) and cAMP phosphodiesterases (PDEs: cAMP to 5′-AMP). Adenylyl cyclases occur throughout the animal kingdom and play diverse roles in cell regulation. Mammalian cells express nine membrane-spanning AC isoform and a tenth soluble AC (Dessauer et al. 2017).

Basic Characteristics and Mechanisms

Classes of Adenylyl Cyclases

Adenylyl cyclases belong to the larger class of purine nucleotide cyclases. These have been divided into classes I–VI (Linder and Schultz 2003). Classes I, II, and IV–VI consist of cyclases from gram-negative bacteria, the extracellular soluble toxins of certain pathogens (e.g. *Bacillus anthracis*, *Bordetella pertussis*, and *Pseudomonas aeruginosa*), and additional bacteria classes, respectively. Class III cyclases include most adenylyl and guanylyl cyclases (catalyzing the formation of cyclic GMP). These enzymes respond to changes in the extracellular environment. In mammals (subclass IIIa) this occurs via hormones, neurotransmitters, odorants, or tastes for transmembrane ACs (AC1–AC9). For the mammalian soluble AC (subclass IIIb) and lower organisms, enzymatic activity responds to changes in ionic factors, bicarbonate, glucose, or serum factors and through osmoregulation, chemotaxis, phototaxis, or pH, in various bacteria.

Mammalian Adenylyl Cyclases

Of the ten known isozymes of mammalian adenylyl cyclase (AC1–AC10; Table 1), all but one are membrane-bound and are regulated via cell surface receptors linked to heterotrimeric ($\alpha\beta\gamma$) stimulatory (G_s) and inhibitory (G_i) guanine nucleotide-dependent regulatory proteins (G-proteins) (Fig. 2, Table 2) (Dessauer et al. 2017). These receptors are referred to as G-protein-coupled receptors, or GPCRs, and mediate effects of stimulatory and inhibitory hormones and neurotransmitters. $G\alpha_s$ stimulates all of the mammalian AC isozymes, except the soluble AC10 (regulation of AC10 is G-protein-independent and differs significantly from the membranous ACs; discussed below). The plant-derived diterpene, forskolin, binds at the interface of the two cytosolic domains (**C1 • C2**; see below) of AC1–AC9 to stimulate enzymatic activity, although AC9 is only weakly stimulated by forskolin and requires the presence of $G\alpha_s$ (Baldwin et al. 2019); forskolin does not activate AC10. The AC isozymes differ more significantly in their responses to $G\alpha_i$ and $G\beta\gamma$ and in the physiological responses they control (Baldwin and Dessauer 2018; Dessauer et al. 2017) (Table 2). For example, $G\alpha_i$ inhibits some but not all isozymes and $G\beta\gamma$ inhibits AC1 and AC8, but significantly stimulates AC2, AC4, and AC7,

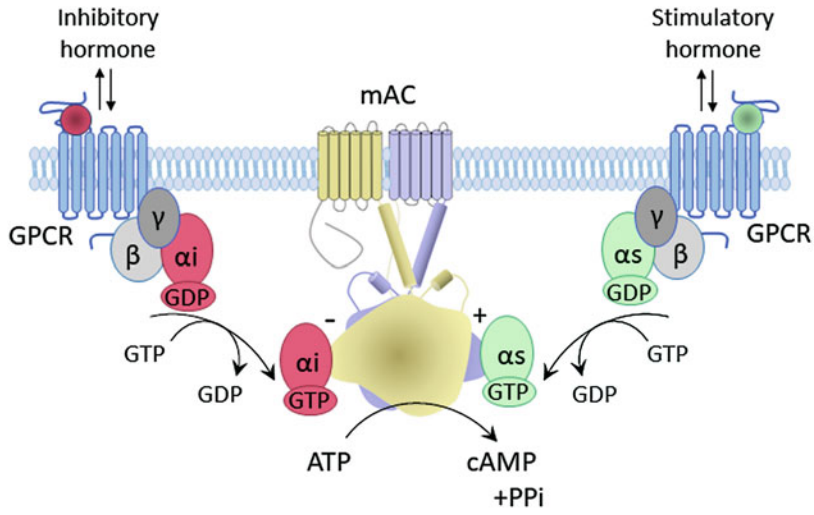
[a]Adenylyl cyclases have been numbered in the order in which they were cloned and sequenced. In databases they are referred to as adcy#; soluble AC10 is sometimes referred to as sAC
[b]Accession numbers are for the Reference Sequence (*RefSeq*) collection of data from the National Center for Biotechnology Information (NCBI). Values pertinent to the human isozymes of adenylyl cyclases are compiled here. The link is http://www.ncbi.nlm.nih.gov/

with weaker stimulatory effects on AC5 and AC6 (Table 2).

Stimulation and inhibition of the enzyme by the GPCR-G-protein cycle occur by analogous mechanisms. Agonists induce hormone receptors to increase nucleotide exchange on Gα (GDP to GTP) which activates the alpha subunit and promotes Gαβγ dissociation (Fig. 2). Consequently, agents that affect either the dissociation of either G_i or G_s or the association of their respective α_s, α_i, or βγ subunits with adenylyl cyclase could affect rates of cAMP formation in enzyme preparations or in intact cells and tissues. There are several important examples. $G\alpha_s$ is stably activated by poorly hydrolyzable analogs of GTP, e.g., GTPγS or GPP(NH)P, and activation is hindered by GDPβS. A less obvious example is fluoride. It activates most mammalian adenylyl cyclases, indirectly by promoting an active form of $G\alpha_s$ ($G\alpha_s$•GDP•AlF_4^-). Another example includes the ADP-ribosyltransferase activities of bacterial toxins. The toxin of *Vibrio cholerae* catalyzes the ADP-ribosylation from NAD of GTP•$G\alpha_s$, and that of *Bordetella pertussis* similarly ADP-ribosylates α_i of GDP•$\alpha_i\beta\gamma$, preventing its dissociation. In both cases the effect is elevated adenylyl cyclase activity and contributes to the pathophysiology of these bacteria. Of therapeutic relevance, of course, are agents acting as agonist or antagonist on GPCRs coupled to adenylyl cyclase, with the prominent example being antagonists of β-adrenergic receptors (i.e., β-blockers).

Activities of all isozymes are affected by Ca^{2+}. At higher concentrations (mM), Ca^{2+} is inhibitory



Adenylyl Cyclases, Fig. 2 Regulation of membrane adenylyl cyclase isoforms (AC1–9) by G-proteins. Hormones bind to G-protein-coupled receptors to activate $G\alpha_s$ or $G\alpha_i$, which leads to stimulation or inhibition, respectively, of adenylyl cyclases (AC1–9). G_s and G_i are GTP-dependent regulatory proteins comprising βγ subunits and their respective α_s and α_i subunits

through competition with divalent cation required for catalysis (see below). At lower concentrations (<μM), Ca^{2+} regulates activity physiologically. This can be (i) through a direct effect at the catalytic active site, increasing activity of AC10 or decreasing activity of AC5 and AC6; (ii) as a Ca^{2+}/calmodulin complex, activating ACs 1, 3, and 8; (iii) with calcineurin to inhibit AC9 or with calmodulin kinase (CaMK) to inhibit AC1 and AC3; or (iv) indirectly through activation of PKC (Table 2; Dessauer et al. 2017). Phosphorylation of adenylyl cyclase varies among the isozymes and is determined by differences in their primary sequences. Phosphorylation catalyzed by protein kinase C (PKC) can be stimulatory or inhibitory depending on the AC isoform (see Table 2), while phosphorylation by cAMP-dependent protein kinase (PKA) or calmodulin kinase (CaMK) is inhibitory and often works in a feedback form of regulation. Raf can also activate ACs 2, 5, and 6. Activity of adenylyl cyclases can be indirectly influenced by the specific phosphorylation of hormone receptors or of G-proteins.

Membrane-bound forms of mammalian adenylyl cyclases exhibit a putative topology with 12 membrane-spanning regions and 2 largely homologous ~40 kDa cytosolic domains (**C_1** and **C_2**) (Fig. 3). Differences in N-terminal and other domains are significant and influence regulation by a variety of agents as noted above (Table 2). AC5 (**C_1**) and AC2 (**C2**) domains have been separately expressed and recombined, and the resulting structure was solved in complex with GTP•$G\alpha_s$ (Fig. 4) (Tesmer et al. 1997). α_s•GTP activates the enzyme through interaction with **C_2**, yielding the active enzyme. More recently, a cryo-EM structure of full-length AC9 bound to GTP•$G\alpha_s$ was solved (Fig. 3) (Qi et al. 2019). There is remarkable similarity with the previous x-ray structures of **C_1•C_2•$G\alpha_s$** within the catalytic core. One notable surprise was the auto-inhibition of AC9 by its C_{2b} region; this appears to be a feature unique to AC9. Inhibition of adenylyl cyclase by $G\alpha_i$ occurs through the interaction with the analogous $G\alpha_s$ site in the **C_1** domain of adenylyl cyclase. The structure obtained with β-L-2′,3′-dd-5′-ATP (a competitive inhibitor of ATP binding) allowed the demonstration that the pseudosymmetric cleft formed by the interface of the **C_1•C_2** domains binds 5′-ATP, forskolin, and two metal cations (Tesmer et al. 1999). The active site shares topology and reaction mechanism with guanylyl cyclases (which share homology within the active site) and with oligonucleotide polymerases.

AC10 (sAC, Adcy10) was initially described as adenylyl cyclase activity in the soluble fraction of rat testis homogenate, but the nature of this enzyme remained elusive for several decades. The unique properties of this "soluble adenylyl

Adenylyl Cyclases, Table 2 Regulatory characteristics of mammalian adenylyl cyclases[a]

[a]Empty cells imply that no information was available. *Direct* effects on adenylyl cyclase activity are as indicated: up (↑) arrow, increase; down (↓) arrow, decrease; or "no Δ" (tested, but no effect on activity seen)

[b]Effects of $G\alpha_i$ or $G\beta\gamma$ are on enzyme stimulated by either $G\alpha_s$ or forskolin. In some instances differences were noted in the effects of different isoforms of β or γ. These are not distinguished here

[c]For effects of Ca^{2+} and/or calmodulin, stimulation of adenylyl cyclase by Ca^{2+} usually requires calmodulin, except in the case of AC10 (sAC). All adenylyl cyclases are inhibited by high (mM) concentrations of Ca^{2+}, through competition with divalent cation required for catalysis (cf. Figures 4 and 5). The inhibition indicated here occurs with low (<μM) concentrations of Ca^{2+}, without calmodulin; inhibition of AC9 by Ca^{2+} is with calcineurin

[d]Ca^{2+}/calcineurin has been observed to inhibit mouse AC9 but not human AC9

[e]AC10 (sAC), a soluble adenylyl cyclase discovered in the testes, is widely distributed and functions as a $HC0_3^-$ ion sensor. It is also stimulated by Ca^{2+}, independently of calmodulin

[f]LTP, long-term potentiation in neuronal function; PKA, cAMP-dependent protein kinase; PKC, protein kinase C; CaM, calmodulin

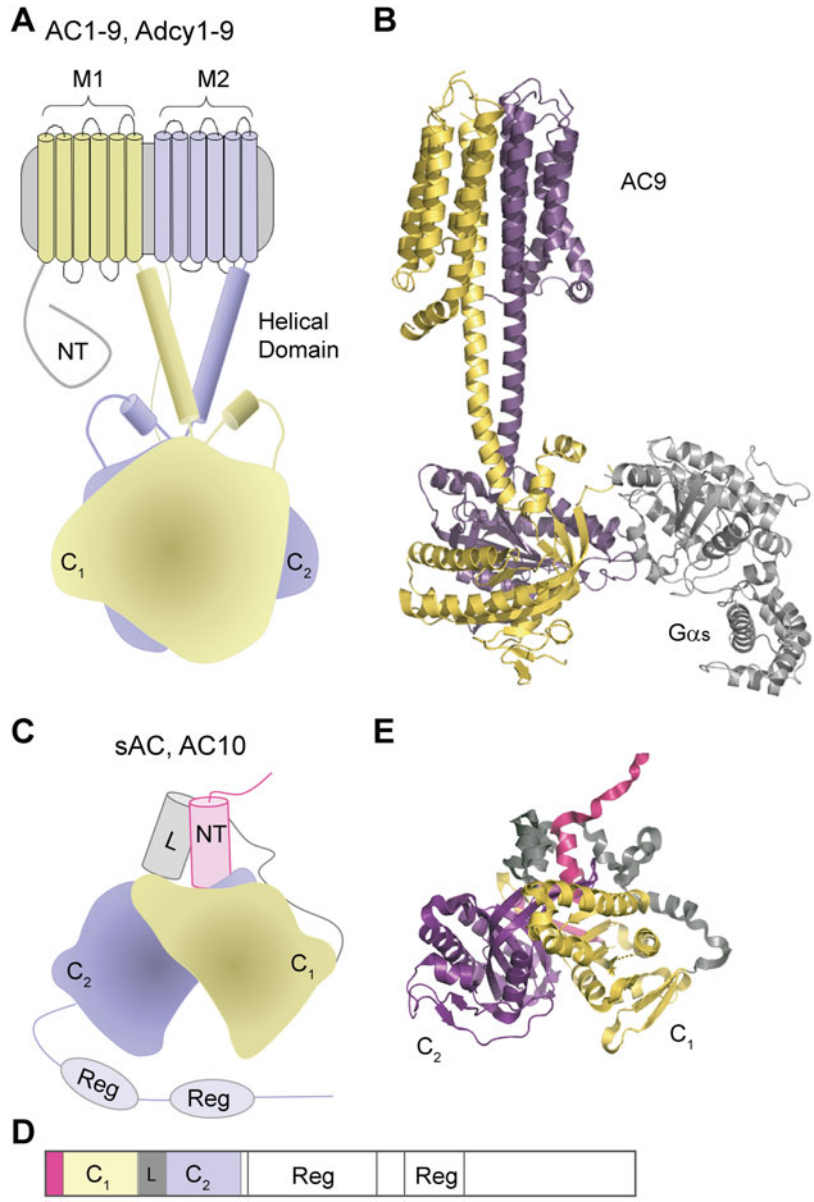
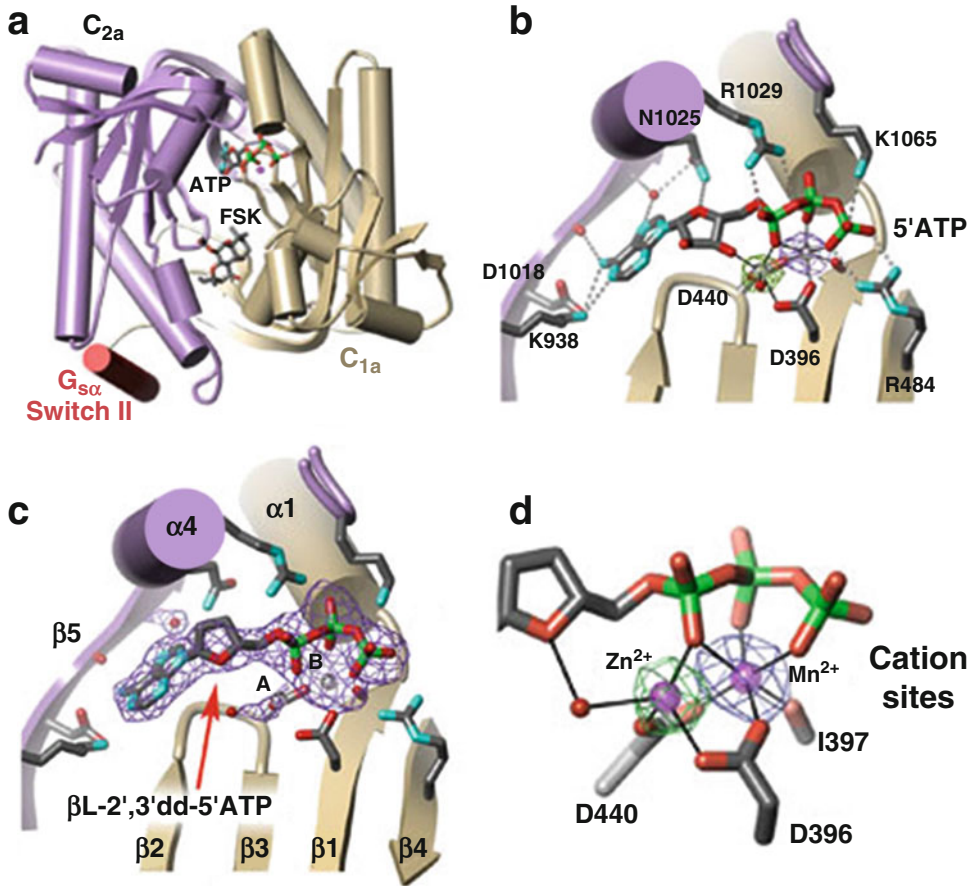
cyclase" were conclusively elucidated with the cloning of testis-derived cDNAs, determination of its regulation, and the subsequent solution of its bicarbonate-bound structure (Kleinboelting et al. 2014). AC10 exhibits an amino acid sequence and domain organization more closely related to cyanobacteria than to the other mammalian AC isoforms (Fig. 3). Domain composition



Adenylyl Cyclases, Fig. 3 Topology and structure of mammalian adenylyl cyclases. (**a**, **b**) Topology and structure of AC1–9 transmembrane AC isoforms. The first set of six transmembrane helices and the C_1 cytoplasmic domain are shown in gold; this structure is repeated (purple) to create the holoenzyme. (**b**) cryo-EM structure of AC9. $G\alpha_s$ (gray) binds to the C_2 domain. (**c**, **d**) Topology and schematic of AC10 (sAC). (**e**) AC10 crystal structure: the C_1 domain is shown in gold, C_2 domain in purple, N-terminus (NT) in pink, and linker domain (L) in gray. (Adapted from Baldwin and Dessauer 2018, Qi et al. 2019, and Kleinboelting et al. 2014)

includes a conserved C_1–C_2 catalytic domain and a carboxyl terminal domain of variable length, with a putative auto-inhibitory domain and other regulatory sites, but no transmembrane motifs. The short splice variant initially found in the testis contains the C_1–C_2 catalytic domains but lacks the extended C-terminus. AC10 activity is insensitive to forskolin and G-protein regulation; it is instead regulated by HCO_3^- and by Ca^{2+} (Table 2). The crystal structure of human AC10 indicates that binding of HCO_3^- disrupts a salt bridge involving an aspartate residue which is involved in the substrate ATP binding site (Kleinboelting et al. 2014). AC10 activity is sensitive to ATP levels in the cell due to its relatively low affinity for ATP, compared to AC1–9. AC10 is also more promiscuous in terms of substrate, as it can also use UTP and CTP to generate the corresponding cyclic nucleotides. Loss of HCO_3^--stimulated adenylyl cyclase activity in the testis leads to complete infertility

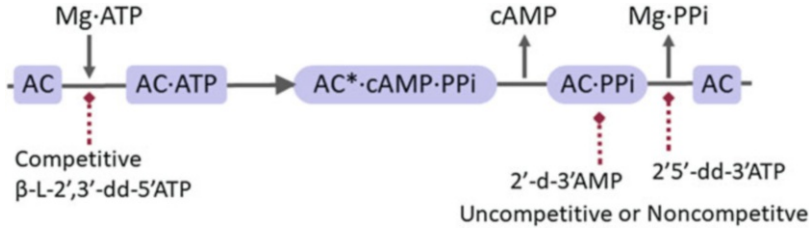


Adenylyl Cyclases, Fig. 4 Catalytic cleft and active site of a chimeric mammalian adenylyl cyclase, AC5-C_1•AC2-C_2•Gα_s. The catalytic cleft is formed by the pseudo-symmetric interaction of the cytosolic domains, C_1 and C_2. Panel (**a**): crystal structure of AC5-C_1•AC2-C_2, indicating binding sites for substrate (5′ATP) and forskolin (FSK) (only switch II domain of Gα_s that interacts with the C_2 domain of AC is shown). Panel (**b**): the catalytic active site modeled with 5′ATP; based on structure with β-L-2′,3′-dd-5′-ATP (see panel **c**). Amino acids involved in substrate binding and catalysis are indicated. Panel (**c**): structure with bound β-L-2′,3′-dd-5′-ATP and loci for two metal sites, A and B. Panel (**d**): enlargement of panel **c** with Zn^{2+} (metal A) and Mn^{2+} (metal B) used in forming the crystal. Catalysis occurs with the metal-catalyzed attack of the ribosyl 3′-OH group of the substrate α-phosphate. (Adapted from Tesmer et al. 1999)

due to defective sperm motility. Localization of sAC in the mitochondria of other cell types is important for PKA-mediated regulation of respiratory chain enzymes and ATP production, while localization in cilia may control ciliary beat frequency (Levin and Buck 2015).

Catalytic Mechanism

Catalysis by adenylyl cyclases involves cation-mediated attack of the 3′-OH on the α-phosphate of 5′-ATP, with PP_i as the leaving group. It is a reversible bireactant sequential mechanism with metal•5′-ATP as substrates and cAMP and metal•PP_i as products (Fig. 5; transition state is depicted as **AC**∗; (Dessauer and Gilman 1997)). Two metal binding sites exist in the catalytic site and are required for catalysis, similar to nucleotide polymerases (Fig. 4) (Tesmer et al. 1999). These are generally occupied by Mg^{2+}, but site A can be occupied by Zn^{2+} (an inhibitor of AC), while Mn^{2+} (an activator of AC) can occupy site B (Fig. 4). Typically, reaction velocities are



Adenylyl Cyclases, Fig. 5 Adenylyl cyclase catalytic cycle. Points during the catalytic cycle at which inhibition by competitive and uncompetitive or noncompetitive nucleotides occur are shown; AC∗ represents the catalytic transition state. (Adapted from Dessauer and Gilman 1997)

considerably greater with Mn^{2+} as cation than with Mg^{2+} due to effects on both K_mATP and V_{max}. K_m values for rat brain cyclase are K_{MnATP}, ~9 μM, and K_{MgATP}, ~60 μM. Notably, activation of adenylyl cyclases by hormones or by $G\alpha_s$, via the active enzyme configuration GTP•α_s•**AC**, causes a reduction in $K_{Mg}{}^{2+}$ of more than an order of magnitude from to $K_{Mg}{}^{2+}$ ~ 860 μM to ~50 μM, without a change in K_{MgATP}.

Miscellaneous Observations

Typical enzyme preparations, whether from native or recombinant sources, are of membranes or membrane extracts that contain enzyme activities that can alter substrate or product concentrations for adenylyl cyclases. These include activities of cyclic nucleotide phosphodiesterases (PDEs) and ATPases, among others, which must be taken into consideration in assays of adenylyl cyclase activities. In addition, the enzyme is protected by thiols, with β-mercaptoethanol and dithiothreitol being the most commonly used. Conversely, adenylyl cyclases are generally susceptible to oxidants, e.g., H_2O_2 (IC_{50} ~ 3 μM) or benzoquinone (IC_{50} ~ 3 μM), and alkylating agents, e.g., *N*-ethylmaleimide (IC_{50} ~ 100 μM). Not surprisingly, the membrane-bound enzyme is susceptible to thermal inactivation (e.g., 50% inactivation at 35° in 10 min). Finally, proteases can alter adenylyl cyclase activity for some isoforms. For example, trypsin and thrombin can cause 5–10-fold activation (AC2 > AC3 > > AC5). The basis for this activation in each case is not clear, though serine proteases are known to cleave $G\alpha_i$, and this could lead to indirect effects on adenylyl cyclase activity. Cleavage of the C-terminal auto-inhibition region of AC9 can also lead to enhanced activity due to a lowered K_m for ATP (Qi et al. 2019).

Bacterial and Other Adenylyl Cyclases

Adenylyl cyclases are found throughout the animal kingdom and serve a variety of roles. Available evidence indicates that there is little sequence homology between these adenylyl cyclases and the membrane-bound mammalian form. They are regulated quite differently from mammalian isoforms. This lack of homology between mammalian and bacterial forms could serve as an advantage, as several class II forms of adenylyl cyclase constitute a toxic factor in mammals, including enzymes from *Bordetella pertussis*, *Bacillus anthracis*, *Pseudomonas aeruginosa*, and *Yersinia pestis*. These enzymes constitute the "toxin class" of adenylyl cyclases. The well-studied adenylyl cyclases of *Bordetella pertussis* and *Bacillus anthracis* are both soluble, Ca^{2+}/calmodulin-dependent, but G-protein-independent enzymes that are exported from the respective bacteria (Tang and Guo 2009). Because these enzymes are then transported into infected cells, adenylyl cyclase actually constitutes a virulence and toxic factor in mammals. Much like the toxin from *Vibrio cholera* that ADP-ribosylates $G\alpha_s$ to increase cAMP, these toxic adenylyl cyclases increase cAMP. For example, the massive cAMP production by CyA from *Bordetella pertussis* results in inhibition of immune cell

function and contributes to pathogenesis of whooping cough. The *B. anthracis* adenylyl cyclase (800 amino acids), also known as "edema factor" (EF), and the *B. pertussis* adenylyl cyclase (1706 amino acids) are large enzymes with multifunctional domains. Some of the toxic effects of these adenylyl cyclases may not be due to cAMP production, as ExoY from *Pseudomonas aeruginosa* is actually much more effective at producing cGMP and cUMP, than cAMP. The fact that the mammalian adenylyl cyclases differ so substantially from these pathogenic virulence and toxic factors gives motive to the idea that small molecule inhibitors of the pathogen adenylyl cyclases may be discovered that do not interact with mammalian forms of the enzyme and can be used clinically to treat these devastating diseases. Derivatives of the antiviral drug PMEA (adefovir) may hold promise, as some inhibit CyA and edema factor with good selectivity over mammalian adenylyl cyclase isoforms (Cesnek et al. 2018).

Drugs

Drugs which indirectly activate or inhibit mammalian adenylyl cyclases are common, especially drugs targeting G-protein-coupled receptors. However agents that act directly on the adenylyl cyclase enzyme have been less well explored. Importantly, for most activators and inhibitors of adenylyl cyclase, high selectivity for specific isozymes has not been demonstrated. The main classes of such agents are derivatives of forskolin and of adenine nucleosides. Forskolin analogs show some selectivity for activation of select isoforms, particularly AC1, while BODIPY-modified forskolin can stimulate AC1 and AC5 but serve as an inhibitor of AC2 (reviewed in Dessauer et al. 2017). Adenosine and its derivatives have long been known to inhibit adenylyl cyclases, with modifications substantially increasing inhibitory potency. Notable are the approximately threefold increase in potency seen with the 2-fluorine substitution on adenine and the increases in potency seen with various modifications to the ribose moiety. The orientation of the ribose (α vs β) and the presence, orientation, or absence of hydroxyl groups clearly contribute to inhibitory potency (Table 3). For example, arabinose and xylose differ from ribose only in the orientation of the 2′- and 3′-OH groups yet exhibit markedly different potencies. The antiviral drug 9-(arabinose)-Ade (also known as Ara-A or vidarabine) is clinically used to treat herpes simplex and varicella zoster viruses, but exhibits some selectivity for inhibition of isoforms AC5 and AC6 (Brand et al. 2013). Of note, acyclic nucleoside phosphonate antiviral drugs (e.g., PMEApp, also known as adefovir) can inhibit mammalian adenylyl cyclases (IC_{50} = 170 nM), the *Bacillus anthracis* toxin edema factor (K_i = 27 nM), and the *Bordetella pertussis* toxin CyaA (K_i = 25 nM), while 7-halo-7-deazapurine analogs of PMEA are potent and selective inhibitors of AC1 (Cesnek et al. 2018).

SQ 22,536 (9-(tetrahydrofuryl)-Ade) lacks the hydroxyl groups present in Ara-A or 9-(xylose)-Ade and is less potent, but offers metabolic and biochemical stability useful for many types of

Adenylyl Cyclases, Table 3 ***Nucleoside inhibitors of adenylyl cyclase***. Assays were with a detergent-dispersed adenylyl cyclase from rat brain and were with 100 μM 5′ATP and 5 mM $MnCl_2$ as substrates. Common name for frequently used inhibitors is indicated in parenthesis

Nucleoside	IC_{50} (μM)

α-Adenosine	>300
9-(arabinose)-Ade (Ara-A; vidarabine)	30
9-(xylose)-Ade	3.2
9-(Tetrahydrofuryl)-Ade (SQ 22,536; THFA)	20
β-2′,3′-dd-ado	9
β-2′,5′-dd-ado	2.8
β-2′,5′-dd-2-F-ado	0.89
β-2′,5′-dd-2,5′-di-F-ado	0.98
Non-nucleoside derivatives	
NKY80	~8–1000

studies. NKY 80 is a non-nucleoside derivative of SQ 22,536. Both SQ 22,536 and NKY 80 show selectivity among the adenylyl cyclase isoforms, inhibiting types 5, 6 > 1, 3 > 2, 4, 7 > 8, 9 (Brand et al. 2013). It is, however, the removal of two of the hydroxyl groups that elicits the largest improvement in inhibitory potency, in particular the 2′,5′-dideoxy modification (Table 3). With these improvements in potency, these cell-permeable compounds, in particular 2′,5′-dd-Ado, Ara-A, SQ 22,536, and NKY 80, have become useful research tools to inhibit transmembrane adenylyl cyclases and lower cAMP levels in isolated cells or intact tissues; these three inhibitors poorly inhibit AC10, with IC_{50} values greater than 1 mM (Bitterman et al. 2013).

An early observation that 2′-d-3′-AMP was a more potent inhibitor of adenylyl cyclases than 2′-d-Ado suggested that the enzyme would accept substitutions at the 3′-ribose position and that phosphate was particularly well tolerated. This led to the generation of a family of 3′-phosphoryl derivatives of 2′,5′-dideoxyadenosine exhibiting ever greater inhibition with the addition of an increasing number of 3′-phosphoryl groups, the most potent of which is 2′,5′-dideoxyadenosine-3′-tetraphosphate (2′,5′-dd-3′-A4P; Table 4) (Desaubry et al. 1996). These constitute a class of inhibitors historically referred to as P-site ligands that caused inhibition of adenylyl cyclase that was kinetically either noncompetitive or uncompetitive (cf. Figure 5; Dessauer and Gilman 1997). Uncompetitive inhibition was due to P-site binding to the product-like transition state (AC-PPi); the polyphosphate inhibitors (2′,5′-dd-3′ATP and 2′,5′-dd-3′-A4P) are non-competitive, binding either AC or AC-PPi state (PPi may simply promote the high-affinity product-like transition state) (Tesmer et al. 2000). Since a round of catalysis is required to generate the AC-PPi state, this mode of inhibition means that potency is dependent on the activity state of the enzyme. The highest potency by P-site inhibitors is observed when adenylyl cyclase is most active. All tested membrane-bound forms of mammalian adenylyl cyclase are inhibited by adenine nucleosides and their 3′-polyphosphates derivatives; bacterial adenylyl cyclases are largely unaffected. Inhibition of AC10 has not been extensively tested but shows inhibition by 2′,5′-dd-3′-ATP (IC_{50} = 0.69 μM) (Bitterman et al. 2013).

All adenylyl cyclases are inhibited competitively by substrate analogs, which bind to the enzyme active site (cf. Figure 4). One of the best competitive inhibitors is β-L-2′,3′-dideoxyadenosine-5′-triphosphate (β-L-2′,3′-dd-5′-ATP; Table 4) (Shoshani et al. 1999). The two inhibitors, 2′,5′-dd-3′-ATP and β-L-2′,3′-dd-5′-ATP (Fig. 6), are comparably potent (Table 4), but inhibit adenylyl cyclase by conformationally distinct mechanisms (cf. Figure 5) by binding within the catalytic cleft in unique structures (Fig. 4).

Development of 2′(3′)-*O*-MANT-derivatives of nucleoside 5′-triphosphates took advantage of the tolerance to large substitutions at the 3′-ribose position (Gille and Seifert 2003) (Table 4). It was surprising, though, that potent inhibition was seen with bases other than adenine, implying that base specificity is less stringent than had been generally assumed. Subsequently, fluorescent derivatives have been made with different fluorophores at 2′- and 3′-positions (see Seifert et al. 2012 and Dessauer et al. 2017). 3′-Substitutions showed advantage over corresponding 2′-substitutions, and 2′(3′)- *O*-MANT-substitutions were clearly preferable to coumarin and dansyl derivatives, but followed the order of guanosine ≥ inosine > adenosine (Table 4). Unfortunately, the MANT-derivatives also inhibit soluble guanylyl cyclase and interact with numerous nucleotide-binding proteins (Seifert et al. 2012).

Inhibitors of the soluble adenylyl cyclase AC10 have not been as well explored as their other mammalian counterparts. AC10 is relatively insensitive to the adenosine analogs (Table 3), but the polyphosphate 2′,5′-dd-3’-ATP will inhibit AC10 (IC_{50} = 0.69 μM), with only a ~15-fold reduction in potency (Bitterman et al. 2013). The catechol derivative of estrogen (2 CE) was the first known inhibitor of AC10, but it shows weak to no selectivity over AC1–9. LRE1 and KH7 are significantly more potent for AC10 compared to the transmembrane isoforms AC1–9 (Table 5). However, KH7 displays off-target and toxic cellular

Adenylyl Cyclases, Table 4 ***Nucleotide inhibitors of adenylyl cyclase***. Enzyme source and assay conditions were as for Table 3. Values obtained for 3′-ATP are overestimations due to the formation of 2′:3′-cAMP from 3′-ATP that occurs nonenzymatically in the presence of divalent cation

Adenylyl Cyclases, Fig. 6 Structures of potent inhibitors of adenylyl cyclase. Structures for 2′,5′-dd-3′-ATP (IC_{50} ∼ 40 nM; noncompetitive inhibitor), β-2′,3′-dd-5′-ATP with Mg^{2+} and Zn^{2+} (IC_{50} ∼ 24 nM; competitive inhibitor), and 3′-MANT-GTP with Mn^{2+} (IC_{50} ∼ 90 nM; competitive inhibitor) are from coordinates obtained for these compounds in respective crystal structures with AC5-$\mathbf{C_1}$•AC2-$\mathbf{C_2}$. The 3′-MANT-group fits into a hydrophobic pocket of the enzyme. Note the difference in contortion of the phosphate chains in these structures relative to positions for divalent cation (shown as small spheres: Mn^{2+}, purple; Mg^{2+}, green; Zn^{2+}, blue)

effects, and its mechanism of inhibition is poorly understood (Bitterman et al. 2013). LRE1 is a more recently developed inhibitor that binds to the bicarbonate allosteric site of AC10 and displays less toxicity than KH7 (Ramos-Espiritu et al. 2016).

Cellular Inhibition of AC

Although the 3′- and 5′-polyphosphate derivatives of the MANT- and related derivatives mentioned above exhibit exquisite inhibitory potency, these compounds are not cell permeable. To take advantage of the potency of such derivatives for studies

Adenylyl Cyclases, Table 5 ***Inhibitors of AC10***. IC_{50} is based on inhibition of purified AC10, while determination of AC1–9 (mAC) used Mn^{2+}/forskolin-stimulation (KH7) or $G\alpha_s$-stimulation (LRE1) of cell lysates (Bitterman et al. 2013)

AC10 (sAC) inhibitors	AC10 (IC_{50}, μM)	Inhibition of mAC
KH7	3.0	None at 500 μM
LRE1 (RU-0204277)	~10	None at 50 μM

Adenylyl Cyclases, Table 6 ***Prodrug inhibition of cAMP formation in intact cells***. The indicated cells were treated for 15 min with 50 μM forskolin and prodrug nucleotides

	OB-1771 preadipocytes	THP1 monocytes
Pronucleotide	IC_{50} (nM)	
2′,5′-dd-3′-AMP-bis(me-SATE)	6.7	260
2′,5′-dd-2F-Ado-3′-P-bis(me-SATE)	9.8	110

with intact cells and tissues, prodrugs have been developed. Prodrugs are precursor molecules that are cell permeable and are then metabolized into an inhibitor by intracellular enzymes. Families of protected monophosphate derivatives have been generated that exhibit all the hallmarks of prodrugs. They are taken up, deprotected, and converted to extremely potent inhibitors of adenylyl cyclase, *but only by intact cells and tissues* (Laux et al. 2004). These prodrugs have been used to block cAMP formation in isolated cells and intact tissue and elicit functional effects (Table 6); however, most MANT-nucleotide derivatives bind other nucleotide-binding proteins.

Cell-permeable AC inhibitors include the nucleoside-based inhibitors and their analogs, particularly 2′,5′-dd-Ado, Ara-A, SQ 22,536, and NKY 80; although not particularly potent, the latter three are widely used but display some isoform selectivity for AC5 and AC6 which limits general use (Brand et al. 2013). One should note that SQ 22,536 and NKY80, but not Ara-A, also serve as antagonists for adenosine A1 and A2a receptors. Other commercially advertised adenylyl cyclase inhibitors should be used with considerable caution. MDL 12330A is a widely used inhibitor for membrane isoforms in intact studies but only shows modest inhibition of AC2 and AC3 (IC_{50} ~100 μM) and not AC5 or AC10 (Seifert et al. 2012; Bitterman et al. 2013); it is not recommended for cellular studies due to its low potency and pleotropic effects. Similarly NB001 is sold as an AC1-selective inhibitor, but it does not inhibit AC1 directly, and its mechanism of action is unknown (Seifert et al. 2012; Brand et al. 2013). Several isoform-selective adenylyl cyclase inhibitors have been developed for cellular-based assays, including SKF83566 (~20-fold selectivity for AC2 over AC1, AC5) (Conley et al. 2013) and ST034307 (selective for AC1 at 30 μM over AC1–9 in cell-based assays) (Brust et al. 2017). Note SKF83566 is also a potent antagonist of dopamine D1 and 5HT-2 receptors (K_i ~0.5 and 11 nM, respectively). The 7-halo-7-deazapurine analogs of PMEA also hold promise for AC1 (IC_{50} = 4–5 μM; tenfold selectivity over AC1, AC5), but also inhibit *B. pertussis* adenylyl cyclase (Cesnek et al. 2018). Currently no drugs on the market exert their main therapeutic effects via direct inhibition of adenylyl cyclase. Clearly additional work is needed to identify not only general inhibitors of mammalian adenylyl cyclase isoforms but also isoform-selective agents that are cell permeable.

Adipocyte-derived factors; Adipocytokines

Definition

Adipose tissue (AT) expresses and secretes a variety of bioactive peptides, termed adipokines, which affect important biological processes in organs such as the liver, brain, pancreas, muscle, intestine, or vascular system. Adipokines play an important role in the regulation of appetite and satiety, energy metabolism, insulin sensitivity and secretion, and inflammatory response (Fasshauer and Blüher 2015). Adipokine secretion reflects the functional state of AT and is an important mechanistic link between obesity and metabolic (e.g., type 2 diabetes (T2D), nonalcoholic fatty liver disease (NAFLD)), cardiovascular (e.g., hypertension, coronary artery disease, stroke), and other diseases (e.g., certain types of cancer, asthma, gout, osteoarthritis) (Fig. 1). Some adipokines are already used as pharmacological treatment or targets or are in early stages of clinical development. In the future, adipokines could gain clinical importance as circulating markers or predictors for metabolic and cardiovascular diseases, for the treatment success of weight-reducing therapies, and also for pharmacological therapy approaches (Blüher 2014).

Basic Characteristics

Adipose Tissue as an Endocrine Organ

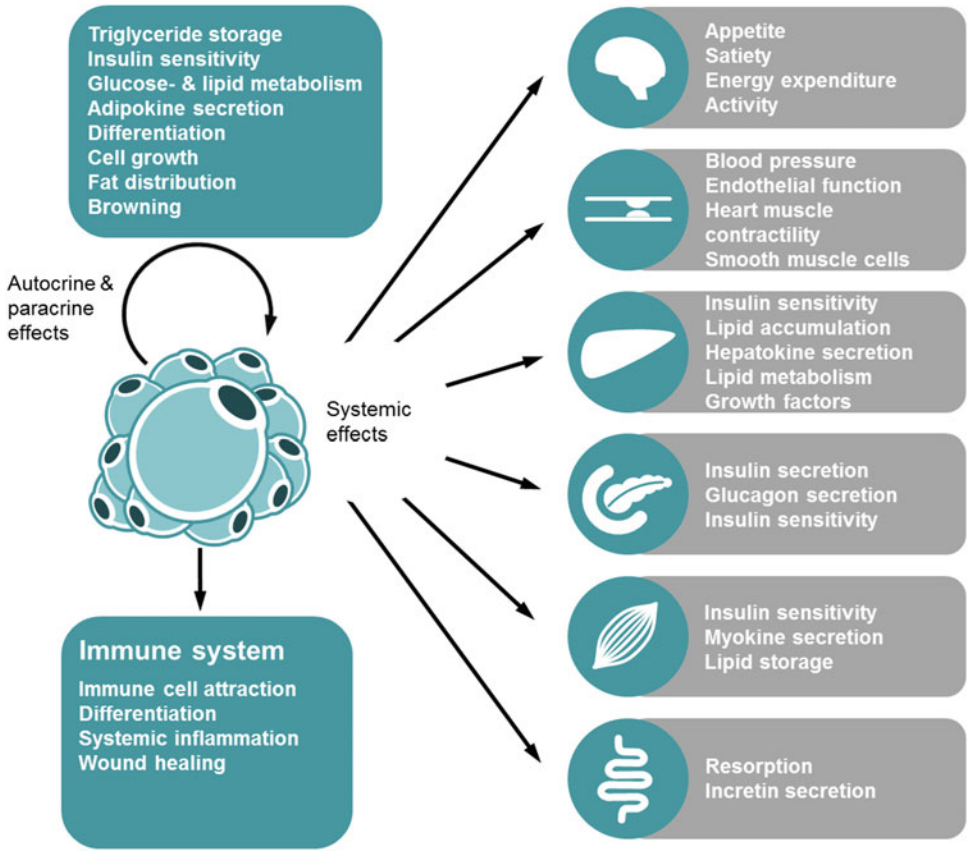
In addition to its important functions as an energy store, mechanical organ protection, and thermoregulation, AT is an active endocrine organ that produces hundreds of peptide hormones known as adipokines (Table 1). Genetic and environmental factors as well as energy overload affect AT size, cell composition in AT, and function. Thus, in obesity, the function of AT is often disturbed. The resulting changes in circulating adipokine levels increase the risk of developing a variety of diseases or predisposing states such as insulin resistance (IR) (Fig. 2) (Blüher 2014).

Therefore, adipokines are considered as valuable tools or targets for the treatment of metabolic and cardiovascular diseases (Table 2).

Leptin: An Adipokine Dysregulated in Obesity Which Influences Appetite, Body Weight, and Vascular Function

Since the discovery of leptin by the group of Jeffrey Friedman in 1994, quickly followed by the cloning of the leptin receptor in 1995, much progress has been made in our understanding of the neuroendocrine control of feeding, energy expenditure, and ultimately whole-body energy homeostasis. Although controversial at the time it was proposed four decades ago, Douglas Coleman's early hypothesis that a circulating factor released from white adipocytes communicates to the brain to regulate body weight (BW) proved to be true with the discovery of leptin (Fève and Bastard 2012).

Leptin signaling is regulated from its release by adipocytes to its transport into the brain where it activates the leptin receptor in key neuro-circuits of feeding control. Plasma leptin concentration is directly proportional to body fat mass, but high leptin levels in obesity are not sufficient to suppress appetite and enhance satiety most likely due to central leptin resistance.



Adipokines, Fig. 1 Different para- and endocrine functions of adipose tissue-derived adipokines. (Modified from Fasshauer and Blüher (2015))

In accordance with an appetite-suppressive effect, leptin-deficient *ob/ob* mice, as well as rare cases of leptin loss of function mutations in humans, develop severe hyperphagia and excessive obesity associated with IR, hyperinsulinemia, and T2D. Moreover, leptin possesses its anti-atherogenic effects indirectly through reduction of hypercholesterolemia and liver steatosis, as well as upregulation of insulin-sensitizing and atheroprotective adiponectin (Hoffmann et al. 2016). Administration of recombinant leptin in *ob/ob* mice and leptin-deficient humans reduces food intake, body weight, and fat mass suggesting that the absence of functional leptin is responsible for the obese phenotype in these states. For the rare cases of monogenetically inherited leptin deficiency in humans, recombinant leptin is now available for compassionate use and leads to significant weight loss. Leptin (metreleptin) is also an approved medication for patients with lipodystrophy (Oral et al. 2002), and further indications such as hypothalamic amenorrhea or Rabson-Mendenhall syndrome are under consideration (Brown et al. 2013).

Adiponectin: Insulin Sensitizer and Potential Endothelial Protector

Adiponectin was cloned in 1995 and 1996 by four independent groups using different experimental approaches (Fasshauer and Blüher 2015). However, only since 2001, it has become clear that adiponectin, unlike all other known adipokines, has a profound insulin-sensitizing effect. Some studies show that adiponectin increases insulin-

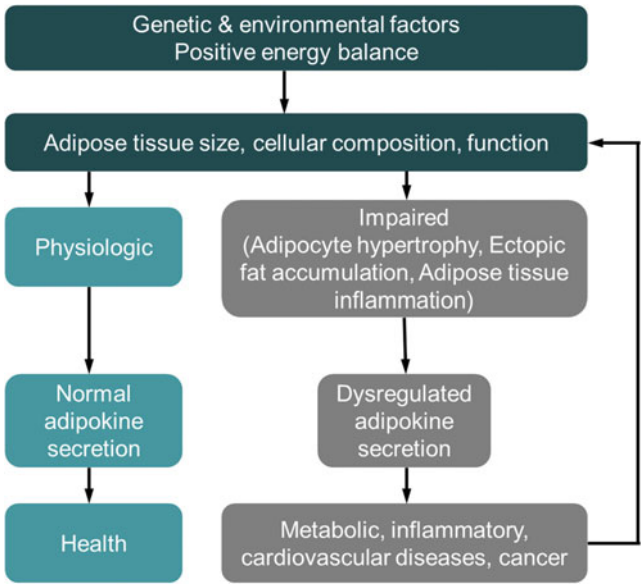
Adipokines, Table 1 Overview about selected adipokines. AdipoQ, adiponectin; C1Q, and collagen domain containing; AFABP, adipose fatty acid-binding protein; ANGPLT8, angiopoietin-like protein 8; AT, adipose tissue; BM, bone marrow; BMP, bone morphogenetic protein; CCL2, CC-chemokine ligand 2; CFD, complement factor D; DDP4, dipeptidyl peptidase 4; FABP4, fatty acid-binding protein 4; FGF21, fibroblast growth factor 21; FIZZ3, cysteine-rich secreted protein; GDF15, growth differentiation factor 15; GLP-1, glucagon-like peptide 1; GIP, glucose-dependent insulinotropic polypeptide; IL-1β, interleukin-1β; IL-1R, interleukin-1β receptor; IR, insulin resistance; MIC-1, macrophage inhibitory cytokine 1; NAG-1, nonsteroidal anti-inflammatory drug-activated gene-1; NGAL, neutrophil gelatinase-associated lipocalin; MCP1, monocyte chemotactic protein 1; NAMPT, nicotinamide phosphoribosyltransferase; OP-1, osteogenic protein-1; PDF, prostate-derived factor; PLAB, placental bone morphogenetic protein; PTGFB, anti-placental TGF-β; Rarres2, retinoic acid receptor responder protein 2; RBP4, retinol-binding protein 4; RIFL, refeeding induced in fat and liver; SP-40, seminal clusterin 40; TGFβ, transforming growth factor β; TIG2, tazarotene-induced gene 2; TIMP-1, tissue inhibitor of metalloproteinase 1; TNF-α, tumor necrosis factor α; VEGF, vascular endothelial growth factor

Adipokine	Synonyms	Mainly expressed and secreted by	Main functions
Adiponectin	AdipoQ	AT	Improvement of insulin sensitivity, antidiabetic, anti-atherogenic, and anti-inflammatory
Adipsin	CFD	AT	Activation of the complement pathway, beneficial role in maintaining β-cell function
ANGPLT8	RIFL	Liver, AT	Improvement of glucose tolerance, promotion of β-cell proliferation
Apelin		Heart, AT, placenta	Inhibition of insulin secretion
Asprosin	Fibrillin 1	AT, placenta	Induction of hepatic glucose production
BMP4		Small intestine, liver, AT	Regulation of adipogenic precursor cell commitment and differentiation, bone and joint development
BMP7	OP-1	Thyroid, placenta, AT	Brown adipogenesis stimulation, food intake reduction
Cathepsins S,L,K		Placenta, AT	Regulation of glucose metabolism and adipose tissue mass
Chemerin	Rarres2, TIG2	AT, liver	Regulation of adipogenesis, chemoattractant protein
Clusterin	SP-40, Apolipoprotein J	Brain, liver, testis, AT	Activation of tumor progression and angiogenesis
DPP4	Cd-26	Small intestine, duodenum, AT, liver	Degradation of GIP and GLP-1
FABP4	AFABP; ap2	AT	Fatty acid uptake, transport, and metabolism
Fetuin-A	Alpha 2-Heremans-Schmid glycoprotein	Liver, AT	Bone metabolism regulation, vascular calcification, IR
FGF21		Liver, AT	Stimulation of adipocyte glucose uptake, activation of thermogenesis, energy expenditure, improvement of glucose, and lipid metabolism
GDF15	PDF; MIC1; PLAB; NAG-1; PTGFB	AT, liver	Biomarker of various pathological states, such as certain tumors, inflammatory diseases, cardiovascular disease, obesity
Gremlin-1		Liver, AT	Inhibition of BMP4 and BMP7
IL-1β		Macrophages	Inflammation
IL-6		Macrophages	Inflammation
Leptin		AT, placenta	Regulation of energy homeostasis, satiety, immune and inflammatory responses, hematopoiesis, angiogenesis, reproduction

(continued)

Adipokines, Table 1 (continued)

Adipokine	Synonyms	Mainly expressed and secreted by	Main functions
Lipocalin 2	NGAL	AT, liver, immune cells	Regulation of IR and inflammation
MCP-1	CCL2	Macrophages	Inflammation, chemoattraction
Nesfatin-1	Nucleobindin derivative 2	AT, testis	Modulation of energy metabolism
Omentin	Intelectin-1	AT	Insulin sensitizer, anti-inflammatory
Progranulin		AT, lung, BM, immune cells	Inflammation, chemoattraction
RBP4		Liver, adipose tissue	Hepatic steatosis, lipid and glucose metabolism, IR
Resistin	FIZZ3	BM, AT, duodenum	Aging, IR, osteoarthritis
TGFβ		Immune cells	Regulation of proliferation, differentiation, and apoptosis
TIMP-1		Placenta, AT, gall bladder	Glucose metabolism
TNF-α		Macrophages	Inflammation
Vaspin		AT, skin	Regulation of food intake and glycemia
VEGF		Endothelial cells	Stimulation of angiogenesis
Visfatin	Nampt	BM, AT	β-Cell function
Wnt1-inducible signaling pathway protein 1		AT	Regulation of adipogenesis and inflammation in AT



Adipokines, Fig. 2 Adipose tissue as an endocrine organ with impact on severe disease entities. (Modified from Fasshauer and Blüher (2015))

Adipokines, Table 2 Adipokine-based pharmacological treatment strategies. BMP7, bone morphogenetic protein 7; DDP4, dipeptidyl peptidase 4; FGF21, fibroblast growth factor 21; GDF15, growth differentiation factor 15; GLP-1, glucagon-like peptide 1; GIP, glucose-dependent insulinotropic polypeptide; IL-1β, interleukin-1β; IL-1R, interleukin-1β receptor; OP-1, osteogenic protein-1; TNF-α, tumor necrosis factor-α

Adipokine	Drug name (agonist/ antagonist)	Mechanism of action (therapeutic potential)	Stage of drug development	Reference
Adiponectin	AdipoRon	Orally active, synthetic small-molecule, adiponectin receptor agonist	Preclinical	(Okada-Iwabu et al. 2013)
BMP7	OP-1	Human recombinant BMP7	Approved for local treatment of bone fractures	(Vaccaro et al. 2008)
DDP4	For example, alogliptin, sitagliptin, linagliptin, saxagliptin, vildagliptin	Delayed degradation of GLP-1 and GIP hormones	DPP4 inhibitors widely used for treatment of type 2 diabetes	(Nauck 2011)
FGF21	LY2405319	Synthetic FGF21 variant	Phase II clinical trial	(Gaich et al. 2013)
GDF15	Recombinant GDF15 (HAS-GDF15)	Half-life extended GDF15	Preclinical (rodent and nonhuman primate studies)	(Mullican et al. 2017)
IL-1β	For example, Anakinra	Human recombinant IL-1R antagonist	Approved for the treatment of rheumatoid arthritis	(Larsen et al. 2007)
Leptin	Metreleptin	Synthetic leptin analogue	Approved for compassionate use for patients with congenital leptin deficiency	(Chou and Perry 2013)
TNF-α	For example, infliximab, etanercept	TNF-a neutralization	Approved for the treatment of rheumatoid arthritis	(Stanley et al. 2011)

induced inhibition of glucose secretion from hepatocytes. Adiponectin also has an insulin-sensitive effect on skeletal muscle, with a C-terminal 16 kDa fragment in particular very potent in stimulating fatty acid oxidation and thus lowering plasma glucose levels (Fasshauer and Blüher 2015). Adiponectin signals to target cells through its receptors AdipoR1, AdipoR2, and T-cadherin. AdipoR1/AdipoR2 double-knockout mice exhibit a phenotype with IR and impaired glucose tolerance, increased inflammation, and oxidative stress in the skeletal muscle, liver, and AT, leading to increased gluconeogenesis and decreased glucose uptake in these mice (Iwabu et al. 2019; Yamauchi et al. 2007). Thus, while adiponectin may indirectly inhibit atherosclerosis through effects on glucose and lipid metabolism, it also directly acts on vascular endothelial and inflammatory cells, thus directly inhibiting atherosclerosis in humans (Iwabu et al. 2019). Studies in mice lacking the adiponectin gene also show that the intima media of vessels was significantly thicker compared to control animals, suggesting a function of adiponectin as an endothelial protective factor (Fasshauer and Blüher 2015). In line with the role of adiponectin as an endogenous insulin sensitizer, in several clinical studies, low adiponectin levels are associated with an increased risk of developing T2D (Fasshauer and Blüher 2015). In obesity, adiponectin serum levels are decreased. Moreover, high circulating adiponectin levels are associated with a significantly lower risk of myocardial infarction in humans (Iwabu et al. 2019). Adiponectin/AdipoR-enhancing and AdipoR-activating agents are potential pharmacological tools for the treatment of obesity and the metabolic syndrome. Indeed, the small-molecule AdipoR-activating compound (adiponectin receptor agonist,

AdipoRon) does not only improve metabolism at the organ level (e.g., skeletal muscle, liver, and AT) but provides antidiabetic properties at the organism level, while it normalizes a shortened life span due to obesity (Okada-Iwabu et al. 2013). In more detail, diminished adiponectin-associated metabolic effect in AdipoR1-/AdipoR2-knockout mice and restoration of obesity-induced metabolic alterations in high-fat-diet-fed mice by AdipoRon administration with implication on fatty acid combustion suggest that AdipoRon is a promising agent for treating T2D (Holland et al. 2017).

Thus, orally active small-molecule adiponectin receptor agonists, such as AdipoRon, could potentially be an important therapeutic agent for patients with NAFLD, T2D, or other comorbidities of obesity. Until today, there are no clinical studies available that directly test the effects of adiponectin or adiponectin analogues on human insulin sensitivity and arteriosclerosis.

FABP4: Lipid Transport Protein Implicated in Several Aspects of the Metabolic Syndrome

Fatty acid-binding protein (FABP) 4 has been identified in a cDNA library from differentiated 3 T3-L1 adipocytes in 1984 and encodes a polypeptide with a molecular mass of 14.6 kDa (Furuhashi 2019). FABP4 mRNA and protein production are significantly induced during adipocyte differentiation. Results from in vitro and in vivo studies suggest that FABP4 expression in adipocytes induces IR, triglyceride (TG) release, and pro-inflammatory gene expression. Furthermore, expression of FABP4 in macrophages appears to be crucial for its effects on atherosclerosis. Thus, FABP4 induces foam cell development by increasing cholesterol and TG accumulation, as well as by inducing expression of pro-inflammatory genes (Hotamisligil and Bernlohr 2015). Macrophage infiltration into AT is stimulated by FABP4. These data indicate that FABP4 might be an interesting therapeutic target for metabolic and vascular disease even if a FABP4 receptor has not yet been discovered. Since 2006, data have accumulated that circulating FABP4 concentrations are positively correlated with markers of the metabolic syndrome and vascular disease in various cross-sectional (Kralisch and Fasshauer 2013).

Several drugs, including statins, eicosapentaenoic acid (EPA)/docosahexaenoic acid (DHA) agents, angiotensin II receptor blockers, and dipeptidyl peptidase-4 inhibitors (DPP4i), can decrease FABP4 levels (Furuhashi 2019). The specific FABP4 inhibitor BMS309403 is an orally active small molecule that interacts with the fatty acid-binding pocket within the interior of FABP4 to inhibit binding of endogenous fatty acids. Treatment with BMS309403 has beneficial effects by improving IR, T2D, NAFLD, and atherosclerosis in experimental models, indicating a therapeutic strategy against several aspects of metabolic syndrome due to chemical inhibition of FABP4. Furthermore, treatment with antagonists of receptors for FABP4, especially PA-bound FABP4, would be a novel therapeutic strategy but require the identification of a FABP4 receptor. In 2015, targeting high serum FABP4 levels using a monoclonal antibody (mAb, CA33) to inhibit FABP4 was introduced (Burak et al. 2015). The antidiabetic effect of CA33 is predominantly linked to the regulation of hepatic glucose output and peripheral glucose utilization. Although no clinical trials have been reported, these results suggest FABP4 mAb-mediated treatment of T2D.

FGF21: Beneficial Effects on Glucose and Lipid Metabolism in Multiple Target Organs

The fibroblast growth factor (FGF) family is a group of multifunctional signaling molecules that have a wide variety of functions. FGF21 was first identified as a 23 kDa protein that increases insulin-independent glucose uptake in murine adipocytes (Sonoda et al. 2017). FGF21 is expressed in several metabolically active organs such as the AT, liver, and muscle and interacts with different tissues (Itoh 2014). FGF21 signaling is mediated by activation of FGF receptor 1 (FGFR1) c with β-Klotho as a cofactor.

FGF21 has thermogenic effects mediated through activation of FGF21 expression in white AT and brown AT expressing Fgfr1c and β-Klotho after cold exposure. In humans, FGF21 activates the thermogenic machinery against hypothermia.

Adiponectin acts as a downstream effector of FGF21 in WAT and mediates the effects of FGF21 on energy metabolism and insulin sensitivity in the liver and skeletal muscle.

Fgf21 single polymorphisms are possibly related with metabolic diseases. In obesity, there are elevated levels of FGF21 and exogenous FGF21 does not work as usual. This fact suggests that obesity is an FGF21-resistant condition (Fisher et al. 2010).

FGF21 treatment leads to beneficial metabolic effects in animal models (Itoh 2014). Therefore, great efforts are being made to identify a pharmacological target. Over the last decade, FGF21 analoga and other forms of agonists that directly activate the FGFR1c/ß-receptor complex have been tested in nonhuman primates and humans, revealing their potential to ameliorate obesity and obesity-related comorbidities. At least nine FGF21-class molecules have been tested in humans, and several compounds are still in different stages of clinical development for the treatment of T2D and NAFLD. To date, approaches targeting FGF21 for anti-obesity and antidiabetic treatment include modified FGF21 as well as agonistic antibodies against the FGF21 receptor – FGF receptor 1 (FGFR1) and the obligatory co-receptor βKlotho. In addition, a novel approach to increase endogenous FGF21 activity by inhibiting the FGF21-degrading protease fibroblast activation protein (FAP) is discussed.

In proof of principle clinical trials, LY2405319, a variant of human FGF21, and PF05231023, a bivalent fusion of human FGF21 to human IgG have been tested (Sonoda et al. 2017). LY2405319 has beneficial effects in these phase 1, placebo-controlled, blinded studies on body weight reduction and fasting insulin and caused significant improvements in dyslipidemia (Sonoda et al. 2017). Noteworthy, the compound did not significantly improve glucose concentrations. The mechanisms contributing to weight loss and other metabolic effects were not clear as food intake or energy expenditure was not measured nor reported in either study. Based on preclinical data, it is likely that FGF21 analogues will affect both energy intake and expenditure; however, the relative contribution of these pathways to weight loss in human subjects is still unknown (Sonoda et al. 2017).

Long-acting FAP-resistant FGF21 analogues and FGFR1/β-Klotho agonist antibodies with a superior pharmacokinetic profile represent an exciting opportunity to expand the therapeutic potential of FGF21-class molecules. In addition, a combination therapy utilizing fibrate and a FAP inhibitor may offer an oral therapy to augment endogenous FGF21 action. Further preclinical and clinical studies should determine whether any of these approaches will be viable to approach the global obesity and T2DM epidemic (Sonoda et al. 2017).

BMP7: An Adipokine that Induces Brown Adipogenesis and Reduces Food Intake and Weight Gain

Bone morphogenetic protein (BMP) 7 is a member of the transforming growth factor (TGF)-β superfamily promoting brown adipocyte differentiation and thermogenic function in adipose progenitor cells and increases brown AT-mediated energy expenditure in vivo (Tseng et al. 2008). Recently, several members of the BMP family of ligands and receptors have been found to associate with obesity-related traits in humans (Blüher 2014); however, a detailed mechanism for how the BMPs affect energy balance and obesity remains to be elucidated. Clinical trials studying the effects of BMP and growth factors in the treatment of pseudoarthrosis and bone defects as well as in coated implants will shed further light on the significance of these factors in inducing bone growth as well as on BMP7 inducing brown adipogenesis, reducing food intake, increasing energy expenditure, and reducing weight gain (Townsend et al. 2012).

Recombinant BMP, marketed under the brand name OP-1 (osteogenic protein 1), is already available for 10 years, but there is little data on standardized clinical implementation in humans. The results of 120 applications are currently assembled, and approval of BMP-7 by the Food and Drug Administration (FDA) is expected in the next few years. Whether the encouraging results of experimental animal studies can be applied to treat human obesity

and metabolic disease will be revealed in the future.

Chemerin: Multifaceted Adipokine Displays Various Roles in the Pathogenesis of Inflammation and Metabolic Disease

Chemerin encoded by the gene retinoic acid receptor responder 2 (Rarres2), also known as tazarotene-induced gene 2 (TIG2), is an adipokine with autocrine, paracrine, and even endocrine roles in vivo (Helfer and Wu 2018). Chemerin is a chemokine highly expressed in the white AT, liver, and lung, while its receptor chemerin chemokine-like receptor 1 (CMKLR1) is predominantly expressed in adipocytes and immune cells. Interestingly, chemerin increases food intake in seasonal animals by acting on hypothalamic stem cells, the tanycytes. In peripheral tissues, chemerin increases cell expansion, inflammation, and angiogenesis in AT, collectively resulting in adiposity (Helfer and Wu 2018).

High chemerin levels are associated with a significant risk for developing metabolic syndrome. It is hypothesized that chemerin is involved in the pathogenesis of metabolic diseases by regulating meta-inflammation, adipocyte plasticity, and glucose metabolism.

With regard to therapeutic options, the novel chemerin (ChemR23) antagonist CCX832 has been shown to protect against chemerin-related arterial contraction, thus linking higher chemerin concentrations in obesity to impaired vascular function (Watts et al. 2013). Sequence analysis revealed a PPARγ response element within the chemerin promoter (Muruganandan et al. 2011); thus, insulin-sensitizing drugs that activate PPARγ might be beneficial for the treatment of obesity and T2D. In support, in normal and leptin-deficient *ob/ob* mice, the PPARγ agonist rosiglitazone increased the expression of chemerin transcript in AT and raised plasma chemerin levels (Helfer and Wu 2018). However, pioglitazone and metformin decreased plasma chemerin levels in patients with T2D (Helfer and Wu 2018). It is therefore not clear whether an agonist or antagonist of chemerin action might be useful for the treatment of T2D and the contribution of chemerin to the pathology of obesity and T2D remains elusive.

Specifically, the pharmacology and signaling properties of chemerin receptors in the hypothalamus have not been characterized. Given the importance of the hypothalamus in sensing and integrating peripheral signals, studies into hypothalamic chemerin signaling might help explaining some of the contradictory findings on the mode of chemerin's action. Furthermore, it is important to understand whether chemerin exerts a pro- or anti-inflammatory response or if the effect is indeed bimodal in different biological systems. Chemerin remains a promising target candidate for the pharmacological treatment of obesity.

Fetuin-A: Circulating Protein Linked to Insulin Resistance and Obesity

Fetuin-A, also termed alpha2-Heremans-Schmid glycoprotein, is a 46 kDa adipokine with multifaceted functions mainly due to its potential interaction with the insulin receptor. In diabetes models, it has been shown that fetuin-A binds the β-subunit of the insulin receptor to attenuate insulin signaling, thereby contributing to IR in T2D. Fetuin-A may also, together with free fatty acids, induce apoptotic signals in pancreatic beta cells, reducing the secretion of insulin and further exacerbating T2D. Associations of fetuin-A levels with the metabolic syndrome have been described (Jirak et al. 2019). Fetuin-A may also serve as a protective agent in severe systemic inflammation. A novel aspect is the putative role of fetuin-A in AT inflammation.

From the clinical perspective, higher circulating fetuin-A levels were associated with increased risk of T2D. However, the causality deserves further analysis (Guo et al. 2018). At the present, there is no indication of a possible therapy strategy using fetuin-A.

GDF15: Stress Response Cytokine with Impact on Energy Homeostasis

GDF15 is a stress response cytokine and a distant member of the TGF-β superfamily, with no close relatives. It acts via a recently identified

receptor called glial-derived neurotrophic factor (GDNF) receptor alpha-like. GDF15 expression and serum levels rise in response to many stimuli that initiate cell stress and as part of a wide variety of disease processes, most prominently cancer and cardiovascular disease. The best documented actions of GDF15 are on the regulation of energy homeostasis. When GDF15 serum levels are substantially elevated in diseases like cancer, it subverts a physiological pathway of appetite regulation to induce an anorexia/cachexia syndrome initiated by its actions on hindbrain neurons. These effects make it a potential target for the treatment of both obesity and anorexia/cachexia syndromes, disorders lacking any highly effective, readily accessible therapies (Tsai et al. 2018).

Recombinant GDF15 and half-life-extended variants of GDF15 demonstrated strong efficacy in lowering body weight and improved metabolic parameters in obese mice, rats, and monkeys (Xiong et al. 2017). However, the knowledge of its pathophysiological function at the molecular level is still limited and requires more investigation. Recent identification of the endogenous receptor for GDF15 may provide additional insight into its molecular mechanisms and relationship to disease states and potential therapy strategies (Emmerson et al. 2018).

IL-1β: Inflammatory Marker of Obesity

Interleukin (IL)-1β – a 17 kDa cytokine – is mainly secreted from immune cells but also by AT. IL-1β is a pro-inflammatory cytokine that has been proven to be effective in the treatment of T2D.

The expression of the IL-1-receptor antagonist is reduced in pancreatic islets of patients with T2D, and high glucose concentrations induce the production of IL-1 β in human pancreatic beta cells, leading to impaired insulin secretion, decreased cell proliferation, and apoptosis.

IL-1β inhibits the function and promotes apoptosis of beta cells. The blockade of IL-1 with the recombinant human IL-1 receptor antagonist (anakinra) has been shown to improve glycemia and beta cell function and reduce markers of systemic inflammation in a double-blind, parallel-group trial involving 70 patients with T2D (Larsen et al. 2007). Therefore, IL-1β, in addition to the direct use of adipokines as a therapeutic strategy, can be indirectly used as target molecules for the treatment of obesity.

TNF-α: Inflammatory Marker of Obesity

TNF-α was first described in animal studies in 1993 as a 25 kDa adipokine that significantly reduces insulin sensitivity in animal models. The IR-inducing effect is mainly caused by an inhibition of insulin signaling molecules. In line with the negative effect of TNF-α on insulin sensitivity, various mouse models of obesity and IR show increased serum concentrations of this protein. TNF-α can bind to two different receptors (Fasshauer and Blüher 2015).

Neutralization of elevated TNF-α levels by antibodies also increases insulin sensitivity in animal models (14). However, these promising data could not be translated into a clinically relevant treatment option in humans. TNF-α protein production in AT is very low, and studies suggest that the serum concentrations of this adipokine do not differ between insulin-resistant and insulin-sensitive volunteers with similar body weights. Of note, in patients with spondyloarthritis, anti-TNF-α therapy contributed to an early significant increase in both visceral and subcutaneous AT after 1–2 years of treatment (Fasshauer and Blüher 2015). Moreover, in a prospective, randomized, double-blind, placebo-controlled pilot study of insulin-resistant obese men, chronic TNF-α neutralization by infliximab did not improve IR and questioned the suggested causative link between adiposity and IR, at least in human disease (Wascher et al. 2011).

A first study on the clinical therapeutic application of TNF-α inhibition was disappointing. In contrast to the animal model, insulin sensitivity was not increased by neutralizing TNF-α. Also in view of the numerous side effects of such a treatment described, it seems unlikely that future therapies of IR, T2D, and obesity will be based on inhibition of this adipokine.

Omentin: A Biomarker of Metabolic Disorders

Omentin-1, also known as intelectin-1, is a recent adipokine of 31 kDa, which is expressed in visceral AT as well as in vascular cells, small intestine, colon, and ovary. The concentration of omentin-1 expression in (pre-)adipocytes is reduced by glucose or insulin and enhanced by FGF21 and corticosteroid (dexamethasone). Multiple experimental data have shown that omentin-1 may play a crucial role in supporting the body's energy metabolism and insulin sensitivity and has anti-inflammatory, anti-atherosclerotic, and cardiovascular protective effects. Clinical studies have shown the use of circulating low omentin-1 levels as a biomarker for obesity, IR, T2D, and atherosclerotic cardiovascular diseases. However, omentin-1 increases to counteract the acute phase after onset of cardiometabolic disorders. These findings indicate that omentin-1 may be a risk factor for cardiometabolic diseases and may also act as an acute-phase reactant by its anti-inflammatory and atheroprotective effects. A therapeutic approach to restoring omentin-1 levels can be beneficial for the prevention or treatment of these diseases. Losing weight, eating a diet rich in olive oil, doing aerobic exercise, and treatment with drugs to lower blood cholesterol (atorvastatin) and antidiabetics (e.g.. metformin and pioglitazone) are effective tools for increasing blood circulation of it. These data support the possible use of omentin-1 as a biomarker and therapeutic target for these pathologies (Watanabe et al. 2017).

In summary, adipokines are signal molecules that are released in relation to the status of adipose tissue function. Adipokines communicate information about energy reserves with the body – especially the brain. In the future, adipokines could gain clinical importance as circulating markers or predictors for metabolic and cardiovascular diseases, for the success of weight-reducing therapies, and also for pharmacological therapy approaches.

Drugs

For examples, see Table 2 (list of relevant drugs summarized in Table 2).

Synonyms

α-Adrenergic receptors; α-Adrenoceptors

Definition

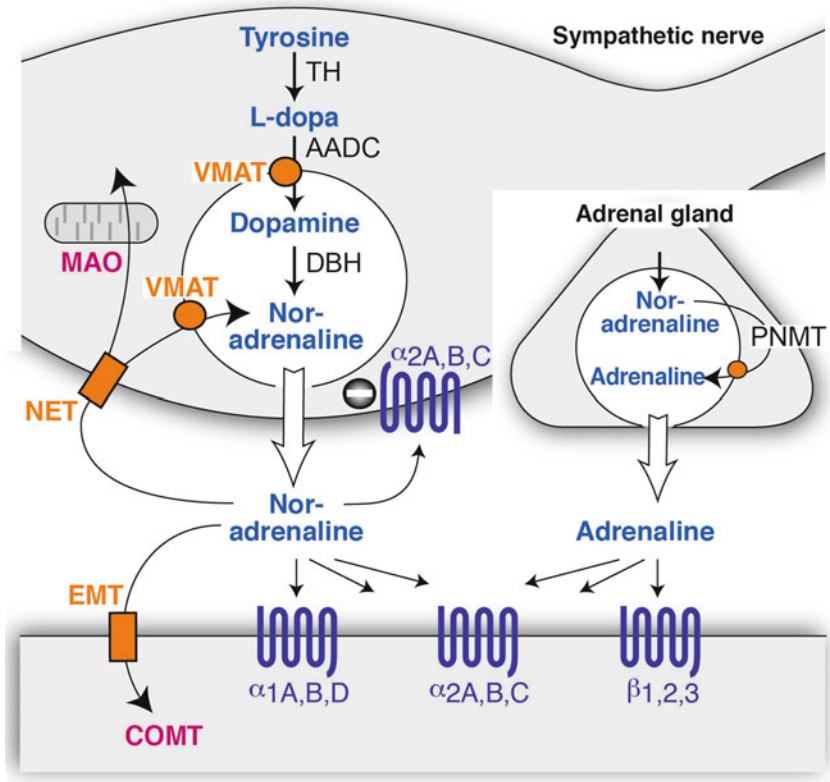
The α-adrenergic system consists of six subtypes of G-protein-coupled receptors which mediate part of the biological actions of the catecholamines adrenaline and noradrenaline. α-Adrenergic receptors (adrenoceptors) are important regulators of smooth muscle cell contraction (α_1-adrenergic receptors) (Akinaga et al. 2019) and presynaptic neurotransmitter release (α_2-adrenergic receptors) and several other functions in the peripheral and central nervous systems (Hein 2006; Starke 2001). In addition, adrenaline and noradrenaline activate β-adrenergic receptors, which stimulate cardiac contractility and rhythm and inhibit bronchial, vascular, and uterine smooth muscle contraction.

Basic Characteristics

The adrenergic system is an essential regulator that increases cardiovascular and metabolic capacity during situations of stress, exercise, and disease. Nerve cells in the central and peripheral nervous system synthesize and secrete the neurotransmitters noradrenaline and adrenaline. In the peripheral nervous system, noradrenaline (norepinephrine) and adrenaline (epinephrine) are released from two different sites: noradrenaline is the principal neurotransmitter of sympathetic neurons that innervate many organs and tissues. In contrast, adrenaline, and to a lesser degree noradrenaline, is produced and secreted from chromaffin cells in the adrenal gland into the circulation (Fig. 1). Thus, the actions of noradrenaline are mostly restricted to the sites of release from sympathetic nerves, whereas adrenaline acts as a hormone to stimulate many different cells via the bloodstream.

Together with dopamine, adrenaline and noradrenaline belong to the endogenous catecholamines that are synthesized from the precursor amino acid tyrosine (Fig. 1). In the first biosynthetic step, tyrosine hydroxylase generates ► l-DOPA which is further converted to dopamine by the aromatic l-amino acid decarboxylase (dopa decarboxylase). Dopamine is transported from the cytosol into synaptic vesicles by a vesicular monoamine transporter (VMAT). In sympathetic nerves, vesicular dopamine β-hydroxylase generates the neurotransmitter noradrenaline. In chromaffin cells of the adrenal medulla, approximately 80% of the noradrenaline is further converted into adrenaline by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT).

Several mechanisms serve to terminate the biological actions of noradrenaline and adrenaline. From the synaptic cleft, most of the released noradrenaline is recycled by reuptake into the nerve terminals via a specific noradrenaline transporter (NET, gene symbol *SLC6A2*). Alternatively, (nor)



α-Adrenergic System, Fig. 1 Synthesis and release of noradrenaline and adrenaline from sympathetic nerve endings (left) and from the adrenal gland (right). Noradrenaline and adrenaline are synthesized from the precursor amino acid tyrosine and are stored at high concentrations in synaptic vesicles. Upon activation of sympathetic nerves or adrenal chromaffin cells, noradrenaline and adrenaline are secreted and can activate adrenergic receptors on surrounding cells (sympathetic nerve), or they enter the blood circulation (adrenaline released from the adrenal gland). Release of noradrenaline from nerve terminals is controlled by presynaptic inhibitory α_2- and activating β_2-adrenergic receptors. Actions of noradrenaline are terminated by uptake into nerve terminals (NET) and synaptic vesicles (VMAT) and by uptake into neighboring cells (EMT). Abbreviations: *AADC*, aromatic l-amino acid decarboxylase; *COMT*, catechol *O*-methyltransferase; *DBH*, dopamine β-hydroxylase; *EMT*, extraneuronal noradrenaline transporter (organic cation transporter); *MAO*, monoamine oxidase; *NET*, noradrenaline (norepinephrine) transporter; *PNMT*, phenylethanolamine-*N*-methyltransferase; *TH*, tyrosine hydroxylase; *VMAT*, vesicular monoamine transporter

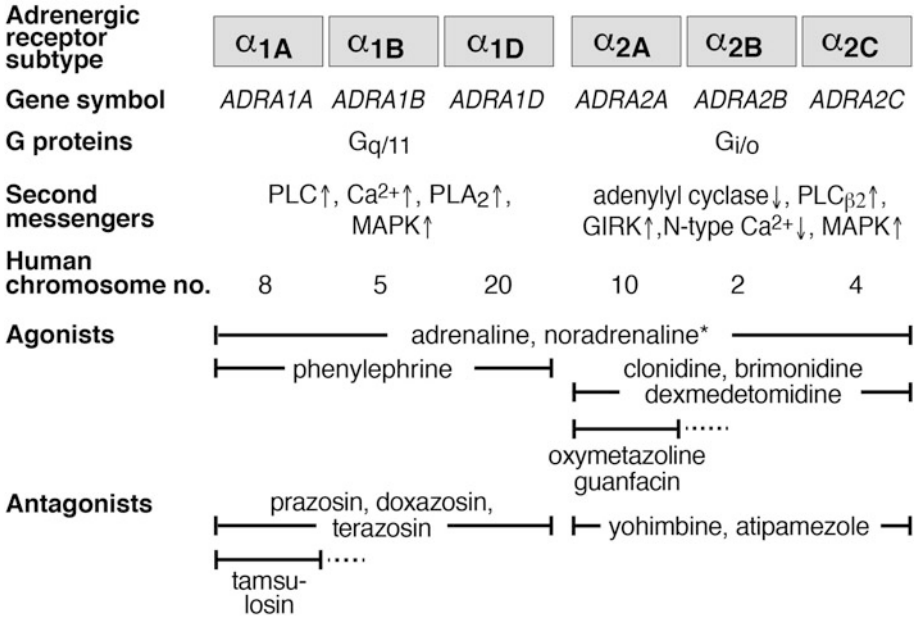
adrenaline can be transported into nonneuronal cells by extraneuronal monoamine transporters, which belong to the family of organic cation transporters (e.g., OCT1-3). The noradrenaline transporter (NET) is blocked by cocaine, tricyclic antidepressants, or selective noradrenaline reuptake inhibitors (SNRIs). After reuptake into the nerve, most of the noradrenaline is transferred into synaptic vesicles. A smaller fraction is destined for degradation by the enzymes monoamine oxidase (MAO, in sympathetic nerves) or ▶ catechol-*O*-methyltransferase (COMT, in neighboring cells). COMT plays a major role in the metabolism of circulating catecholamines. MAO and COMT are widely distributed, and inhibitors of these enzymes are used for the treatment of mental depression (MAO-A inhibitor, moclobemide) or Parkinson's disease (MAO-B inhibitor, selegiline).

The biological actions of adrenaline and noradrenaline are mediated via nine different ▶ G-protein-coupled receptors, which are located in the plasma membrane of neuronal and

nonneuronal target cells. These receptors are divided into two different groups, α-adrenergic receptors and β-adrenergic receptors (see β-adrenergic system). The distinction between α- and β-adrenergic receptors was first proposed by Ahlquist in 1948 based on experiments with various catecholamine derivatives to produce excitatory (α) or inhibitory (β) responses in isolated smooth muscle systems. Initially, a further subdivision into presynaptic α_2- and postsynaptic α_1-receptors was proposed. However, this anatomical classification of α-adrenergic receptor subtypes was later abandoned. Six α-adrenergic receptors have been identified by molecular cloning: three α_1-adrenergic receptors (α_{1A}, α_{1B}, α_{1D}) and three α_2-subtypes (α_{2A}, α_{2B}, α_{2C}) (Fig. 2). Due to the lack of sufficiently subtype-selective ligands, the unique physiological and pathophysiological roles of these α-receptor subtypes, for the most part, have been identified by studies in mice that carry deletions in the genes encoding for individual α-receptor subtypes.

The structure of the α_{2B}-adrenergic receptor in complex with the G protein G_o was recently identified by cryo-electron microscopy (Yuan et al. 2020). The α_2-agonist dexmedetomidine interacts with the α_{2B}-receptor mostly via aromatic and van der Waals interactions, which is different from adrenaline's interaction with the β_2-adrenergic receptor via ionic or hydrogen bonds (Yuan et al. 2020).

α_1-Adrenergic receptors mediate contraction and hypertrophic growth of vascular smooth muscle cells and cardiac myocytes (Akinaga et al. 2019). The three α_1-receptor subtypes share 75% identity in their transmembrane domains, whereas the degree of homology between α_1- and α_2-receptors is significantly smaller (35–40%). Due to initial discrepancies between the pharmacological subtype classification, mRNA and protein expression data, and experiments with cloned α_1-receptor subtypes, some confusion exists in the early literature with respect to the assignment of α_1-receptor subtype nomenclature. In the present terminology, α_{1A} (gene symbol *ADRA1A*), α_{1B} (gene symbol *ADRA1B*), and α_{1D}-receptors (*ADRA1D*) can be distinguished (Altosaar et al.



α-Adrenergic System, Fig. 2 Subtypes of α-adrenergic receptors, their signaling pathways, and agonist and antagonist binding profiles. *Adrenaline and noradrenaline can also activate β-adrenergic receptors (see β-adrenergic system). PLA_2, *PLC*: phospholipases A, C; *GIRK*: G-protein-activated inwardly rectifying potassium channel, *MAPK*: mitogen-activated protein kinase

2019). All three subtypes seem to be involved in the regulation of vascular tone, with the α_{1A}-receptor maintaining basal vascular tone and the α_{1B}-receptor mediating the constrictory effects of exogenous α_1-agonists. Cardiac α_1-receptors increase contractile force and mediate anti-apoptotic and hypertrophic effects (O'Connell et al. 2014). All α_1-receptor subtypes can activate Gq-proteins, resulting in intracellular stimulation of phospholipases C, A_2, and D, mobilization of Ca^{2+} from intracellular stores and activation of mitogen-activated protein kinase and PI3 kinase pathways. Mutagenesis of receptor subtypes has led to the identification of a number of amino acids involved in agonist binding and receptor activation as well as binding sites for antagonists within the receptor's binding crevice (Cotecchia et al. 2004).

Three genes encoding for α_2-adrenergic receptor subtypes have been identified from several species, termed α_{2A}, α_{2B}, and α_{2C}, respectively (Fig. 2). The pharmacological profile of the α_{2A}-subtype differs significantly between species, thus giving rise to the pharmacological subtypes α_{2A} in humans, rabbits, and pigs and α_{2D} in rats, mice, and guinea pigs. Part of the pharmacological difference between α_{2A}- and α_{2D}-receptors can be explained by a Ser-Ala mutation in the fifth transmembrane helix of the α_{2A}-receptor rendering this receptor less sensitive to the antagonists, rauwolscine and yohimbine. α_2-Adrenergic receptors regulate a wide range of signalling pathways via interaction with multiple heterotrimeric $G_{i/o}$ proteins including inhibition of adenylyl cyclase, stimulation of phospholipase D, stimulation of mitogen-activated protein kinases, stimulation of K^+ currents, and inhibition of Ca^{2+} currents. The three α_2-receptor subtypes have unique patterns of tissue distribution in the central nervous system and in peripheral tissues. The α_{2A}-receptor is expressed widely throughout the central nervous system including the locus coeruleus, brain stem nuclei, cerebral cortex, septum, hypothalamus, and hippocampus. In the periphery, α_{2A}-receptors are expressed in the kidney, spleen, thymus, lung, and salivary gland. The α_{2B}-receptor primarily shows peripheral expression (the kidney, liver, lung, and heart) and only low-level expression in thalamic nuclei of the central nervous system. The α_{2C}-receptor appears to be expressed primarily in the central nervous system (striatum, olfactory tubercle, hippocampus, and cerebral cortex), although very low levels of its mRNA are present in the kidney.

α_{2A}-, α_{2B}-, and α_{2C}-receptors are located presynaptically and function to inhibit noradrenaline release from sympathetic nerves as part of a negative feedback loop (Schlicker and Feuerstein 2017; Starke 2001). Activation of these receptors leads to decreased sympathetic tone and decreased blood pressure and heart rate (Hein et al. 1999). Central α_{2A}-receptors mediate sedation and analgesia (Hein 2006). Sedation induced by α_2-receptors follows a similar hypothalamic circuit as recovery sleep in response to sleep deprivation (Zhang et al. 2015).

α_{2B}-Receptors mediate contraction of vascular smooth muscle (Link et al. 1996; MacMillan et al. 1996), and they are required for placenta development (Philipp et al. 2002), and in the spinal cord they are essential components of the analgesic effect of nitrous oxide. Upon stimulation by agonists, α_1- and α_2-receptor signalling pathways are attenuated by several mechanisms at the receptor and postreceptor levels (see β-adrenergic system).

Drugs

Therapeutically, α_1-receptor-mediated vasoconstriction contributes to the beneficial actions of adrenaline applied as an emergency medicine during hypotensive or anaphylactic shock. Addition of adrenaline or noradrenaline to local anaesthetics retards diffusion of the local anaesthetic from the site of injection and thereby prolongs its action. α_1-Receptor antagonists including prazosin, doxazosin, and terazosin are used to treat patients with hypertension. However, α_1-receptor antagonists are no longer first-line

antihypertensive agents (Williams et al. 2018) since the ALLHAT clinical trial revealed that hypertensive patients taking doxazosin had a higher risk of developing congestive heart failure than patients with diuretic treatment. Tamsulosin is the first α_1-receptor antagonist with selectivity for the α_{1A}-receptor over α_{1B}- and α_{1D}-subtypes. The α_{1A}-selectivity is thought to contribute to the beneficial actions of tamsulosin in the treatment of benign prostate hypertrophy without strong hypotensive effects.

At present, no drugs have been approved for clinical use that can activate α_2-receptor subtypes with high selectivity. However, oxymetazoline and guanfacine have some selectivity for α_{2A} versus α_{2B} and α_{2C} (Altosaar et al. 2019). Clonidine stimulates all three α_2-subtypes with similar potency. Clonidine lowers blood pressure in patients with hypertension, and it decreases sympathetic overactivity during opioid withdrawal. In intensive and perioperative care, clonidine and dexmedetomidine are potent sedative and analgesic α_2-agonists and can prevent postoperative shivering. Guanfacine has been approved for treatment of attention deficient hyperactivity disorder (ADHS) in children and adolescents. Clonidine and its derivative brimonidine lower intraocular pressure of glaucoma patients when applied locally. Moxonidine may have less sedative side effects than clonidine when used as an antihypertensive. It has been suggested that moxonidine activates "imidazoline receptors" instead of α_2-receptors. However, the molecular identity of "imidazoline receptors" has not been revealed, yet (Bousquet et al. 2020). The α_2-receptor agonists oxymetazoline and xylometazoline are being used as nasal decongestants. At present, selective α_2-receptor antagonists are not used in human medicine. However, in veterinary practice the α_2-receptor antagonist atipamezole can rapidly reverse anaesthesia mediated by the α_2-agonist medetomidine. In the future, subtype-selective drugs may greatly improve the therapy of diseases involving α_1- or α_2-adrenergic receptor systems.

α-Adrenoceptors

► α-Adrenergic System

Adrenomedullin Receptor

► Calcitonin Family Receptors

Adrenomedullin/Intermedin

A. J. Clark and G. Ladds
University of Cambridge, Cambridge, UK

Synonyms/Abbreviations

Adrenomedullin: AM, ADM

Adrenomedullin 2: AM2, ADM2, Intermedin, IMD

Definition

Adrenomedullin (AM) and Adrenomedullin 2 (AM2) or Intermedin (from here on referred to solely as Adrenomedullin 2) are members of the calcitonin gene-related peptide (CGRP) superfamily of peptides. These peptide hormones are agonists at, and exert their physiological effects through the calcitonin receptor-like receptor (CLR). The peptides have a multitude of different biological activities; foremost among them is AM's potent activity as a vasodilator. It also plays a key regulatory role in the cardiovascular and lymphatic system, as well as in angiogenesis, and vascular homeostasis. AM2 has effects on the cardiovascular system, adipose tissue, macrophages, and the kidney; it can also activate the sympathetic nervous system.

Basic Characteristics

AM was first discovered in 1993 (Kitamura et al. 1993) and AM2 by two groups in 2004 (Roh et al. 2004; Takei et al. 2004). They are from a peptide family also containing calcitonin (CT), calcitonin gene-related peptide (CGRP) – α and β form in humans, and amylin (Hay et al. 2018). Within this superfamily there are a few residues which are highly conserved and found in all members: these are two N-terminal cysteines forming a disulfide-bonded ring structure and a threonine within this structure (Schönauer et al. 2017). Compared to the other members of the superfamily AM and AM2 are most closely related to each other, despite having only limited sequence homology (28%) (Zhang et al. 2018).

AM and AM2 are 52 and 53 amino acids in length, respectively. The human AM gene is located on chromosome 11 and contains 4 exons and 3 introns. It is translated into the 185 amino acid long precursor prepro-AM which is eventually converted into mature AM (Schönauer et al. 2017). The human AM2 gene is found on chromosome 22 and codes for prepro-AM2 which is 148 amino acid residues in length before it is converted into mature AM2 (Zhang et al. 2018) Mature $AM2_{1–53}$ can also be cleaved into $AM2_{1–47}$ and $AM2_{1–40}$.

Currently antibodies cannot distinguish between them, and the prominence of each in vivo remains uncertain. As does the physiological and pharmacological relevance of these cleavage fragments (Zhang et al. 2018).

Pharmacology

Both AM and AM2 act at a Class B GPCR – the CLR. It is suggested that they also have some activity at the calcitonin and amylin receptors. The CLR is unique in that it needs to associate with a receptor activity-modifying protein (RAMP) to form a functional receptor. There are three known RAMPs (RAMP1, 2, and 3), and each has an extracellular N-terminus, one intracellular domain, and an intracellular C-terminus. AM and AM2 bind all three functional receptor-RAMP complexes with varying affinities (Hay et al. 2018).

While the predominant CLR signaling pathway is through G_s and cAMP, there is also evidence for G_i coupling and cAMP inhibition, as well as G_q coupling and intracellular Ca^{2+} release. The extent to which pathways are activated is determined by both the receptor/RAMP combination and the bound peptide (AM or AM2).

CLR/RAMP1 forms the CGRP receptor, CLR/RAMP2 forms the AM_1 receptor, and CLR/RAMP3 forms the AM_2 receptor. When comparing the pharmacology of the human peptides at the human receptors, AM2 has activity at all three receptors (measured in terms of cAMP) and appears to be most potent at activating the AM2 receptor. AM also activates all three receptors with its activity at AM_1 and AM_2 significantly higher than at the CGRP receptor. Comparing the peptides with each other they have similar potencies at the CGRP and AM_2 receptor, with the main difference being AM's significantly greater potency at the AM_1 receptor (Hay et al. 2018), although further research is needed to elucidate the precise differences in signaling between the peptide-receptor combinations in cellular systems where the receptors are endogenously expressed.

The signaling bias of AM and AM2 through pathways beyond purely cAMP has recently been documented. There is evidence of this at the CGRP receptor where AM elicits a comparatively weak cAMP response (G_s). However, it has been shown that AM in fact also signals through G_i proteins at the CGRP receptor (Hay et al. 2018). Providing an explanation for the weak cAMP signal induced. Thus far these results have only been shown in overexpression systems and need demonstrating in the native system in order to determine the physiological relevance of AM and AM2's biased signaling.

In terms of internalization and receptor recycling, research suggests AM can drive the internalization of CGRP, AM_1, and AM_2 receptors. Furthermore, when AM internalizes with AM_1 it likely stays bound throughout the internalization and degradation process (Schönauer et al. 2017); little is known at present about AM2-driven internalization.

Physiology, Pathophysiology, and Therapeutic Potential

AM is mainly synthesized and secreted by endothelial cells and vascular smooth muscle cells, and has been detected in many tissues and organs including the heart, lung, liver, kidney, placenta, spleen, thyroid, adrenal medulla, and central nervous system (Schönauer et al. 2017). In comparison AM2 is widely expressed throughout the body, and particularly high expression levels are seen in the hypothalamus, pituitary, heart, GI tract, kidney, and circulation. It is believed to play a protective role in the renal and cardiovascular systems, inhibiting ER stress, inflammation, and oxidative stress (Takei et al. 2004).

AM is reported to be cardioprotective through regulating cell proliferation and antiapoptotic pathways in the vasculature. AM can also increase cardiac output by causing vasodilation of coronary vessels and decreasing vascular resistance (Schönauer et al. 2017). The potent vasodilatory effects of AM are important in the lung circulation and can decrease vascular resistance in pulmonary hypertension as well as protecting against hypoxic pulmonary damage. AM2 acts similarly; having been demonstrated to increase blood flow and decrease vascular resistance in many organs

including the heart, lungs, liver, and kidneys (Zhang et al. 2018).

AM is involved in lymphangiogenesis and the control of lymphatic vascular function through stabilizing the lymphatic endothelial barrier and sustaining vascular permeability (Schönauer et al. 2017). AM is also expressed alongside CLR and RAMP2 in osteoblasts and promotes bone growth and mineralization (Schönauer et al. 2017). There is a large increase in plasma AM in healthy pregnant women and it plays a role in decidualization, implantation, and placentation. Equally AM2 is elevated in pregnancy and has a hypotensive effect, while low AM2 levels are associated with preeclampsia (Zhang et al. 2018).

Several clinical trials have been performed using AM in patients, due to the potential protective effects AM might provide in multiple disease states. Two examples include trails using AM in patients with pulmonary hypertension and myocardial infarction. The possible use of AM as a therapy option comes with the advantages and disadvantages often associated with peptide drugs, such as high potency and low toxicity, but also low bioavailability and stability (Schönauer et al. 2017).

While the circulating plasma concentration of AM and AM2 is generally low, it can be greatly increased in the disease state. One of these diseases is diabetes where plasma levels of AM in patients are significantly high. It is not yet completely clear whether AM contributes to the disease state or acts as a protective factor.

AM can, however, act as a tumor survival factor through its angiogenic, proliferative, and antiapoptotic effects. It is produced by cancer cells and endothelial cells, and its expression has been shown to be upregulated in multiple tumor types. It can be involved in multiple stages of cancer development including tumor progression and invasion (Schönauer et al. 2017).

In the case of AM2, levels are increased during myocardial infarction and acute coronary syndrome (Zhang et al. 2018), and multiple studies have suggested that it plays a protective role in these conditions, particularly during ischemic cardiac injury (Zhang et al. 2018).

Advanced Glycation End-Proteins

Kamyar Asadipooya
Division of Endocrinology and Molecular Medicine, Department of Medicine, University of Kentucky, Lexington, KY, USA

List of Abbreviations

ADAM10	A disintegrin and metalloproteinase domain-containing protein 10
AF	Atrial fibrillation
AGE	Advanced glycation end-product

ARDS	Acute respiratory distress syndrome
CPOD	Chronic obstructive pulmonary diseases
DIAPH1 or mDia1	Protein diaphanous homolog 1
GOL1	Glyoxalase 1
HMBG1	High-mobility group box 1
LPA	Lysophosphatidic acid
LPS	Lipopolysaccharide
MAC-1	Macrophage adhesion ligand-1
NF-κB	nuclear factor κ-light-chain-enhancer of activated B cells
PTH	Parathyroid hormone
RAGE	Receptor for AGE
TLR	Toll-like receptors

Definition

The role of advanced glycation end-products (AGEs) in initiating, promoting, and worsening of metabolic derangement has been highlighted during recent years. There are well-reported connections between AGEs production and not only the development of metabolic syndrome and diabetes, but also micro- and macrovascular complications of diabetes (Asadipooya and Uy 2019; Ruiz et al. 2020).

AGEs are the products of irreversible non-enzymatic reactions between a reducing sugar and macromolecules (proteins, lipids, or nucleic acids). The condensation and oxidation process between reducing sugar and proteins, lipids, or nucleic acid leads to the production of AGEs. The process of AGEs production usually occurs in the background of hyperglycemia, but can also happen in other situations such as consumption of high fat diet, excessive alcohol consumption, smoking, renal failure, inflammation, and aging (Asadipooya et al. 2019; Asadipooya and Uy 2019). AGEs not only have direct toxic effects but also interact with other receptors, which leads to inflammation and oxidant injury. Generally, there are contributing factors that result AGEs production and ended up developing diseases or affecting the course of diseases with worsening outcomes.

Basic Mechanisms

General

The chemistry of glycation is complex and AGEs are highly heterogeneous molecules that can accumulate in various tissues and plasma. The process of AGEs accumulation is associated with oxidative stress and inflammation, which lead to changes in metabolic activities and even more AGEs production. However, scavenger receptors, such as CD36, can block AGEs mediated injury. AGEs enter into the cells through CD36, undergo degradation, and are eventually eliminated by kidneys. In addition, detoxification by AGE receptor complex is another defense mechanism against AGEs. Moreover, the enzyme glyoxalase 1 (GOL1) plays a key role in the detoxification of AGEs by regulating the production and function of pre-AGEs species, such as methylglyoxal and its derivatives (Asadipooya et al. 2019; Ott et al. 2014; Senatus and Schmidt 2017).

AGEs can cause oxidant injury and inflammation directly or through interaction with various receptors, including AGE-receptor complexes, scavenger receptors, and the multiligand receptor for AGEs (RAGE) (Asadipooya and Uy 2019; Ruiz et al. 2020). The multiligand receptor for AGEs (RAGE) on cell membrane is a well-studied receptor since the 1990s (Schmidt et al. 1992). RAGE is structurally like an immunoglobulin with an extracellular domain, transmembrane part, and intracellular portion. The extracellular portion contains one variable and two constant parts (figure). It interacts with not only AGEs, but also with other ligands, such as high-mobility group box 1 (HMGB1), S100/calgranulins, amyloid-b peptide, and other forms of amyloid, complement proteins, macrophage adhesion ligand-1 (MAC-1), lysophosphatidic acid (LPA), and lipopolysaccharide (LPS).

AGE-RAGE interaction can lead to signal transduction and initiation of different intrinsic signaling pathways, including Ras–mitogen-activated protein kinase, PI3K/Akt, Src/RhoA, JAK/STAT, and NADPH oxidase. This leads to an increase in the levels of transcription factors, such as Egr-1 and NF-κB (nuclear factor κ-light-chain-enhancer of activated B cells), and then

their translocation into nucleus. Finally, these processes result in cellular and tissue consequences besides helping as a feed forward loop to increase AGEs production (Asadipooya et al. 2019; Asadipooya and Uy 2019; Ott et al. 2014; Ruiz et al. 2020).

RAGE has multiple isoforms, including truncated or soluble RAGE (sRAGE) and endogenous secretory RAGE (esRAGE). Soluble RAGE (sRAGE) is the product of cleavage of the extracellular part of the RAGE, which lacks transmembrane and intracellular parts. The alternatively spliced RNA variant of RAGE leads to the production of esRAGE. Both sRAGE and esRAGE lack intracellular portions and are not stable on cell membrane. They act as decoy receptors that block the interaction between RAGE and AGEs or other RAGE ligands (Asadipooya et al. 2019; Asadipooya and Uy 2019; Ruiz et al. 2020) **(Figure)**.

AGEs and Diseases

AGEs form endogenously or derive from exogenous sources such as diet, alcohol, smoking, and air pollutants (Asadipooya et al. 2019; Ruiz et al. 2020). In addition to exogenous sources of AGEs, the other conditions, such as aging and inflammation that increase AGEs production, are associated with disease conditions such as obesity, insulin resistance, diabetes, cardiovascular diseases, and osteoporosis. The path of obesity, insulin resistance, diabetes, and cardiovascular diseases moves through complex metabolic and inflammatory events. Increase in AGEs production and their interaction with RAGE are the important parts of the metabolic and inflammatory events. Circulatory AGEs accumulate in tissues, which leads to the production of damaged proteins and reactive oxygen species, induction of inflammation, and finally, organ damage. AGEs, especially high fat and processed food derived AGEs, contribute to the adipocyte hypertrophy, obesity, and its consequences such as metabolic disturbances and insulin resistance (Asadipooya et al. 2019; Asadipooya and Uy 2019; Ruiz et al. 2020).

Notably, the role of AGE-RAGE interaction and its implications in diseases development and complications are relatively well known. RAGE is able to bind to different ligands. RAGE and its ligands not only contribute to diabetes development, but also have crucial roles in diabetic macrovascular and microvascular complications (Asadipooya and Uy 2019; Ruiz et al. 2020). Glucose or lipid oxidation may lead to the AGEs production. Conversely, RAGE and its ligand could be the potential cause of glucose and lipid metabolic abnormalities (Wang et al. 2020). In addition, RAGE and its ligands have fundamental roles in the immunometabolic system, thermogenesis, and energy metabolism (Hurtado Del Pozo et al. 2019), which can lead to obesity, insulin resistance, and diabetes. In addition to its role in obesity and diabetes, the metabolic conditions, such as PCOS, that are associated with insulin resistance have correlation with AGEs (Ruiz et al. 2020). Furthermore, RAGE and its ligands participate in aging, atherosclerosis, vascular calcification, and peripheral arterial disease in diabetic and nondiabetic settings. They contribute to thrombosis and thrombotic disorders (Egaña-Gorroño et al. 2020; Reynaert et al. 2016). AGEs have correlation with cardiac rhythm abnormalities, such as atrial fibrillation (AF) (Egaña-Gorroño et al. 2020). The role of AGE-RAGE signaling pathway in the development of AF by affecting atrial structure and electrical remodeling (Prasad 2020) highlights the significance of AGE-mediated tissue damages. AGE-RAGE axis is also involved in osteoporosis and chronic obstructive pulmonary diseases (COPD) development and progression (Reynaert et al. 2016). RAGE in plasma has positive correlation with acute respiratory distress syndrome (ARDS) development (Van Der Zee et al. 2020) and its inhibition can reduce inflammation and tissue injury due to ARDS (Audard et al. 2019). Furthermore, RAGE activation triggers a positive feedback loop, collaborates with immune pathways, such as Toll-like receptors (TLR)-related pathways, and leads to strengthening of RAGE signaling and cell death. The cross talk between RAGE and TLR is potentially the important mechanism and treatment target for neuroinflammatory diseases (Gąsiorowski et al. 2018). HMGB1 and its receptors (RAGE and TLR4) contribute to amyotrophic lateral sclerosis

pathogenesis (Paudel et al. 2020). Moreover, RAGE can affect apoptotic proteins. It participates in cancer cell progression by upregulating antiapoptotic proteins and downregulating proapoptotic proteins (El-Far et al. 2020).

In summary, AGEs production and accumulation, AGE-RAGE interaction, RAGE interaction with other ligands, and AGEs interaction with other receptors (such as TLRs) result in regulation of inflammatory response and cell proliferation, motility, survival and differentiation besides affecting apoptosis, autophagy, energy metabolism, and thermogenesis (Asadipooya et al. 2019; Hurtado Del Pozo et al. 2019; Sorci et al. 2013). As a result, they are the cause of or correlate with aging and noncommunicable diseases.

It is worth mentioning that RAGE and its ligands have critical roles in initiation and regulation of inflammation. RAGE inhibition reduces inflammation, but may affect macrophage phagocytosis and tissue homeostasis (Asadipooya et al. 2019). RAGE could be the potential cause of antibody-mediated autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, development (Eichhorst et al. 2019). It has a potential role in maintaining chronic inflammation and sustainability of inflammatory bowel disease (Ciccocioppo et al. 2019). Moreover, inhibition of RAGE has protective roles in infectious diseases and sepsis (Zhao et al. 2018).

Nevertheless, AGE-RAGE signaling pathway seems to have some protective roles. It is evident the hyperlipidemic RAGE deficient mouse does not have higher risk of developing fatty liver and atherosclerosis on western diet compared to hyperlipidemic wild type mouse (Bijnen et al. 2018). In addition, RAGE deficiency attenuates PTH-mediated bone formation and causes loss of lean mass (Asadipooya and Uy 2019). Furthermore, RAGE plays an important role in the regulation of immune response, inflammation, fibrosis, tissue regeneration, and repair (Asadipooya et al. 2019; Sorci et al. 2013).

Diagnostic Opportunities

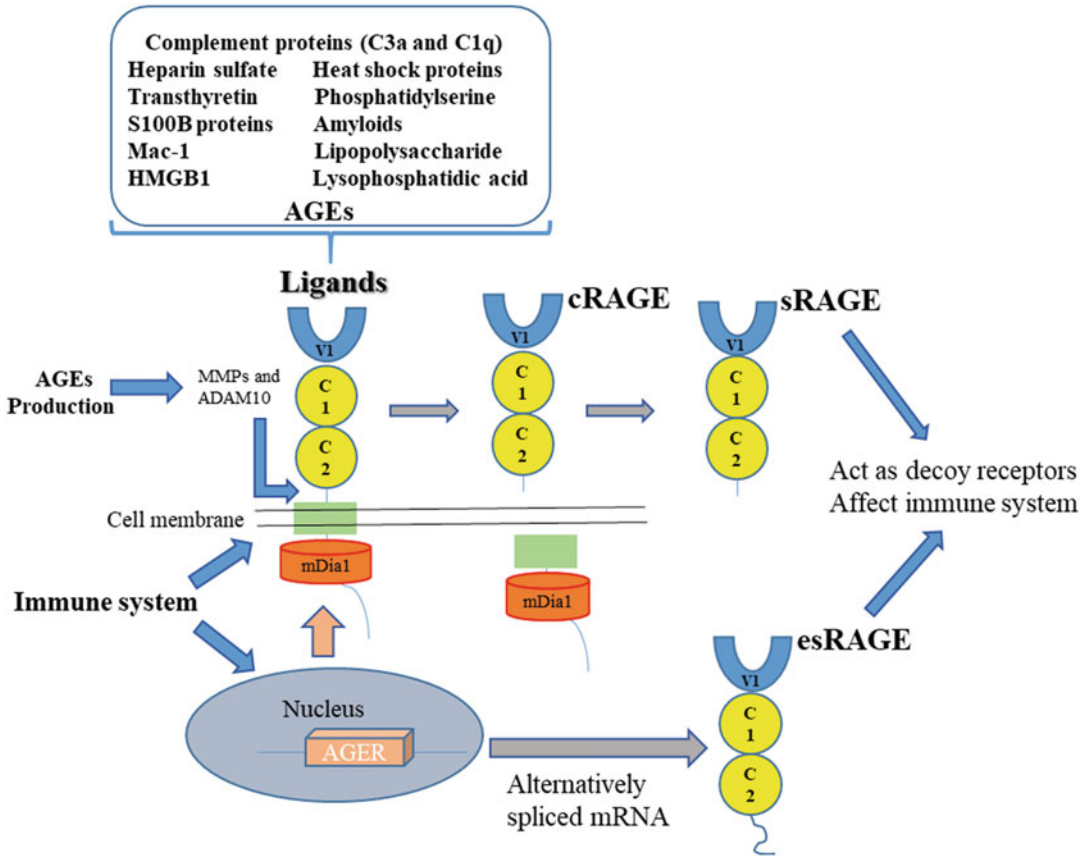
Although the concept of sRAGE application looks interesting in terms of its correlation with different clinical outcomes and potential therapeutic utilities, it faces some limitations. The correlation between sRAGE or esRAGE and different clinical outcomes seems to be bidirectional. Increase in AGE creation can induce ADAM10 (matrix metalloproteinases or a disintegrin and metalloproteinase domain-containing protein 10), which leads to RAGE cleavage and sRAGE production. In addition, contribution of the immune system in esRAGE production and its positive correlation with AGEs (Asadipooya et al. 2019; Asadipooya and Uy 2019; Yamagishi and Imaizumi 2007) can explain the bidirectional correlation of soluble RAGE with different clinical conditions. In other words, elevated sRAGE could be due to an increase in AGE production or RAGE destruction (Asadipooya 2019).

Pharmacological Intervention

There are tons of therapeutic interventions to mitigate or block the AGE-RAGE signaling pathway. Current approaches target AGEs, RAGE, or post-receptor signaling pathway. In addition, they may ameliorate the AGE-RAGE related complications. These include sRAGE (a ligand decoy), Anti-RAGE antibodies, small-molecule RAGE antagonists, or inhibitor of cytoplasmic domain of RAGE (ctRAGE)-DIAPH1 interaction, Aptamers or genetic suppression of RAGE by siRNA (Asadipooya and Uy 2019). In addition, there are medications or agents that reduce AGEs induced damages, such as antidiabetic medications (metformin, GLP-1 agonists), antihypertensive medications (Angiotensin II receptor blocker and angiotensin converting enzyme inhibitor), antioxidants (statins), medications with anti-inflammatory properties (bisphosphonates), and natural substances (vitamin D and K) (Asadipooya and Uy 2019; Byun et al. 2017).

Furthermore, sRAGE technically blocks AGE-RAGE interaction and can protect the high fat fed mouse from weight gain and insulin resistance (Song et al. 2014) or reduce angiotensin II mediated endothelial damage (Jeong et al. 2019), but may increase or decrease other RAGE ligands such as HMGB1 (Jeong et al. 2019; Song et al.

2014). Moreover, AGEs are highly heterogeneous and recombinant sRAGE cannot bind to all of them. In addition, AGE-RAGE signaling is associated with some beneficial effects (Asadipooya et al. 2019; Asadipooya and Uy 2019) as lack of RAGE could not reduce fat deposition in liver (Bijnen et al. 2018). As a result, although sRAGE has protective roles against AGE-RAGE associated pathologies, its use in clinical practice is facing barriers, including heterogeneity of AGEs, accessibility of sRAGE to its ligands, and loss of the beneficial effects of RAGE signaling pathway. However, transfecting immune cells (macrophage) with a lentivirus that carries sRAGE may improve the clinical outcomes of the sRAGE, as macrophage can increase accessibility of sRAGE to RAGE ligands (Asadipooya et al. 2019; Asadipooya and Uy 2019). Additionally, DIAPH1 (mDia1) has an important role in cytoskeleton and cell organelle kinetics. It interacts with cytoplasmic domain of RAGE and is responsible for stabilizing RAGE on cell membranes. DIAPH1 in humans is associated with sensorineural hearing loss and platelets disorders (Asadipooya et al. 2019; Egaña-Gorroño et al. 2020). Technically, targeting DIAPH1 can reduce stability of RAGE on cell membrane, which leads to reduction of harmful effects of RAGE without



Advanced Glycation End-Proteins, Fig. 1 Schematic representation of RAGE and the process of soluble RAGE (sRAGE and esRAGE) production. DIAPH1 (mDia1) interacts with cytoplasmic domain of RAGE and stabilizes the RAGE on cell membrane. Absence of DIAPH1 affects intracellular response of AGE-RAGE signaling pathway. The RAGE (gene name is AGER) interacts with its known ligands, such as AGEs, HMGB1, S100 family proteins, etc. The RAGE ligands bind to the extracellular domains of RAGE. The AGEs, matrix metalloproteinases (MMPs), or ADAM10 and immune system contribute to sRAGE production. sRAGE can bind to RAGE ligands without activating intracellular signaling. Additionally, sRAGE affects immune function and has protective roles. The extracellular domain of RAGE includes V1 (variable part) and C1 and C2 (constant parts)

losing beneficial effects. Hence, efforts to target RAGE or reduce RAGE stability might improve the clinical outcomes in metabolic syndrome, obesity, diabetes, and diabetic complications (Fig. 1).

Synonyms

Cyclic AMP-dependent protein kinase anchoring proteins; Protein kinase A anchoring proteins

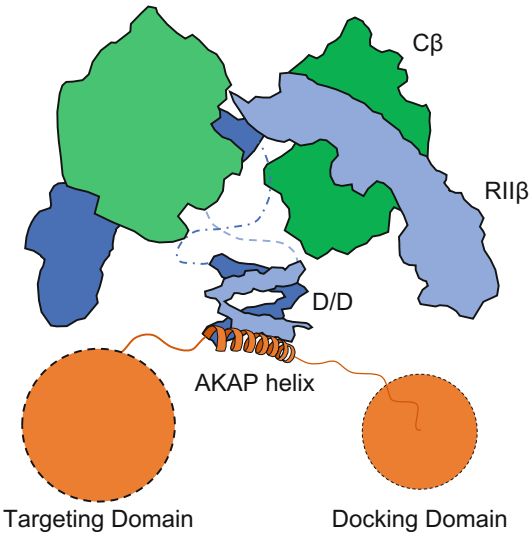
Definition

AKAPs are a diverse family of about 50 scaffolding proteins, which are defined by their ability to bind the regulatory subunits of cyclic AMP-dependent protein kinase (PKA; Fig. 1) [reviewed in (Welch et al. 2010)]. PKA is an abundant and ubiquitously expressed protein kinase. However, despite its ubiquity in signaling processes, there are only four isoforms of the PKA regulatory subunit with which to impart specificity in localization. Instead, the diversity of AKAPs that tether PKA along with other signaling proteins, including G protein-coupled receptors, adenylyl cyclases, kinases, phosphodiesterases, and phosphatases, among others, to create multivalent signaling complexes, dictates their localization and integrates cellular signaling processes at specific sites and times. The compartmentalization of signaling by AKAPs contributes to the specificity of cellular responses to extracellular cues.

Basic Mechanisms

AKAP-Dependent Control of cAMP/PKA Signaling

A large variety of extracellular stimuli including hormones and neurotransmitters stimulate the generation of the second messenger molecule 3′,5′-cyclic adenosine monophosphate (cAMP) by the activation of adenylyl cyclase, which catalyzes the conversion of ATP to cAMP. While cAMP binds to several effector proteins including ion channels, cAMP-dependent guanine-nucleotide-exchange



A-Kinase Anchoring Proteins (AKAPs), Fig. 1 A-kinase anchoring protein (AKAP) interaction with cAMP-dependent protein kinase (PKA). The unifying characteristic of canonical AKAPs is the presence of a structurally conserved amphipathic binding helix (orange) which binds in a hydrophobic cleft created by the docking and dimerization (D/D) domains of the regulatory (R) subunits of PKA. The N-terminal D/D domain is connected to the rest of the protein by an intrinsically disordered linker region (blue dotted lines). In the inactive state, PKA forms a tetramer consisting of a dimer of two R subunits (blue) each bound to one catalytic subunit (C, green). The binding of two molecules of cAMP to each R subunit takes places in the cyclic nucleotide-binding (CNB) domains A and B, causing a conformational change that results in the release of the C subunits, which can then phosphorylate downstream substrate proteins. In addition to the amphipathic binding helix, AKAPs contain unique docking domains, which bind further signaling proteins to create larger signaling complexes, which among other components can include phosphodiesterases, phosphatases or other kinases, and a targeting domain, which tethers the AKAP complex to specific cellular compartments. AKAPs without a targeting domain such as GSK3β interaction protein (GSKIP) are located in the cytosol. A few AKAPs possess catalytic activity such as the RhoGEF activity in AKAP-Lbc conferred by a DH domain. The proteins within the AKAP family range in size from 81 amino acids (AKAP18α) to more than 3000 amino acids (AKAP-Lbc or AKAP450) and are without obvious sequence homology

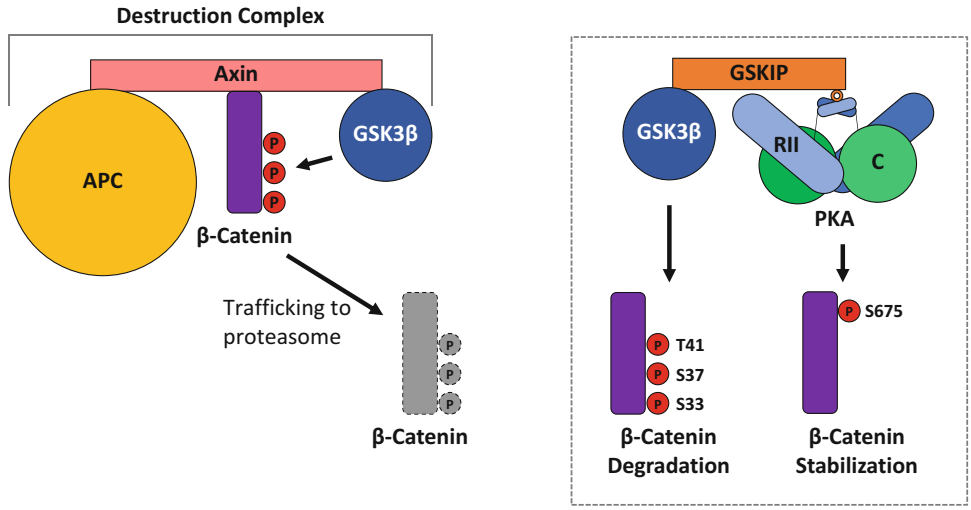
factors (Epacs), and the more recently discovered Popeye proteins [reviewed in (Swan et al. 2019)], PKA is its main intracellular receptor.

The classical PKA holoenzyme consists of two regulatory subunits (RIα, RIβ, RIIα, RIIβ) which form homodimers. Each R subunit is bound to a single catalytic subunit (Cα, Cβ, Cγ), creating a tetramer with two regulatory and two catalytic subunits. However, it is likely, based on the evidence that the copy number of R subunits greatly exceeds that of C subunits, that most regulatory subunits are not bound to catalytic subunits at any given time (Walker-Gray et al. 2017). Each of the regulatory subunits contains two cyclic nucleotide-binding domains (CNBs), which exhibit sequential binding to cAMP, meaning it takes four molecules of cAMP to fully activate a PKA holoenzyme (Taylor et al. 2013; Herberg et al. 1994; Zhang et al. 2012). The binding of the second cAMP molecule to each regulatory subunit elicits a conformational change that displaces the catalytic subunit from the regulatory subunit (Taylor et al. 2012). The free catalytic subunit requires no further activation to phosphorylate downstream targets (Keshwani et al. 2012). The PKA catalytic subunit transfers the γ-phosphate from ATP to consensus sites on many different substrate proteins and thereby modulates their activity through reversible phosphorylation reactions [reviewed in (Taylor and Kornev 2011)].

Different external stimuli mediate the activation of specific pools of PKA located at defined sites within subcellular compartments including mitochondria, nuclei, exocytic vesicles, sarcoplasmic reticulum, or the cytosol (Welch et al. 2010; Zaccolo and Pozzan 2002). The diversity of AKAPs that tether PKA to such cellular compartments allows for its local activation, and, acting in a coordinated manner with other signaling molecules, the consequent phosphorylation of particular substrates in close proximity, creating specificity in its activation (Langeberg and Scott 2005). Spatial and temporal coordination of PKA signaling through compartmentalization by AKAPs is considered essential for the specificity of PKA-dependent cellular responses to a particular external stimulus (Wong and Scott 2004). It remains somewhat unclear what molecular mechanisms drive the inactivating reassociation of catalytic subunits with regulatory subunits. However, there is an emerging understanding that the interplay of free and bound C subunits in conjunction with the localization, affinity, and stoichiometry of free regulatory subunits may be essential to the commencement and cessation of signaling cascades, and there are indications that localization and membrane association driven by AKAPs may play a role (Walker-Gray et al. 2017). There is also some conjecture that the PKA catalytic subunit might not be released from regulatory subunits at all and may instead be active while still bound to the regulatory subunit in a manner that would no longer require the interaction of the C subunit ATP-binding cleft with the substrate or pseudosubstrate sequences of the R subunits and would be independent of the binding of cAMP (Smith et al. 2017). In this model, the N-terminal disordered region would act as a tether between the AKAP bound D/D and the CBDs, which are in turn associated with the C subunit, thereby imparting an active radius of about 125 Å from the anchoring location in which substrates could be phosphorylated. Fig. 2 illustrates the local control of PKA by the AKAP GSKIP, which is involved in Wnt signaling.

AKAP-PKA interactions play a role in a variety of cellular processes including β-adrenoceptor-dependent regulation of cardiac myocyte contraction or vasopressin-mediated water reabsorption.

The tethering of PKA through AKAPs by itself is not sufficient to compartmentalize and control a cAMP/PKA-dependent pathway. Cyclic AMP readily diffuses throughout the cell. Therefore, discrete cAMP/PKA signaling compartments are only conceivable if this diffusion is limited. Phosphodiesterases (PDEs) establish gradients of cAMP by local hydrolysis of the second messenger and thereby regulate PKA activity locally [reviewed in (Musheshe et al. 2018; Bers et al. 2019). Several AKAPs interact with PDEs and thus play a role at this level of control [reviewed in (Maurice et al. 2014; Ercu and Klussmann 2018). For example, the interaction of muscle-specific mAKAP with cAMP-specific PDE4D3 and the ryanodine receptor (RyR) facilitates hydrolysis of cAMP



A-Kinase Anchoring Proteins (AKAPs), Fig. 2 The AKAP-GSK3β interaction protein (GSKIP) colocalizes PKA and GSK3β for control of β-catenin in the canonical Wnt signaling cascade. Though the spatial and temporal picture is still evolving, our current understanding suggests that in the absence of Wnt signaling, a relatively large complex of proteins known as the "destruction complex" forms in the cytosol. The destruction complex consists of axin (pink), a largely disordered protein which plays an important scaffolding role in the destruction complex and which binds to the kinases glycogen synthase kinase 3β (GSK3β, dark blue) and casein kinase (CK1, not shown), as well as adenomatous polyposis coli (APC, yellow), a tumor suppressor which in turn binds to the transcription activator protein β-catenin (Song et al. 2014; Dema et al. 2016). This complex directs the phosphorylation of β-catenin by GSK3β at threonine-41 and serines-33 and 37, which in turn leads to its targeting for ubiquitination and ultimately degradation in the proteasome. When Wnt signaling is initiated, the ligand binds to the single-pass low-density lipoprotein receptor-related protein 5/6 (LRP5/6) transmembrane proteins and G protein-like receptors from the Frizzled family, which in turn recruit the destruction complex, preventing the degradation of β-catenin. Under these conditions, GSKIP (orange), which binds GSK3β as well as PKA, coordinates the inactivation of GSK3β by PKA-mediated phosphorylation of GSK3β serine-9 and helps coordinate the stabilizing phosphorylation of β-catenin at serine 675. The inactivation of GSK3β prevents the phosphorylation and subsequent degradation of β-catenin, resulting in its increased concentration in the cell and ultimately its passage into the nucleus and downstream expression of Wnt signaling-induced genes

in the vicinity of RyR at the sarcoplasmic reticulum of cardiac myocytes. Local cAMP hydrolysis maintains mAKAP-associated PKA activity low. An increase in the cAMP level exceeding the PDE4D3 hydrolyzing capacity activates PKA, which phosphorylates RyR and increases the open probability of this Ca^{2+} channel. PKA also phosphorylates PDE4D3 and thereby enhances PDE4D3 activity. This again increases local cAMP hydrolysis, switches off PKA, and eventually reduces RyR phosphorylation. This negative feedback loop regulating RyR phosphorylation is completed by association of mAKAP with protein phosphatase 2A (PP2A), dephosphorylating RyR. Dephosphorylation decreases the channel open probability of RyR.

AKAP-PKA Binding

Canonical AKAPs contain an alpha helix in which one side presents a hydrophobic surface while the other side presents a hydrophilic surface, which is known as an amphipathic helix (Newlon et al. 2001). The hydrophobic surface of the amphipathic helix binds to a corresponding hydrophobic region formed by regulatory subunits of PKA. As the name suggests, the association of the AKAP with the regulatory subunit and the regulatory subunits with each other takes place in an ordered region of the N-terminus known as the docking and dimerization (D/D) domain. The D/D domains of two R subunits come together to form a four helical-X-type bundle in which a hydrophobic cleft is created that binds to the hydrophobic face of the AKAP amphipathic

helix (Banky et al. 2003; Sarma et al. 2010; Gold et al. 2006; Götz et al. 2016). Differences in the structure and affinity between type I and type II regulatory subunit D/Ds underlie the differences in RI- and RII-specific AKAPs. There is also an emerging understanding that additional residues outside of this cleft-helix interaction may play an important part in AKAP recognition and binding affinity (Götz et al. 2016).

AKAP-Dependent Integration of Cellular Signaling

In addition to PKA, PDEs, and protein phosphatases involved in cAMP signaling, AKAPs interact with other signaling proteins the activation of which depends on other second messenger molecules, including Ca^{2+}. AKAPs may bind additional kinases such as protein kinases C (PKC) and D (PKD) and protein phosphatases like calcium/calmodulin-dependent phosphatase (calcineurin, protein phosphatase 2B, PP2B). This scaffolding function allows AKAPs to integrate cellular signaling processes. For example, rat AKAP150, and its human ortholog AKAP79, bind PKA, PKC, and calcineurin (Patel et al. 2017). In neurons, AKAP150-bound PKC is activated through an M1 muscarinic receptor-induced pathway that depends on the G protein Gq and leads to elevation of cytosolic Ca^{2+} and diacylglycerol. AKAP150 interacts directly with M channels, which are K^+ channels that negatively regulate neuronal excitability, and facilitates PKC phosphorylation which in turn inhibits the channel. AKAP79 coordinates the phosphorylation of AMPA channels. Cyclic AMP-activated, AKAP79-bound PKA phosphorylates and thereby activates the channels. A rise in cytosolic Ca^{2+} activates AKAP79-bound calcineurin, which in turn dephosphorylates the channels. The dephosphorylation mediates the rundown of AMPA channel currents. Another example is AKAP-Lbc.

AKAP-Lbc binds PKA, PKC, and PKD and possesses intrinsic catalytic activity (Rho guanine-nucleotide-exchange factor (RhoGEF) activity). Through its RhoGEF activity, it catalyzes the exchange of GDP for GTP on the small GTPase Rho. The GTP form of Rho is active and induces the formation of F-actin-containing stress fibers. Agonists stimulating receptors coupled to the G protein G_s may mediate activation of AKAP-Lbc-bound PKA, which in turn phosphorylates AKAP-Lbc. Subsequently, a protein of the 14-3-3 family binds to the phosphorylated site and inhibits the RhoGEF activity. In contrast, agonists stimulating receptors coupled to the G protein G_{12} increase the RhoGEF activity.

AKAPs Optimize the Limited Repertoire of Cellular Signaling Proteins

Intriguingly, the same AKAP may coordinate regulation of different target proteins. In hippocampal neurons, AKAP150 positions PKA and calcineurin to modulate AMPA channels and maintains PKC inactivity. In superior ganglial neurons, AKAP150 facilitates PKC phosphorylation of M channels while keeping PKA and calcineurin inactive. The difference is due to the interaction of AKAP150 with the scaffolding protein SAP97, which occurs in hippocampal neurons but not in superior ganglial neurons. SAP97 positions AKAP150 such that PKA and calcineurin are in close proximity to AMPA channels. Thus, by variation of a single interacting partner, an AKAP optimizes the usage of the limited set of cellular signaling proteins. In summary, the function of AKAPs goes far beyond controlling cAMP/PKA signaling by simply tethering PKA to cellular compartments and confining the access of PKA to a limited set of local substrates. AKAPs are scaffolds forming multiprotein signal transduction modules that coordinate and integrate cellular signaling processes.

Pharmacological Intervention

Disturbances of compartmentalized cAMP signaling in processes such as the ones mentioned above cause or are associated with major diseases including heart failure, diabetes insipidus, diabetes mellitus, obesity, diseases of the immune system including AIDS, cancer, and neurological disorders including schizophrenia. However, AKAPs participating in compartmentalized cAMP signaling networks are not targeted by

drugs which are currently applied for the treatment of such diseases. Recently, clinically relevant intracellular protein-protein interactions have gained much interest as potential drug targets. The cell-type specificity of such interactions and the finding that mostly only selected isoforms of proteins interact with each other offers great opportunities for highly selective pharmacological intervention. For targeting AKAP-dependent protein-protein interactions, initially peptides non-selectively displacing PKA from all AKAPs have been developed.

In renal collecting duct principal cells, arginine vasopressin (AVP) regulates water reabsorption from primary urine by triggering the PKA activation and subsequent redistribution of aquaporin-2 (AQP2) from intracellular vesicles into the plasma membrane [reviewed in (Vukicevic et al. 2016). The redistribution depends on the compartmentalization of PKA by AKAPs including AKAP18δ. The PKA-anchoring disruptor peptides displace PKA and inhibit the AVP-induced redistribution of AQP2 and thereby water reabsorption. In heart failure, an elevated level of AVP causes a predominant localization of AQP2 in the plasma membranes of the renal principal cells and through this excessive water retention contributing to edema. Considering this, the disruption of AKAP-PKA interactions may be a viable treatment option. This and other examples suggest that cell-type-specific pharmacological intervention at selected AKAP-PKA interactions is a feasible concept for the treatment of human diseases and have further spurred the search for small molecule inhibitors of this interaction [reviewed in (Baltzer and Klussmann 2019). Peptidomimetics as well as the first small molecule that non-selectively target AKAP-PKA interactions in a similar manner to the disruptor peptide are available (Schäfer et al. 2013; Christian et al. 2011). More selective small molecules targeting the interaction of AKAP-Lbc and RhoA have recently been discovered (Schrade et al. 2018; Diviani et al. 2016). The examples illustrate that finding modulators of AKAP-dependent protein-protein interactions is a feasible concept.

Alzheimer's dementia; Dementia due to Alzheimer's disease; Morbus Alzheimer

Definition

Alzheimer's disease (AD), named after the psychiatrist and neuropathologist Alois Alzheimer, is an age-associated, chronic, and progressive neurodegenerative illness and the most common cause of neurocognitive disorder (dementia) in the elderly. AD is characterized by a disease duration of two to four decades, starting with 10–20 years of biochemical, cellular, and neurodegenerative changes in the brain (the preclinical or pre-symptomatic phase). In this initial stage, neuropathological changes appear in the brain, such as extracellular amyloid plaque deposits, intraneuronal neurofibrillary tangles, and brain atrophy. This stage is followed by at first subtle but not debilitating cognitive symptoms, finally leading into a progressive worsening and impairment of executive functions (the clinical or symptomatic phase), which makes an unassisted life impossible (Aisen et al. 2017). Age is the most important risk factor for AD with approximately every fifth 85-year-old suffering from dementia (in large part due to AD). It is projected that 100 million individuals will be affected by the year 2050 worldwide, if no progress is made in prevention and treatment (Collaborators GBDD 2019).

Basic Mechanisms

General

The key pathological hallmarks of AD are extracellular amyloid plaque deposits, intracellular neurofibrillary tangles (NFTs), and brain atrophy. In the past, these pathological, AD-specific alterations could only be confirmed via autopsy. However, modern diagnostic tests, using positron emission tomography (PET) scans (to detect plaques and tangles) and magnetic resonance imaging (to estimate brain atrophy), can reliably reveal these abnormalities in patients (Masters et al. 2015).

Amyloid plaques are mainly comprised of the protein fragment amyloid-β (Aβ). These plaques can be detected in patients with a PET amyloid tracer, such as ^{11}C-Pittsburgh compound B. Based on pre-established thresholds, i.e., the global cortical standard uptake value ratio, individuals will be categorized as being amyloid positive or

negative. In the surrounding of Aβ plaques, various abnormalities can be observed, such as the loss of synapses and neurons, dystrophic neurites, as well as indicators of inflammation.

NFTs occur inside neurons and consist of the hyperphosphorylated form of the microtubule-associated protein tau (MAPT). Similar to amyloid plaques, NFTs can be detected in patients using PET tau tracers (Leuzy et al. 2019). The occurrence of NFTs in AD dementia is often followed by signs of neurodegeneration, which can be visualized in patients with structural magnetic resonance imaging. These three major AD pathologies start appearing in the preclinical phase of the disease, and once brain atrophy is well advanced, cognitive symptoms manifest, and individuals transition from the preclinical into the clinical phase (Fig. 1). The exact molecular mechanism that is responsible for the progressive neurodegeneration and ultimately dementia is unknown.

Sporadic Alzheimer's Disease

The vast majority of symptomatic AD cases manifest without a clear inheritance pattern after age 65 and are therefore termed late-onset or sporadic AD. It has been hypothesized that sporadic AD is caused by a combination of lifestyle and genetic risk factors and likely involves a complex cellular phase involving various cell types and signaling pathways (De Strooper and Karran 2016). A major genetic factor known to increase the risk for AD is the ε4-allele of APOE, which codes for the apolipoprotein E, a glycoprotein that transports lipids. Three alleles of APOE exist: ε2, ε3, and ε4. While the ε4 allele is associated with an increased risk, ε2 is associated with a decreased risk. Carriers of the ε4 allele show more pronounced cerebral Aβ plaque depositions.

In genome-wide association studies, other genetic loci were identified, which contribute to a person's risk of developing dementia. These loci affect gene products that have roles, among others, in endosomal vesicle trafficking, inflammatory/immune response, and lipid metabolism. Such processes potentially affect production, aggregation, and/or clearance of Aβ (Van Cauwenberghe et al. 2016). In addition to genetic factors, lifestyle factors, e.g., cardiovascular risk (midlife hypertension, obesity, physical inactivity, diabetes mellitus, and smoking), as well as depression and low educational attainment, may contribute to the overall risk for sporadic AD (Livingston et al. 2017).

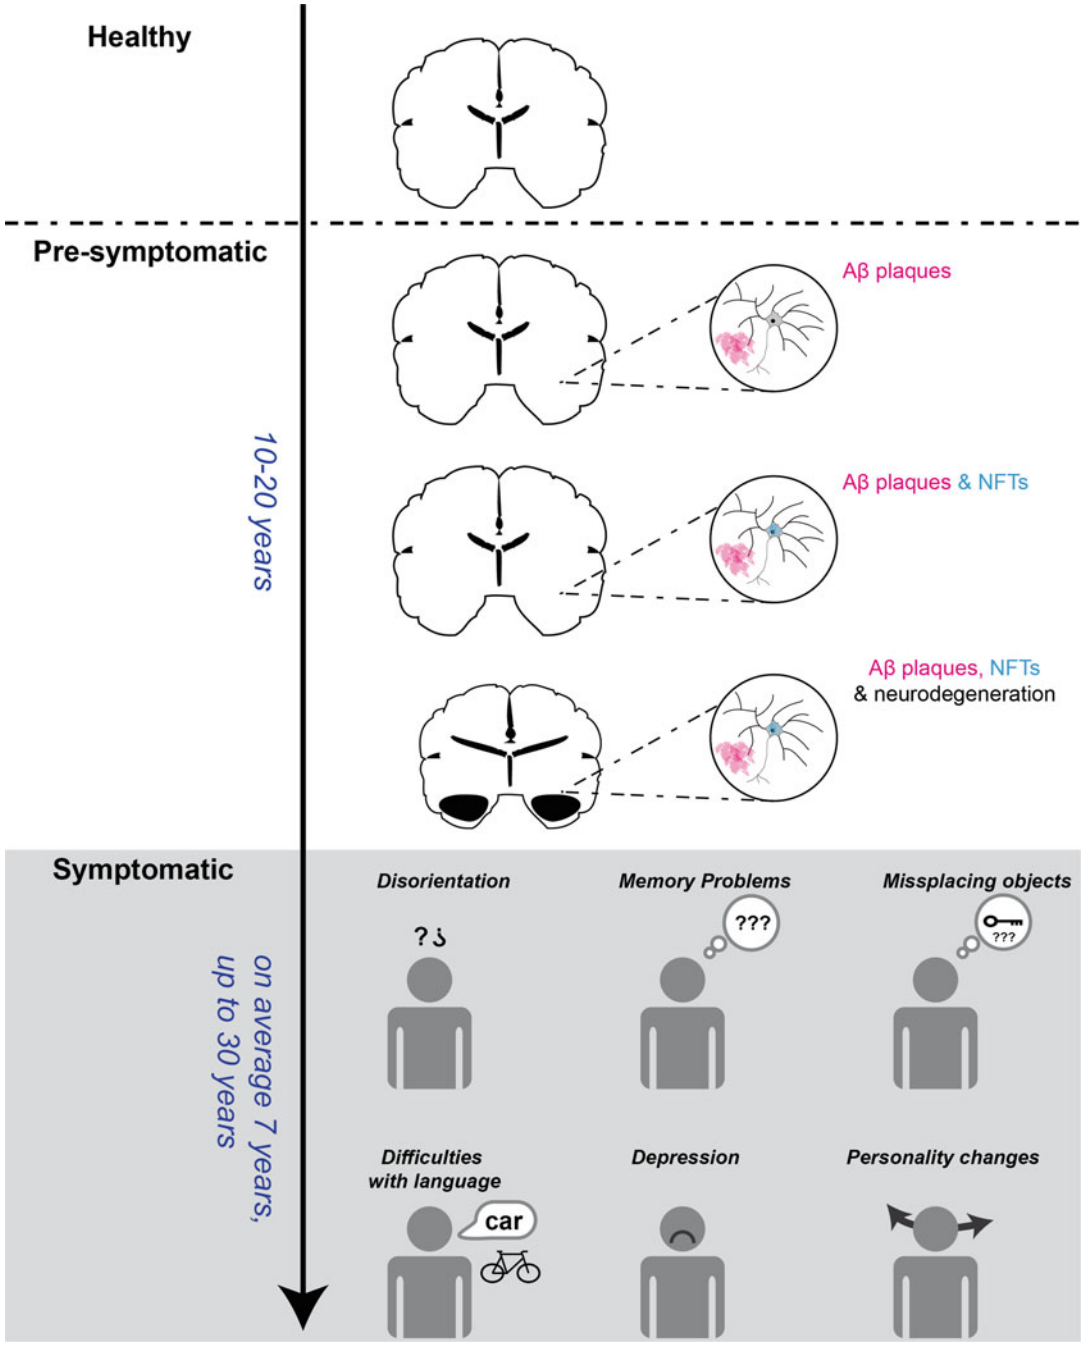
Familial Alzheimer's Disease

In rare cases, AD has a genetic cause and generally follows an autosomal dominant inheritance pattern. This hereditary form of AD is called familial Alzheimer's disease (FAD). FAD symptoms manifest earlier than in sporadic AD (before the age of 65), and it is therefore classified as early-onset AD; however, clinical symptoms and the overall course of the disease are very similar in both forms. To date, mutations in three genes have been identified to cause FAD: *amyloid precursor protein (APP), presenilin 1 (PSEN1), and presenilin 2 (PSEN2)* (Bohm et al. 2015).

Aβ Production, Clearance, and Aggregation

While there is no well-described physiological function of Aβ, its production and clearance are processes that occur in healthy organisms. Aβ is derived from the sequential proteolysis of the amyloid precursor protein (APP) by a process called regulated intramembrane proteolysis. APP is a type-I transmembrane protein that is part of an evolutionarily conserved protein family, which includes the amyloid precursor-like proteins 1 (APLP1) and 2 (APLP2). APP and APLPs are functionally redundant; however, the Aβ sequence in APP is unique and is not conserved in APLP1 or APLP2.

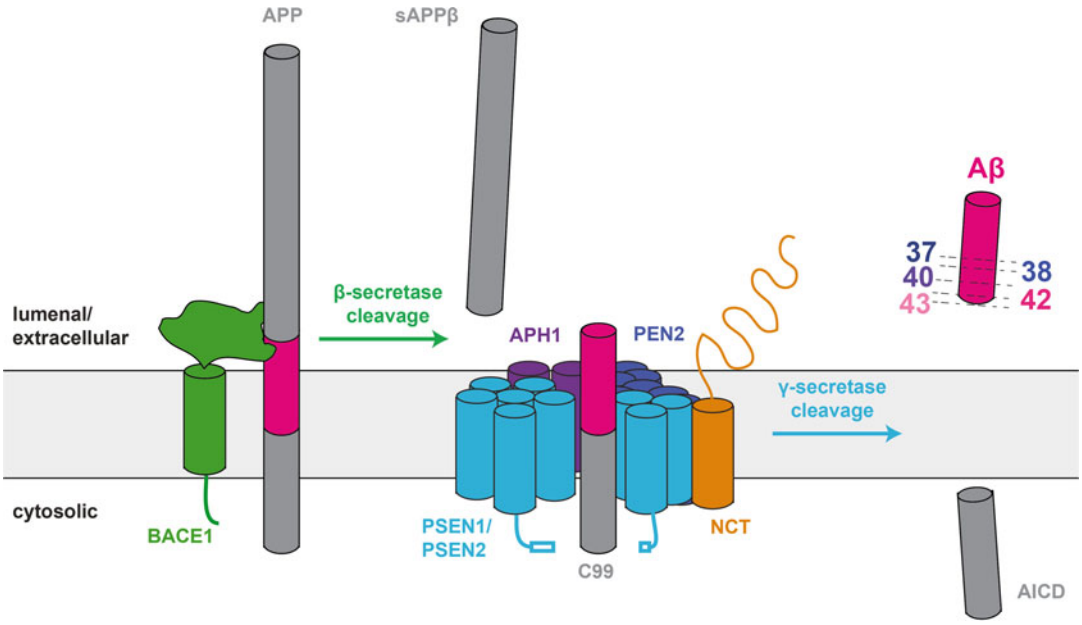
The initial step in Aβ production is catalyzed by the β-secretase (BACE1), which cleaves APP in its ectodomain to generate soluble APPβ (sAPPβ) and a C-terminal membrane-bound fragment with 99 amino acid residues (C99). BACE1 activity is pH-regulated (optimal at pH 4.5), and therefore, the bulk of BACE1-mediated APP cleavage takes place in the endolysosomal system. In a subsequent step, the γ-secretase [a multiprotein complex, consisting of presenilin 1 (PSEN1) or presenilin 2 (PSEN2), anterior



Alzheimer's Disease, Fig. 1 The preclinical phase of Alzheimer's disease is characterized by the sequential appearance of amyloid-β (Aβ) plaques, neurofibrillary tangles (NFTs), and signs of neurodegeneration. Once neurodegeneration is advanced, patients transition into the clinical phase of the disease, and cognitive symptoms appear. Progressive worsening of neurodegeneration and cognitive impairment continue until an independent life becomes impossible

pharynx defective 1 (APH1), presenilin enhancer 2 (PEN2), and nicastrin (NCT)] recognizes C99 as a substrate and generates the APP intracellular domain (AICD) and Aβ peptides of varying lengths. The γ-secretase can cleave at various sites in a consecutive manner, generating Aβ peptides mainly with 37–43 amino acids that can be detected in body fluids and serve as potential biomarkers. The most abundant Aβ forms are comprised of 38 (Aβ38), 40 (Aβ40), or 42 (Aβ42) amino acids (Fig. 2). These various Aβ peptides are produced by a sequential proteolytic cleavage mechanism. The cuts at the cytoplasmic ends of the transmembrane sequence (i.e., the ε-site, which can occur at two different positions) produce AICD (residues 50–99 or 49–99) and membrane-bound Aβ49 or Aβ48. The membrane-bound fragments are further processed into Aβ46 or Aβ45 (at the ζ-site). Aβ46 is further processed into Aβ43 and Aβ40, whereas Aβ45 is the direct precursor of Aβ42, implying that Aβ42 and Aβ40 belong to two different product lines (Munter et al. 2007).

While both Aβ40 (minor species) and Aβ42 (major species) exist in amyloid plaques, Aβ42 is more prone to form oligomers, which are thought to contribute to cognitive decline in AD (Glabe 2006). Within the brain, the concentration of Aβ is severalfold higher than in the periphery, and several mechanisms, such as interstitial fluid drainage, cellular uptake, passive elimination, and enzymatic degradation, are responsible for Aβ clearance from the brain and ultimately from the body (Bates et al. 2009). Thus, it has been proposed that in many cases of FAD, Aβ (especially Aβ42) is chronically overproduced, the Aβ42/Aβ40 ratio is increased, or the Aβ aggregation kinetics are altered. In sporadic AD, impaired Aβ clearance may be responsible for its increased cerebral retention.



Alzheimer's Disease, Fig. 2 Amyloid-β (Aβ) is derived from the amyloid precursor protein (APP). First, the β-secretase (BACE1) cleaves APP within its ectodomain, generating sAPPβ and C99. Second, C99 is cleaved by the γ-secretase complex, generating Aβ peptides of varying lengths, with Aβ40, Aβ38, and Aβ42 being the most abundant species detected in the brain, among others like Aβ37 and Aβ43

Amyloid Hypothesis

Based on pathological findings from sporadic AD and genetic evidence from FAD, the Aβ peptide (especially Aβ42 or even longer, more hydrophobic forms) has a central role in the cause of the disease (Hardy and Selkoe 2002). Accordingly, the entire cascade is initiated by cerebral Aβ oligomer formation (which is followed or accompanied by the appearance of Aβ plaques), which subsequently leads to synaptic dysfunction, inflammation, NFT pathology, and neurodegeneration.

Pharmacological Intervention

General

There is currently no cure for AD. Several symptomatic treatments are approved and used to improve the clinical state of patients; however, these interventions do not delay the progression of the disease. There is an urgent need for disease-modifying interventions, and while several strategies were successful in transgenic animal models of AD, none of these treatments proved efficacious for AD patients.

Symptomatic Treatment

Acetylcholinesterase inhibitors, such as galantamine, rivastigmine, donepezil, tacrine, and others, are used to treat the cognitive symptoms of AD. These drugs counteract the decreased levels of acetylcholine in the brain of AD patients, which is caused by a loss of cholinergic neurons. Acetylcholinesterase inhibitors delay the breakdown of acetylcholine into acetate and choline, thereby increasing the level and duration of action of the neurotransmitter (Mehta et al. 2012).

Memantine is a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist, which prevents excessive receptor activation and Ca^{2+} influx. In AD and other neurodegenerative diseases, excitatory networks tend to get over-activated (a process called excitotoxicity), and drugs such as memantine can counteract this process by decreasing the effect of the excitatory neurotransmitter glutamate (van Marum 2009).

In addition to acetylcholinesterase inhibitors and NMDA receptor antagonists, AD patients can receive antidepressant, anxiolytic, and antipsychotic medications.

Approaches Toward Disease-Modifying Treatment

Numerous approaches for potentially disease-modifying AD treatments are pursued, and while several attempts were successful in preclinical models (transgenic animal models of AD), none of these could be translated into the clinic yet.

Major strategies aim at a reduction of Aβ production by directly targeting the secretases that are involved in its formation (De Strooper et al. 2010). BACE1 inhibitors can effectively lower Aβ production; however, no beneficial outcome was observed in patients (Barao et al. 2016). Besides its essential role in Aβ production, BACE1 has additional important functions, such as ectodomain shedding of APP-unrelated substrates and even in vivo Aβ clearance (Barao et al. 2016; Liebsch et al. 2019). Such crucial enzymatic roles challenge the BACE1 inhibition approach. Furthermore, γ-secretase inhibitors and modulators have been developed that can either block its entire activity or specifically reduce the formation of Aβ42 by interfering with the sequential proteolytic cleavage mechanism (Olsson et al. 2014). While γ-secretase inhibitors showed strong side effects (likely due to the importance of γ-secretase cleaving other substrates, which would ultimately interfere with essential functions of membrane proteins/receptors), γ-secretase modulators did not alter the cognitive decline in AD patients (Bursavich et al. 2016).

Alternative approaches aim at removing or neutralizing cerebral Aβ by passive immunization (Mo et al. 2017). Antibodies targeting specific regions of the peptide can facilitate Aβ clearance from the brain; however, until today, these are not approved for therapeutic use.

Taking up the challenges, trials with anti-Aβ antibodies and secretase inhibitors and modulators are continued. Ideally, Aβ-targeting treatments should begin in the pre-symptomatic phase of the disease, before overt and possibly

nonreversible neurodegeneration occurs. Therefore, such approaches may be beneficial for disease prevention and must be started decades before symptom onset.

AMP-Activated Protein Kinase

D. Grahame Hardie
Division of Cell Signalling and Immunology, School of Life Sciences, University of Dundee, Dundee, Scotland, UK

Synonyms

AMPK

Definition

AMP-activated protein kinase (AMPK) is a member of the serine/threonine protein kinase family, which modify other proteins (*target proteins*) by attaching phosphate groups to the side chains of serine or threonine, thus modifying their function. The primary role of AMPK is to sense energy status by monitoring the cellular ratios of AMP:ATP and ADP:AMP. Once activated by energy stress, AMPK acts to restore homeostasis by switching off downstream processes consuming ATP (such as cell growth and proliferation) while switching on catabolic processes generating ATP (such as glucose uptake and mitochondrial biogenesis). AMPK is also involved in regulating whole-body energy balance and has been identified as a key target in treating disorders such as obesity and type 2 diabetes.

Basic Characteristics

Structure

AMPK occurs universally in the form of heterotrimeric complexes containing a catalytic α subunit and regulatory β and γ subunits (Ross et al. 2016). Humans express multiple isoforms of each subunit (α1, α2; β1, β2; γ1, γ2, γ3), encoded by distinct genes. These can give rise to up to 12 heterotrimeric combinations that display differences in regulatory properties, subcellular locations, tissue-specific expression, and/or interactions with drugs.

Regulation

AMPK complexes are normally only significantly active when phosphorylated at a threonine residue within the kinase domain of the α subunit, usually referred to as Thr172 (Hawley et al. 1996). Thr172 phosphorylation is a widely used biomarker for AMPK activation and is primarily catalyzed by a complex containing the upstream kinase, LKB1 (Hawley et al. 2003; Woods et al. 2003). The gene encoding LKB1 (*STK11*) was originally identified by human genetics to be a tumor suppressor, introducing a link between AMPK and cancer that is still being investigated (Vara-Ciruelos et al. 2019).

Canonical Regulation by Adenine Nucleotides

The AMPK-γ subunits contain four tandem repeats of sequence motifs known as CBS repeats, which are involved in binding of the regulatory ligands AMP, ADP, and ATP. They form a pseudosymmetrical disk-shaped structure with one repeat in each quadrant. In the center of this disk are four potential binding sites for regulatory nucleotides, although only three are utilized (Xiao et al. 2007). The critical site is formed by repeat 3 (CBS3); binding of AMP at this site causes conformational changes in the AMPK complex that trigger activation by three complementary mechanisms: (i) allosteric activation; (ii) promotion of Thr172 phosphorylation by LKB1; and (iii) inhibition of Thr172 dephosphorylation by protein phosphatases (Ross et al. 2016). Binding of ATP at CBS3 opposes all of these effects, so that the AMPK complex is activated by increases in the cellular AMP:ATP ratio. Binding of ADP to CBS3, at higher concentrations than AMP, also mimics the effects of AMP, except that it does not cause allosteric activation. Increases in cellular ADP:ATP ratios indicate that the energy status of the cell has been compromised but are always accompanied by even larger changes in AMP due to displacement of the reaction catalyzed by adenylate kinases ($2ADP \leftrightarrow ATP + AMP$). For

this reason, increases in AMP:ATP are a particularly sensitive indicator of cellular energy stress.

Noncanonical Regulation by Hormones Involved in Regulation of Whole-Body Energy Balance

A second upstream kinase that phosphorylates Thr172 is the Ca^{2+}/calmodulin-dependent kinase, CaMKK2, which is activated by hormones that trigger intracellular release of Ca^{2+} ions. These include ghrelin, which is released from the stomach during fasting, promoting appetite and hence whole-body energy intake by activation of AMPK in specific neurons of the hypothalamus (Yang et al. 2011). Some hormones have the opposite effect, including leptin that is released from adipocytes containing high stores of fat. Leptin inhibits AMPK in specific hypothalamic neurons, possibly by triggering phosphorylation of a regulatory sequence near the C-terminus of the α subunit (Dagon et al. 2012), thus repressing appetite and whole-body energy intake.

Noncanonical Activation by Glucose Starvation

AMPK is also activated by depriving cells of glucose – in some cell types, this is associated with increases in AMP:ATP/ADP:ATP ratios and can thus occur in part via the canonical mechanism described above. However, in other cells, AMPK is activated by glucose starvation without accompanying changes in adenine nucleotides, as long as an alternative carbon source such as glutamine is available; AMPK is also activated in livers of fasted mice without any apparent changes in nucleotides (Zhang et al. 2017). Under these circumstances, activation involves the translocation of a complex between LKB1 and the adapter protein Axin and of AMPK, to the surface of the lysosome where they associate with each other as well as the resident lysosomal proteins, p18/LAMTOR1 and the vacuolar ATPase (Zhang et al. 2017). The absence of glucose is sensed as a drop in the binding of the glycolytic intermediate fructose-1,6-bisphosphate (FBP) to the glycolytic enzyme FBP aldolase; this appears to cause inhibition of Ca^{2+} release by TRPV channels that occur at ER/lysosome contact sites, thus affecting interaction of the channels with the vacuolar ATPase (Li et al. 2019).

Downstream Targets of AMPK

One activated, AMPK can phosphorylate numerous downstream targets at specific serine or threonine residues within well-defined sequence motifs, with over 60 being currently identified (Hardie et al. 2016). A full description of these is beyond the scope of this article, but in general AMPK switches off ATP-consuming anabolic pathways required for cell growth while switching on catabolic processes that generate ATP. These effects can occur both via direct phosphorylation of metabolic enzymes and also via phosphorylation of proteins affecting gene expression. A good example is the ACC1 isoform of acetyl-CoA carboxylase, the first enzyme in the pathway of de novo fatty acid synthesis from acetyl-CoA. While ACC1 is inactivated by direct phosphorylation by AMPK (Munday et al. 1988), expression of its mRNA is also switched off via phosphorylation of multiple transcription factors (Li et al. 2011; Kawaguchi et al. 2002). On the other hand, phosphorylation by AMPK of the ACC2 isoform, which is associated with mitochondria, is involved in acute activation of fatty acid oxidation (Merrill et al. 1997). Thus, AMPK activation switches on fatty acid oxidation, a catabolic pathway that plays an important role in whole-body energy expenditure, while switching off fatty acid synthesis, an energy-consuming anabolic pathway required for cell growth. AMPK also switches on glucose uptake involving the glucose transporters GLUT1 and GLUT4, in part via phosphorylation and degradation of the α-arrestin family member TXNIP, which otherwise promotes ubiquitination and consequent reuptake of the glucose transporters from the plasma membrane via endocytosis (O'Donnell and Schmidt 2019). Finally, AMPK enhances mitochondrial function in cells not only by promoting biogenesis of new mitochondrial components (Zong et al. 2002) but also by triggering removal of damaged

components, by promoting mitochondrial fission (Toyama et al. 2016) and recycling of the resulting fragments by *mitophagy*, a specialized form of autophagy (Egan et al. 2011).

Drugs

Interest in the AMPK system greatly increased when it was reported to be activated by metformin, still the primary drug used to treat type 2 diabetes today (Zhou et al. 2001). Metformin mainly acts on the liver and gut due to its cellular uptake by organic cation transporters expressed in those cells. It is now clear that its ability to acutely inhibit hepatic glucose production does not require AMPK (Foretz et al. 2010), but another important component of metformin action is its long-term ability to enhance hepatic insulin sensitivity. In mice this requires the phosphorylation of both the ACC1 and ACC2 isoforms of acetyl-CoA carboxylase by AMPK, thus reducing the elevated lipid storage in the liver that is strongly associated with insulin resistance (Fullerton et al. 2013).

Numerous drugs and natural products have now been shown to activate AMPK in preclinical studies, and they can now be divided into three groups according to the mechanisms by which they cause its activation (Fig. 1).

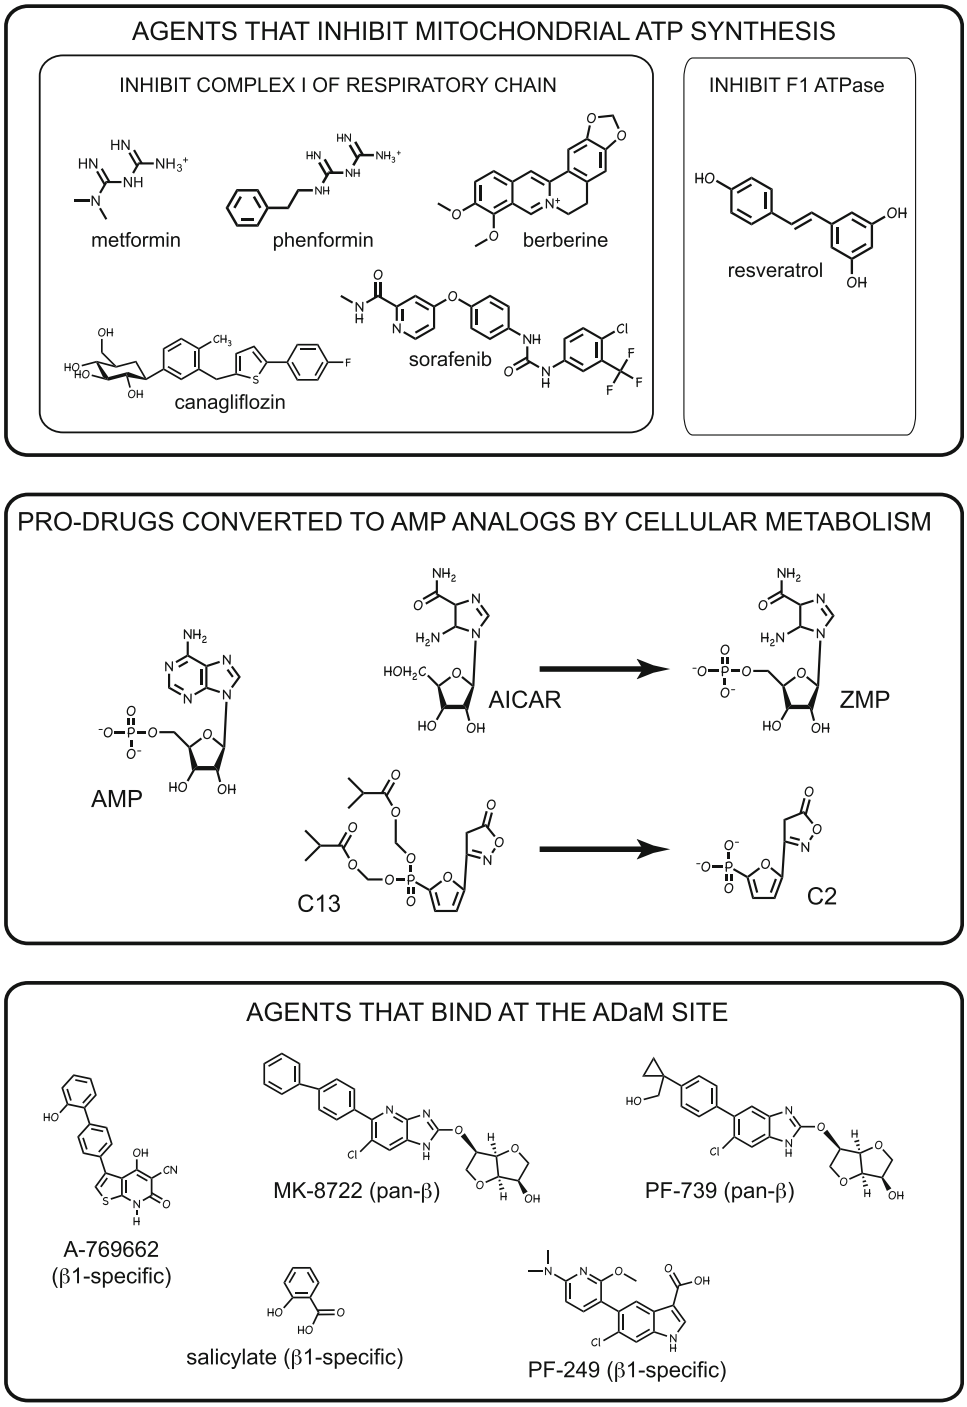
Agents That Act Indirectly by Inhibiting Mitochondrial Function

In most cells, mitochondria produce much of the cellular ATP, so agents that inhibit their function will activate AMPK indirectly by the canonical AMP-dependent mechanism. Agents that act in this this manner can be identified by their failure to activate AMPK complexes containing arginine-glycine (RG) mutations in the critical CBS3 site of the γ subunit (Hawley et al. 2010). They include the antidiabetic drug metformin, which inhibits complex I of the mitochondrial respiratory chain. Metformin and a related biguanide, phenformin, are derivatives of *galegine*, originally extracted from the medicinal herb *Galega officinalis*. AMPK is also activated by many other natural plant products, including *resveratrol* and *berberine* (Hawley et al. 2010). Berberine is used in traditional Chinese medicine, and, remarkably, more than 400 papers now describe compounds from traditional medicines that activate AMPK. Although the mechanisms by which most of these activate AMPK are not known, we suspect that many may be inhibitors of mitochondrial function. Most are so-called secondary plant metabolites (meaning that they are not essential for growth under ideal conditions) and may be defensive compounds produced to deter infection by pathogens or grazing by insects or other herbivores. Interestingly, they are often stored either in the vacuole or the cell wall of plant cells, where they would not come into contact with the plant's own mitochondria (Shitan 2016).

Finally, AMPK is also activated via "off-target" mitochondrial inhibition by at least two drugs that are in use clinically, although previously thought to be solely directed at other targets. These are the SGLT2 inhibitor *canagliflozin*, used to treat diabetes (Hawley et al. 2016), and the protein-tyrosine kinase inhibitor *sorafenib*, used to treat some cancers (Ross et al. 2017).

Prodrugs That Are Converted by Cellular Metabolism into AMP Analogs

The first compound reported to activate AMPK in intact cells was 5′-aminoimidazole-4-carboxamide riboside (AICAR), which is taken up into cells via adenosine transporters and converted by adenosine kinase to the monophosphorylated ribotide, ZMP (Fig. 1). ZMP mimics all three effects of AMP to activate AMPK and has been widely used as an experimental tool to study downstream consequences of AMPK activation. However, ZMP is around 50-fold less potent than AMP in activating AMPK (Corton et al. 1995) and only works because ZMP accumulates inside cells to millimolar concentrations. At those concentrations it is perhaps no surprise that ZMP should have "off-target," AMPK-independent effects. For example, its ability to cause acute hypoglycemia in mice is due to the ability of ZMP to mimic the inhibition



AMP-Activated Protein Kinase, Fig. 1 AMPK activators grouped according to their mechanism of action. See text for details

of the gluconeogenic enzyme, fructose-1,6-bisphosphatase, by AMP (Hunter et al. 2018).

An agent that activates AMPK by a related mechanism is compound 13 (C13), a diisopropyl phosphonate ester that is taken up into cells and converted by cellular esterases to the AMP analog C2 which, surprisingly, is a more potent activator of AMPK than AMP itself (Gomez-Galeno et al. 2010). C2 does not affect other AMP-sensitive enzymes such as fructose-1,6-bisphosphatase and is also highly specific for AMPK complexes containing α1, with no activation of α2 complexes (Hunter et al. 2014).

Agents That Activate AMPK by Binding the Allosteric Drug and Metabolite (ADaM) Site

The ADaM site is located between one surface of the carbohydrate-binding module (CBM) on the AMPK-β subunits and the surface of the small lobe of the kinase domain on the α subunit, opposite to the catalytic site (Xiao et al. 2013). This site is of great interest because, being formed by the juxtaposition of two different subunits, it is unique to AMPK. The first compound shown to bind there was A-769662, derived from a high-throughput screen that searched for allosteric activators of AMPK (Cool et al. 2006). A-769662 and most other ADaM site activators cause a large allosteric activation of AMPK, with just a modest increase in Thr172 phosphorylation caused by inhibiting its dephosphorylation.

A curious feature of the ADaM site is that almost all compounds currently known to bind there are synthetic molecules, rather than natural products. The one exception is salicylate (Hawley et al. 2012), but salicylate is a plant product and is not known to occur in animals unless it is ingested. The ADaM site is therefore a type of *orphan receptor* – most researchers in the field assume there is a natural ligand that binds there (hence the "*a*nd Metabolite" element of the ADaM acronym), but such a ligand has not yet been identified. Salicylate (in the form of willow bark extract) has been used by humans as a medicine since ancient times and is usually now administered in the form of acetylsalicylic acid (ASA or aspirin). While ASA itself acts by inhibiting cyclooxygenases and hence the synthesis of prostanoid messengers, salicylate is rapidly generated in vivo from ASA by cellular esterases, and some therapeutic effects of aspirin might be mediated by AMPK (Hawley et al. 2012).

A-769662 has poor oral availability, but subsequent screens produced more potent and orally available ADaM site activators, such as MK-8722 (Myers et al. 2017), PF-739 (Cokorinos et al. 2017), and PF-249 (Salatto et al. 2017). All of these compounds are more potent activators of β1- rather than β2-containing complexes, and some (like A-769662 and PF-249) are essentially β1-specific. However, MK-8722 and PF-739 are *pan-β activators* that do activate β2-containing complexes in vivo. This is significant because it means that they activate AMPK in skeletal muscle, which only expresses β2 and not β1. This enabled the direct demonstration that drugs that activate AMPK and thus promote glucose uptake in skeletal muscle would significantly lower plasma glucose in animal models of insulin resistance, both in mice and nonhuman primates (Myers et al. 2017; Cokorinos et al. 2017). None of these compounds have yet proceeded into human clinical trials, possibly because they cause the potentially adverse effect of cardiac hypertrophy in animals (Myers et al. 2017). Promisingly, however, more short-acting ADaM site activators have been shown to be just as effective as MK-8722 in lowering plasma glucose and insulin in rodent models of insulin resistance and diabetes, although they did not cause cardiac hypertrophy (Muise et al. 2019).

[2]School of Biological Sciences and Maurice Wilkins Centre for Molecular Biodiscovery, The University of Auckland, Auckland, New Zealand

Synonyms

Diabetes-associated peptide; Islet amyloid polypeptide

Definition

Amylin was discovered in 1987 and was identified as the major component of islet amyloid, which is commonly found in patients with type 2 diabetes (T2D). Amylin belongs to the calcitonin peptide family, which includes calcitonin (CT), α- and β-calcitonin gene-related peptide (CGRP), adrenomedullin, and intermedin/adrenomedullin 2. Members of this family play important roles in the regulation of several important homeostatic processes and thus have been drug targets of interest (Hay et al. 2015).

Amylin is a naturally occurring ~4 kDa peptide hormone composed of 37 amino acids with an intramolecular disulfide bridge between cysteine residues at positions 2 and 7 and an amidated C-terminus. Both of these are essential for amylin to carry out its biological activity (Bower and Hay 2016).

The gene encoding human amylin is located on chromosome 12, which transcribes in humans as an 89-amino acid precursor. The precursor is then converted to the 67-amino acid proamylin with the removal of the signal peptide and is stored in β-cell granules with insulin and C-peptide. The biologically active 37-amino acid form of amylin is derived through proteolysis and posttranslational modifications of proamylin. The process involves proteolytic cleavage of proamylin at pairs of basic residues at the C-terminus and N-terminus with carboxypeptidase E and prohormone convertases 1/3 and 2, followed by the formation of a disulfide bond between positions 2 and 7 and amide formation at the C-terminal tyrosine (Westermark et al. 2011).

Amylin is primarily synthesized in the pancreatic islet β-cells. Expression of amylin has also been detected in the gastrointestinal system, lung tissue, and nervous system. It is co-synthesized and co-secreted with insulin by pancreatic β-cells at a ratio of approximately 10–100:1 (insulin:amylin) in response to nutrient stimuli (Zhang et al. 2016).

Amylin circulates in the plasma at concentrations of 3–5 pM in the fasting state of normoglycemic subjects and increases to 15–25 pM after eating (postprandially). Plasma amylin is deficient in type 1 diabetes (T1D) patients, due to a lack of functional β-cells. In contrast, amylin increases in the initial phase of T2D, followed by a diminished capacity to secrete amylin in late-stage T2D, corresponding to β-cell dysfunction (Hay et al. 2015).

Basic Characteristics

Physiological Role

Amylin is a neuroendocrine hormone that acts centrally. It is highly conserved phylogenetically, which often indicates a significant role physiologically. Amylin reportedly has several biological roles. These include regulation of energy homeostasis, acting as an adiposity signal, bone metabolism, blood pressure regulation, and locomotor activity (Hay et al. 2015). However, most evidence indicates that the main role of amylin is in complementing insulin in the regulation of nutrient influx into the circulation and maintenance of energy homeostasis.

Glucose Regulation

Amylin is co-secreted with insulin in response to nutrient stimuli, and the role of insulin as a regulator of blood glucose is well-known. It is suggested that amylin works synergistically with insulin rather than directly to suppress

postprandial blood glucose levels. Amylin is the third most important and active pancreatic islet hormone behind insulin and glucagon for the regulation of glucose homeostasis. Studies have found that amylin regulates postprandial glycemia by several mechanisms including slowing gastric emptying, decreasing postprandial glucagon secretion, and promoting satiety thus preventing postprandial spikes in blood glucose levels (Zhang et al. 2016). Insulin promotes absorption of glucose from the bloodstream into peripheral tissues, while amylin controls the entry of glucose from ingested food into the bloodstream by slowing gastric emptying. The rate of gastric emptying is important in blood glucose homeostasis, as a slower rate delays carbohydrate from entering the small intestine, thus limiting the inflow of meal-derived glucose into the bloodstream. Amylin is well established to inhibit gastric emptying. This effect is observed in humans; administration of an amylin analogue, pramlintide, delays gastric emptying in T1D and T2D patients (Ryan et al. 2009). Another key step of postprandial glucose regulation is to halt further endogenous production of glucose from energy stores. Amylin has been shown to hinder glucagon release which in turn stops hepatic gluconeogenesis and glycogenolysis (Lutz 2010).

Satiety

Amylin is well documented to play a role in reduced eating by inducing meal-ending satiation. The anorectic actions of amylin represent a physiological effect as it is rapidly released following a meal, and exogenous amylin administration reduces eating within minutes. Studies have shown that the effect of reduced meal size is dose-dependent and chronic administration of amylin resulted in a sustained reduction in food intake. Furthermore, this action is blocked by an amylin receptor antagonist, AC187. The effects are likely to be mediated via the area postrema (AP) of the brainstem as the anorectic effect of amylin was abolished in rats with lesions in the AP region (Lutz 2010).

Adiposity Signal

It has been proposed by Morton et al. (2006) that there are three criteria to fulfill to be considered as an adiposity signal. The hormone should (1) circulate in the blood at a level proportionate to body adiposity and able to access to the brain and (2) promote weight loss through neural systems which regulate energy homeostasis, and (3) inhibition of these neuronal actions results in body weight and adiposity gain. Numerous studies have demonstrated amylin may play a role as an adiposity signal as it shares similar characteristics to well-known adiposity signal hormones, i.e., insulin and leptin. Higher basal plasma amylin is found in obese rats and overweight/obese humans compared to lean controls. Moreover, chronic peripheral or central amylin administration in rats resulted in weight reduction by lowering of adiposity, whereas amylin antagonist treatment increased food intake and body adiposity (Lutz 2010).

Energy Expenditure

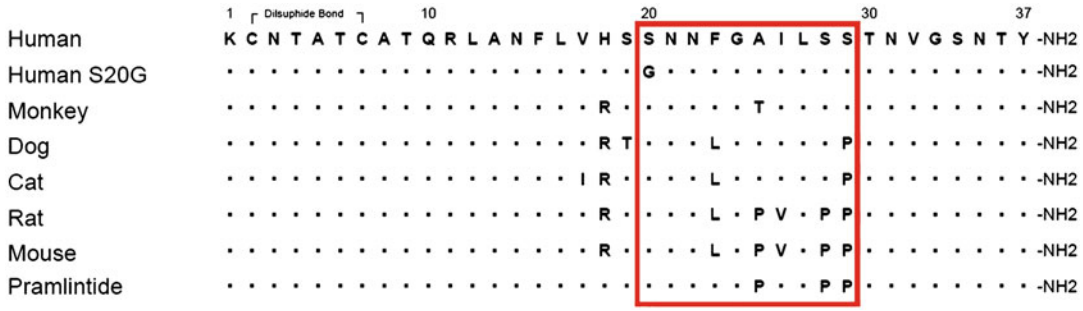
There are a number of studies on the effect of amylin on energy expenditure. The experimental observations are based on the assessment of energy expenditure by indirect calorimetry. Acute administration of the long-acting amylin receptor agonist salmon CT has been reported to increase energy expenditure in the rat. However chronic peripheral administration of amylin exhibited the same energy output as control rats but had lower food intake and weight (Lutz 2010).

Additionally, transgenic mice that overexpress either human amylin or receptor activity-modifying protein (RAMP) 1 of an amylin receptor complex have shown increased energy expenditure and higher body temperature. Mice overexpressing RAMP1 also had increased sympathetic nerve activity in thermogenic brown adipose tissue (regulator of energy expenditure and body fat in humans and rodents), and addition of a β-adrenergic receptor antagonist inhibits the activity (Lutz 2010).

Pathological Roles

It has been proposed that aberrant protein aggregation to form amyloid deposits is the underlying cause of several diseases such as T2D, Alzheimer's, and Parkinson's disease.

Amylin's amino acid sequence is highly conserved through evolution. Amylin shares at least



Amylin, Fig. 1 Single-letter code amino acid sequences of amylin in the human, human variant (S20G) monkey, dog, cat mouse, rat, and pramlintide. Box highlights the amyloidogenic region. Dots correspond to conserved residues with human amylin sequence

80% sequence identity across mammalian species. However, human, feline, and nonhuman primate forms of amylin have the propensity to form amyloid, while rat/mouse amylin lacks fibrillogenicity (Fig. 1). Studies have demonstrated that the variations detected in the region between amino acids 20 and 29 are critical for amyloid formation because this region contains five of six differences found between human and rat amylin. Most notably, rodent amylin has three proline substitutions at positions 25, 28, and 29, which are known as β-*sheet breakers* that greatly attenuate fibril formation. It is now recognized that amylin fragments 8–20, 10–19, and 30–37 also form amyloid fibrils (Westermark et al. 2011).

Islet amyloid formation starts with soluble monomeric amylin associating into soluble β-sheet oligomeric states. These oligomers then subsequently assemble into protofibrils arranged in parallel or antiparallel β-pleated sheets. Once protofibrils are formed, it rapidly aggregates into insoluble fibrils, and further aggregation of fibrils results in islet amyloid (Westermark et al. 2011).

Numerous transgenic rodent models overexpressing human amylin in islet β-cells develop diabetes, and increasing transgene expression resulted in increased β-cell apoptosis and earlier onset of diabetes (Westermark et al. 2011). The current consensus is that the aggregation intermediate of the soluble oligomer of human amylin is the main culprit that constitutes the toxic species and not the fibrils. A study using time-lapse atomic force microscopy captured human amylin oligomers forming, thus confirming their existence in vitro. Human amylin preparations with few preformed fibrils are highly toxic to β-cells, and conversely, amylin preparations with ample preformed fibrils are low in toxicity. Furthermore, dissociating the pre-existing aggregates into monomers restored the high cytotoxic potential. Rifampicin is a potent inhibitor of fibril development, but not an inhibitor of the formation of amylin oligomers. It did not prevent β-cells from apoptosing, supporting the notion that the amylin oligomers are the toxic species (Raleigh et al. 2017).

Several mechanisms of human amylin cytotoxicity have been proposed, but the exact causes of cell death are still not completely defined. Currently, human amylin aggregates which mediate apoptosis by triggering several apoptotic signals and membrane disruption through the formation of ion channels and/or direct interaction to affect membrane integrity are the two main widely accepted hypotheses (Westermark et al. 2011). However, one must take into consideration that in vitro and transgenic animal model studies may not fully reflect the slow process of islet amyloid deposition in human T2D patients. It is also important to note that islet cell cytotoxicity and islet amyloidosis are not universal features that occur in all T2D patients. Thus, human amylin cytotoxicity could be one of the many contributors to T2D pathogenesis in humans (Raleigh et al. 2017).

Islet Amyloid and T2D Progression

Human amylin is a major component of islet amyloid deposition. It has been documented that between 40% and 100% of T2D patients have amyloid deposits in their pancreatic islets. It has

been proposed that the formation of islet amyloid is related to β-cell dysfunction and reduced β-cell mass, causing diminishing insulin secretion, contributing to the pathogenesis of T2D. Additionally, extended exposure of pancreatic islets to high glucose environments has been shown to selectively favor amylin secretion, thus increasing the risk of islet amyloid formation and β-cell deterioration (Westermark et al. 2011).

Recent studies have also reported that amylin deposition was found in the kidney and heart of T2D patients. Renal amylin deposition was found in postmortem tissue from patients with diabetic nephropathy, and the amount of deposition was correlated with disease severity. Significant accumulation of large amylin oligomers, fibrillar tangles, and plaques was also found in failing hearts from patients with obesity and/or T2D, but not in normal hearts and failing hearts from lean humans without diabetes (Despa and DeCarli 2013).

Human Amylin and Alzheimer's Disease

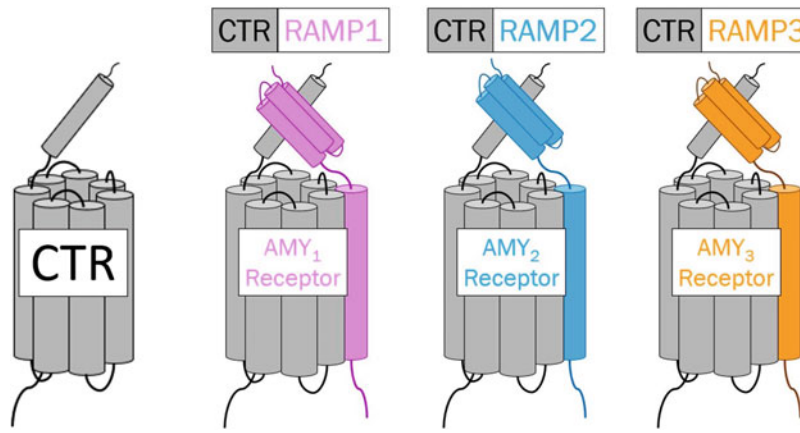
There has been interest in the connection between amylin and Alzheimer's disease (AD). T2D and AD are more prevalent with aging and share many clinical and biochemical features indicating common pathogenic mechanisms. Both diseases feature amyloid deposits: human amylin in the pancreas and amyloid β (Aβ) in the brain, respectively. Human amylin aggregation has been found to be linked to β-cell death, while Aβ formation causes neuronal cell loss. A meta-analysis also revealed that T2D patients have a 60% greater risk of developing AD (Vagelatos and Eslick 2013). There have been several studies into the potential involvement of amylin in AD. However, these are conflicting as to whether it is a beneficial or contributory factor to AD. Therefore, more work is required to understand this.

Amylin Receptors

Amylin receptors designated as AMY_1, AMY_2, and AMY_3 are comprised of heterodimerized complexes formed from the CT receptor (CTR) interacting with one of three accessory proteins called RAMPs (Fig. 2). CTR is a seven-transmembrane-domain Class B G protein-coupled receptor (GPCR) encoded on chromosome 12 in humans. There are two main splice variants of human CTR being $hCT_{(a)}$ as the major subtype and $hCT_{(b)}$. The RAMPs are single-domain transmembrane proteins with subtypes RAMP1, RAMP2, and RAMP3. Six amylin receptors can form from the two CTR isoforms plus one of three RAMPs (Hay et al. 2015).

Amylin receptors are widely distributed in the brain as identified through radioligand binding studies. The most abundant sites of the amylin receptors are found in the nucleus accumbens, the AP of the brainstem, and the hypothalamus. It is thought that the AP, which does not have a blood-brain barrier (thereby allowing access to circulatory peptides), could be an important site for amylin action (Hay et al. 2015).

To date, extensive studies have reported on the pharmacological properties of these receptors.



Amylin, Fig. 2 A schematic diagram of the amylin receptors AMY_1, AMY_2, or AMY_3. Receptors are generated from the interaction of the calcitonin receptor with RAMP1, RAMP2, or RAMP3

Amylin, Table 1 Development of amylin receptor agonist-based drugs

Drug/company	Therapy area	Status of drug
Pramlintide acetate (Amylin Pharmaceuticals, AstraZeneca)	Type 1 and 2 diabetes	Launched
Pramlintide + A21G human insulin (Adocia)	Type 1 diabetes	Phase 2 clinical
AM-833 (Novo Nordisk)	Obesity	Phase 2 clinical
BI-473494 (Boehringer)	Cardiovascular disease; diabetes mellitus; metabolic disorder; obesity	Phase 1 clinical
DACRA-089 (Eli Lilly & Co)	Diabetes mellitus; nonalcoholic steatohepatitis; obesity	Phase 1 clinical
Pramlintide + human insulin (BioChaperone), (Adocia)	Type 1 diabetes	Phase 1 clinical
Pramlintide + metreleptin (Amylin/ Takeda)	Obesity	Discontinued
Davalintide	Obesity	Discontinued
Pramlintide development for Alzheimer's disease (WE Biosciences Llc)	Alzheimer's disease	National Institute on Aging funded We Biosciences Llc for development

However, the physiological relevance of each of the amylin receptor subtypes is still not fully elucidated. Study of amylin receptor function is complicated by lack of antagonists that can block specific subtypes of amylin receptors and the fact that some amylin receptors can also be activated by CGRP. Hence, it is still unknown which combination of CTR and RAMP is the functional amylin receptor in AP or the other brain regions.

Drugs

Pharmaceutical companies have been focusing on drug development based on amylin function in glycemic and energy regulation (Table 1). Preclinical studies have considered inhibition of amylin aggregation as a potential therapeutic strategy against T2D.

Amylin Receptor Agonist-Based Drugs

Approved Drugs

Pramlintide was the first FDA-approved amylin-based drug, which is approved for use as an adjunct to insulin for T1D and insulin-treated T2D. Human amylin's self-aggregation properties to form an insoluble compound in a number of solvents make it unsuitable for pharmaceutical use directly. However, this issue is circumvented by substituting proline for the positions 25 (alanine), 28 (serine), and 29 (serine) of amylin to result in a soluble, stable synthetic analogue, pramlintide (Fig. 1). Most importantly, this analogue possesses similar beneficial action to naturally occurring amylin (Bower and Hay 2016). Various clinical data in T1D and T2D patients showed that pramlintide therapy decreases A1C by 0.2–0.6% and the 2-h postprandial hyperglycemia by 3.4–5 mmol/L. Pramlintide was also found to reduce the weight of diabetic patients after 1-year of study (Ryan et al. 2009). One of the issues with pramlintide is incompatibility with insulin due to the formulation pH. Pramlintide is formulated at pH 4 to maintain solubility, whereas insulin is formulated at a neutral pH. Thus patients are required to take both drugs separately, and multiple injections per day can become a burden (Bower and Hay 2016). This currently limits its clinical use and has driven the search for novel amylin mimetics.

Exploratory Drugs

There is strong interest in improving the potency and pharmacokinetics of amylin agonists to

Amylin, Table 2 Development of amylin aggregation inhibitor-based drugs

Drug	Active indication	Status of drug
Antihuman amylin oligomer antibodies (Tel Aviv University)	Type 2 diabetes	Discovery
Human amylin aggregation inhibitor (Zyentia)	Type 2 diabetes	Discontinued

achieve a more patient-friendly treatment of metabolic diseases.

Lipidation, PEGylation, and glycosylation are common strategies to modify peptides by the covalent attachment of polyethylene glycol (PEG), oligosaccharides, or fatty acids. Each aims to improve drug properties such as half-life, metabolic stability, and receptor binding. PEGylation and glycosylation have been tested so far, but further investigation is warranted (Bower and Hay 2016). Other amylin mimetics include davalintide and DACRA-089 (Bower and Hay 2016).

Combination therapy of amylin agonists with other hormones such as leptin, PYY, and cholecystokinin could also prove to be useful for weight loss. Pramlintide plus leptin has been investigated extensively. Leptin plays a role in the long-term signal of energy balance. Yet, obese rodents and humans are largely nonresponsive to exogenous leptin treatment. Studies have shown that amylin may improve leptin sensitivity and restore leptin responsiveness in obesity. Pramlintide with metreleptin, an analogue of leptin, has been selected to advance toward phase 3 clinical trial. However, it was halted due to antibody development against metreleptin in patients (Hay et al. 2015).

The strategies aforementioned lay the foundation for continuing trials examining drug design, development, and therapy for amylin-based pharmacotherapy that may prove to be a promising approach for weight loss, diabetes, and potentially other disorders.

Amylin Aggregation Inhibitor-Based Drug

There has been some success with small peptides that interact with human amylin to attenuate the aggregation process in vitro and in vivo to inhibit amyloidosis (Table 2). Alternative inhibitors like tetracycline, Congo red, and rutin have been reported to be effective in vitro and in vivo. Moreover, aromatic and polyphenol compounds such as resveratrol (a substance in red wine) and epigallocatechin-3-gallate (a substance in green tea), respectively, have been suggested as potential inhibitors (Raleigh et al. 2017).

Analgesics

Christoph Stein
Experimentelle Anaesthesiologie, Charité Campus Benjamin Franklin, Freie Universität, Berlin, Germany

Synonyms

Pain medication

Definition

Analgesics interfere with the generation and/or transmission of impulses following noxious stimulation (nociception) in the nervous system. This can occur at peripheral and/or central levels of the neuraxis. The therapeutic aim is to diminish the perception of pain.

Nonsteroidal Anti-inflammatory Drugs
Opioid Systems

Mechanisms of Action

Analgesics aim at modulating the generation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors/ion channels transducing/transmitting noxious stimuli (e.g., peptide receptors, Ca^{++} channels). Clinically used drugs include opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), antiepileptics, and antidepressants. Local anesthetics are used for local and regional anesthetic techniques. Mixed drugs (e.g., tramadol, tapentadol, serotonin/noradrenaline reuptake inhibitors) combine various mechanisms (Table 1). Acute and chronic pain are substantially different conditions. The treatment of chronic pain must include non-pharmacological approaches and address psychosocial influences (Dowell et al. 2016; Kaiser et al. 2017).

Opioids

Opioids act on heptahelical G-protein-coupled receptors. Three main types of opioid receptors (μ, δ, κ) have been identified. Additional subtypes (e.g., μ_1, μ_2), possibly resulting from gene polymorphisms, splice variants, or alternative processing, have been proposed. Opioid receptors are localized and can be activated along all levels of the neuraxis including peripheral and central processes of primary sensory neurons (nociceptors), spinal cord (interneurons, projection neurons), brainstem, midbrain, and cortex. All opioid receptors couple to G-proteins (mainly G_i/G_o) and arrestins. G-protein activation leads to inhibition of adenylyl cyclase, decreased conductance of voltage-gated Ca^{++} channels, and opening of rectifying potassium channels, and arrestin coupling induces receptor internalization. Subsequently, neuronal activity and the release of excitatory (pronociceptive) neurotransmitters are reduced. A prominent example is the suppression of tachykinin (substance P) release from primary sensory neurons within the spinal cord and from their peripheral terminals in injured tissue. At the postsynaptic membrane, opioids produce hyperpolarization by opening K^+ channels, thereby preventing excitation or propagation of action potentials in second-order projection neurons. In addition, opioids inhibit sensory neuron-specific tetrodotoxin-resistant Na^+ channels, TRPV1 channels, and excitatory postsynaptic currents evoked by glutamate receptors in the spinal cord. The result is decreased transmission of nociceptive stimuli at all levels of the neuraxis and profoundly reduced perception of pain (Stein 2016). Endogenous opioid receptor ligands are derived from the precursors pro-opiomelanocortin (encoding β-endorphin), pro-enkephalin (encoding Met-enkephalin and Leu-enkephalin), and prodynorphin (encoding

Analgesics, Table 1 Analgesics

Drugs	Targets	Mechanisms	Functional consequences	Side effects
Opioids	G-protein-coupled μ-, δ-, κ-receptors	↓ cAMP ↓ Ca^{++} currents ↑ K^+ currents	↓ excitability of peripheral and central neurons ↓ release of excitatory neurotransmitters	μ, δ: sedation, nausea, euphoria/reward, respiratory depression, constipation κ: dysphoria/aversion, diuresis, sedation
NSAIDs	Cyclooxygenases (COX-1, COX-2)	↓ prostaglandins ↓ thromboxanes	↓ sensitization of sensory neurons ↑ inhibition of spinal neurons	Gastrointestinal ulcers, perforation, bleeding, renal impairment, myocardial infarction, stroke
Antiepileptics	Na^+, Ca^{++} channels GABA receptors	↓ Na^+ currents ↓ Ca^{++} currents ↑ GABA receptor activity	↓ excitability of peripheral and central neurons ↓ release of excitatory neurotransmitters	Sedation, dizziness, cognitive impairment, ataxia, hepatotoxicity, thrombocytopenia
Antidepressants Serotonergic drugs	Noradrenaline/5-HT transporters Na^+, K^+ channels, 5-HT receptors	↓ noradrenaline/5-HT reuptake ↓ Na^+ currents ↑ K^+ currents, cAMP modulation	↓ excitability of peripheral and central neurons ↓ release of excitatory neuropeptides ↓ neurogenic inflammation ↑ vasoconstriction	Cardiac arrhythmia, myocardial infarction, peripheral vascular occlusion, sedation, constipation, dizziness, blurred vision

dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe-[Met/Leu] sequence at their amino terminals, known as the opioid motif. β-Endorphin and the enkephalins are potent antinociceptive agents acting at μ and δ receptors. Dynorphins can elicit both pro- and antinociceptive effects via κ-opioid and/or glutamate receptors. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors do not contain the pan-opioid motif but bind to μ-receptors with high selectivity (Stein 2016).

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs inhibit cyclooxygenases (COX), the enzymes that catalyze the transformation of arachidonic acid (a ubiquitous cell component generated from phospholipids) to prostaglandins and thromboxanes. Two isoforms, COX-1 and COX-2, are expressed in peripheral tissues and in the central nervous system. In response to injury and inflammatory mediators (e.g., cytokines, growth factors), both isoforms can be upregulated, resulting in increased concentrations of prostaglandins. In the periphery, prostaglandins (mainly PGE_2) sensitize nociceptors by phosphorylation of ion channels (e.g., Na^+, TRPV1) via EP receptor activation. As a result, nociceptors become more responsive to noxious mechanical (e.g., pressure, hollow organ distension), chemical (e.g., acidosis, bradykinin, neurotrophic factors), or thermal stimuli. In the spinal cord, PGE_2 blocks glycinergic neuronal inhibition, enhances excitatory amino acid release, and depolarizes ascending neurons. These mechanisms facilitate the generation of impulses in nociceptors and their transmission through the spinal cord to higher brain areas. By blocking COX, prostaglandin formation diminishes. Subsequently nociceptors become less responsive to noxious stimuli, and spinal neurotransmission is attenuated (Brune and Patrignani 2015).

Antiepileptics

Antiepileptics are primarily used in neuropathic pain resulting from lesions to the peripheral (e.g., diabetes, herpes) or central nervous system (e.g., stroke) (Wiffen et al. 2013). Such syndromes have been attributed to ectopic activity in sensitized nociceptors from regenerating nerve sprouts, recruitment of previously "silent" nociceptors, and/or spontaneous neuronal activity. This can result in sensitization of primary afferents and subsequent sensitization of ascending neurons. In addition, increased expression and trafficking of ion channels (e.g., Na^+, Ca^{++}, TRP) and increased activity at glutamate receptor sites have been demonstrated. Proposed mechanisms of action of antiepileptics include neuronal membrane stabilization by blockage of pathologically active voltage-sensitive Na^+ channels (e.g., carbamazepine, lacosamide, lamotrigine), blockage of voltage-dependent Ca^{++} channels (gabapentin, pregabalin, topiramate), inhibition of presynaptic release of excitatory neurotransmitters (gabapentin, lamotrigine), and enhancing the activity of γ-aminobutyric acid (GABA) receptors (valproate, clonazepam, pregabalin, topiramate) (Finnerup et al. 2015; Wiffen et al. 2013).

Antidepressants/Serotoninergic Drugs

Antidepressants are used for the treatment of neuropathic pain and headache. They include the classic tricyclic compounds and are divided into nonselective noradrenaline/serotonin reuptake inhibitors (e.g., amitriptyline, imipramine, clomipramine, venlafaxine), preferential noradrenaline reuptake inhibitors (e.g., desipramine, nortriptyline), and selective serotonin reuptake inhibitors (e.g., citalopram, paroxetine, fluoxetine). Serotonin (5-hydroxytryptamine; 5-HT) is a monoamine neurotransmitter in the sympathetic nervous system, in the gastrointestinal tract, and in platelets. It acts on 5-HT receptors expressed at all levels of the neuraxis and in blood vessels. Within the spinal cord, serotoninergic neurons contribute to endogenous pain inhibition. With the exception of 5-HT_3 (a ligand-gated ion channel), 5-HT receptors are G-protein-coupled receptors. The reuptake block leads to a stimulation of endogenous monoaminergic pain inhibition in the spinal cord and brain. In addition, tricyclics have glutamate receptor antagonist, opioid enhancing, Na^+ channel blocking, and K^+ channel opening effects, which can suppress peripheral and central sensitization (Finnerup et al. 2015).

$5\text{-HT}_{1B/1D}$ agonists (triptans) are effective against neurovascular (migraine, cluster) headaches. Migraine is related to the release of neuropeptides (e.g., calcitonin gene-related peptide; CGRP) from trigeminal sensory neurons innervating meningeal and intracranial blood vessels. This leads to vasodilation, an inflammatory reaction, and subsequent pain. Triptans inhibit neurogenic inflammation via 5-HT_{1D} receptors on trigeminal afferents, with possible additional sites of action on thalamic neurons and in the periaqueductal gray. The activation of vascular 5-HT_{1B} receptors constricts meningeal (and coronary) vessels. The latter effects have stimulated the search for non-vasoconstrictor approaches such as selective 5HT_{1F} agonists and CGRP antagonists (Gonzalez-Hernandez et al. 2018).

Clinical Use and Side Effects

Whereas acute pain (e.g., associated with surgery or trauma) is usually amenable to drug therapy, chronic pain is a complex disease in its own right and needs to be differentiated into malignant (cancer-related) and noncancer (e.g., musculoskeletal, neuropathic) pain. Acute and cancer-related pain are commonly treatable with opioids, NSAIDs, and/or local anesthetic blocks. Chronic noncancer pain (CNCP) requires a multidisciplinary approach including non-pharmacological (e.g., psychological, physiotherapeutic) treatment strategies (Reinecke et al. 2015; Kaiser et al. 2017; Dowell et al. 2016). Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, epidural, topical, intraarticular, transnasal) are used, depending on the clinical circumstances. Local anesthetics are used topically and in regional (e.g., epidural, perineural) anesthetic techniques for the treatment of acute (e.g., associated with surgery or child birth) and some cancer-related chronic pain syndromes.

Opioids

Opioids are the most effective drugs for severe acute and cancer-related chronic pain. They are not appropriate as sole analgesics in CNCP (Reinecke et al. 2015). Lack of fundamental knowledge and misconceptions about the management of CNCP have contributed significantly to the current opioid crisis (Dowell et al. 2016; Babu et al. 2019). All commonly available agents (e.g., morphine, codeine, methadone, fentanyl) are μ-agonists. Naloxone is a nonselective antagonist at all three receptors (μ, δ, κ). Partial agonists must occupy a greater fraction of the available functional receptors than full agonists to induce a response (e.g., analgesia) of equivalent magnitude. Mixed agonist/antagonists (e.g., buprenorphine, butorphanol, nalbuphine, pentazocine) may act as agonists at low doses and as antagonists (at the same or a different receptor) at higher doses. Such compounds typically exhibit ceiling effects for analgesia, and they may elicit an acute withdrawal syndrome when administered together with a pure agonist. All three receptors mediate analgesia but differing side effects. μ-Receptors mediate respiratory depression, sedation, reward/reinforcement, euphoria, nausea, and constipation. Animal studies have shown that δ-agonists produce similar side effects, whereas κ-agonists elicit dysphoric, aversive, sedative, and diuretic effects. Tolerance and physical dependence usually occur with prolonged administration of pure agonists, and abrupt discontinuation or antagonist administration can evoke a withdrawal syndrome. Because G-protein activation occurs not only in sensory neurons (leading to pain relief) but also in neurons driving respiration, arousal, and intestinal peristalsis and in neurons suppressing reward/reinforcement, systemically administered μ-opioids can elicit respiratory depression (apnea), sedation, constipation, dependence, and addiction (Stein 2018; Fields and Margolis 2015; Negus and Freeman 2018).

Opioids are effective in the periphery (e.g., topical or intraarticular administration), at the spinal cord (intrathecal or epidural administration), and systemically (e.g., intravenous or oral administration). The clinical choice of particular compounds is based on pharmacokinetic considerations (route of administration, desired onset or duration, lipophilicity) and on side effects associated with the respective route of drug delivery. Dosages are dependent on patient characteristics, type of pain, and route of administration. Recent guidelines recommend to limit opioid treatment to the lowest dose and shortest duration possible (Dowell et al. 2016; Babu et al. 2019). Systemically and spinally administered μ-opioids can produce similar side effects, depending on dosage and rostral/systemic redistribution. Side effects (e.g., respiratory depression) can be minimized by careful dose titration and close patient monitoring or can be treated by co-medication (e.g., with laxatives) or naloxone (Babu et al. 2019). No adverse effects have been reported upon local/peripheral application of small, systemically inactive doses.

NSAIDs

Less severe pain states (e.g., early arthritis, menstruation, headache, minor surgery) are commonly treated with NSAIDs (e.g., aspirin, ibuprofen, indomethacin, diclofenac). NSAIDs are mostly used orally. Some agents are available for parenteral, rectal, or topical application. Over-the-counter availability and self-medication have led to frequent abuse and toxicity. All available NSAIDs, including acetaminophen and aspirin, are associated with gastrointestinal and/or cardiovascular side effects, related to their relative selectivity for COX-1 and COX-2. Inhibition of COX-1 leads to blockade of thromboxane production and impairment of platelet function (bleeding), decrease of tissue-protective prostaglandins (gastrointestinal ulcers, perforation), and decrease of renal vasodilatory prostaglandins (nephrotoxicity). In contrast to the other NSAIDs, aspirin (acetylsalicylic acid) causes irreversible inactivation of COX-1 and COX-2 in most patients, which underlie its prolonged suppression of platelet activation and unique cardioprotective effects. Acetaminophen has no measurable anti-inflammatory effects at therapeutic doses, but inhibits pain primarily through suppression of PGE_2 synthesis. The development of selective COX-2 inhibitors was driven by the assumption that COX-2 expression is selectively induced in inflamed tissue. It is now clear that COX-2 is constitutively expressed in several tissues (e.g., gastrointestinal epithelium, vascular endothelium, spinal cord) and that

COX-2 inhibition decreases formation of vasodilatory prostacyclin. Thus, COX-2 inhibitors confer an increased risk of thrombosis, myocardial infarction, hypertension, and stroke. COX inhibitors can cause anaphylactic reactions, and diverse interactions with co-administered drugs (e.g., steroids, coumarin, serotonin reuptake inhibitors) have to be observed in clinical practice (Brune and Patrignani 2015).

Antiepileptics

Antiepileptics are used for neuropathic pain and for migraine prophylaxis (Gonzalez-Hernandez et al. 2018; Wiffen et al. 2013). They are frequently co-administered with antidepressants. The most common adverse effects are impaired mental (somnolence, dizziness, cognitive impairment, fatigue) and motor function (ataxia) which limit clinical use, particularly in elderly patients. Other side effects include hepatotoxicity, thrombocytopenia, and sometimes life-threatening dermatologic and hematologic reactions. Plasma drug concentrations should be monitored. Evidence from clinical trials particularly supports the use of gabapentin and pregabalin (Finnerup et al. 2015; Wiffen et al. 2013).

Antidepressants/Serotoninergic Drugs

Antidepressants are used for neuropathic pain and migraine prophylaxis (Finnerup et al. 2015; Gonzalez-Hernandez et al. 2018). Tricyclics may require monitoring of plasma drug concentrations to achieve optimal effect and avoid toxicity. Block of cardiac ion channels by tricyclics can lead to life-threatening arrhythmias. In patients with ischemic heart disease, there may be increased mortality, and in patients with recent myocardial infarction, arrythmia, or cardiac decompensation, tricyclics are contraindicated. Tricyclics also block histamine and cholinergic and adrenergic receptor sites. Further adverse events include sedation, nausea, constipation, dizziness, and blurred vision (Gonzalez-Hernandez et al. 2018). Triptans narrow coronary arteries via 5-HT_{1B} receptors at clinical doses and should not be administered to patients with risk factors or manifest hypertensive, coronary, cerebrovascular, or peripheral vascular disease. Many triptans have the potential for drug-drug interactions (e.g., with monoamine oxidase inhibitors, propranolol, cimetidine, hepatic P450-metabolized medications). Triptans should be restricted to patients with migraine-associated disability (Gonzalez-Hernandez et al. 2018).

Other Drugs

Ergot alkaloids are still in use as antimigraine drugs. They produce cranial and systemic vasoconstriction and can interact with serotonin, dopamine, and α-adrenoreceptors. For the prophylaxis of migraine, β-blockers, antidepressants, antiepileptics, Ca^{++} channel blockers, and reuptake inhibitors of noradrenaline/serotonin are also used (Gonzalez-Hernandez et al. 2018). Cannabinoids have attracted huge public attention, but systematic reviews and prospective studies have not confirmed their efficacy, tolerability, or safety in pain treatment (Häuser et al. 2018). CGRP antagonists/antibodies and opioid ligands leading to preferential (biased) activation of G-proteins are under intense investigation, but superiority over currently available drugs or significant reduction of side effects has not been demonstrated to date (Negus and Freeman 2018; Gonzalez-Hernandez et al. 2018; Stein 2018). The combined administration of different classes of drugs may increase the risk of overdose (Babu et al. 2019).

AADs, Antiarrhythmic agents

Definition

Antiarrhythmic drugs (AADs) are a group of pharmaceuticals used to treat or prevent heart rhythm disorders (cardiac arrhythmias) by altering the electrophysiological properties of the heart, typically through direct interaction with ion channels, receptors, or pumps/exchangers (Dan et al. 2018).

Basic Characteristics

Clinical Use

During a normal heartbeat, electrical impulses generated in the sinoatrial node conduct across the atria to the atrioventricular node. After a brief delay, the electrical impulse rapidly conducts along the His-Purkinje conduction system, resulting in synchronous activation of both ventricles that is necessary for optimal pump function of the heart. During cardiac arrhythmias, electrical impulse formation and/or conduction is disturbed, leading to excessively fast, slow, or irregular electrical activity of one or more parts of the heart. Although cardiac arrhythmias can be completely asymptomatic, they often lead to palpitations, dizziness, or fatigue, decreasing quality of life. Moreover, arrhythmias are associated with increased morbidity and mortality, with more than 50% of

sudden cardiac deaths attributed to ventricular arrhythmias (Camm 2017).

Despite a growing trend toward non-pharmacological therapy (e.g., electrical cardioversion and catheter ablation), it is not possible to apply invasive interventions to all patients due to the very large size of the patient population. Thus, AADs remain the cornerstone of antiarrhythmic therapy. AADs are used for the acute termination of arrhythmias (restoration of normal sinus rhythm, i.e., cardioversion), prevention of new arrhythmia occurrence (long-term sinus rhythm maintenance), or management of persistent arrhythmias (e.g., reducing ventricular rate in atrial fibrillation [AF]) (Dan et al. 2018). Acute pharmacological cardioversions are typically performed through intravenous application of AADs, with the exception of cardioversion of AF in a subset of patients without structural heart disease, in whom high-dose oral formulations are used (a so-called "pill-in-the-pocket" approach). Long-term sinus rhythm maintenance or arrhythmia management (rhythm and rate control) is performed with oral AADs in patients who do not qualify for more invasive catheter ablation procedures or in conjunction with these procedures (Camm 2017; Dan et al. 2018).

Mechanisms of Action

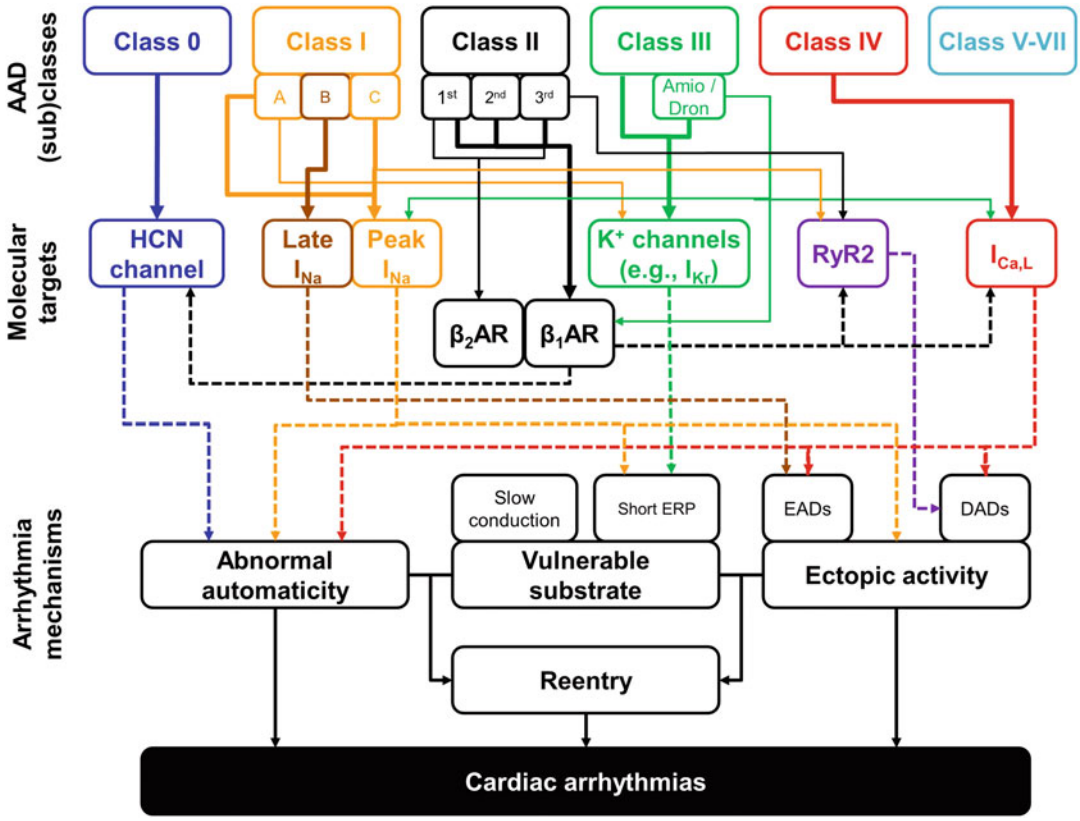
Antiarrhythmic Mechanisms

Conceptually, cardiac arrhythmias require a vulnerable substrate resulting from genetic predisposition, advancing age, or cardiovascular and systemic diseases, as well as a dynamic factor (e.g., sympathetic activation, inflammation, or electrolyte disturbances) explaining their sudden initiation (Heijman et al. 2017). Abnormal automaticity, triggered activity, and reentry are considered the major arrhythmogenic mechanisms (Mankad and Kalahasty 2019). At the cellular level, triggered activity is promoted by secondary depolarizations occurring during (early afterdepolarizations, EADs) or after (delayed afterdepolarizations, DADs) the normal electrical activation. EADs typically occur during conditions of excessive prolongation of cardiac electrical activity (prolonged repolarization duration), whereas DADs are favored by conditions of Ca^{2+} overload. Triggered activity can itself maintain an arrhythmia when occurring repetitively at sufficiently high frequency, or can initiate reentry, the foremost arrhythmia-maintaining mechanism, in a vulnerable substrate. This substrate can be structural (e.g., scar tissue leading to slow, heterogeneous electrical conduction) and/or functional (e.g., functional disturbance in electrical cell-to-cell conduction or short effective refractory periods [ERP]) (Heijman et al. 2017).

AADs can exert antiarrhythmic effects by inhibiting acute initiating factors (e.g., in the case of β-adrenoceptor blockers), reducing the likelihood of ectopic activity by reducing cellular excitability (e.g., Na^{+}-channel blockers), or decreasing substrate vulnerability (e.g., prolonging ERP; Fig. 1) (Heijman et al. 2017). As discussed below, most of the currently available drugs affect multiple electrophysiological components and arrhythmia mechanisms. Of note, although several cardiovascular drugs (e.g., inhibitors of the renin-angiotensin-aldosterone system) may also slow the development of a vulnerable substrate and thus may have indirect antiarrhythmic effects, they typically do not have direct electrophysiological effects and are therefore not considered classical AADs, although they have been incorporated as upstream therapy in more recent classification systems (Lei et al. 2018).

(Proarrhythmic) Side Effects

Ventricular proarrhythmia is a well-known adverse side effect of AADs. In the early 1990s, the Cardiac Arrhythmia Suppression Trial (CAST) and Survival with Oral D-Sotalol (SWORD) studies showed increased mortality in patients treated with AADs, highlighting the potentially severe consequences of these proarrhythmic side effects (Camm 2017). AAD-induced proarrhythmia is attributed to excessive prolongation of cardiac electrical activity (refractoriness), promoting EAD generation, or due to slowing of conduction velocity. However, there is substantial heterogeneity in both the antiarrhythmic efficacy and occurrence of proarrhythmic side effects, making the optimal clinical use of AADs



Antiarrhythmic Drugs, Fig. 1 Schematic overview of antiarrhythmic drug (AAD) classes, major molecular targets, and their impact on fundamental arrhythmia mechanisms (AAD classes are adapted from the 2018 classification by Lei et al. 2018). Primary targets of Class 0–IV AADs are indicated with thick solid lines and share the same color as the AAD class. Additional molecular targets of Class I, II, and III AADs are indicated with thin lines. Arrhythmia mechanisms affected by inhibition of a specific molecular target are connected with dashed lines. For example, inhibition of the L-type Ca^{2+} current ($I_{Ca,L}$) reduces abnormal automaticity in nodal tissue and reduces the likelihood of early and delayed afterdepolarizations (EADs and DADs, respectively). 1st/2nd/3rd refers to different generations of β-adrenoceptor (βAR) blockers. Amio/Dron, amiodarone/dronedarone; HCN, hyperpolarization-activated cyclic nucleotide-gated; I_{Na}, Na^+ current; I_{Kr}, rapidly activating delayed rectifier K^+ current; RyR2, type 2 ryanodine receptor channel

challenging (Dan et al. 2018; Heijman et al. 2017). For example, despite comparable AAD efficacy in men and women, the risk of pro-arrhythmic side effects is greater in women (Dan et al. 2018). The causes underlying these diverse effects remain incompletely understood and likely involve a combination of genetic susceptibility, heterogeneous cardiac remodeling as a result of multiple interacting comorbidities, and altered pharmacokinetic properties due to drug-drug interactions or disease-induced alterations in drug metabolism (including differential electrophysiological effects of metabolites) or drug elimination. In addition, acute and long-term drug effects may differ due to drug-induced remodeling of the electrophysiological properties of the heart.

Molecular Targets

Most clinically available AADs directly block one or more ion channel subtypes in the sarcolemmal membrane of cardiomyocytes, thereby reducing the corresponding ion currents and altering the electrophysiological properties of the heart. Common electrophysiological targets are hyperpolarization-activated, cyclic

nucleotide-gated (HCN) channels, the cardiac Na^+ current (I_{Na}), the L-type Ca^{2+} current ($I_{Ca,L}$), and the rapidly activating delayed rectifier K^+ current (I_{Kr}) (Fig. 1) (Heijman et al. 2017; Mankad and Kalahasty 2019). HCN channels contribute to cardiomyocyte automaticity, and their inhibition reduces spontaneous depolarization in the sinoatrial and atrioventricular nodes, His-Purkinje system, or diseased myocardium. Inhibition of I_{Na} reduces excitability, making triggered activity less likely, and prolongs ERP, reducing the likelihood of reentry. However, inhibition of I_{Na} may also slow conduction velocity, promoting reentrant arrhythmias. $I_{Ca,L}$ inhibition can reduce Ca^{2+} overload, decreasing the occurrence of DADs, and inhibits atrioventricular conduction, lowering the ventricular response rates during supraventricular arrhythmias. On the other hand, $I_{Ca,L}$ inhibition may decrease ERP, increasing the likelihood of reentry. Several K^+ currents are involved in the electrical recovery (repolarization) of the heart. I_{Kr} is a major target for AADs. Inhibition of I_{Kr} prolongs ERP, but excessive prolongation may promote EADs and so-called "torsade des pointes" (TdP) arrhythmias. Of note, many other drugs (non-AADs and non-cardiovascular drugs) also target I_{Kr} and may produce drug-induced proarrhythmia. Assessing I_{Kr} inhibition is therefore a standard component of safety screening during drug development.

Cardiac β-adrenoceptors are another important AAD target (Grandi and Ripplinger 2019). Their acute inhibition indirectly affects cardiac electrophysiology through modulation of cyclic nucleotide-gated channels and ion channel phosphorylation, reducing automaticity and lowering atrioventricular conduction. In addition, β-adrenoceptor blockers can reduce DAD-promoting intracellular Ca^{2+}-releases, and long-term use may have antiarrhythmic effects by improving cardiac metabolism and limiting adverse remodeling.

Besides these classical molecular targets, several others have been modulated by new experimental AADs (Heijman et al. 2017). These include Ca^{2+}-handling proteins contributing to proarrhythmic DADs, including the ryanodine receptor channel type 2 (RyR2) and Na^+/Ca^{2+}-exchanger, as well as gap junctions responsible for electrical cell-to-cell communication, key intracellular signaling molecules such as Ca^{2+}/calmodulin-dependent protein kinase-II (CaMKII), and additional cardiac ion channels. In particular, inhibition of I_{Na}, I_{Kr}, $I_{Ca,L}$, and β-adrenoceptors affects electrophysiological properties throughout the heart. Recently, significant efforts have been made to identify region-specific targets. For example, a number of relatively selective blockers of atrial-predominant ion channels, including the ultrarapid delayed rectifier K^+ current (I_{Kur}), the acetylcholine-activated inward rectifier K^+ current ($I_{K,ACh}$), and the two-pore domain K^+ channel 3.1, have been developed. Such drugs hold promise for selective therapy of AF without the risk of ventricular proarrhythmia, but so far initial clinical trials have been unsuccessful, and no compounds have been approved for clinical use.

Drugs

Based on the seminal work of Singh and Vaughan Williams, AADs have traditionally been divided into Na^+-channel blockers (Class I), β-adrenoceptor blockers (Class II), K^+-channel blockers (Class III), and non-dihydropyridine Ca^{2+} channel blockers (Class IV) (Dan et al. 2018; Lei et al. 2018). Several extensions of this AAD classification have been developed to better reflect the multiple mechanisms of action of each AAD (e.g., in the Sicilian Gambit classification) or to include newer compounds (e.g., in the 2018 extension of the Vaughan Williams classification by Lei et al. (2018)). The molecular mechanisms, key pharmacological properties, and clinical applications of commonly used AADs, grouped according to this last classification, are briefly discussed below and are summarized in Table 1. In general, few of these AADs were specifically developed for their antiarrhythmic properties. Indeed, most compounds were derived from naturally occurring substances (e.g., cardiac glycosides, quinidine) or originally developed for the treatment of other cardiovascular diseases (e.g., amiodarone and ranolazine for angina pectoris)

Antiarrhythmic Drugs, Table 1 Overview of commonly used antiarrhythmic drugs (AADs) belonging to Classes 0–IV, their targets, mechanisms, and indications

	Drug	Molecular targets	Mechanisms targeted	Common indications/uses
Class 0: HCN channel blockers				
0	Ivabradine	HCN channels	↓ Abnormal automaticity	Management of angina Inappropriate sinus tachycardia
Class I: Na^+ channel blockers				
IA	Ajmaline	I_{Na}, I_{Kr}	N/A	Diagnosing Brugada syndrome
IA	Disopyramide	I_{Na}, I_{Kr}	↓ Ectopic activity (↓ excitability)	Rhythm control of vagal AF Hypertrophic obstructive cardiomyopathy (combined with Class II or IV AADs)
IA	Procainamide	I_{Na}, I_{Kr}	↓ Ectopic activity (↓ excitability) ↓ Reentry (↑ repolarization)	Acute cardioversion of hemodynamically stable VT Preexcited AF
IA	Quinidine	I_{Na}, I_{Kr}, I_{to}	↓ Ectopic activity (↓ excitability) ↓ Reentry (↑ repolarization)	Brugada syndrome, short-QT syndrome and idiopathic VF
IB	Lidocaine	I_{Na}	↓ Ectopic activity (↓ excitability)	Local anesthesia VT (i.v. only)
IB	Mexiletine	I_{Na}, $I_{Na,late}$	↓ Ectopic activity (↓ excitability, ↓EADs)	VT (notably in LQTS3) Suppression of PVCs Chronic pain
IB	Ranolazine	$I_{Na,late}$, I_{Kr}, RyR2, I_{Na}	↓ Ectopic activity (↓ EADs and ↓ DADs)	Angina pectoris Rhythm control of AF VT (e.g., in LQTS3)
IC	Flecainide	I_{Na}, I_{Kr}, RyR2	↓ Ectopic activity (↓ excitability) ↓ Reentry (↑ post-repolarization refractoriness)	Acute cardioversion (w.o. structural heart disease) Rhythm control of AF (w.o. structural heart disease)
IC	Propafenone	I_{Na}, βAR, I_{Kr}, RyR2	↓ Ectopic activity (↓ excitability) ↓ Reentry (↑ post-repolarization refractoriness)	Acute cardioversion (w.o. structural heart disease) Rhythm control of AF (w.o. structural heart disease)
Class II: autonomic inhibitors

(Heijman et al. 2017). Please note that the AADs presented below are not available in every country and some regional preferences in their use exist.

Class 0: Hyperpolarization-Activated Cyclic Nucleotide-Gated (HCN) Channel Blockers

Ivabradine is the only clinically approved HCN channel blocker. It blocks the pacemaker (HCN) current, reducing diastolic depolarization and pacemaker activity in the sinoatrial node, and is primarily used to lower heart rate (and thereby energy demand) in patients with stable angina pectoris not fully managed by β-adrenoceptor blockers (Koruth et al. 2017). In line with its primary negative chronotropic properties, a potential role for off-label use in the treatment of inappropriate sinus tachycardia has also been suggested (Koruth et al. 2017). Furthermore, in recent studies using heterologous expression systems, ivabradine blocks I_{Kr} and I_{Na} at therapeutically relevant concentrations, potentially explaining its effects on ventricular rate in patients with AF. Of note, in other AAD classifications, ivabradine is sometimes included in a class with miscellaneous drugs (Class V) (Dan et al. 2018; Heijman et al. 2017).

Class I: Na^+ Channel Blockers

Class I AADs bind Na^+ channels in their open and/or inactivated states, inhibiting the inflow of Na^+. As such, the extent of I_{Na} inhibition by Class I AADs depends on channel activity, a concept termed "use dependence." As a result, Class I AADs are more potent at fast rates (frequent opening of Na^+ channels) or during ischemia, when depolarization of the resting membrane potential promotes Na^+ channel inactivation. Different Na^+ channel blocker subtypes have been defined based on their relative affinities for individual states and their on/off kinetics (Lei et al. 2018).

Class IA drugs such as ajmaline, disopyramide, procainamide, and quinidine typically exhibit a high affinity for the open state of the Na^+ channel, intermediate dissociation kinetics with time constants of 1–10 s, and concomitant I_{Kr} inhibition (Aguilar and Nattel 2015). Quinidine was the first drug used to treat symptoms of

cardiac arrhythmias (palpitations). Besides I_{Na}, it inhibits I_{Kr} and the transient outward K^+ current, significantly prolonging repolarization duration. Quinidine was initially used for sinus rhythm maintenance in AF patients and prevention of recurrences of ventricular arrhythmias by reducing ectopic activity and prolonging repolarization duration. However, adverse gastrointestinal effects and syncopal events ("quinidine syncope") due to drug-induced TdP arrhythmias were relatively common (Aguilar and Nattel 2015; Camm 2017). Quinidine has also been associated with increased mortality, resulting in a decrease in its use. Although it is no longer available in several countries, a renewed interest in quinidine has developed recently for the treatment of several inherited arrhythmogenic disorders (Brugada syndrome, short-QT syndrome, and idiopathic ventricular fibrillation) (Mankad and Kalahasty 2019). Procainamide also inhibits I_{Na} and I_{Kr} and is used for the acute cardioversion of hemodynamically stable ventricular tachycardias and in patients with accessory pathways and preexcited AF, slowing conduction across the accessory pathway and lowering ventricular rate (Dan et al. 2018). Although classified as Class I AADs, ajmaline and disopyramide are not commonly used for antiarrhythmic therapy (Dan et al. 2018). Ajmaline is used to unmask concealed arrhythmogenic phenotypes regulated by I_{Na} dysfunction (e.g., Brugada syndrome). Disopyramide is a Class IA AAD with negative inotropic effects and can be used to suppress ventricular ectopy (Dan et al. 2018) or in combination with β-adrenoceptor or Ca^{2+}-channel blockers in patients with hypertrophic obstructive cardiomyopathy. In addition, disopyramide has significant anticholinergic effects, responsible for most of its adverse effects.

Class IB AADs block the Na^+ channel in the inactivated state with rapid dissociation kinetics (time constants of 0.1–1 s (Aguilar and Nattel 2015)), thereby having limited effect under normal physiological conditions but pronounced I_{Na}-blocking effects in depolarized tissue (Mankad and Kalahasty 2019). Lidocaine is a local anesthetic used intravenously for the prevention or treatment of ventricular arrhythmias by decreasing cardiomyocyte excitability. For example, a lidocaine bolus is used prior to aortic cross-clamp removal during bypass surgery to prevent cardiac arrhythmias. Its extensive first-pass effects preclude oral use. Mexiletine is an orally available Class IB AAD with similar electrophysiological effects as lidocaine (Mankad and Kalahasty 2019). It can suppress ventricular ectopy and tachycardia and has particular relevance in the treatment of long-QT syndrome type 3 (Dan et al. 2018), which is linked to gain-of-function mutations in the cardiac Na^+ channel, where it directly inhibits the dysfunctional I_{Na} responsible for QT prolongation and EAD-mediated arrhythmogenesis.

Class IC AADs flecainide and propafenone block Na^+ channels in both the open and inactivated states with slow on/off kinetics and are commonly used for the management of supraventricular tachycardias and AF (Aguilar and Nattel 2015). Both AADs reduce ectopic activity, prolong ERP, and destabilize reentrant activity. ERP prolongation is due to a combination of I_{Kr} inhibition and increased post-repolarization refractoriness (i.e., the period after repolarization during which the tissue is unexcitable). In addition, the *S*-enantiomer of propafenone has β-adrenoceptor-blocking properties (Aguilar and Nattel 2015). Flecainide and propafenone are used for acute cardioversion of AF (either through intravenous application or as "pill-in-the-pocket" approach with high oral doses) as well as long-term sinus rhythm maintenance in patients without structural heart disease (Aguilar and Nattel 2015; Dan et al. 2018). In addition, recent experimental data have suggested that both AADs also stabilize RyR2 gating, potentially exerting antiarrhythmic effects by preventing Ca^{2+}-handling abnormalities and providing rationale for the clinical use of flecainide in patients with catecholaminergic polymorphic ventricular tachycardia due to RyR2 mutations (Heijman et al. 2017).

Ranolazine is an antianginal drug with high affinity for the late (persistent) component of I_{Na} and additional I_{Kr} and RyR2-blocking properties, which may prevent proarrhythmic Ca^{2+}-handling abnormalities and stabilize repolarization (Aguilar and Nattel 2015; Heijman et al. 2017).

In the 2018 AAD classification, it is designated as a Class ID drug, although other classifications have listed it as Class IB (due to the structural similarity to lidocaine) or Class V ("other drugs") (Lei et al. 2018). A number of experimental and clinical studies have demonstrated the antiarrhythmic potential of ranolazine for atrial and ventricular arrhythmias. These include patients with long-QT syndrome type 3 in whom ranolazine can directly inhibit the disease-causing increase in late I_{Na}, similar to mexiletine, as well as patients with AF (Dan et al. 2018; Heijman et al. 2017). Of note, studies with a more selective late I_{Na} inhibitor (eleclazine) were recently halted (Heijman et al. 2017).

Class II: Autonomic Inhibitors

Chronic autonomic dysfunction promotes hypertrophy, apoptosis, and fibrosis and contributes to the progression of multiple cardiovascular diseases, whereas acute sympathetic/parasympathetic imbalance is a well-accepted trigger of cardiac arrhythmias (Grandi and Ripplinger 2019). Excessive sympathetic stimulation may produce Ca^{2+} overload due to elevated heart rates and hyperphosphorylation of Ca^{2+}-handling proteins, thereby promoting DADs and triggered activity. Under physiological conditions, repolarization-prolonging effects of $I_{Ca,L}$ hyperphosphorylation are offset by augmentation of the slowly activating delayed rectifier K^+ current (I_{Ks}). However, in the diseased heart, sympathetic stimulation can cause proarrhythmic repolarization instability when I_{Ks} is downregulated or dysfunctional due to genetic mutations (in the case of long-QT syndrome types 1 and 5).

In accordance with the diverse proarrhythmic potential of autonomic dysfunction, the protective effects of β-adrenoceptor blockers have been established in a wide range of cardiovascular diseases and include several antiarrhythmic actions (Grandi and Ripplinger 2019). Inhibition of β-adrenoceptors has negative chronotropic effects and inhibits abnormal automaticity. Due to their negative dromotropic effects (inhibition of atrioventricular conduction), they are commonly used for rate control in AF. In addition, β-adrenoceptor blockers reduce the likelihood of ventricular tachyarrhythmias and sudden cardiac death in patients with myocardial infarction and/or heart failure by prolonging ERP, reducing triggered activity due to Ca^{2+} overload and attenuating electrophysiological heterogeneity due to inhomogeneous hyper-/hypo-innervation. Finally, long-term β-adrenoceptor blocker use may prevent proarrhythmic remodeling by reducing myocardial energy consumption and oxidative stress.

β-adrenoceptor blockers are typically divided into three subgroups (Grandi and Ripplinger 2019). First-generation β-adrenoceptor blockers (e.g., propranolol) have similar affinity for β_1- and β_2-adrenoceptor subtypes, whereas the second generation (e.g., metoprolol, atenolol, or bisoprolol) have a higher affinity for β_1-adrenoceptors. Most of the proarrhythmic effects of sympathetic stimulation have been attributed to β_1-adrenoceptors. Finally, third-generation β-adrenoceptor blockers have vasodilatory effects. For example, carvedilol inhibits both β_1- and β_2-adrenoceptor isoforms and α_1-adrenocepters. It also has anti-inflammatory and antioxidant effects. Finally, experimental work has suggested that direct RyR2-stabilizing effects of carvedilol may contribute to its antiarrhythmic effects (Heijman et al. 2017).

Digitalis and other cardiac glycosides inhibit the Na^+-K^+-ATPase, increasing intracellular Na^+ levels, leading to inhibition of the Na^+/Ca^{2+} exchanger and elevation of intracellular Ca^{2+}, resulting in increased contractility (positive inotropic effect). In addition, digitalis has parasympathomimetic effects, resulting in inhibition of atrioventricular condition, and is used for rate control in AF patients (Scalese and Salvatore 2017). This is the reason that cardiac glycosides, which traditionally belonged to the category of "other drugs," are included in Class II in the 2018 AAD classification. On the other hand, digitalis-induced Ca^{2+}-handling abnormalities and related DADs may have proarrhythmic effects, and its safety remains a topic of intense debate (Scalese and Salvatore 2017).

Class III: K^+ Channel Blockers

Dofetilide is a selective I_{Kr} blocker approved in the United States for the acute cardioversion of

atrial fibrillation and for long-term rhythm control. Its primary antiarrhythmic mechanism of action is prolongation of repolarization, and it is available in oral and intravenous forms (Mankad and Kalahasty 2019). Ibutilide is a Class III agent approved for acute cardioversion that is only available in intravenous form because of extensive first-pass metabolism (Mankad and Kalahasty 2019), similar to lidocaine. Besides inhibition of I_{Kr}, ibutilide activates a slow inward Na^+ current, further promoting repolarization prolongation. Sotalol is a 1:1 racemic mixture of a selective I_{Kr} blocker (D-sotalol) and a combined I_{Kr}/β-adrenoceptor blocker (L-sotalol) approved for the acute and long-term treatment of both atrial and ventricular arrhythmias (Mankad and Kalahasty 2019). Most Class III drugs, including dofetilide, ibutilide, and sotalol, have the largest repolarization-prolonging effects at slow rates, when baseline action potential duration is already long, a concept known as reverse use dependence (Mankad and Kalahasty 2019). Class III AADs have been associated with drug-induced proarrhythmia due to excessive repolarization prolongation, particularly at slow rates or under conditions favoring abnormal repolarization (e.g., hypokalemia). As such, treatment initiation should be performed under ECG monitoring and is contraindicated in patients with congenitally prolonged repolarization (long-QT syndrome) (Mankad and Kalahasty 2019). Experimental work has suggested that chronic application of dofetilide and other Class III drugs associated with increased risk of TdP arrhythmias increases the late component of I_{Na}, contributing to excessive prolongation of repolarization that may cause TdP.

Although originally developed as an antianginal agent, amiodarone is generally considered the most effective AAD available. It is associated with relatively low proarrhythmic risks compared to other Class III AADs and is the only AAD approved for treatment of patients with heart failure (Heijman et al. 2013). Amiodarone is used for cardioversion and rhythm control of AF, and to treat and prevent ventricular tachycardia (e.g., to reduce the intervention rate of implantable cardioverter defibrillators). Its efficacy and safety likely result from a complex interaction between numerous molecular targets. Indeed, amiodarone inhibits a wide range of ion channels and receptors, including I_{Kr}, I_{Na}, $I_{Ca,L}$, and β-adrenoceptors, thus exhibiting effects of all four original Vaughan Williams AAD classes (Lei et al. 2018; Mankad and Kalahasty 2019). Amiodarone also has less pronounced reverse use-dependent effects. Amiodarone is highly lipophilic, resulting in a very long half-life (30–100 days) and necessitating long and high oral loading doses to accelerate the onset of drug activity, although intravenous application has a rapid onset of action. Of note, there are significant electrophysiological differences between intravenous amiodarone and chronically administered oral amiodarone, including a smaller repolarization prolongation, little effect on sinus rate, and more potent antiadrenergic activity with intravenous application. These differences are likely in part due to additional effects of metabolites and due to electrical remodeling that develops during chronic amiodarone treatment. Despite its potent antiarrhythmic effects, the use of amiodarone is limited by potentially severe extra-cardiac toxicity, including thyroid dysfunction and pulmonary toxicity, resulting in drug discontinuation in up to 20% of patients during long-term therapy.

The striking antiarrhythmic efficacy combined with extra-cardiac toxicity of amiodarone prompted the development of safer derivatives. Dronedarone lacks the iodine moieties partially responsible for amiodarone's toxicity and is significantly less lipophilic (Heijman et al. 2013). Like amiodarone, dronedarone inhibits a wide range of ion channels, exhibiting effects of all four Vaughan Williams classes. However, there are important electrophysiological differences between both AADs, including a significantly higher affinity for $I_{K,ACh}$ with dronedarone (Heijman et al. 2013). A direct comparison of both drugs in patients with AF showed fewer side effects but also higher arrhythmia recurrence rates with dronedarone. Nonetheless, the randomized, double-blind Athena trial comparing dronedarone to placebo for the treatment of atrial fibrillation has been the only trial with AADs showing prognostic benefit (reduction of the

composite primary endpoint hospitalization due to cardiovascular events or death) (Heijman et al. 2013). On the other hand, in later trials in AF patients with concomitant heart failure (Andromeda) or in patients with permanent AF (Pallas), dronedarone was associated with increased mortality (Heijman et al. 2013). In the Pallas trial, this was attributed to pharmacokinetic interactions between dronedarone and digoxin.

Vernakalant is the most recent AAD approved for clinical use in Europe and Canada. It is available for intravenous pharmacological cardioversion of recent-onset AF and acts by prolonging ERP (Dan et al. 2018). Vernakalant is considered an AAD with atrial-predominant effects due to inhibition of I_{Kur} and $I_{K,ACh}$ and preferential inhibition of atrial I_{Na} due to a state-dependent block favoring the inactivated state of the channel (Aguilar and Nattel 2015; Dan et al. 2018). In experimental studies vernakalant's antiarrhythmic effects are primarily due to increased post-repolarization refractoriness (due to I_{Na} inhibition) and conduction slowing, suggesting that it should be considered a Class I AAD rather than a Class III AAD (Aguilar and Nattel 2015).

Class IV: Ca^{2+} Channel Blockers and Ca^{2+}-Handling Modulators

Verapamil and diltiazem inhibit $I_{Ca,L}$ and are primarily used to reduce atrioventricular conduction, lowering the ventricular response rate during supraventricular tachycardia and AF (Mankad and Kalahasty 2019). In addition, they can be used for the treatment of high blood pressure and angina. Verapamil additionally inhibits I_{Kr} and is sometimes used for the treatment of migraine and cluster headaches (off-label use). Both AADs can have significant negative inotropic effects due to inhibition of cardiomyocyte $I_{Ca,L}$ and are therefore contraindicated in patients with reduced cardiac function (Mankad and Kalahasty 2019). Combinations with other drugs inhibiting sinoatrial or atrioventricular nodal activity (e.g., β-adrenoceptor blockers) are also contraindicated due to the increased risk of symptomatic bradycardia or atrioventricular block. Due to their short half-lives, verapamil and diltiazem are administered as extended-release preparations. Both AADs are also moderate inhibitors of P-glycoprotein and CYP3A4, potentially resulting in pharmacokinetic interactions with other drugs. For example, dose reduction of the non-vitamin-K oral anticoagulant dabigatran is recommended when taken in conjunction with verapamil (Dan et al. 2018).

In the recent 2018 AAD classification, modulators of Ca^{2+}-handling proteins other than L-type Ca^{2+} channels have been included in Class IV. Although RyR2 stabilizers and inhibitors of the Na^{+}/Ca^{2+}-exchanger have indeed shown antiarrhythmic properties in experimental models, no clinically approved compounds are currently available (Heijman et al. 2017).

Classes V–VII

Classes V–VII in the 2018 AAD classification contain mechanosensitive channels (Class V), gap junction modulators (Class VI), and upstream therapy (Class VII) (Lei et al. 2018). Although some compounds in Class V (including GsMtx-4, a nonselective inhibitor of stretch-activated channels from tarantula spider venom) and Class VI (including rotigaptide and danegaptide) have shown antiarrhythmic potential in experimental studies (Woods and Olgin 2014), there are currently no ongoing clinical trials or clinically approved drugs available. Upstream therapy with angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, aldosterone antagonists, or statins may prevent development or worsening of the vulnerable substrate, thus indirectly exerting antiarrhythmic effects (Woods and Olgin 2014). However, direct antiarrhythmic effects of these drugs appear limited and studies in patients have produced mixed results regarding prevention of arrhythmic death, likely in part because of differences in preexisting irreversible remodeling.

Conclusion

AADs remain the cornerstone of antiarrhythmic therapy. Although numerous AADs are available, they were not developed based on specific arrhythmia mechanisms and have complex

electrophysiological effects, including a significant risk of proarrhythmic side effects. New insights into arrhythmia mechanisms have recently been obtained, and promising experimental compounds have emerged, but no new AADs for the clinical management of cardiac arrhythmias are currently foreseen.

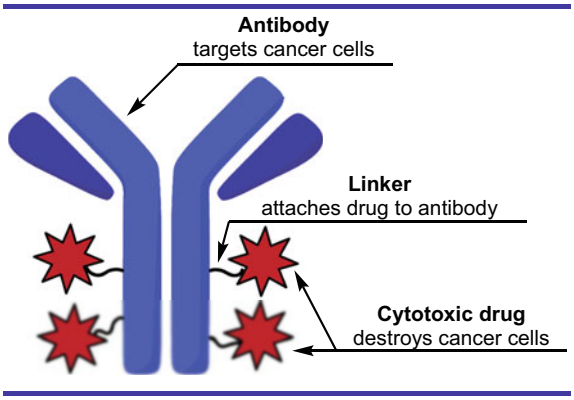
ADC; ADCs

Definition

Antibody drug conjugates (ADCs) are hybrid therapeutics that combine the specificity of monoclonal antibodies with the potent cytotoxicity of small-molecule drugs. ADCs are designed for targeted delivery of the cytotoxic payload directly to the desired site of action to increase efficacy and minimize off-target effects. ADCs consist of three essential components – the antibody, the drug, and the chemical linker connecting the two (Fig. 1). Accordingly, careful consideration is given to the design of each part. An optimal ADC has high target cell specificity, a long circulation half-life, minimal immunogenicity, and low off-target toxicity (McCombs and Owen 2015).

(a) ***Antibody:*** Monoclonal antibodies are the targeting agent in ADC therapies. The development of a successful antibody for an ADC therapy requires an antigen that is prevalent on the target cells and absent in normal tissue in order to allow for specific targeting to the tumor (Chau et al. 2019). It is important to



Antibody Drug Conjugates, Fig. 1 Critical components of an ADC

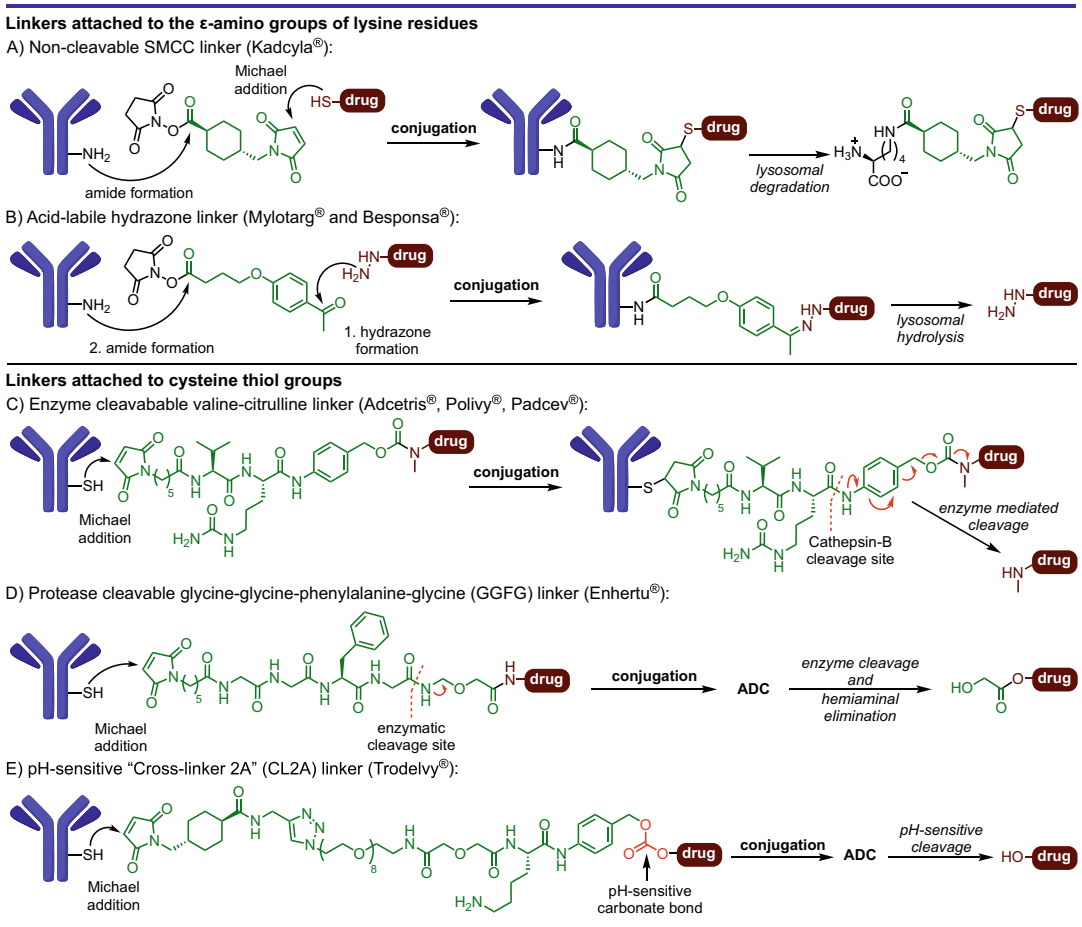
note that serious ADC side effects can arise from antigen expression on unrelated cell types. For example, HER2 expression in heart tissue can lead to cardiotoxicity in trastuzumab-based ADCs (Kondapalli 2016). After antigen selection, antibodies are developed against the desired target. It is critical for the antibody to be able to induce receptor-mediated internalization for the ADC to be effective. The majority of antibodies in approved ADCs are of the IgG1 isotype, with IgG4 as the second isotype used (Mylotarg® and Besponsa®) (Khongorzul et al. 2020). Importantly, either of these isoforms impart long half-life, providing pharmacokinetic advantages to the ADC product compared to the free small-molecule drug. In order to minimize immunogenicity, these antibodies are humanized, with the exception of one chimeric ADC (Adcetris®) that has been approved. Minimal antibody engineering is required since drug conjugation can occur with native amino acid residues (Khongorzul et al. 2020).

(b) ***Payload:*** Several criteria must be met in choosing an appropriate payload for ADCs including: solubility, amenability to conjugation, stability, and potency. The drug must be hydrophilic enough to allow for both conjugation to the antibody in aqueous conditions and stability of the resulting conjugate. Many potential drugs suffer from low solubility, which can be somewhat ameliorated by employing hydrophilic linkers. The payloads must also bear chemically functional handles, such as amines, to allow for conjugation. Consideration is given to how modification to contain a functional handle may affect the efficacy of the drug. Further, the payload must remain stable during circulation and cellular processing in order to maintain efficacy after reaching the cytosolic target (McCombs and Owen 2015). Finally, the site-specific delivery of ADCs allows for the use of extremely potent drugs; in fact, these drugs are generally too toxic to be given as a single agent with potencies 100- to 10,000-fold greater than standard chemotherapeutics (Nejadmoghaddam et al. 2019). The drug classes that have been employed by clinically approved ADCs include calicheamicins (Mylotarg® and Besponsa®), mertansines (Kadcyla®), auristatins (Adcetris®, Polivy®, and Padcev®), and camptothecins (Enhertu® and Trodelvy®) (Chau et al. 2019; Khongorzul et al. 2020; Nicolaou and Rigol 2019).

(c) ***Linker*:** The linker has two critical roles: (1) stable attachment of the drug to the antibody without premature release in circulation and (2) release of the drug after localization to disease cells. With respect to release mechanisms, linkers are divided into two classes: noncleavable and cleavable. Noncleavable linkers depend on the degradation of the antibody once internalized into the lysosome and release drug with the linker still covalently

attached, as with Kadcyla® (McCombs and Owen 2015). More commonly, cleavable linkers are broken down by components of the lysosomal environment to release the payload. Several cleavage mechanisms have been investigated, including acidic pH hydrolysis, thiol reduction, and protease cleavage (McCombs and Owen 2015; Nejadmoghaddam et al. 2019). The most prevalent cleavage mechanism occurs from the specific recognition of a dipeptide (such as valine-citrulline) by lysosomal enzymes, which results in the release of free drug (Dubowchik et al. 2002).

(d) ***Conjugation Chemistry:*** Final construction of the ADC requires conjugation of the linker and drug to the native antibody. Two conjugation methods are seen in FDA-approved ADC products to date: (1) lysine conjugation and (2) cysteine conjugation. For lysine conjugation, an activated N-hydroxysuccinimide ester on the linker reacts with accessible lysine residues on the surface of the ADC to produce a stable amide bond. Similarly, native cysteines are commonly used for conjugation. First, interchain disulfide bonds are reduced to provide a free cysteine for conjugation. Next, the side-chain thiol undergoes Michael addition into a linker bearing a pendant maleimide, creating a stable linkage. The proposed advantages of cysteine conjugation include a more controllable drug to antibody



Antibody Drug Conjugates, Fig. 2 Conjugation and lysosomal cleavage mechanisms of lysine and cysteine conjugated ADCs

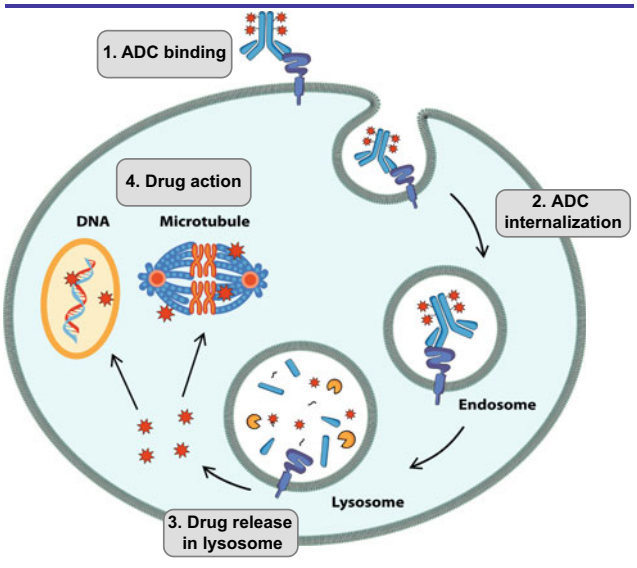
ratio (DAR) and more homogenous product. Figure 2 outlines the linkers, conjugation strategies, and release mechanisms of the current FDA-approved ADCs (McCombs and Owen 2015; Nicolaou and Rigol 2019).

Mechanism of Action

(a) ***ADC mechanism:*** Antibody drug conjugates work through the antibody-mediated targeted delivery of cytotoxic payloads directly to tumor cells (Chau et al. 2019). As illustrated in Fig. 3, once an ADC is in circulation, the antibody will bind to cells bearing the targeted antigens. After antigen binding, internalization of the antigen-ADC complex occurs, passing through early endosomes and endosomes, ultimately reaching the lysosome. Once inside the lysosome, cleavage of the drug from the ADC occurs. This can happen via several different mechanisms. For non-cleavable linkers, proteolytic degradation of the antibody itself releases the linker-drug complex. In the case of cleavable linkers, several lysosomal pathways can occur, depending on the type of linker employed (see Fig. 2 for details).

By this mechanism, the ADC acts as a prodrug, sparing normal tissue from the toxic effects of the drug while the ADC is in circulation. Instead, lysosomal release of the free drug within the target cells results in targeted tumor cell killing.

(b) ***Drug mechanism of action:*** The cytotoxic warheads on the clinically approved ADCs can be broken down into two categories: (1) DNA damaging agents and (2) antimitotic agents. Mylotarg® and Besponsa® both bear a calicheamicin γ_1^I-derived payload that causes double-stranded DNA damage through single and double strand cuts. Enhertu® and Trodelvy® are equipped with camptothecin derivatives that work by inhibiting topoisomerase 1 by stabilizing its complex with DNA, prohibiting religation and ultimately triggering apoptosis. The other FDA-approved ADCs employ antimitotic agents. Adcetris®, Polivy®, and Padcev® bear monomethyl auristatin E (MMAE), which binds to tubulin and inhibits polymerization, ultimately inhibiting cell division.



Antibody Drug Conjugates, Fig. 3 Mechanism of action of an ADC at a tumor cell

Antibody Drug Conjugates, Table 1 Summary of FDA-approved antibody drug conjugates

Drug name (trade name)	Disease indication	Molecular target		Conjugation site	Linker	Side effects
		mAb (target)	Drug (target)			
Gemtuzumab ozogamicin (Mylotarg®)	Newly diagnosed CD33-positive acute myeloid leukemia (AML) or relapsed/refractory AML	Humanized IgG4k (anti-CD33)	Calicheamicin derivative (causes DNA strand scission)	Native lysine	Acid-labile acetyl butyrate linker (hydrazone)	Hemorrhage, infection, fever, nausea, vomiting, constipation, headache, increased alanine and aspartate aminotransferase, rash, mucositis Risk: hepatotoxicity
Brentuximab vedotin (Adcetris®)	Relapsed Hodgkin lymphoma and relapsed systemic anaplastic large cell lymphoma	Chimeric IgG1k (anti-CD30)	MMAE (blocks tubulin polymerization)	Interchain cysteine	Protease cleavable linker (Val-Cit)	Neutropenia, anemia, peripheral sensory neuropathy, nausea, fatigue, constipation, diarrhea, vomiting, pyrexia
Trastuzumab emtansine (Kadcyla®)	HER2-positive metastatic breast cancer previously treated with trastuzumab and a taxane	Humanized IgG1k (anti-HER2)	DM1 – mytansine derivative (inhibits microtubules)	Native lysine	Noncleavable thioether linker (SMCC)	Fatigue, nausea, increased transaminases, musculoskeletal pain, hemorrhage, thrombocytopenia, headache, peripheral neuropathy, arthralgia
Inotuzumab ozogamicin (Besponsa®)	Relapsed or refractory CD22-positive B-cell precursor acute lymphoblastic leukemia	Recombinant humanized IgG4 (anti-CD22)	Calicheamicin derivative (causes DNA strand scission)	Native lysine	Acid-labile acetyl butyrate linker (hydrazone)	Thrombocytopenia, neutropenia, nausea, leukopenia, infection, abdominal pain, febrile neutropenia, anemia, fatigue, hemorrhage, pyrexia, headache, liver damage, hyperbilirubinemia Risk: hepatotoxicity

Polatuzumab vedotin-piiq (Polivy®)	Relapsed or refractory diffuse large B-cell lymphoma in combination with bendamustine and rituximab	Humanized IgG1 (anti-CD79b)	MMAE (blocks tubulin polymerization)	Interchain cysteine	Protease cleavable linker (Val-Cit)	Neutropenia, thrombocytopenia, anemia, peripheral neuropathy, fatigue, diarrhea, pyrexia, decreased appetite, pneumonia
Enfortumab vedotin-ejfv (Padcev®)	Locally advanced or metastatic urothelial cancer who have received a PD-1 or PD-L1 inhibitor and a platinum-containing chemotherapy	Human IgG1 (against Nectin-4)	MMAE (blocks tubulin polymerization)	Interchain cysteine	Protease cleavable linker (Val-Cit)	Fatigue, peripheral neuropathy, decreased appetite, rash, dry skin, alopecia, nausea, dysgeusia, diarrhea, dry eye, pruritus Risk: diabetic ketoacidosis
Trastuzumab deruxtecan-nxki (Enhertu®)	Unresectable or metastatic HER2-positive breast cancer who have received two or more prior anti-HER2 based regimens in the metastatic setting	Humanized IgG1k (anti-HER2)	Deruxtecan – exatecan derivative (topoisomerase I inhibitor)	Interchain cysteine	Lysosomal protease cleavable tetrapeptide (Gly-Phe-Leu-Gly; GFLG)	Nausea, fatigue, vomiting, alopecia, constipation, cough, decreased appetite, anemia, neutropenia, diarrhea, leukopenia, thrombocytopenia Risk: interstitial lung disease, embryo-fetal toxicity
Sacituzumab govitecan-hziy (Trodelvy®)	(adult patients) Metastatic triple negative breast cancer (mTNBC) who have received at least two prior therapies	Humanized IgG1k (anti-TROP2)	SN-38 – active metabolite of irinotecan (topoisomerase I inhibitor)	Interchain cysteine	pH-sensitive CL2A	Nausea, vomiting, neutropenia, anemia, alopecia, diarrhea, fatigue, constipation, decreased appetite, rash, abdominal pain

Similarly, Kadcyla® utilizes a mytansine-derived payload, DM1, which also inhibits microtubule assembly by binding to tubulin (Nicolaou and Rigol 2019).

Clinical Use

To date, FDA-approved ADCs have only been developed to treat cancer with specific indications for lymphomas and leukemias (Table 1). The majority of ADCs are designated to treat solid tumors with three ADCs indicated to treat breast cancer (Kadcyla® (U.S. Food and Drug Administration 2019a), Enhertu® (U.S. Food and Drug Administration 2019b), and Trodelvy® (U.S. Food and Drug Administration 2020)), and one ADC each for Hodgkin lymphoma (Adcetris® (U.S. Food and Drug Administration 2018a)), large B-cell lymphoma (Polivy® (U.S. Food and Drug Administration 2019c)), and urothelial cancer (Padcev® (U.S. Food and Drug Administration 2019d)). Two ADCs are designated to treat liquid tumors, one for acute myeloid leukemia (Mylotarg® (U.S. Food and Drug Administration 2017)) and one for acute lymphoblastic leukemia (Besponsa® (U.S. Food and Drug Administration 2018b)). Regardless of indication, ADCs are supplied as lyophilized powders, formulated in acidic buffer with various excipients. Following reconstitution in saline or specified diluent, ADCs are administered by IV injection or infusion. Several side effects have been reported for ADCs, with nausea, neutropenia, and fatigue among the most common (refer to Table 1 for details).

ADCs are actively being researched in order to further address the major challenges including low payload potency, immunogenicity, and off-target toxicity. Further, ADCs are being explored for applications outside of cancer therapy.

Synonyms

Blood thinners

Definition

Anticoagulants are drugs that alter the biochemical processes of blood clotting resulting in the prevention or reduction of blood coagulation. They are the mainstay of pharmacotherapy for thrombosis prevention and treatment. The coagulation system is a homeostatic regulation process by which the blood is balanced between states of clotting (coagulation) and bleeding (free flow). This complex process is an integral part of maintaining a healthy cardiovascular system, ensuring that any trauma to the vasculature is sufficiently controlled in order to avoid excessive blood loss and hemodynamic compromise. Conversely, excessive activation of this system may result in thrombosis, an intravascular clot formation that disrupts blood circulation.

Hypercoagulability, stasis, and injury/trauma (otherwise referred to as Virchow's triad) contribute to the formation of a thrombus (Esmon 2009). Hypercoagulability, or thrombophilia (an increased tendency of blood to form thrombus), is common in cancer, pregnancy, patients who use oral contraceptives, and in patients with certain genetic disorders including antiphospholipid syndrome, homocysteinemia, or those with genetic deficiencies in antithrombin III, protein C or S, and/or factor V. Blood stasis (the tendency for blood pooling or stagnation) is associated with increased risk of clotting cascade activation. Prolonged periods of immobility (traveling or bedridden individuals) and cardiovascular disorders including arrhythmias and heart failure predispose patients to stasis and thrombosis. Trauma and injuries, such as accidents or surgeries, promote the activation of the coagulation cascade due to physiologic changes in the blood vessel wall (Esmon 2009). When triggered, the clotting cascade may result in thrombosis, often referred to as venous thromboembolism (VTE). VTE includes both deep vein thrombosis (DVT) and pulmonary embolism (PE).

A DVT occurs most commonly in the veins of the legs and if left untreated, a portion of the thrombus may break off and travel in the blood stream, now called an embolus, to another part of the body. Among the worst locations for an embolus to lodge is in the pulmonary veins. This is known as a PE, which has a high morbidity and mortality rate, as it blocks the flow of blood through the pulmonary system, rendering a patient unable to adequately perform oxygen exchange. About half of all DVT cases are asymptomatic, contributing to large differences in prevalence estimates (Haines 2003). Symptomatic VTE, including either DVT and/or PE, is thought to affect between 300,000 and 600,000 Americans yearly, and of those cases, an estimated 10–30% of them result in death (Beckman et al. 2010). VTE also has numerous complications and is associated with a significant economic burden (Beckman et al. 2010).

The presence of VTE and conditions that may predispose a patient to a VTE may indicate the need for pharmacological intervention. If

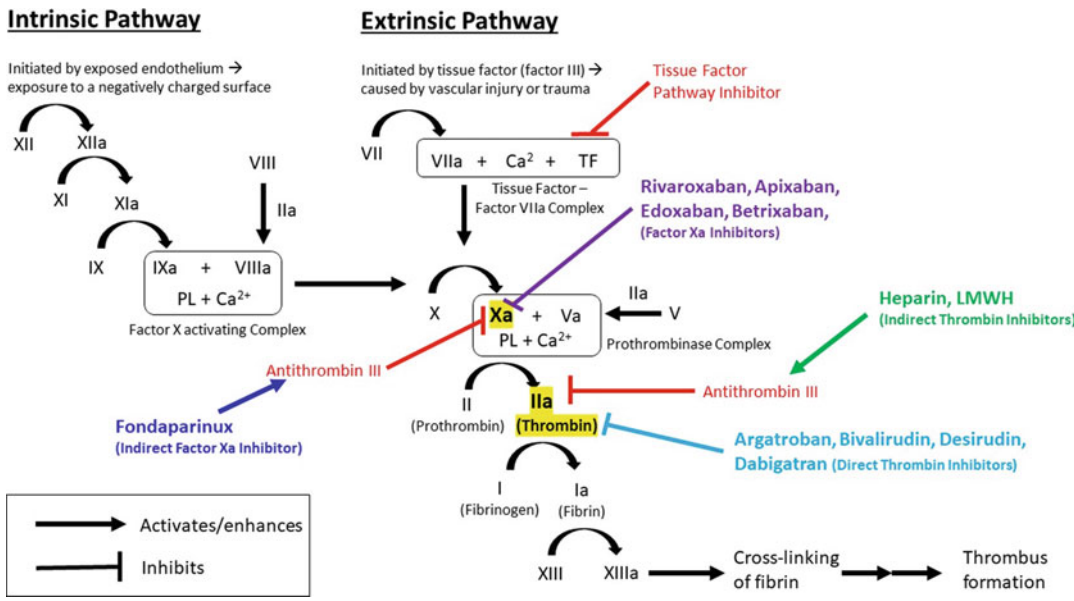
appropriate, some patients may be candidates for mechanical intervention to prevent VTE, such as the use of interpneumatic compression devices or compression stockings. However, mechanical intervention is not completely effective and is reserved for those with low VTE risk and high bleeding risk. Drugs that slow or halt the coagulation cascade are known as anticoagulants, and work through various mechanisms involving the numerous proteins, or clotting factors, that make up the coagulation cascade (Fig. 1). Regardless of their mechanism, anticoagulant drugs are indicated for the prevention and/or treatment of VTE.

Mechanism of Action

Anticoagulants mostly target the coagulation cascade. In order to fully understand the mechanism of action of the various anticoagulants, it is necessary to have a general understanding of the coagulation cascade (Fig. 1). There are two pathways – intrinsic and extrinsic, which are initiated by different factors. These pathways converge to form the common pathway (Davie et al. 1991). The intrinsic pathway is initiated by the exposure of factor XII to a negatively charged surface, mainly, an exposed endothelium. The extrinsic pathway is initiated by tissue factor (factor III). While the extrinsic pathway is largely involved in homeostasis and the intrinsic pathway is not, both play important roles in the pathogenesis of VTE. The two pathways converge at factor X, which is activated to Xa, and the common pathway proceeds to activate thrombin from prothrombin, followed by the activation of fibrin from fibrinogen (Smith et al. 2015). The cross-linking of fibrin strands forms the framework of the thrombus (Fig. 1). The majority of anticoagulant drugs binds and inhibits different factors or proteins that play a key role in the coagulation cascade. Table 1 provides a list of the available clinically relevant anticoagulants. Based on their mechanisms of action, anticoagulant drugs are classified into four types – direct and indirect thrombin inhibitors, vitamin K antagonists, and factor Xa inhibitors.

Indirect Thrombin Inhibitors

Indirect thrombin inhibitors include heparins and their synthetic analogue, fondaparinux. Heparin is a naturally occurring polymer of



Anticoagulants, Fig. 1 Description of the clotting cascade indicating the targets for the various anticoagulants

Anticoagulants, Table 1 An overview of medically approved anticoagulant drugs, adapted from Kustos and Fasinu 2019

General Class/MOA	Drug Name and Year of First Approval	Labeled Indications	Adult Dosing (with normal renal & hepatic function)	Route of Administration	Approved Reversal Agent
Vitamin K Antagonist	Warfarin (1954)	• VTE prophylaxis and treatment (associated with Afib or cardiac valve replacement) • Adjunct to reduce the risk of systemic embolism after MI	INR-adjusted-based dosing Goal INR is 2–3 for most patients Goal INR for mitral valve replacement is 2.5–3.5	Oral	Vitamin K and/or Prothrombin Complex Concentrate
Indirect Thrombin Inhibitors	Heparin (1940s)[a]	• VTE prophylaxis and treatment (associated with thromboembolic disorders or Afib) • Prevention of clotting in arterial or cardiac surgery • Anticoagulant for extracorporeal circulation or dialysis procedures	*VTE Treatment*: 80 unit/kg IV bolus, then 18 unit/kg/h IV infusion *VTE Prophylaxis*: 5000 units q8h Target anti-Xa level 6 h post-dose: 0.3–0.7 units/mL	Injectable Intravenous or Subcutaneous	Protamine ➔ 100% reversal
	Low Molecular Weight Heparins (LMWH): • Dalteparin (1994) • Enoxaparin (1993) • Tinzaparin (2000)	• VTE prophylaxis (in hip, knee, abdominal, thoracic, cardiac, or neurosurgery; in patients with restricted mobility; trauma; pregnancy) • Thrombosis treatment and secondary prophylaxis (wide variety of indications) • Thromboprophylaxis in acute coronary syndrome (unstable angina, NSTEMI, STEMI) or cardioversion in Afib/atrial flutter	*DVT Treatment*: 1 mg/kg q12h OR 1.5 mg/kg q24h *VTE Prophylaxis*: 40 mg q24h Target anti-Xa level 4 h post-dose: 0.5–1.1 units/mL	Injectable Subcutaneous	Protamine ➔ 60% reversal
Direct thrombin Inhibitors	Argatroban (2000)	• Prophylaxis or treatment of thrombosis in patients with HIT • Anticoagulant for percutaneous coronary intervention (PCI)	*Prophylaxis/treatment of thrombosis in HIT*: 2 mcg/kg/min and adjust based on aPTT (goal 1.5–3 times baseline) *PCI*: 350 mcg/kg bolus, then 25 mcg/kg/min infusion and adjust based on ACT	Injectable Intravenous	N/A
	Bivalirudin (2000)	• Anticoagulant for percutaneous coronary intervention (PCI), including patients with HIT	*Before PCI*: 0.1 mg/kg bolus, then 0.25 mg/kg/h until PCI *During PCI*: 0.75 mg/kg bolus, then 1.75 mg/kg/h for the duration of procedure	Injectable Intravenous	N/A

(continued)

Anticoagulants, Table 1 (continued)

General Class/MOA	Drug Name and Year of First Approval	Labeled Indications	Adult Dosing (with normal renal & hepatic function)	Route of Administration	Approved Reversal Agent
	Dabigatran (2010)	• VTE treatment and prevention in patients who have been treated with a parenteral anticoagulant for 5 to 10 days • VTE prophylaxis in total hip arthroplasty (THA) • Stroke prevention in Afib	*VTE Treatment (after initial therapy with a parenteral anticoagulant for 5 days):* 150 mg BID *Afib*: 150 mg BID *THA*: 110 mg given 1–4 h after surgery, then 220 mg QD for 10–14 d	Oral	Idarucizumab (Praxbind)
	Desirudin (2003)	• DVT prophylaxis in hip-replacement surgery	15 mg q12h	Injectable Subcutaneous	N/A
	Lepirudin[b] (1998)	• HIT • Prevention of VTE in patients with HIT	0.4 mg/kg IV bolus, followed by 0.15 mg/kg/h IV infusion for 2–10 days (or as clinically indicated)	Injectable Subcutaneous	N/A
Indirect Factor Xa Inhibitor	Pentasaccharide – Fondaparinux (2001)	• DVT or PE treatment in conjunction with warfarin • VTE prophylaxis in surgical patients	*VTE Treatment:* *<50 kg ➔ 5 mg QD* *50–100 kg ➔ 7.5 mg QD* *>100 mg ➔ 10 mg QD* *VTE Prophylaxis*: 2.5 mg QD	Injectable Subcutaneous	N/A
Factor Xa Inhibitors	Apixaban (2012)	• Treatment of VTE and to reduce recurrence of VTE following initial therapy • Prevention of stroke and systemic embolism in NVAF • Prophylaxis of VTE post-op in hip or knee arthroplasty	*VTE Treatment:* 10 mg BID for 7 days, then 5 mg BID *Afib*: 5 mg BID; if patient has any 2 of the following then 2.5 mg BID ➔ age ≥ 80, weight ≤ 60 kg, or SCr ≥1.5 mg/dL *Knee/hip arthroplasty*: 2.5 mg BID starting 12–24 h after surgery *Secondary prevention*: 2.5 mg BID (following 6 months of initial therapy)	Oral Tablet	Andexanet Alfa
	Betrixaban (2017)	• Prophylaxis of VTE in medical patients	*VTE prophylaxis*: 160 mg as a single dose on day 1, followed by 80 mg once daily for 35 to 42 days	Oral Capsule	N/A
	Edoxaban (2015)	• Treatment and prevention of recurrent VTE following 5–10 days of parenteral anticoagulant • Prevention of stroke and systemic embolism in NVAF	*VTE*: If >60 kg ➔ 60 mg QD If ≤60 kg ➔ 30 mg QD *Afib*: 60 mg QD	Oral Tablet	N/A

	Rivaroxaban (2011)	• Treatment of VTE • Prophylaxis of VTE in total hip or knee arthroplasty • Prevention of stroke and systemic embolism in NVAF • Reduce the risk of cardiovascular events in CAD or PAD • Indefinite anticoagulation to reduce the risk of recurrent VTE	*VTE treatment*: 15 mg BID w/ food for 21 days, followed by 20 mg QD w/ food *Knee/hip arthroplasty*: 10 mg QD starting 6–10 h after surgery *Afib*: 20 mg QD w/ evening meal *CAD/PAD*: 2.5 mg BID (with or without aspirin) *Secondary prevention*: 10 mg QD (following 6 months of initial treatment) *Indefinite anticoagulation*: reduced intensity dosing	Oral Tablet	Andexanet Alfa

VTE = venous thromboembolism, *Afib* = atrial fibrillation, *MI* = myocardial infarction, *DVT* = deep vein thrombosis, *PE* = pulmonary embolism, *STEMI* = ST-elevated myocardial infarction, *NSTEMI* = non-ST-elevated myocardial infarction, *HIT* = heparin-induced thrombocytopenia, *CAD* = coronary artery disease, *PAD* = peripheral artery disease

Note: VTE includes DVT and PE

[a]Heparin was first described as being an effective anticoagulant as early as 1916, and was grandfathered in after the establishment of the US FDA

[b]Bayer, the pharmaceutical company that produced lepirudin, stopped further production of the drug since May 31, 2012

glycosaminoglycans first described in the 1940s and which has been well studied and characterized for its anticoagulant activity. It consists of chains of *d*-glucosamine alternating with a form of uronic acid, either glucuronic acid or iduronic acid. Unfractionated heparin (UFH) is a heterogeneous mixture of large polysaccharides with molecular weight ranging from 3000 to 30,000. The low-molecular-weight heparins (LMWHs) are made as fragments of the UFH through chemical and/or enzymatic depolymerization reactions (Table 2).

Heparins exert anticoagulant effect by binding and activating antithrombin III (Hirsh et al. 1995). Antithrombin III naturally inhibits thrombin as well as factor Xa and is involved in homeostasis. However, its inhibitory activity is potentiated (about 1000 times) by the binding of heparins, which causes a conformational change in antithrombin III. This is achieved through the action of the unique but randomly distributed pentasaccharide sequence in the heparin polymeric chains.

While both UFH and LMWHs are available for subcutaneous administration, UFHs are generally poorly bioavailable and often require large doses (>30,000 U/day). To achieve rapid anticoagulation, UFH can be given intravenously. By contrast, LMWHs, including enoxaparin, dalteparin, and tinzaparin (no longer available in the United States), have satisfactory bioavailability following subcutaneous administration. They also have a longer half-life with a more predictable dose-dependent therapeutic response. They are preferred over UFH in most clinical settings.

UFH is indicated for prophylaxis and treatment of thromboembolic disorders (including both DVT and PE) and thromboembolic complications associated with atrial fibrillation, prevention of clots in arterial and cardiac surgery, and as an anticoagulant for extracorporeal circulation and dialysis. Enoxaparin is indicated for the treatment of DVT, prophylaxis of VTE (including both DVT and PE), and for use during an acute coronary syndrome (including prophylaxis of complications due to unstable angina or non-ST-elevation myocardial infarction and treatment of acute ST-elevation myocardial infarction). Similar to enoxaparin, dalteparin is indicated for VTE prophylaxis, but is only indicated for non-ST elevation acute coronary syndromes. Its use for VTE treatment is limited to pediatric and cancer

Anticoagulants, Table 2 Examples of approved low molecular weight heparins

LMWHs	Trade name	Average molecular weight	Elimination half-life (h)	Bioavailability (%)	Anti-Xa/ anti-IIa ratio	Countries of approval
Ardeparin	Normiflo	6000	3.0	92	2.1	USA (withdrawn)
Certoparin	Sandoparin	5400	4.1	2.2	2.4	Germany
Bamiparin	Zibor	3600	5.5	96	8.0	Bulgaria, Poland
Dalteparin	Fragmin	5500	3–5	87	2.7	Germany, Japan, UK, USA
Enoxaparin	Levonox, Clexane	4500	4.5	92	3.8	Germany Spain, USA
Nadroparin	Fraxiparin	4500	3.7	89	3.3	France, Germany
Parnaparin	Fluxum	4500	4.3	90	2.3	Italy
Reviparin	Clivarin	4300	3.6	95	4.2	Canada, Germany
Tinzaparin	Innohep	6500	3.4	87	2.7	Denmark, Germany, USA

patients. Because they are effective, relatively inexpensive, have a rapid onset of action, and have a variety of indications, heparins are often used as first-line agents in an inpatient setting for VTE prophylaxis and treatment (Serhal and Barnes 2019). In general, UFH is administered subcutaneously for VTE prophylaxis and intravenously for other indications. Enoxaparin is only administered intravenously for acute coronary syndrome and subcutaneously for all other anticoagulation indications. Dalteparin is only administered subcutaneously.

Both UFH and LMWH are safe for use in hepatic impairment and do not require dose adjustments. However, dose adjustments are required for LMWHs (unlike UFH) in patients with renal impairment. UFH is monitored using the anticoagulation lab tests called the activated prothrombin time (aPTT) and anti-factor Xa level. Doses are adjusted based on results. While it is not required, anti-factor Xa levels may be monitored while using LMWHs in certain high-risk populations. Heparins should be avoided in patients with history of heparin-induced thrombocytopenia and uncontrolled active bleeding, and in circumstances where appropriate blood coagulation tests cannot be performed. The effect of heparins can be reversed, in cases of toxicity or severe bleeding, with protamine sulfate.

Fondaparinux is a synthetic sulfated pentasaccharide developed from the antithrombin pharmacophoric portions of heparin. The substitution of some of the sulfate groups on fondaparinux has yielded idraparinux (a drug in development), which has a longer half-life (5–6 times) allowing for a potential once-weekly administration. Fondaparinux potentiates the effects of antithrombin III, but in a manner that is more selective for the inhibition of factor Xa (Paolucci et al. 2002). Its dose-response is predictable like LMWHs. Fondaparinux is indicated for the treatment of VTE (both DVT and PE) and VTE prophylaxis specifically in surgical patients. Fondaparinux is contraindicated in patients with severe renal impairment, defined as a creatinine clearance (CrCl) of less than 30 mL/min. Renal dose adjustments are required for a CrCl of 30–50 mL/min. Administered subcutaneously, the dose of fondaparinux is also titrated based on anti-factor Xa levels.

Direct Thrombin Inhibitors

Direct thrombin inhibitors (DTIs) directly bind to and inhibit thrombin to prevent the progression of the clotting cascade (Fig. 1). DTIs inhibit both soluble thrombin and fibrin-bound thrombin and offer advantages over heparins and warfarin. The anticoagulant response to DTIs is more predictable because they do not bind to other plasma proteins nor induce immune-mediated thrombocytopenia (unlike heparins), and they possess antiplatelet activity. There are currently four DTIs approved in the United States for parenteral administration: bivalirudin, desirudin, lepirudin, and argatroban (Table 3). Dabigratran is the only orally available DTI with several others in development. Along with factor Xa inhibitors (see section below), dabigatran is referred to as a direct-acting oral anticoagulants.

Anticoagulants, Table 3 Comparative overview of the parenteral direct thrombin inhibitors

	Relative affinity for thrombin	Plasma half-life (h)	Clearance	Dose adjustment requirement
Argatroban	Lowest	0.75	Liver	30–50% reduction in liver failure; avoid in severe heart failure
Bivalirudin	Intermediate	0.4	20% renal excretion; liver	15–50% reduction if CL_{CR} is 15–60 mL/min; avoid if $CL_{CR} < 15$ mL/min
Desirudin	Highest	2.0	Kidney	If $CL_{CR} < 60$ mL/min
Lepirudin	Highest	1.5	Kidney	15–50% reduction if CL_{CR} is 15–60 mL/min; avoid if $CL_{CR} < 15$ mL/min

Desirudin and lepirudin are products of recombinant technology in *Saccharomyces cerevisiae* using hirudin, a naturally occurring peptide originally isolated and characterized from the salivary glands of blood-sucking leeches (*Hirudo medicinalis*). They have high affinity for thrombin, binding to both the active site and an exosite domain to form irreversible complexes. Bivalirudin is a synthetically engineered polypeptide analogue of hirudin with relatively weaker and reversible thrombin binding compared to desirudin and lepirudin. Argatroban is a small molecule that effectively but reversibly binds and inhibits thrombin. Dabigatran etexilate is a small molecule prodrug that is rapidly metabolized to dabigatran after administration. It is a potent and reversible orally bioavailable DTI. It has a rapid onset of action and has lower risk for drug interactions, as it is not metabolized by the cytochrome P450 enzymes. Furthermore, it does not require routine monitoring, and has a wider safety margin and a fixed-dose administration (Di Nisio et al. 2005).

Argatroban and bivalirudin are administered intravenously specifically in instances of heparin-induced thrombocytopenia (HIT). Argatroban may be used as thrombosis prophylaxis or treatment in patients with HIT as well as for percutaneous coronary intervention in patients at high risk for developing HIT. Bivalirudin is indicated specifically for percutaneous coronary intervention in patients at high risk for developing HIT. Dabigatran's indications include treatment and prevention of VTE, VTE prophylaxis in total hip arthroplasty, and prevention of stroke in nonvalvular atrial fibrillation. In order to use dabigatran to treat VTE, the patient must have been treated with a parenteral anticoagulant for 5–10 days before the initiation of dabigatran. Dabigatran is affected by renal impairment and is a substrate of p-glycoprotein, and as such, dosing should be adjusted based on renal function.

Vitamin K Antagonists

Most anticoagulants exert their activity on certain factors at various steps in the coagulation cascade with the exception of the vitamin K antagonists (VKAs). VKAs inhibit the vitamin K epoxy reductase complex (VKORC1), an enzyme required to convert vitamin K to its active form (Whitlon et al. 1978). The biochemical activation of the clotting factors II, VII, IX, and X involves gamma-glutaryl carboxylation, a process that requires the active reduced form of vitamin K, which forms a complex with the carboxylase enzyme. VKAs, by inhibiting VKORC1, indirectly prevent the activation of these clotting factors to reduce progression of the clotting cascade (Whitlon et al. 1978). Coumarins are the most relevant vitamin K antagonists, with warfarin being the only one approved for therapeutic anticoagulation in humans. Warfarin, as used in drug formulations, is a racemic mixture of the two (*R* and *S*) optically active isomers in roughly equal proportions. The *S*-warfarin isomer is about five times as potent as the *R*-isomer with regard to VKORC1 inhibition. Following oral administration, warfarin is well absorbed. It is metabolized in the liver through the actions of CYP2C9 (*S*-isomer) and CYP3A4 (*R*-isomer).

It is approved for oral administration for long-term anticoagulation following a thrombotic event and for prevention in at-risk patients. Major challenges to the use of warfarin include its narrow therapeutic index and interindividual variability in therapeutic response. It is a substrate of CYP2C9 and is therefore subjected to consequential drug interactions in the presence of concomitant medications. In maintaining adequate response and preventing deleterious side effect including intracranial bleeding, the international normalized ratio (INR) is used to monitor warfarin response, with recommended therapeutic ranges being 2.0–3.0 for most disease indications. The risk of hemorrhage is directly related to INR, with higher INR values corresponding to a higher risk of bleeding. The risk of serious bleeding is also higher in patients of advanced age, patients with chronic renal disease, liver failure, cardiovascular comorbidities, or those with concurrent antiplatelet medications. Another important consideration with warfarin use is the genetic variation in *CYP2C9* and *VKORC1* gene expression. It is now well known that individuals with the poor metabolizer *CYP2C9* phenotype are unable to metabolize warfarin, and the resulting accumulation

Anticoagulants, Table 4 Indications and year of approval of factor Xa inhibitors

	Rivaroxaban	Apixaban	Edoxaban	Betrixaban
Year of Approval	2011	2012	2015	2017
Administration with food	Depending on the dosage (high dose with food)	With or without food	With or without food	With food
Half-life (h)	5–13	8–15	10–14	19–27
T-max (h)	2–4	3–4	1–2	3–4
Clearance	50% renal, 50% metabolism	27% renal, 73% hepatic	50% renal, 50% hepatic/ enterobiliary	<10% renal, >80% hepatobiliary

may precipitate deleterious bleeding. Phenotypic expression of poor-function *VCOR1* has been well documented resulting in therapeutic failure with warfarin.

In the event of toxicity or overdosage, the effect of warfarin can be neutralized by the administration of vitamin K or different combinations of clotting factors.

Factor Xa Inhibitors (Direct-Acting Oral Anticoagulants)

Along with dabigatran, factor Xa inhibitors are DOACs. They are small molecule compounds that inactivate factor Xa by binding directly to its active site. The first to be approved in this new class was rivaroxaban which binds reversibly and competitively to both unbound and clot-bound factor Xa. Other anticoagulants in this class include apixaban, edoxaban, and betrixaban. They are approved for a wide variety of indications (Table 1) and are gaining favorability in the outpatient setting due to their favorable pharmacokinetic and safety profile. DOACs and warfarin are now the mainstay of outpatient anticoagulation therapy. The DOACs are often preferred over warfarin because of their relatively reduced bleeding risk and lower tendency for drug interactions. They have wider margins of safety and a more predictable dose-response relationship. Furthermore, there is no required routine coagulation monitoring for patients taking DOACs, unlike for other anticoagulants. Some of the disadvantages to DOACS include cost and limited experience in clinical utility (Mekaj et al. 2015). The four currently available factor Xa inhibitors are compared in Table 4.

Safety Considerations and Reversal

Therapeutic interventions aimed at maintaining homeostatic balance and preventing blood clots have the expected tendency to tilt the balance towards bleeding. Thus, apart from the known side effects of the individual anticoagulants, severe and life-threatening bleeding is a serious consequence of anticoagulation. The degree to which an anticoagulant is prone to induce bleeding is one of the considerations in the clinical choice of anticoagulants. More importantly, the availability of reversal agents (antidotes) in cases of life-threatening bleeding, or the need for emergency surgery, is a determining factor for anticoagulant choice. Table 1 provides an overview of available anticoagulants and their reversal agents.

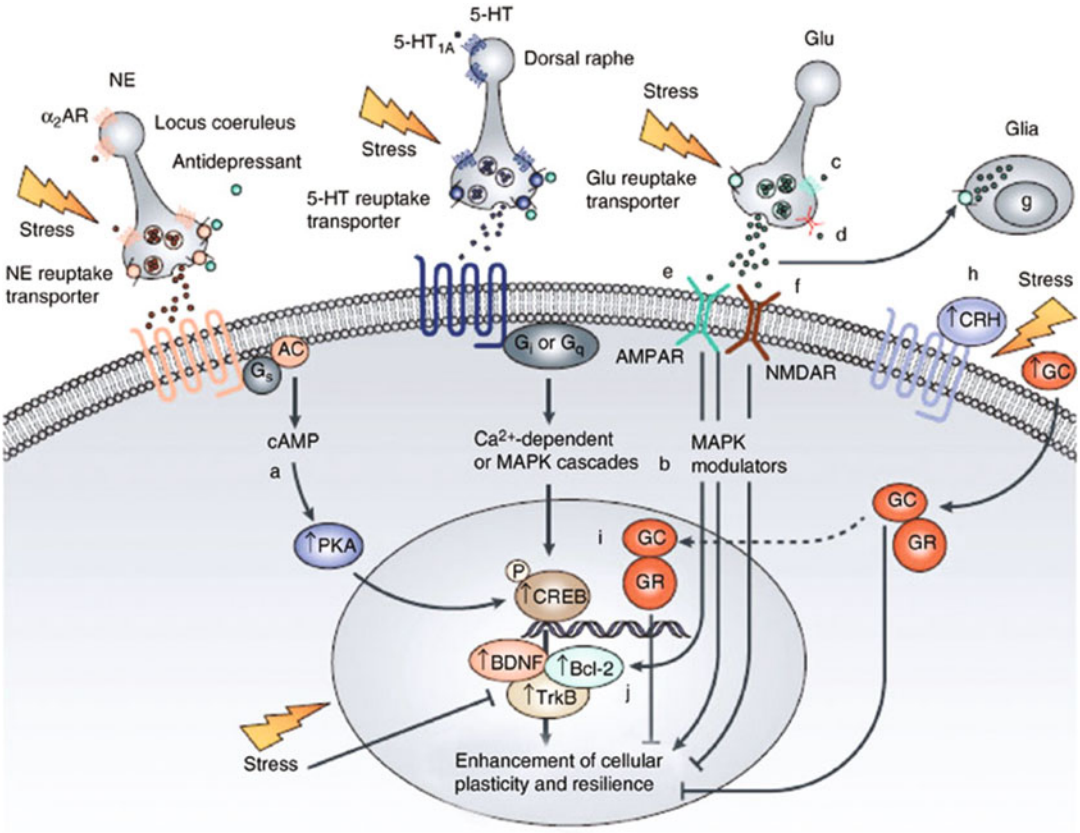
Definition

Antidepressants are small heterocyclic molecules entering the circulation mostly after oral administration and passing the blood–brain barrier to bind at numerous specific sites in the brain. They are used for treatment of depression, panic disorders, generalized anxiety disorder, social phobia, obsessive compulsive disorder, and other psychiatric disorders and nonpsychiatric states.

Mechanism of Action

Most available antidepressants enhance neurotransmission of biogenic amines, mainly norepinephrine and serotonin, to a lesser extent dopamine. Once released from specialized vesicles at the presynaptic nerve terminal, neurotransmitters enter the synaptic cleft and bind to respective receptors at the postsynaptic cell membrane, thus modulating the associated signaling cascades (Fig. 1). Additionally, some of them bind to presynaptically localized receptors that regulate the amount of transmitter released. The



Antidepressant Drugs, Fig. 1 Effects of stress as a model for depression and the reversal by use of antidepressants. Multiple intracellular targets might be involved in the regulation of plasticity and resilience by antidepressants, which block extracellular transporters. (Adapted from Agid et al. 2007)

cell membrane of presynaptic nerve terminals also contains reuptake transporters that clear the synaptic cleft from biogenic amines. Once reshuffled into the presynaptic compartment, the neurotransmitter is degraded by monoamine oxidase (MAO). These two molecular processes, reuptake through specific transporters and enzymatic degradation by MAO, are targeted by most of the antidepressant drugs. For example, the selective serotonin reuptake inhibitors (SSRIs; citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) and the so-called dual acting drugs (the selective serotonin/noradrenaline reuptake inhibitors venlafaxine, duloxetine, and milnacipran and the noradrenergic/selective serotonergic drug mirtazapine), which became the mainstay for the treatment of the majority of depressed patients, either prevent clearance of serotonin and/or noradrenaline from the synaptic cleft by blocking the presynaptic transporter and thus amplify receptor-mediated events postsynaptically or antagonize specific pre- and postsynaptic receptors. Analogous effects are those by norepinephrine reuptake inhibitors, while MAO inhibitors act by reducing norepinephrine or serotonin degradation and thus increase the releasable amount of neurotransmitter from the respective vesicles. These drugs do not exert prompt antidepressant effects as it takes weeks or months until clinical amelioration occurs. The exact mode of action by which antidepressants work is still not resolved, but there is consensus that their primary

action, i.e., binding to cell membrane transporters, triggers a manifold of events, some of which are depicted here (Fig. 1; Agid et al. 2007).

One such hypothesis submits that most antidepressants enhance the expression of cyclo-AMP response element binding protein (CREB), which is a transcription factor that after phosphorylation binds to cyclo-AMP response elements localized in the promoter region of many genes including that coding for brain-derived neurotrophic factor (BDNF) (Berton and Nestler 2006). The latter neurotrophin was found to be decreased in the hippocampus of chronically stressed rats, serving as animal model of depression. When treated with antidepressants, BDNF expression increases, possibly through enhanced phospho-CREB-driven transactivation of the *BDNF* gene. Overexpression of mutant CREB prevented decreased neurogenesis in adult hippocampus. While many pieces of this hypothesis are in line with an antidepressant-induced enhancement of neurogenesis, evidence is lacking that this effect is the same through which antidepressants regulate emotional states. Morphological studies on brains of depressives failed to detect evidence for neuronal deterioration in the hippocampus. Moreover the increase of *BDNF* gene transcription as induced by antidepressants is possibly an unspecific response to a xenobiotic molecule. Whether increased transcription of BDNF conveys antidepressant effects is yet not proven, as mouse mutants where BDNF production is lowered by heterozygous gene deletion failed to show behavioral abnormalities. Also, data on drug-induced changes in BDNF peptide concentrations are not giving a clear picture.

Another hypothesis derives from the clinical observation that impaired stress hormone regulation is a cardinal symptom among patients with an acute major depressive episode. If stress hormones (primarily cortisol secreted by adrenocortical glands and corticotropin released from the pituitary) are monitored longitudinally in these patients, those who respond to drug treatment show a trend toward neuroendocrine normalization, while those where stress hormone regulation continues to be altered have a much worse outcome, i.e., they fail to respond or they relapse. Studies using transgenic mice with glucocorticoid receptor impairment show some behavioral and functional features reminiscent of depression. Some of these abnormalities disappear under antidepressants, which is in line with a drug-induced improvement of corticosteroid receptor function. When ligand-activated, these gluco- and mineralocorticosteroid receptors form homo- and heterodimers that interact with corticotropin-releasing hormone (CRH) in many ways. This is of relevance in this context because clinical and basic studies have shown that overexpression of CRH in many brain areas is causally related to development and course of depression. The effect of antidepressants has therefore consequences upon CRH secretion, and it is believed that these antidepressants may work through this corticosteroid receptor-driven signaling pathway, suppressing the depressogenic and anxiogenic effects of CRH acting through CRH type 1 receptors (CRHR1). CRH from the paraventricular nucleus (PVN) of the hypothalamus is released into the hypophyseal portal system and triggers the release of corticotrophin (ACTH) from the anterior pituitary via stimulation of CRH1 receptors. ACTH, in turn, stimulates the secretion of glucocorticoid hormones (cortisol in humans or corticosterone in rodents) from the adrenal cortex. Increased glucocorticoid levels suppress hypothalamic CRH expression via negative feedback through hippocampal and hypothalamic glucocorticoid receptors.

Thus, the antidepressant-induced behavioral and neuroendocrine changes in patients together with their observed molecular actions upon stress hormone signaling pathways have triggered the search for new pharmacological approaches to understand how antidepressants might work and ultimately to discover better drugs.

Novel antidepressants are rather directly acting on receptors or are so-called multimodal drugs. For instance, agomelatine is a melatonergic MT_1 and MT_2 receptor agonist and a selective serotonergic 5-HT_{2B} and 5-HT_{2C} receptor antagonist, vortioxetine is a serotonin receptor antagonist with serotonin reuptake inhibition, vilazodone is a serotonin 5-HT_{1A} autoreceptor partial agonist with serotonin reuptake inhibition, and trazodone

is a serotonin 5-HT_2 antagonist. Tianeptine seems to paradoxically increase serotonergic concentrations in the synaptic cleft. However, this does not represent its major mode of action. Opioidergic and glutamatergic mechanisms may play a major role for its efficacy as an antidepressant. Ingredients of St. John's wort have mild serotonin-/noradrenaline-/GABA- and glutamate reuptake inhibiting properties. The older tricyclic antidepressants like amitriptyline are also noradrenaline and/or serotonin reuptake inhibitors but also show antagonistic effects on different cerebral receptors like α1-adrenergic, cholinergic, histaminergic receptors. Figure 2 summarizes the major targets of most of the approved antidepressants.

N-methyl-D-aspartate (NMDA)-glutamatergic neurotransmission system blockers such as ketamine, CP-101,606 (traxoprodil), GLYX-13 (rapastinel), NRX-1074 (apimostinel), and riluzole gained much attention in the context of antidepressant treatment (Fasipe 2019). They increase glutamate release and finally enhance intracellular protein synthesis and synapse number and function. However, an opioidergic mechanism is also discussed with ketamine.

In the absence of a robust pathogenetic model for depression, hypotheses-driven research has limitations that hopefully can be overcome by unbiased approaches. However, some links between neurobiology and depression have already been found, e.g., low baseline hippocampal volume; disturbed connectivity and elevated anterior cingulated activity as measured by functional MRI, PET, and EEG; and activated microglia, hinting to an inflammatory background in major depression (Kraus et al. 2019). Immunological effects are part of the action of approved antidepressants (Eyre et al. 2016).

Moreover, minocycline, a broad-spectrum antibiotic, has generated considerable interest in neuroscience research because of its brain penetration and off-target anti-inflammatory effects, being currently under investigation as an antidepressant drug. The neurosteroid brexanolone, which is a positive allosteric modulator of γ-aminobutyric acid type A ($GABA_A$) receptors and needs to be injected, has been approved by the FDA for the treatment of postpartum depression.

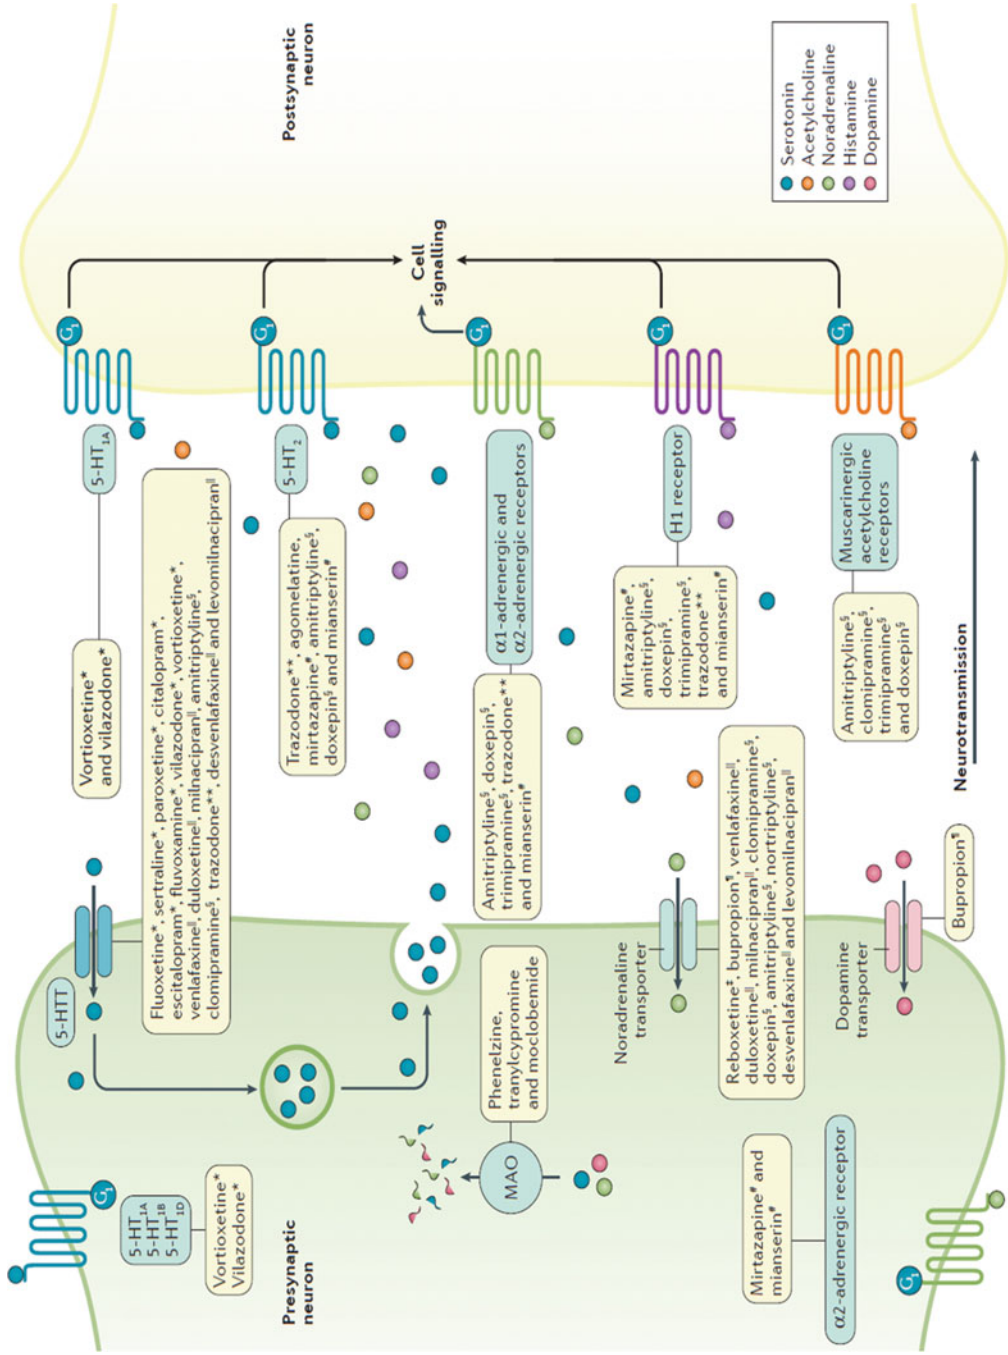
Genetic research in major depression has proven difficult. Like most complex diseases, depression is a polygenic disorder arising from the combined effect of many genetic variants with individually small effect sizes. By now, several sources provide evidence for the polygenic architecture of depression, despite a lack of genome-wide significant loci. Polygenic risk scoring uses association statistics from a discovery GWAS to weight the genotypes of individuals in an independent test sample and sums these effects across multiple SNPs into a polygenic risk score (PRS). Differences in PRS between cases and controls in the independent sample show that the PRS is capturing genetic susceptibility that is predictive of disease status. PRS for MDD shows modest, although significant, prediction for depression in independent samples (Mullins and Lewis 2017).

Clinical Use and Side Effects

Major depressive disorder is a serious mental health condition that affects up to 16% of people in the United States during their lifetimes and about 7% of the US population per year. In addition, patients with major depressive disorder have a substantial risk of suicidal behavior. Approximately two thirds of patients with major depressive disorder have a response to currently marketed antidepressant agents.

Antidepressants were serendipitously discovered in the 1950s, and the first generation of these drugs was constituted by tricyclic molecules. The refinement among the second and third generation of these drugs resulted in molecules that have less side effects, are better tolerated, and consequently enjoy much better acceptance. Given the personal and socioeconomic burden of depression, the undertreatment of this disabling and potentially life-threatening clinical condition seems neither ethical nor prudent.

While antidepressants have proven to be effective drugs, several drawbacks and caveats need to be resolved, such as fast, satisfactory response and higher proportion of remission. The NMDA receptor channel ionophore antagonist ketamine



Antidepressant Drugs, Fig. 2 Most of the receptor, transporter, or channel binding shown here represent functional antagonism. It is related either to effects or side effects. ∗SSRIs, §tricyclic antidepressants, #α2-adrenergic receptor antagonists, ∗∗serotonin antagonist and reuptake inhibitor, ‖SNRIs, ‡NRIs, ¶NDRIs. (Adapted from Otte et al. 2016)

and its enantiomer esketamine have been proposed as fast-acting substances able to overcome these impediments. Since the first randomized controlled trial in the early millennium, numerous studies have explored the antidepressant efficacy of ketamine. Clear evidence has emerged that a single infusion exerts a significant antidepressant and antisuicidal effect in both unipolar and bipolar depression. A few studies suggest that antidepressant response can be improved and maintained by repeated administration. Although intravenous application has been most common, subcutaneous, intramuscular, and intranasal application has also been successful, the latter obtaining an FDA approval for treatment-resistant depression. However, issues surrounding potential toxicity, such as hemodynamic effects, cognitive and dissociative side effects, and abuse potential, need to be addressed before precise positioning among the other antidepressants can occur.

Pharmacogenetics in combination with refined clinical research might improve prediction of effects and side effects. Matching patients to the antidepressant that is most likely to be effective and less likely to harm through adversive reactions is the main goal of all modern therapies. Patient characteristics including sex, age, anxiety level, premedication, and family history (genetic load) do not predict better or worse response to a particular antidepressant drug or drug class. However, the fact that all drugs are equally effective between comparison groups does not mean that they are equally effective for individual patients. It is now hoped that combination of clinical data, including functional assessments, e.g., neuroendocrine, neuroimaging, and neuropsychology together with information from genotyping, i.e., identification of a collection of single nucleotide polymorphisms (SNPs), will ultimately lead to choosing a first-line antidepressant based upon individual data. In practice, a genotype-guided medication selection is yet not in reach, but several minor innovations emerging from hypothesis-driven research are, such as glucocorticoid signaling (FKBP5) and serotonin neurotransmission (SLC6A4 and HTR2A) (Fabbri et al. 2017). Another new development of immediate clinical usefulness is the analysis of genetic variability in the cytochrome P450 enzyme system in patients, which may elucidate clinically relevant changes in drug metabolization and adverse reactions. For example, if a patient receives an SSRI such as fluoxetine, which blocks the P4502D6 enzyme, and an antiarrhythmic, which is metabolized by the same enzyme, a fatal increase of the cardiotropic drug may occur. Other possible candidates involved in pharmacokinetics are P-glycoproteins, which are important regulators of a drug's blood–brain barrier passage. It was recently shown that many antidepressants are substrates of P-glycoprotein, which, if overexpressed, can extrude the antidepressant out of the brain cells into the circulation, thus preventing central effects that may lead to therapy resistance. Polymorphisms in the ABCB1 gene leading to differential P-glycoprotein expression and activity are already used in certain clinical circumstances.

Side effects of antidepressants usually occur during the first days of treatment and tend to diminish over time. The side effect profile can be easily derived from the transporter binding profile. Serotonergic drugs might cause headaches, appetite loss, nervousness, sweating, and sexual dysfunction and noradrenergic drugs palpitations, sweating, anxiety, and drowsiness. Anticholinergic antidepressants show side effects like constipation, blurred vision, memory dysfunction, and dry mouth, while antihistaminergic drugs exhibit side effects like sedation, hypotension, and weight gain. Antiadrenergic properties are associated with postural hypotension and reflex tachycardia.

Antiepileptic Drugs

Arne Reimers
Division of Laboratory Medicine, Department of Clinical Chemistry and Pharmacology, Lund University Hospital, Lund, Sweden

Synonyms

Anticonvulsant drugs; Anticonvulsants; Anticonvulsive drugs; Antiseizure drugs

Definition

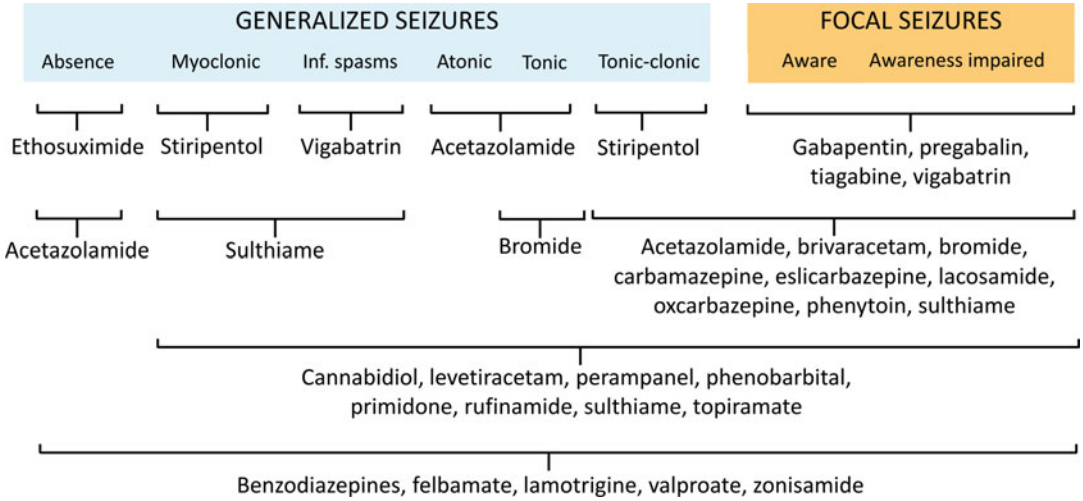
Antiepileptic drugs (AEDs) are used to treat epilepsy, i.e., the repeated occurrence of unprovoked epileptic seizures. They are also used in other conditions, e.g., bipolar disorder, neuropathic pain, or migraine. None of the available AEDs does cure epilepsy. Instead, they suppress epileptic discharges in the brain, thereby reducing seizure frequency. For this reason, they are sometimes called anticonvulsants or antiseizure drugs. Nevertheless, the official ATC code for these drugs as designated by the WHO is "N03A Antiepileptics."

The prevalence of epilepsy is about 0.7% worldwide, with equal distribution between sexes. Thus, epilepsy is among the four most common neurologic disorders. The incidence vs. age curve is U-shaped, meaning that the incidence of epilepsy is highest at both extremes of age. At young age, epilepsy is mostly due to connatal brain disease, hypoxia at birth, genetic, or unknown causes, while at old age, epilepsy is mostly caused by brain tumors or stroke. This has direct implications on treatment as different etiologies may lead to different types of epilepsy, and there are only few AEDs that are effective in all of them (Fig. 1).

Some AEDs may even aggravate certain seizure types and are thus contraindicated in these. Hence, it is of utmost importance that the patient's type of epilepsy is correctly identified as this will define the range of suitable AEDs.

Approximately 70% of people with epilepsy become seizure-free by medical treatment. Despite a large number of new AEDs launched during the past 30 years, many of them with new mechanisms of action (MOAs), this number has not changed. For these reasons, new AEDs are constantly being developed (Fig. 2). AEDs that came onto the market before 1990 are commonly referred to as first-generation AEDs, drugs launched thereafter as second generation. Drugs currently under clinical development include newly developed compounds as well as old, repurposed drugs, e.g., anakinra, cannabidivarin, fenfluramine, selurampanel, everolimus, ganaxolone, medium-chain fatty acids, padsevonil, and more. Many of these represent innovative MOAs, and some are discussed in this chapter.

AEDs are used both prophylactically (maintenance treatment) and acutely. Acute treatment means stopping ongoing prolonged seizure



Antiepileptic Drugs, Fig. 1 Spectrum of antiepileptic efficacy of commonly used antiepileptic drugs

activity such as status epilepticus or acute manic episodes.

All AEDs aim at reestablishing the balance between excitatory and inhibitory mechanisms in the brain, thereby reducing paroxysmal neuronal firing. Consequently, almost all AEDs modulate either glutamatergic or GABAergic neurotransmission or transmembrane ion currents (Fig. 3).

For most AEDs, more than one MOA has been documented (Table 1).

These diverse pharmacological actions may explain their clinical efficacy in different seizure types and a variety of non-epileptic medical conditions. Naturally, the number of identified MOAs is highest for the oldest AEDs because they have been more intensively studied than the newer ones. Some AEDs share certain structural similarities and MOAs, while other are structurally similar but have different MOAs and different clinical effects (Fig. 4a, b).

Acetazolamide

Mechanism of Action

The exact mechanism by which acetazolamide (ACZ) exerts its antiepileptic activity is not entirely clear. ACZ is a sulfonamide and a potent inhibitor of the enzyme carbonic anhydrase (CA) which exists in several subfamilies and isoforms. Other AEDs that also contain a sulfonamide structure like topiramate or zonisamide share this MOA. Inhibition of CA increases CO_2 and decreases HCO^{3-}concentrations, leading to reduced pH. Increased H^+-concentrations reduce cation currents through NMDA receptors and Ca^{++} currents through voltage-dependent calcium channels and, thus, neuronal excitability. Another proposed MOA of ACZ is activation of myosin light chain kinase (MLCK, an enzyme involved in synaptic vesicle recirculation), resulting in altered synaptic transmission (Bertone et al. 2017). Other data suggest that ACZ reduces neuronal firing by reducing $HCO3^-$ efflux through $GABA_A$ receptors, thereby stabilizing membrane potential and hampering depolarization (Hamidi and Avoli 2015).

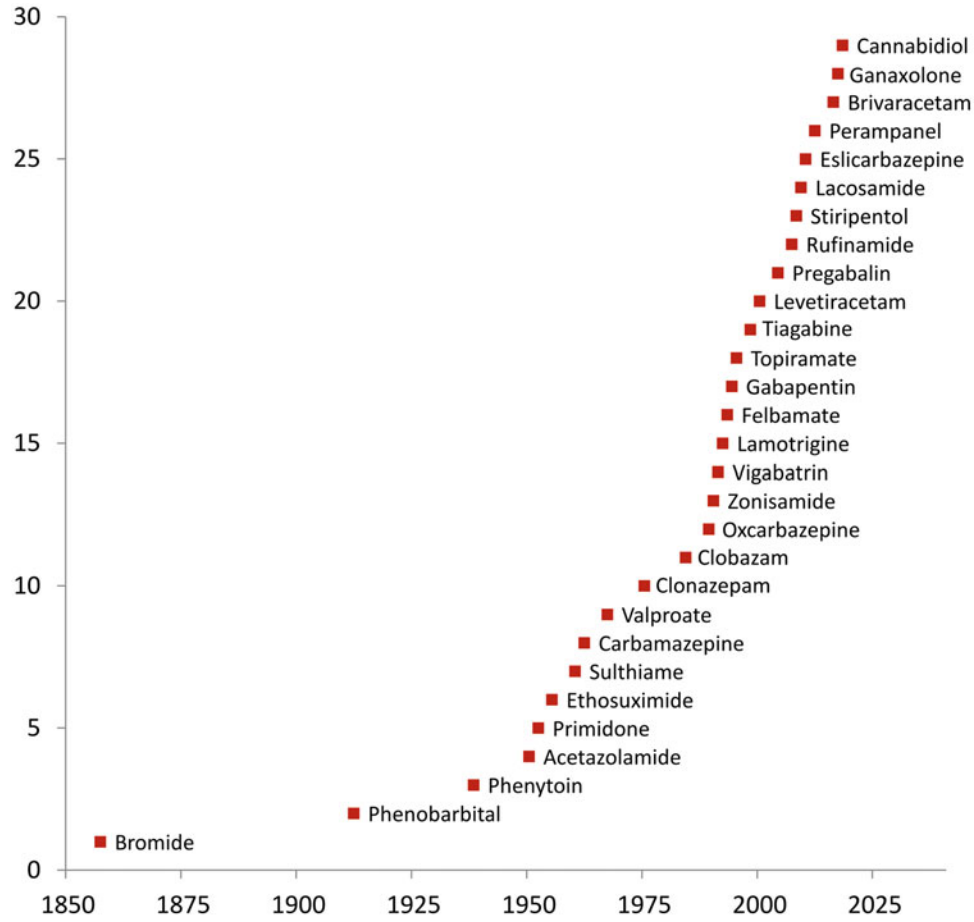
Clinical Use

AZA has been shown to be effective in treating partial, myoclonic, absence, and primary generalized tonic-clonic seizures (Reiss and Oles 1996). Besides, it is used for treating altitude sickness, glaucoma, and other medical conditions.

Brivaracetam

Mechanism of Action

Brivaracetam (BRV) is an analogue of levetiracetam (LEV; Fig. 4). Both are derivatives



Antiepileptic Drugs, Fig. 2 Year of introduction of currently available antiepileptic drugs (AEDs). Several less used or abandoned AEDs (e.g., mephenytoin, trimethadione, retigabine) are not shown

of the older nootropic agent piracetam. BRV, like LEV, binds to the synaptic vesicle protein SV2A. This protein is located in the vesicle wall in terminal ends of neurons and in endocrine cells. It plays a central role in the exocytosis of neurotransmitter molecules into the synaptic cleft. BRV's binding to it results in decreased synaptic transmission. As this affects both excitatory and inhibitory neurotransmitters, it is not entirely clear how this MOA leads to reduced spreading of epileptic activity in the brain. BRV's affinity to the SV2A protein is reportedly 15–30-fold higher than LEV's. BRV is also a NMDA receptor antagonist and reduces excitatory glutamatergic transmission. It does not seem to act on AMPA and kainate receptors nor does it have GABAergic activity. Furthermore, it does not seem to have any effect on voltage-gated sodium, potassium, or calcium channels (Klein et al. 2018).

Owing to its differing pharmacokinetic profile, BRV may reach effective concentrations in brain tissue faster than LEV after IV administration. This is irrelevant for maintenance therapy but could be an advantage in acute situations like status epilepticus where the time to cessation of epileptic activity is negatively correlated with outcome.

Figure created with BioRender

Clinical Use

BRV is licensed for add-on treatment of partial seizures with or without secondary generalization in children and adults. It is available as an intravenous formulation for use in status epilepticus.

Bromide

Mechanism of Action

Bromide (BR) is a halogen and administered as its potassium or sodium salt. It exerts its antiepileptic effect by replacing up to 30% of the chloride atoms in cerebral intra- and extracellular fluids, which leads to neuronal hyperpolarization (Plumlee 2004).

Clinical Use

In several clinical studies, BR has shown moderate-excellent efficacy in focal, tonic, and tonic-clonic seizures. However, it frequently induces sedation as well as gastrointestinal and dermatological adverse effects and has unfavorable pharmacokinetics. Hence, it is mainly used as a drug of third choice in severe epilepsy syndromes of

Tiagabine	TGB								Synaptic GABA-reuptake inhibitor
Topiramate	TPM	+	+	+	+			+	Inhibition of carbonic anhydrase
Valproate	VPA	+	+	+	+				Aspartate inhibition, HDAC inhibition
Vigabatrin	VGB								Irreversible inhibition of GABA- transaminase
Zonisamide	ZNS	+	+	+	+		+		Inhibition of carbonic anhydrase

childhood. BR is also used by veterinarians to treat epilepsy in dogs and other animals.

Cannabidiol

Mechanism of Action

Cannabidiol (CBD) is one of the most abundant phytocannabinoids found in the plants *Cannabis sativa* and *C. indica*. In contrast to tetrahydrocannabinol (THC) which accounts for most of the psychotropic effects of cannabis, CBD has only weak affinity to, and rather antagonistic actions at, CB1 and CB2 receptors. Accordingly, it has been found that CBD does not induce a high, which is of importance for its safety profile including its abuse potential.

It has been shown that CBD reduces neuronal excitation by modulating intracellular calcium concentrations through antagonism at the G protein-coupled receptor 55 (GPR55). It also acts on other orphan GPRs like GPR3, GPR6, and GPR12. In addition, it desensitizes the transient receptor potential vanilloid (TRPV) 1 and probably other TRPV channels which may be of significance for its analgesic effects. Further, CBD inhibits adenosine reuptake at A1 and A2 receptors, blocks sodium channels, and acts on the equilibrative nucleoside transporter 1 (ENT-1) as well as the mitochondrial voltage-dependent anion-selective channel 1 (VDAC-1). Data also suggest that it has serotonergic properties and reduces dopaminergic transmission (Gaston and Friedman 2017). The plethora of pharmacological mechanisms may explain the broad spectrum of CBD's clinical effects.

Clinical Use

Purified CBD is currently licensed for the treatment of two severe forms of epilepsy, Lennox-Gastaut syndrome and Dravet syndrome. Current data show that it reduces the frequency of focal and generalized seizures including drop attacks, but not absences. Besides, it is widely used (with and without a prescription) for non-licensed indications including pain, anxiety, depression,

schizophrenia, and neurodegenerative diseases like amyotrophic lateral sclerosis, Parkinson's disease, Huntington's chorea, and Alzheimer's disease. Its neuroprotective efficacy in the latter indications is attributed to its anti-inflammatory and antioxidant properties. CBD is also part of nabiximols which is a 50/50 mixture of CBD and THC. Nabiximols is licensed for the treatment of MS-related spasticity. Like pure CBD, nabiximols is used for a variety of off-label indications.

Carbamazepine

Mechanism of Action

Carbamazepine (CBZ) has a tricyclic ring structure and was synthesized in 1953 in an attempt to repeat the success of the antipsychotic, chlorpromazine. It was, however, first marketed to treat trigeminal neuralgia and subsequently became a first-line treatment of epilepsy. CBZ is traditionally classified as a sodium channel blocker, but it has multiple MOAs. It binds to postsynaptic, voltage-dependent sodium channels when they are in their inactive state (i.e., when the membrane is depolarized), thereby prolonging this inactive state and reducing high-frequency repetitive firing. Normal, physiologic firing is affected only minimally. In addition, CBZ reduces synaptic signal transmission by blocking presynaptic sodium channels as well as glutamatergic NMDA receptors. CBZ also interacts with $GABA_A$ receptors, presumably via the benzodiazepine binding site (Ambrosio et al. 2002). Apart from these signaling systems typically involved in the generation of epileptic activity, CBZ has been shown to increase serotonin release and inhibit serotonin reuptake. It also modulates adenosine and dopaminergic neurotransmission. These effects may be relevant for its efficacy in psychiatric conditions such as bipolar disorder.

Clinical Use

CBZ is a first-line drug for focal and generalized tonic-clonic epileptic seizures. It worsens absence seizures, probably by enhancing $GABA_A$ receptor activity in the ventrobasal thalamus, and is therefore contraindicated in patients who have this type of seizures. Besides, CBZ is used in bipolar disorder and trigeminal neuralgia and to prevent seizures in alcohol withdrawal.

Clobazam

Mechanism of Action

Clobazam (CLB) is a 1,5-benzodiazepine, meaning that its nitrogen atoms are situated in the 1- and 5-positions of the diazepine ring instead of the usual 1- and 4-positions. CLB and its active metabolite, N-desmethylclobazam, bind to the $GABA_A$ receptor at the benzodiazepine binding site (Rudzinski et al. 2016; Riss et al. 2008). This increases the opening frequency of the ion channel when it is activated by GABA, without affecting the duration of the open state. The result is an enhanced influx of chloride (Cl^-) ions which leads to hyperpolarization of the neuronal cell membrane and, thus, reduced excitability of the neuron.

Clinical Use

CLB was originally introduced as an anti-anxiety drug. It is also effective against focal and generalized epileptic seizures, and it is licensed for the adjunctive treatment of seizures associated with Lennox-Gastaut syndrome (LGS) in patients 2 years of age or older. It allegedly has less pronounced sedative properties than other benzodiazepines, a characteristic that is ascribed to its 1,5-structure.

Clonazepam

Mechanism of Action

All benzodiazepines are effective against focal and generalized seizures. While lorazepam and diazepam are preferentially used to stop acute prolonged seizures including status epilepticus, few benzodiazepines are used for maintenance treatment. Clonazepam (CLZ) is the only benzodiazepine that by its ATC code (N03A E01) is classified as an AED. Like CLB, CLZ binds to the benzodiazepine binding site at the $GABA_A$ receptor and reduces neuronal

excitability through allosteric modulation (Riss et al. 2008).

Clinical Use

CLZ is licensed for monotherapy or as an adjunctive treatment of the Lennox-Gastaut syndrome. Due to its unfavorable safety profile (mainly sedation) and development of tolerance, it is a drug of second or third choice. Besides, it is widely prescribed for other psychiatric conditions, many of them off-label. There is also a considerable amount of drug abuse with CLZ.

Eslicarbazepine

Mechanism of Action

Eslicarbazepine (ESL) is the S-enantiomer of licarbazepine, the primary and active metabolite of oxcarbazepine (see below) which in turn is a derivative of carbamazepine. Licarbazepine was formerly called MHD or monohydroxy derivative (of oxcarbazepine) and later renamed. ESL is available as a prodrug, eslicarbazepine acetate, which after entering the body is rapidly converted to ESL. Like CBZ, ESL blocks voltage-gated sodium channels. In contrast to CBZ, it does not affect the fast inactivation state but enhances slow inactivation of the sodium channel, thereby reducing sustained repetitive neuronal firing. In vitro experiments have also shown that ESL reduces NMDA currents but only at supratherapeutic concentrations. A ligand-binding study did not support the hypothesis that ESL binds to the NMDA receptor nor any other ligand-operated receptors, ion channels, or transporters (Ambrosio et al. 2002).

Clinical Use

ESL is currently licensed as adjunctive treatment of focal-onset epilepsies in adults.

Ethosuximide

Mechanism of Action

Ethosuximide (ESM) is a succinimide and, although not a barbiturate, chemically similar to phenobarbital (Fig. 4). However, its main MOA is not related to GABA. Instead, ESM blocks low-threshold T-type calcium channels (LTCCs) which are predominantly expressed in the hypothalamus. The hypothalamus plays a crucial role in the generation of the typical 3-Hz spike-and-wave discharges seen in the EEG during absence seizures. The exact kind of interaction of ESM with LTCCs is not known. Moreover, not all studies found an effect of ESM on neuronal calcium currents. ESM has also been found to block non-inactivating sodium currents in thalamocortical neurons (White et al. 2007). This potential dual effect on thalamic and thalamocortical neurons may explain ESMs strong efficacy in treating absence seizures. It has also been hypothesized that ESM acts on GHB- and dopamine-mediated neurotransmission and increases nitric oxide release. However, experimental support for these hypotheses is scarce. ESM is poorly fat-soluble, and it is assumed that its site of action is on the outer side of the neuronal cell membrane. There are other succinimides like mesuximide and phensuximide, but they are rarely used.

Clinical Use

ESM is a first-line agent to treat absence seizures. Interestingly, and in contrast to all other AEDs, ESM is clinically effective exclusively in this type of seizures. This supports the notion of a selective action on hypothalamic neurons.

Felbamate

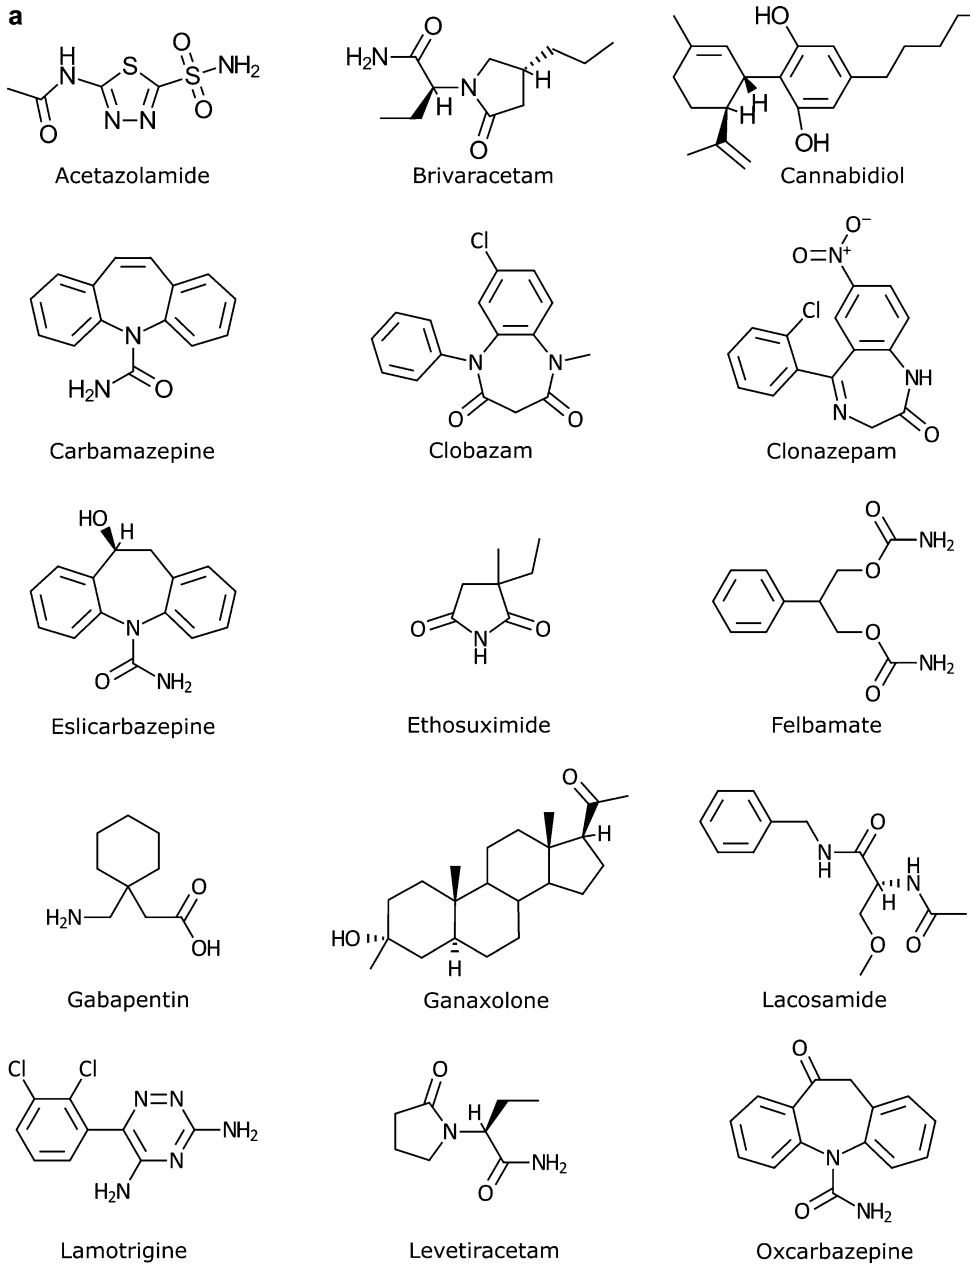
Mechanism of Action

Felbamate (FBM) is chemically related to meprobamate. It prolongs the duration of GABA-evoked chloride currents in cortical and hippocampal neurons. Accordingly, FBM has shown clinical efficacy against absence seizures. The binding site at the $GABA_A$ receptor is most likely distinct from the benzodiazepine binding site and the barbiturate binding site as FBMs effect is not blocked by flumazenil, and FBM does not affect the barbiturate-induced potentiation of GABA-mediated chloride currents. FBM also acts as a NMDA receptor antagonist, presumably through

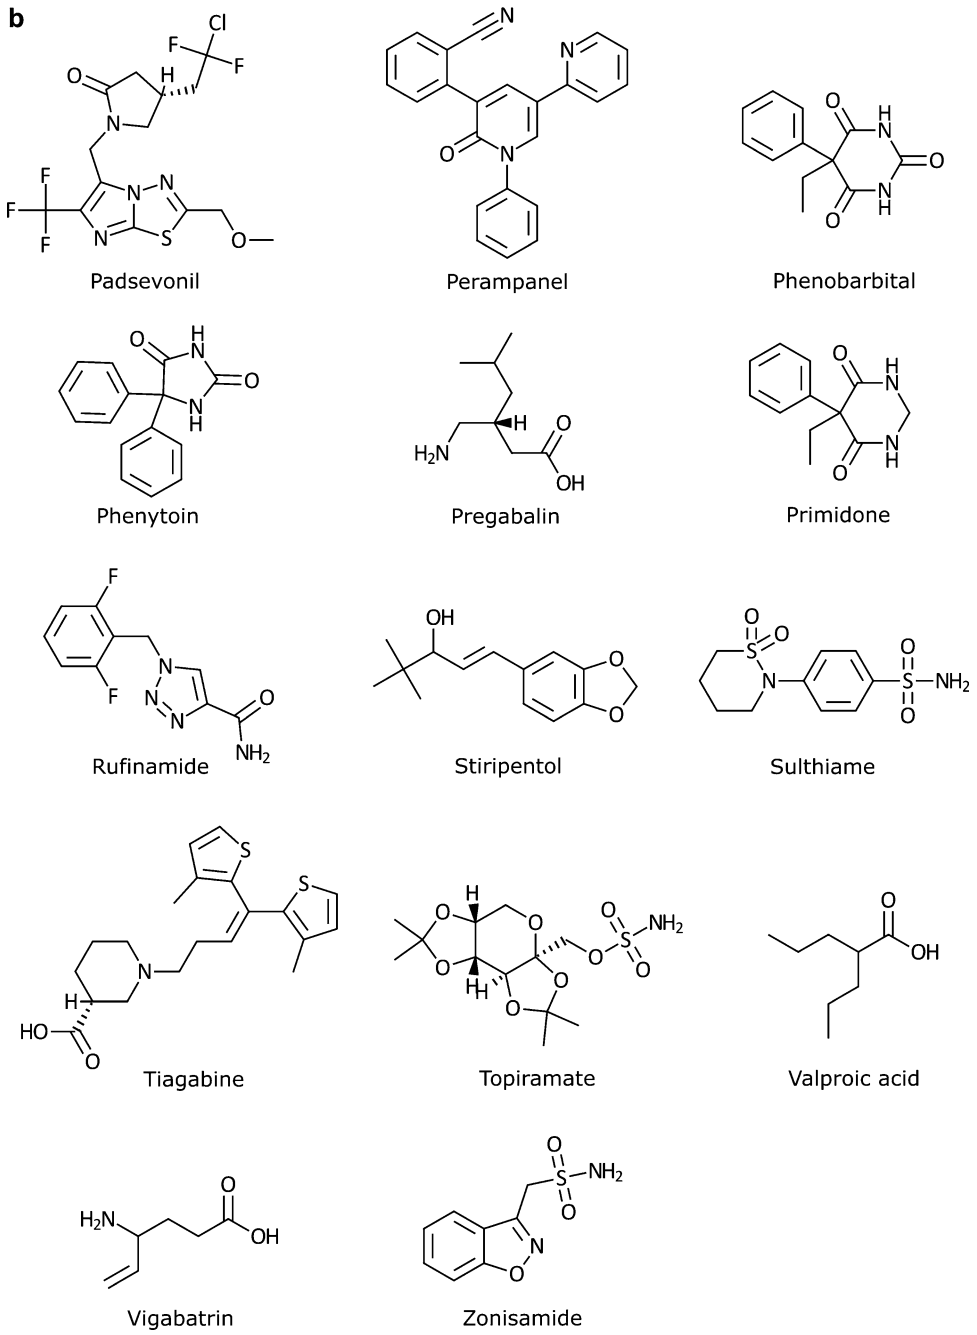
interaction at the glycine binding site. Like CBZ, FBM blocks voltage-dependent sodium channels by binding to them in their inactive state. Finally, FBM blocks voltage-dependent high threshold calcium currents (White et al. 2007).

Clinical Use

FBM has shown efficacy in all kinds of epilepsy including severe forms like Dravet-syndrome or Lennox-Gastaut syndrome. However, its clinical use is limited because it, like its sibling



Antiepileptic Drugs, Fig. 4 (continued)



Antiepileptic Drugs, Fig. 4 The chemical structures of antiepileptic drugs discussed in this chapter

meprobamate, may induce aplastic anemia with a mortality rate around 30%. In addition, FBM may induce severe hepatic failure. The manufacturer recommends using FBM only in those patients who do not respond well to other treatments and whose epilepsy is so severe that the risk of developing aplastic anemia or liver failure is outweighed by the potential benefit of felbamate treatment.

Gabapentin

Mechanism of Action

Gabapentin (GBP) is one of several compounds chemically engineered as GABA analogues (others, e.g., pregabalin and vigabatrin). The idea was to create antiepileptic drugs that mimic GABA. Indeed, GBP showed moderate antiepileptic efficacy in clinical studies. Its MOA, however, is not related to an action on GABA receptors. Instead, GBP exerts its effects by binding to the $\alpha_2\delta$-subunit at presynaptic L-, N-, and P-/Q-type voltage-gated calcium channels, thereby reducing presynaptic excitation and, consequently, neurotransmitter release into the synaptic cleft. This appears to reduce the release of all major neurotransmitters including the neuropeptides substance P and calcitonin gene-related peptide which are involved in nociception. It has long been known that GBP exerts synergistic effects together with glutamate antagonists in chronic pain states, and recently it has been reported that one of the two $\alpha_2\delta$ isoforms, $\alpha_2\delta$-1, physically interacts with NMDA receptors (Zhou et al. 2018). Such $\alpha_2\delta$-NMDA receptor coupling is of significance not only for pain signaling but also for memory and learning, and it has indeed been reported that GBP therapy is associated with a decline in memory, executive function, and attention. In addition, GBP may exert analgesic effects through reduction of protein kinase C and by suppressing transient receptor potential (TRP) ion channels like TRPA1 (Kukkar et al. 2013). There are also data suggesting that GBP may increase GABA levels in the brain by modulating glutamic acid decarboxylase and other enzymes involved in the synthesis of GABA, but these effects most likely play only a minor role in mediating GBP's clinical effects.

Clinical Use

GBP has only moderate efficacy as an antiepileptic drug. It is licensed for the treatment of focal seizures with and without secondary generalization, but, owing to its excellent analgesic properties, it is mainly used as a therapeutic agent in various neuropathic pain conditions, e.g., polyneuropathy or postherpetic neuralgia, usually in combination with other analgesics. It is also used to treat essential tremor.

Ganaxolone

Mechanism of Action

Ganaxolone (GNX) is a synthetic, 3-beta-methylated analog of the endogenous neurosteroid brexanolone (also known as allopregnanolone) which is derived from progesterone. The methyl group prevents the molecule from being converted back to progesterone which could induce hormonal adverse effects. GNX enhances GABA-evoked chloride currents by allosteric modulation of $GABA_A$ receptors at a binding site different from benzodiazepines (Greenfield 2013). In contrast to benzodiazepines, GNX also acts on extrasynaptic $GABA_A$ receptors (Chuang and Reddy 2019). The latter two properties of GNX may have benefits particularly in the treatment of status epilepticus that did not respond to first-line treatment with benzodiazepines alone.

Clinical Use

Although effective in animal models of epilepsy and early phase I and II studies, GNX showed no better efficacy than placebo in a randomized, placebo-controlled clinical trial in treatment-refractory patients with focal epilepsy. The manufacturer has initiated pivotal studies with ganaxolone in children with rare epilepsy syndromes like CDKL5 deficiency disorder or PCDH19-related epilepsy and is currently conducting studies in refractory status epilepticus.

Lacosamide

Mechanism of Action

Lacosamide (LCM) is a synthetic, "functionalized" amino acid. While naturally occurring L-amino acids (except cysteine) are S-enantiomers, LCM's biological activity has been mainly attributed to its R-enantiomer. LCM acts on voltage-gated sodium channels. Unlike other sodium channel blockers like CBZ or lamotrigine but similar to ESL, LCM enhances the slow

inactivation of these ion channels. The exact molecular target and mechanism of action have so far not been identified, although some data suggest an interaction with the batrachotoxin-binding site of the sodium channel (Errington et al. 2006). As a second MOA, LCM modulates the activity of the collapsin-response mediator protein 2 (CRMP2) which is involved in controlling neuronal plasticity (Wilson and Khanna 2015). This may represent a neuroprotective and antiepileptogenic MOA. The nature of the interaction of LCM with CRMP2 remains unclear. No other MOAs have been demonstrated so far. Radioligand binding studies and electrophysiology experiments suggest that LCM does not act at other ion channels or any major neurotransmitter receptor nor does it inhibit synaptic transmitter reuptake.

Clinical Use

LCM is licensed as monotherapy and adjunctive treatment of focal onset epileptic seizures in children and adults. It has also shown efficacy in stopping status epilepticus. In addition, it has been used to treat neuropathic pain.

Lamotrigine

Mechanism of Action

Lamotrigine (LTG) was originally developed with the intention to design a folic acid antagonist since it was (then) believed that folic acid antagonism was an antiepileptic MOA. In fact, LTG is an effective AED while being only a weak inhibitor of dihydrofolate reductase. Its supposed main MOA is the blockade of presynaptic, voltage-dependent sodium channels, thereby reducing synaptic neurotransmission. It is thought that this predominantly affects excitatory transmitters such as glutamate and aspartate. In addition, LTG also blocks L-, N-, and P- but not T-type calcium channels (White et al. 2007). This may account for its effectiveness in treating absence seizures. Besides, LTG is an antagonist at 5-HT_3 receptors. While other 5-HT receptors are G protein-coupled, the 5-HT_3 receptor is a ligand-gated ion channel (sodium, potassium, and calcium ions). Experimental data suggest that it is involved in promoting anxiety and seizure activity. LTG is also an effective treatment in bipolar disorder, particularly with depressive symptoms. It is not clear how it exerts this effect. Several hypotheses exist: LTG is an agonist at σ-(sigma) receptors, a characteristic it shares with several antidepressants, e.g., citalopram or fluoxetine, and other psychotropic compounds. In vitro experiments suggest that it also acts as an antagonist at $GABA_A$ receptors in the amygdala, a brain structure involved in emotions and fear. Finally, there is evidence that LTG dampens the NMDA receptor-mediated arachidonic acid cascade, thereby interfering with arachidonic acid-derived prostanoids like PGE_2 that promote neuroinflammation (Ramadan et al. 2012). At present, this effect on the arachidonic acid metabolic cascade is the only MOA known to be shared by all mood stabilizers (i.e., lithium, CBZ, LTG, and valproate), which supports the notion that this MOA plays a major role in treating bipolar disorder.

Clinical Use

LTG is used to treat epileptic seizures of focal or generalized onset in children and adults, either in monotherapy or as add-on treatment. It is also effective as a mood stabilizer and is licensed for the prophylactic treatment of bipolar disorder. Besides, there is extensive off-label use for a variety of other affective and schizoaffective disorders, mainly those that are primarily characterized by depressive symptoms.

Levetiracetam

Mechanism of Action

Levetiracetam (LEV) is a derivative of piracetam, a compound mainly used as nootropic drug since the 1960s. It is generally assumed that LEV exerts its antiepileptic effects through an interaction with the synaptic vesicle protein SV2A, a protein involved in calcium-dependent exocytosis of neurotransmitters. The way of LEV's molecular interaction with SV2A has not been fully elucidated, but it is assumed that transmitter exocytosis is

downregulated either via reduced calcium inward currents or other mechanisms. Indeed, it has been demonstrated that LEV inhibits presynaptic transmembrane calcium currents, probably through an (as yet unidentified) intracellular mechanism (Vogl et al. 2012). However, LEV also increases brain concentrations of GABA, interacts with the $GABA_A$ receptor, and diminishes glutamatergic excitation by modulation of NMDA and AMPA receptors as well as upregulation of glial glutamate transporters (Cortes-Altamirano et al. 2016). Data also suggest that LEV leads to neuronal hyperpolarization by opening potassium channels and that it acts on serotonergic and α_2-adrenergic signaling paths as well as μ-opioid receptors. It is not clear how much each of these mechanisms contributes to its clinical effects.

Clinical Use

LEV is used as a first-line treatment in monotherapy or as add-on treatment of both focal and generalized epileptic seizures. It is also used as a treatment of status epilepticus. Small studies suggest some efficacy in migraine and hyperalgesia. Based on experimental as well as clinical studies in humans, LEV has also been suggested as a neuroprotective agent.

Oxcarbazepine

Mechanism of Action

Oxcarbazepine (OXC) is the 10-keto analog of CBZ. While it is pharmacologically active and thus per definition not a prodrug, its plasma half-life is only 1–4 h as it is rapidly converted to its main (and active) metabolite, licarbazepine (10-hydroxy-carbamazepine), which has a much longer plasma half-life and therefore is considered the active form of OXC. OXC and licarbazepine block voltage-dependent sodium channels in a manner similar to CBZ. In parallel to CBZ, licarbazepine also decreases glutamatergic neurotransmission by modulating NMDA receptor function. OXC but not licarbazepine also potentiates $GABA_A$ receptor currents. In addition, licarbazepine blocks high-voltage-dependent N-type calcium channels and increases a hyperpolarizing potassium current (Ambrosio et al. 2002).

Clinical Use

The clinical spectrum of efficacy mimics CBZ; hence, it is used alone or in combination for the treatment of focal onset seizures with or without secondary generalization in children and adults. OXC appears to be somewhat better tolerated than CBZ although allergic cross-reactivity exists. It is not widely used in psychiatric conditions, though.

Padsevonil

Mechanism of Action

Padsevonil (PSL) is a newly developed AED that shares with BRV and LEV an oxygen-substituted pyrrolidine ring but looks otherwise chemically unrelated. In contrast to BRV and LEV, it binds to all known isoforms of the SV2 vesicle protein, i.e., SV2A, SV2B, and SV2C. As with BRV and LEV, the exact mechanism of this interaction is not fully understood. In addition, PSL acts as a partial agonist at the $GABA_A$ receptor through the benzodiazepine binding site (Wood et al. 2020). Experimental studies so far did not provide evidence for an interaction with other molecular targets like ion channels, other receptors, transporters, or enzymes.

Clinical Use

PSL is currently under clinical investigation regarding its safety, drug interaction potential, and efficacy as a treatment for focal seizures in adults.

Perampanel

Mechanism of Action

Perampanel (PER) is a selective, noncompetitive, allosteric antagonist at the AMPA receptor, thereby reducing glutamate-evoked calcium currents and, hence, excitatory postsynaptic

potentials (Ceolin et al. 2012). It has been demonstrated that PER has no effect on NMDA or kainate receptors. No other MOAs have been established so far for this drug.

Clinical Use

PER is a used as an adjunctive AED for the treatment of focal seizures with or without secondary generalization and primarily generalized tonic-clonic seizures.

Phenobarbital

Mechanism of Action

Phenobarbital (PB) acts as a GABA agonist through allosteric modulation of the $GABA_A$ receptor. Its binding site and mode of action are distinct from those of the benzodiazepines. While benzodiazepines increase the opening frequency of the chloride channel, PB does not affect the frequency but prolongs the duration of the channel's open state (White et al. 2007). In vitro, PB blocks sodium currents only in supratherapeutic concentrations and exerts weak antagonism at the AMPA receptor and no effect on calcium channels or NMDA receptors.

Clinical Use

PB was the first chemically synthesized compound used as an AED. Its antiepileptic properties were discovered by serendipity when it was observed that agitated psychiatric patients who also had epilepsy experienced a marked reduction in seizure frequency when they were given PB for sedation. PB is a broad-spectrum AED with efficacy in all types of seizures except absences. However, owing to its marked sedative properties, its drug interaction potential, and the availability of alternative AEDs, PB is no longer a favorite choice for maintenance treatment of epilepsy in high-income countries. It is still among the first-line drugs for the treatment of benzodiazepine-refractory status epilepticus. Because of its effectiveness and low cost, it is classified as an essential drug by the WHO and frequently used in low-income countries. PB is also used as treatment of various acute withdrawal syndromes (opiates, alcohol, etc.) including neonatal abstinence syndrome. In very high doses, it is used in euthanasia. Veterinarians use PB to treat epilepsy in animals.

Phenytoin

Mechanism of Action

Phenytoin (PHT, diphenylhydantoin) was developed with the intention to find an AED with less sedating properties than PB. In fact, its chemical structure is identical to PB's except in the 5-position where PB's ethyl group has been replaced by a second phenyl ring (Fig. 4). This change gives PHT a completely different pharmacological profile. While it, like PB, enhances $GABA_A$ receptor-mediated chloride currents, PHT also prolongs the inactive state of voltage-gated sodium channels and blocks L- and T-type calcium channels, thereby reducing sustained repetitive neural firing (Delorenzo and Sun 2002). It further stabilizes the neuronal cell membrane by increasing the activity of Na^+-/K^+-ATPase which leads to a hyperpolarization of the cell membrane. Intracellularly, PHT interferes with the calcium-calmodulin complex which affects phosphorylation steps in various enzyme systems, and it diminishes the activity of second-messenger systems like cAMP and cGMP. It is not clear whether these effects are direct ones or consequences of PHT's membrane-stabilizing actions. Finally, data suggest that PHT affects release and reuptake of various neurotransmitters including norepinephrine, glutamate, and GABA. The clinical relevance of these latter effects remains to be determined.

Clinical Use

PHT was the first AED without pronounced sedative effects and is still one of the most effective drugs to treat tonic-clonic seizures and status epilepticus. Like PB though, its use is declining in high-income countries due to its side effects, drug interaction potential, and the availability of equally effective AEDs with a better safety profile.

Pregabalin

Mechanism of Action

Like GBP, pregabalin (PGB) was designed as a GABA analog, and the two compounds are chemically similar. Its molecular MOAs resemble those of GBP, i.e., binding to the α2δ-subunit of presynaptic L- and P-/Q-type voltage-gated calcium channels (McKeage and Keam 2009). Sparse documentation suggests weak GABAergic effects, presumably through increased GABA synthesis, although this is not thought to be of clinical relevance. Like GBP, PGB does not bind to $GABA_A$ or $GABA_B$ receptors nor does it affect GABA reuptake or breakdown. Another parallel to GBP is its ability to reduce cognitive performance, presumably via interfering with the α2δ-NMDA receptor complex.

Clinical Use

Like GBP, PGB is only moderately effective as an AED and has thus been mainly marketed as a treatment for chronic pain. Despite being two to four times more potent than GBP as an analgesic, PGB offers no major advantage over GBP, but its pharmacokinetics are somewhat more favorable. In analogy to GBP, treatment of chronic pain states constitutes its main area of use. Moreover, it is used as an anti-anxiety drug, in restless legs syndrome, and in several other off-label indications. PGB can allegedly induce highs and euphoria, and it has a documented potential for drug abuse. Its prescription has therefore been restricted in several countries.

Primidone

Mechanism of Action

Primidone (PRM) or desoxyphenobarbital is a derivative of PB; the only difference is that one of PB's three carbonyl groups has been replaced by a methyl group (Fig. 4). However, PRM is biotransformed to PB and another (much less potent) active metabolite, phenylethylmalonamide (PEMA). Data on PRM's MOA are lacking, mainly because it has long been believed that it is only a prodrug for PB. However, PRM has antiepileptic properties by itself and has in some studies even shown stronger therapeutic efficacy than PB. It has been speculated that PRM's MOA involves blockade of sodium or calcium channels. This speculation is justified since another PB derivative, ethosuximide (ESM), acts via blockade of calcium channels. In an animal model of essential tremor that uses genetically $GABA_A$ receptor deficient mice, PRM showed significant reduction of tremor-like symptoms (Hedera et al. 2013). This indicates at least one MOA that does not involve $GABA_A$ receptors. In human studies, a significant reduction in tremor can be seen already 1 h after the first administration, i.e., long before relevant serum concentrations of PB are achieved. Taken together, there is sufficient reason to postulate that PRM is not a prodrug.

Clinical Use

PRM is effective against focal and generalized tonic-clonic seizures. Due to its adverse effect profile, mainly mediated through its metabolite PB, it is only a treatment of second or third choice. PRM is also used as first-line treatment of essential tremor, as an alternative to propranolol.

Rufinamide

Mechanism of Action

Rufinamide (RUF) is a triazine and, as such, structurally similar to lamotrigine. RUF prolongs the inactive state of voltage-gated sodium channels, thus limiting the spread of neuronal excitation. In light of its broad spectrum of efficacy, both in animal models of different forms of epilepsy and clinically, this MOA alone may not fully explain its clinical profile. In vitro studies have demonstrated an antagonistic effect of RUF on the metabotropic (= G protein-coupled) glutamate receptor 5 (mGluR5), but only at comparably high concentrations. RUF exerts neuroprotective effects against kainic acid (KA)-induced neuronal damage in the hippocampus of rats and mice. It has not been elucidated whether this is mediated

through KA receptor antagonism or other MOAs (Striano et al. 2018). Treatment with RUF produced improved cognitive function and increased neurogenesis in the hippocampus of aged gerbils through upregulation of insulin-like growth factor 1 (IGF-1), its receptor (IGF-1R), and phosphorylated cAMP-response element-binding protein (p-CREB). These actions may also contribute to RUF's neuroprotective effects.

Clinical Use

RUF has received orphan drug status for the adjunctive treatment of seizures associated with Lennox-Gastaut syndrome (LGS), a severe form of epilepsy that comprises different kinds of seizures. It appears to possess particular efficacy against atonic seizures (drop attacks) that often occur with LGS.

Stiripentol

Mechanism of Action

Stiripentol (STP) is chemically unrelated to other AEDs. It is an allosteric modulator of both synaptic and extrasynaptic subtypes of the $GABA_A$ receptor, increasing both the opening frequency and opening time of the chloride channel. Its binding site at the receptor is distinct from that of benzodiazepines and neurosteroids. Some data suggest that it may act at the barbiturate binding site. In addition, STP inhibits neuronal lactate dehydrogenase (LDH). This leads via intermediate steps to reduced levels of ATP which in turn triggers ATP-sensitive potassium channels in the cell membrane to open. The resulting potassium efflux leads to membrane hyperpolarization and reduced excitability (Nickels and Wirrell 2017). STP is the only AED known to act through this MOA.

Clinical Use

STP is mainly used for the treatment of Dravet syndrome, a severe form of epilepsy in children. Preliminary clinical experience also suggests efficacy in the treatment of benzodiazepine-refractory status epilepticus, most likely due to its action on extrasynaptic $GABA_A$ receptors.

Sulthiame

Mechanism of Action

Sulthiame (STM) contains a sulfonamide moiety. In parallel with other AEDs that share this characteristic, STM acts as an inhibitor of carbonic anhydrase (CA; for detailed description of this MOA, see acetazolamide). It is also a moderate blocker of voltage-dependent sodium channels, thereby reducing the generation of repetitive action potentials (Madeja et al. 2001). There are also data suggesting that STM increases regional GABA concentrations in the brain, while decreasing glutamate levels. It is not clear how exactly STM exerts these effects; they may be consequences of CA inhibition.

Clinical Use

STM has traditionally been used to treat focal and secondarily generalized tonic-clonic seizures, but it has reportedly also some efficacy in myoclonic seizures and infantile spasms. It is an AED of first choice in benign focal epilepsy with centrotemporal spikes (BECTS).

Tiagabine

Mechanism of Action

Tiagabine (TGB) has a unique MOA as it is the only AED known to act by binding to the GABA transporter GAT-1. This interaction reduces the uptake of extracellular GABA which results in increased GABA concentrations in the synaptic cleft and prolonged GABA-mediated inhibitory postsynaptic potentials (Greenfield 2013).

Clinical Use

TGB is effective as add-on treatment of focal onset seizures. It is also used off-label in anxiety and panic disorder. Its use is limited because of unfavorable pharmacokinetics and its alleged ability to aggravate certain seizure types including

status epilepticus. TGB has also been associated with new onset seizures and status epilepticus in patients without epilepsy.

Topiramate

Mechanism of Action

Topiramate (TPM) is a sulfonamide with a heterotricyclic ring substituent containing fructose. It has several MOAs. Being a sulfonamide, it inhibits carbonic anhydrase (for details, see acetazolamide). It also blocks voltage-operated sodium channels, leading to reduced repetitive firing. TPM inhibits excitatory postsynaptic potentials evoked by glutamate through an interaction with both NMDA and kainate/AMPA receptors. It enhances chloride currents through allosteric modulation of $GABA_A$ receptors via a binding site that is distinct from benzodiazepines. In addition, it blocks high-voltage-activated calcium channels (White et al. 2007). In animal experiments, TPM has shown neuroprotective effects by reducing oxidative stress, inflammation, and apoptosis. It is not clear whether this is mediated by one or more of the mentioned MOAs or by other MOAs as TPM presumably also modulates α_2-adrenergic, dopaminergic, and other signaling pathways like CREB and BDNF (Motaghinejad et al. 2017).

Clinical Use

TPM is effective against all seizure types except absences. Owing to its safety profile, mainly its negative cognitive effects, it is a drug of second choice. It is also used to treat essential tremor and alcohol dependence and to prevent migraine. Since weight loss is among its adverse effects, it is sometimes used as a weight loss agent.

Valproic Acid (Valproate)

Mechanism of Action

Valproic acid (VPA) is a short chain, branched fatty acid (chemically: dipropyl acetic acid). It is commonly named after its anion, valproate. VPA's antiepileptic properties were discovered by serendipity when it was used as a solvent to test new antiepileptic drug candidates. VPA is traditionally described as a GABAergic drug because it increases brain levels of GABA. The exact molecular mechanism underlying this effect is unknown. Inhibition of GABA degrading enzymes such as GABA transaminase and succinate-semialdehyde dehydrogenase as well as inhibition of the reuptake of GABA from the synaptic cleft has been suggested. Further MOAs of VPA are the blockade of voltage-gated sodium channels and T-type calcium channels as well as enhancement of potassium currents through M-channels. VPA also reduces excitatory neurotransmission by glutamate (via NMDA receptors) and aspartate (Kay et al. 2015). Besides, VPA is an inhibitor of histone deacetylase (HDAC). HDAC plays a major role in the epigenetic regulation of gene expression. In a genetic rat model of absence epilepsy, chronic treatment with VPA significantly reduced the later development of absence epilepsy and increased brain histone acetylation, paralleled by reduced HDAC1 and HDAC3 expression (Citraro et al. 2020). This suggests that HDAC inhibition by VPA may contribute to its antiepileptic efficacy and, more importantly, may prevent the development of epilepsy itself.

Clinical Use

VPA is a first-line, potent AED that is effective against all types of epileptic seizures and status epilepticus. It is also used as a mood stabilizer in bipolar disorder including acute manic episodes and in the prophylactic treatment of migraine. The clinical significance of VPA's HDAC-inhibiting properties is currently under investigation, mainly in oncology and neurodegenerative disorders.

Vigabatrin

Mechanism of Action

Chemically, vigabatrin (VGB) is a GABA molecule with a vinyl substituent at the γ-carbon

atom; hence, it is also named γ-vinyl-GABA (Fig. 4). Its similarity to GABA may explain its MOA which is inhibition of the GABA-degrading enzyme, GABA-transaminase (GABA-T). This inhibition is irreversible, and while the plasma half-life of VGB is only 5–7 h, elevated GABA concentrations in human cerebrospinal fluid have been measured for 1 week and longer after the last VGB dose. This duration is defined by the re-synthesis rate of GABA-T. Hence, VGB is an example of a so-called hit-and-run drug. There is also sparse evidence that VGB may modulate the conversion of α-ketoglutarate to glutamate *and* vice versa by inhibiting glutamate dehydrogenase (Ben-Menachem 2011). The relevance of this for the clinical effects of VGB is unclear. There is at present no evidence for other MOAs of VGB although it induces irreversible visual field defects by damaging the retina in up to 30–50% of patients. Several explanations for this adverse effect including GABA toxicity and taurine depletion have been suggested, but the exact mechanism remains to be determined.

Clinical Use

VGB is effective in the treatment of adults with partial seizures with impaired consciousness and in children with infantile spasms. Because of its safety profile, it is not a first-choice AED.

Zonisamide

Mechanism of Action

Like other AEDs that contain a sulfonamide moiety, zonisamide (ZNS) is an inhibitor of carbonic anhydrase (for details of this MOA, see acetazolamide). In addition, it acts as an inhibitor of voltage-dependent sodium and T-type calcium ion channels and exerts GABAergic effects through increased GABA release and inhibition of presynaptic GABA reuptake via GAT-1. ZNS is also an inhibitor of monoamine oxidase B (MAO-B). These multiple MOAs may explain its broad-spectrum clinical efficacy (Reimers and Ljung 2019).

Clinical Use

ZNS has shown efficacy against all types of epileptic seizures including absences. It is used alone and in combination with other AEDs. Because of its adverse effect profile, particularly cognitive impairment, it is used as a second-line drug. It is also licensed for the treatment of Parkinson's disease.

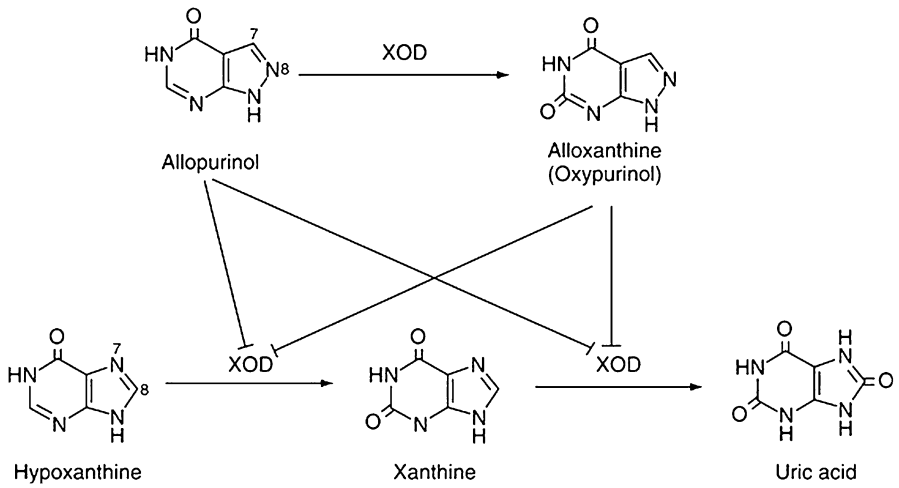
Drugs for the treatment/management of gout and/or hyperuricemia

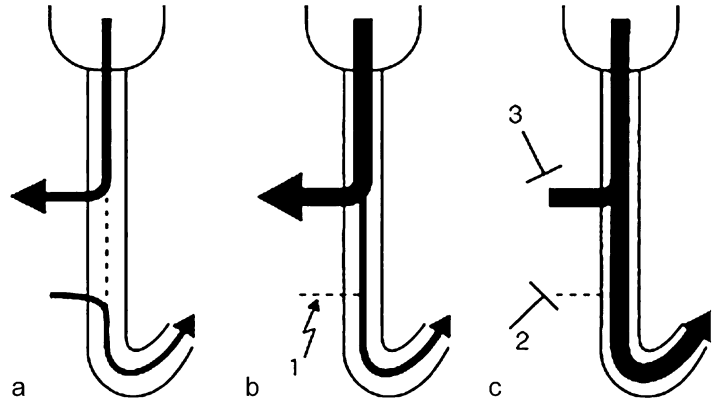
Definition

Pathophysiology and Clinical Manifestations of Gout

Uric acid is the end product of purine catabolism in man. Purines originate from food and the degradation of nucleic acids and nucleotides. Xanthine oxidase (XOD) is the key enzyme in purine degradation. XOD converts hypoxanthine to xanthine and xanthine to uric acid, respectively (Fig. 1). Uric acid is filtered in the glomerulus of the kidney, is almost completely absorbed in the proximal tubules, and secreted more distally (Fig. 2). At physiological pH (<7.4), uric acid exists predominantly in its ionic form (urate). At lower pH, the fraction of uric acid molecules (protonized form) increases. This is important because uric acid possesses a lower solubility than urate. Thus, a decrease in pH, as it occurs in inflammed tissue and in the tubules, facilitates the formation of uric acid crystals, which are the initial cause of gout. Of importance for therapeutic intervention is the fact that xanthine and hypoxanthine are more soluble than uric acid. Specifically, by preventing uric acid formation through XOD inhibition, the excretion of xanthine and hypoxanthine increases, and the risk of uric acid crystal formation decreases. An increase of the serum uric acid concentration above 416 µmol/L is referred to as hyperuricemia and is associated with an increased risk of uric acid crystal formation and acute attacks of gouty



Antigout Drugs, Fig. 1 Xanthine oxidase-catalyzed reactions. Xanthine oxidase converts hypoxanthine to xanthine and xanthine to uric acid, respectively. Hypoxanthine and xanthine are more soluble than uric acid. Xanthine oxidase also converts the uricostatic drug allopurinol to alloxanthine. Allopurinol and hypoxanthine are isomers that differ from each other in the substitution of positions 7 and 8 of the purine ring system. Although allopurinol is converted to alloxanthine by xanthine oxidase, allopurinol is also a xanthine oxidase inhibitor. Specifically, at low concentrations, allopurinol acts as a competitive inhibitor, and at high concentrations it acts as a noncompetitive inhibitor. Alloxanthine is a noncompetitive xanthine oxidase inhibitor. XOD: xanthine oxidase



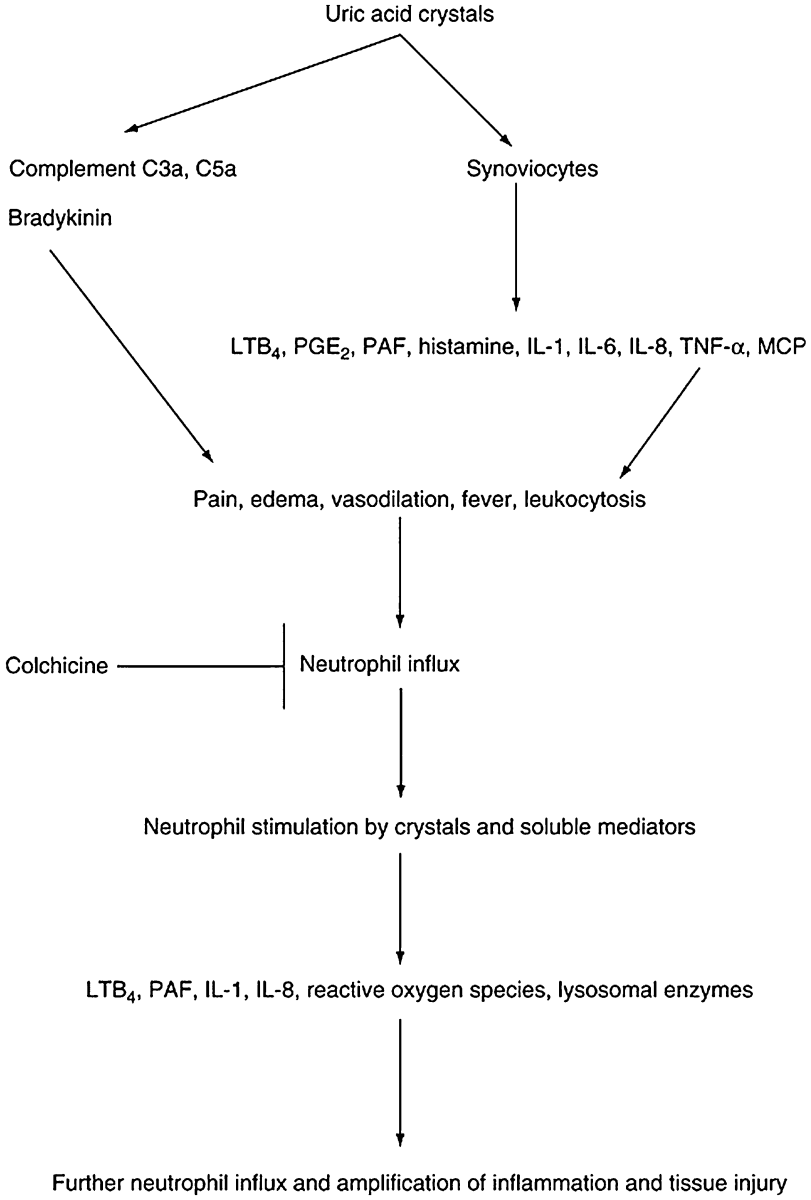
Antigout Drugs, Fig. 2 Reabsorption and secretion of uric acid in the proximal renal tubulus. (**a**) Normal situation. Uric acid is completely reabsorbed in the proximal segment of the renal tubulus and secreted more distally. (**b**) Situation in untreated hyperuricemia. In most genetically caused cases of gout, uric acid secretion is defective (*1*). (**c**) Situation in hyperuricemia under treatment with uricosouric drugs (*2*); inhibition of uric acid secretion by uricosuric drugs at low doses (*3*). Inhibition of uric acid secretion and reabsorption by uricosuric drugs in therapeutic doses. The inhibition of uric acid secretion with low doses of uricosuric drugs can further increase blood levels of uric acid and induce attacks of acute gouty arthritis

arthritis. With a serum uric acid level of 535 μmol/L, the annual incidence of gouty arthritis is 4.9–5.7%.

Hyperuricemia can have genetic causes or acquired causes. A defect of hypoxanthine-guanine phosphoribosyl transferase is the cause of Lesch–Nyhan syndrome, resulting in increased uric acid production. Among the genetically caused defects, impaired renal uric acid secretion is a very common cause of gout. Myeloproliferative diseases, a purine-rich diet (e.g., meat, beer, beans, peas, oatmeal, or spinach), obesity, and alcoholism are common causes of acquired hyperuricemia and result from increased uric acid production. Renal diseases and the application of certain drugs such as the tuberculostatic drug pyrazinamide, thiazide diuretics, loop diuretics, or acetylsalicylic acid at doses of up to 1–2 g/day and the immunosuppressant cyclosporin A are acquired causes of impaired uric acid secretion.

Gout is the consequence of hyperuricemia and is caused by uric acid deposits in joints, tendons, bursae, kidney, and urinary tract. In the USA, the prevalence of gout is $<1\%$ for all ages and both sexes. The prevalence of gout is higher in men than in women and exceeds 5% in men ≥ 65 years. These epidemiologic data are important for drug therapy since older patients are more sensitive to side effects of antigout drugs than younger patients. In the initial stage, gout is characterized by asymptomatic hyperuricemia. In the second stage, the disease manifests itself by acute gouty arthritis. The third (intercritical) stage is asymptomatic, and the fourth stage is characterized by progressive uric acid deposits in joints, tendons, bursae, kidney, and urinary tract (tophus formation). Uric acid deposits result in the deformation and loss of function of joints and recurrent episodes of urate lithiasis. Uric acid deposits in the kidney and urate lithiasis can ultimately result in renal failure.

Figure 3 illustrates important pathophysiologic events leading to acute gouty arthritis. Once the concentration of uric acid exceeds its solubility, uric acid crystals form in the synovial fluid of joints. Subsequently, the uric acid crystals are phagocytosed by synoviocytes that form the inner cell layer of joints. Next, synoviocytes release numerous mediators of inflammation including leukotriene B_4 (LTB_4), prostaglandin E_2 (PGE_2), platelet-activating factor (PAF), histamine, interleukins (ILs) 1, 6, and 8, and tumor necrosis factor-α that in conjunction with products of the complement cascade (C5a and C3a) and kinins (bradykinin) induce an

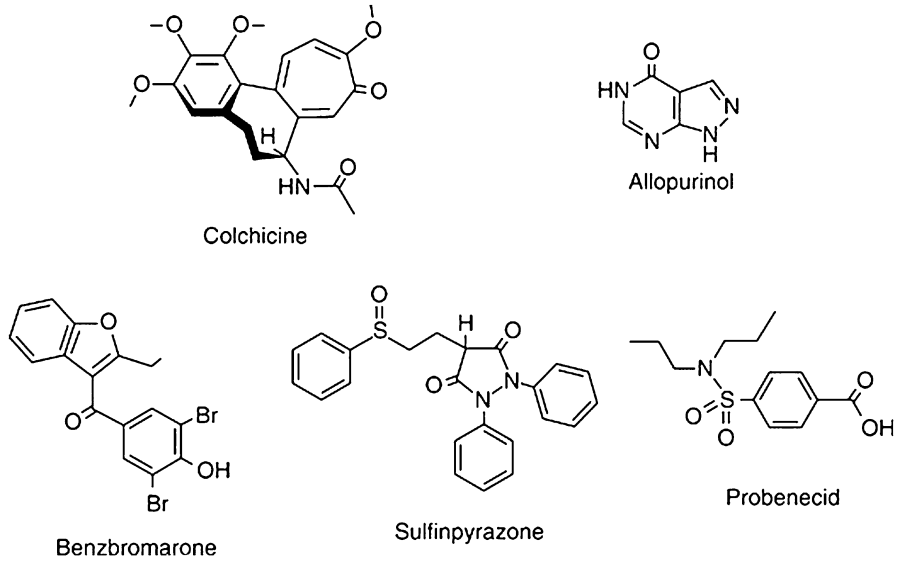


Antigout Drugs, Fig. 3 Important pathophysiologic events in acute gouty arthritis. Uric acid crystals activate the complement cascade, the formation of kinins, and the release of various mediators of inflammation from synoviocytes that phagocytose uric acid crystals. The combined action of the released mediators induces a strong inflammatory reaction that is further enhanced by neutrophils. Neutrophils migrate along a concentration gradient to loci in which C5a, LTB $_4$, PAF, and IL-8 are produced (chemotaxis). Accordingly, C5a, LTB $_4$, PAF, and IL-8 are also referred to as chemoattractants. Neutrophils phagocytose uric acid crystals. Upon exposure to uric acid crystals and chemoattractants, neutrophils release various mediators of inflammation, reactive oxygen species, and lysosomal enzymes. The concerted effects of all these compounds amplify the inflammatory reaction even further. Colchicine interrupts the vicious cycle of inflammation predominantly by inhibiting neutrophil chemotaxis. IL-1, interleukin 1; IL-6, interleukin 6; IL-8, interleukin 8; LTB $_4$, leukotriene B $_4$; MCP, monocyte chemoattractant protein; PAF, platelet-activating factor; PGE $_2$, prostaglandin E $_2$; TNF-α, tumor necrosis factor-α

inflammatory response. Moreover, LTB $_4$, PAF, C5a, and IL-8 attract polymorphonuclear leukocytes (neutrohpils). Neutrophils migrate into affected joints along a concentration gradient of these inflammatory mediators (chemotaxis). Accordingly, LTB $_4$, PAF, C5a, and IL-8 are also referred to as chemoattractants. Once present in joints, neutrophils phagocytose uric acid crystals. Uric acid crystals and chemoattractants trigger the release of cytotoxic lysosomal enzymes, NADPH oxidase-catalyzed formation of reactive oxygen species, LTB $_4$ formation, and the release of other proinflammatory molecules from neutrophils. The latter molecules attract additional neutrophils and mononuclear phagocytes. Moreover, neutrophils generate lactate that decreases the pH within the joint and further accelerates uric acid crystal formation. Oxygen radicals and lysosomal enzymes cause damage to tissues. Thus, the presence of uric acid crystals in joints triggers a vicious cycle, resulting in an extremely painful inflammation. A typical localization of acute gouty arthritis is the first metatarsal joint of the foot (podagra). The diagnosis of acute gouty arthritis is confirmed by the detection of urate crystals in the joint or tophus.

Antigout Drugs

Figure 4 shows the structures of commonly employed antigout drugs. The treatment of acute gouty arthritis aims at rapidly reducing the pain and inflammatory reaction Emmerson 1996; Frampton 2015; Khanna et al. 2014; Lange et al. 2001; Schlesinger and Schuhmacher 2001). This aim can be achieved by treatment with colchicine. In addition, nonsteroidal anti-inflammatory drugs (NSAIDs), glucocorticoids, and adrenocorticotropic hormone (ACTH) can be used to treat acute gouty arthritis. However, since NSAIDs and glucocorticoids are used in numerous other commonly occurring inflammatory conditions, they are not per se considered specific antigout drugs. Glucocorticoids can be given systemically (orally, intramuscularly, or intravenously) or locally into afflicted joints. The long-term goals of gout treatment are the prevention of acute gouty arthritis, the prevention of urate lithiasis and renal failure, and the resorption of existing uric acid deposits in



Antigout Drugs, Fig. 4 Structures of commonly used antigout drugs. Colchicine is an alkaloid from the autumn crocus *Colchicum autumnale* and inhibits tubulin polymerization. Allopurinol is an isomer of xanthine and inhibits uric acid formation (uricostatic drug). Benzbromarone, sufinpyrazone, and probenecid are uricosuric drugs and inhibit uric acid reabsorption in the proximal tubulus of the kidney

the joints and urinary tract. The long-term therapy aims at reducing the serum concentration of uric acid below 357 μmol/L. Therapy with the uricostatic drug allopurinol and the uricosuric drugs benzbromarone, sulfinpyrazone, or probenecid can accomplish the long-term goals. These drugs are well tolerated in most patients. Uricostatic and uricosuric drugs can be combined. Additionally, low doses of colchicine can be used to prevent the occurrence of acute gouty arthritis. However, as is unfortunately often the case with classic diseases, there are only few well-conducted clinical studies assessing the clinical efficacy and safety of antigout drugs.

Mechanism of Action

Colchicine

Colchicine is an alkaloid from the autumn crocus *Colchicum autumnale.* Colchicine binds to the cytoskeletal protein tubulin and, thereby, prevents microtubule formation. As a result, colchicine inhibits neutrophil chemotaxis and the influx of these cells into areas containing uric acid crystals (Fig. 3). Colchicine also inhibits neutrophil phagocytosis. As a result, colchicine interrupts the vicious cycle of inflammation in gouty arthritis. However, because of its mechanism of action, colchicine is most effective only when given in the early stages of gouty arthritis, that is, within 24 h. Otherwise, the inflammatory reaction may be too advanced. Specifically, colchicine is effective in >90% of patients when given within the first few hours after the start of the attack, but after 24 h, the responsiveness decreases to 75%. Given the very significant side effects of colchicine, it is absolutely crucial to initiate colchicine therapy as early as possible.

Allopurinol

Allopurinol is an analog of hypoxanthine and is converted to alloxanthine by XOD. Both allopurinol and hypoxanthine inhibit XOD (Fig. 1). Alloxanthine is a noncompetitive inhibitor of XOD as is allopurinol at high concentrations. At low concentrations, allopurinol is a competitive inhibitor of XOD. As a result of XOD inhibition, the formation of the poorly soluble uric acid is reduced, whereas the formation of the more soluble metabolites hypoxanthine and xanthine is increased. Because of the good solubility of hypoxanthine and xanthine, formation of hypoxanthine/xanthine crystals is a rare complication of allopurinol treatment. Another consequence of XOD inhibition is the accumulation of the precursor of xanthine, inosine. Inosine inhibits the key enzyme of de novo purine synthesis, phosphoribosyl-pyrophosphate amidotransferase. The allopurinol metabolite allopurinol ribonucleotide also inhibits phosphoribosyl-pyrophosphate amidotransferase. Inhibition of purine biosynthesis contributes to the antihyperuricemic effects of allopurinol.

Uricosuric Drugs

Depending on the dose applied, uricosuric drugs inhibit tubular reabsorption and tubular secretion of uric acid in the kidney differentially (Fig. 2). At low (subtherapeutic) doses, uricosuric drugs inhibit uric acid secretion without inhibiting reabsorption. Therefore, low doses of uricosuric drugs can actually increase serum levels of uric acid and trigger acute attacks of gouty arthritis. At higher, that is, therapeutic doses, uricosuric drugs inhibit both tubular secretion and tubular reabsorption. Since inhibition of tubular reabsorption is quantitatively more important than inhibition of tubular secretion, the net effect is an increased renal elimination of uric acid. In order to avoid formation of uric acid crystals in the kidney and urinary tract, it is important that the pH of the urine is kept >6.0. This goal can be achieved by the oral administration of potassium sodium hydrogen citrate, sodium bicarbonate, or acetazolamide. In addition, it is mandatory that the patient drinks at least 3 L per day to avoid formation of uric acid crystals.

New Drugs

Febuxostat is a highly potent mixed-type inhibitor of XOD with Ki values in the 0.5–3 nM-range. Febuxostat displays high selectivity relative to a large number of other purine- and pyrimidine-metabolizing enzymes.

Canakinumab is a humanized monoclonal antibody neutralizing IL-1. By this mechanism, canakinumab exerts an anti-inflammatory effect.

Clinical Use (Including Side Effects)

Colchicine

Daily doses of 3–8 mg (6–8 times 0.5–1.0 mg) are used for the treatment of acute gouty arthritis. For prophylaxis, daily doses of 0.5–1.5 mg are used, but the use of colchicine for prophylaxis is controversial. The side effects of colchicine are very significant. About 80% of the patients experience gastrointestinal problems including nausea, vomiting, and diarrhea. The antimitotic effects of colchicine can result in thrombocytopenia, agranulocytosis, hair loss, and azoospermia. In the central nervous system, confusion, ascending paralysis, respiratory failure, and seizures have been reported. These side effects can be explained by the fact that intact microtubules are essential for proper transport functions in neuronal axons. Moreover, colchicine can cause myopathy. Because of the significant side effects, many physicians prefer to treat acute gouty arthritis with NSAIDs or glucocorticoids. Although colchicine is a classic antigout drug, colchicine can also be used to treat other inflammatory diseases including amyloidosis, Dupuytren's contracture, Behcet's syndrome, vasculitis, various forms of hepatic cirrhosis, pulmonary fibrosis, pericarditis, and various inflammatory diseases of the skin. Colchicine is extensively metabolized through the hepatic cytochrome CYP 3A4. Accordingly, inhibitors of CYP 3A4 such as diltiazem, gestodene, grapefuit juice, ketoconazole, and macrolide antibiotics prolong and enhance the pharmacological (and toxic) effects of colchicine. Drugs that are inactivated via CYP 3A4 such as steroid hormones, lidocaine, midazolam, quinidine, terfenadine, nifedipine, and verapamil can also prolong colchicine action. Because of its antimitotic effects, colchicine should not be used in pregnant women.

Allopurinol

The daily dose of allopurinol is 300–600 mg. In combination with benzbromarone, the daily allopurinol dose is reduced to 100 mg. In general, allopurinol is well tolerated. The incidence of side effects is 2–3%. Exanthems, pruritus, gastrointestinal problems, and dry mouth have been observed. In rare cases, hair loss, fever, leukopenia, toxic epidermolysis (Lyell syndrome), and hepatic dysfunction have been reported. Allopurinol inhibits the metabolic inactivation of the cytostatic drugs azathioprine and 6-mercaptopurine. Accordingly, the administered doses of azathioprine and 6-mercaptopurine must be reduced if allopurinol is given simultaneously.

Uricosuric Drugs

Benzbromarone The daily dose of benzbromarone is 50–200 mg. In combination with allopurinol, the benzbromarone dose is reduced to 20 mg. Benzbromarone is well tolerated. Rare side effects are headaches, gastrointestinal problems, and exanthems.

Probenecid The daily dose of probenecid is 0.5–3.0 g. Probenecid is well tolerated, and there are few serious side effects. In less than 10% of the treated patients, gastrointestinal disturbances, hypersensitivity, and skin reactions occur.

Sulfinpyrazone The daily dose of sulfinpyrazone is 200–400 mg. The side effects of sulfinpyrazone are comparable with those of probenecid. A potential therapeutic advantage of sulfinpyrazone in patients with coronary heart disease and thromboembolic diseases is its inhibitory effect on platelet aggregation.

Inflammation

New Drugs

Febuxostat The daily dose of febuxostat is 80–120 mg. The drug is used in chronic gout in cases in which allopurinol is ineffective or not tolerated. Febuxostat causes vomiting, diarrhea, headache, and allergic reactions. There is an ongoing discussion whether the use of febuxostat is associated with an increased cardiovascular risk.

Canakinumab Canakinumab is a "biological" and has to be injected subcutaneously. The drug is used in acute gout in cases in which NSAIDs, colchicine, or glucocorticoids are ineffective or not tolerated. Canakinumab can cause allergic reactions at the injection site and infections of the respiratory or urinary tract.

Synonyms

Antihypertensives; Blood pressure lowering drugs

Definition

Reducing blood pressure by pharmacological means reduces cardiovascular morbidity and mortality rates. Benefits include protection from stroke, coronary events, heart failure, progression of renal disease, progression to more severe hypertension, and, most importantly, mortality from all causes. Owing to the complexity of the pathogenesis of hypertension, antihypertensive drugs are directed against a variety of pharmacological targets in various cell types in different organs involved in blood pressure control.

Mechanism of Action

The fundamental mechanisms involved in blood pressure control have been outlined in chapter "► Blood Pressure Control." In addition to direct neuronal modulation of arterial pressure, two neurohumoral systems, i.e., the sympathetic nervous system and the renin–angiotensin–aldosterone system (RAS), play a pivotal role in blood pressure control. Both systems are always either directly or indirectly affected by treatment with any antihypertensive drug. The most important antihypertensive agents for clinical use can be categorized into eight different drug classes (Table 1, Fig. 1).

Angiotensin-Converting Enzyme (ACE) Inhibitors

The core of the RAS pathway involves the conversion of angiotensinogen to angiotensin I (Ang I) by renin followed by its conversion to angiotensin II (Ang II) by ►angiotensin-converting enzyme (ACE). This class of drugs inhibits competitively the activity of ACE to decrease the availability of Ang II at both angiotensin type 1 (AT1) and angiotensin type 2 (AT2) receptors in the blood and tissues including the vasculature, kidney, heart, and brain (Paul et al. 2006; Arendse et al. 2019). Ang II, the main effector of the RAS, is a potent vasoconstrictor and promotes aldosterone synthesis and secretion, thus increasing sodium and water reabsorption and increasing blood pressure. Blocking the production of Ang II results in vasodilation of small resistance arteries, reduction in total peripheral resistance, and blood pressure lowering while preserving cardiac output. ACE inhibitors blunt the expected increase in sympathetic nervous activity typically seen after vasodilation, hence preventing the increase in heart rate despite blood pressure lowering (Benowitz 2015). Their use is not associated with postural hypotension, presumably due to a reset of baroreceptor function.

Nevertheless, ACE inhibitors could only partially block the RAS due to production of Ang II by alternative non-ACE enzymatic pathways, such as chymase which can attenuate the blood pressure lowering effect of ACE inhibitors during chronic therapy (Arendse et al. 2019). In this respect, other

Antihypertensive Drugs, Table 1 Common side effects, contraindications, and clinical application of antihypertensive drugs

Class of drug		Side effects	Selected contraindications	Clinical use
Primary agents				
ACE inhibitors		Cough, hyperkalemia, angioedema	Pregnancy, hyperkalemia, bilateral renal artery stenosis, history of ACE inhibitor-associated angioedema	First line
ARBs		Hyperkalemia	Pregnancy, hyperkalemia, bilateral renal artery stenosis	First line
Beta-blockers		Fatigue, hyperglycemia, bronchospasm, weight gain bradycardia, sinoatrial or atrioventricular block, dyslipidemia, vivid dreams	Asthma, bradycardia, high-grade sinoatrial or atrioventricular block	First line[a]
CCBs	DHP	Edema, headache, flushing, tachycardia, gingival hypertrophy	Tachyarrhythmia, heart failure (HFrEF, class III or IV), preexisting severe leg edema	First line
	Non-DHP	Bradycardia, sinoatrial or atrioventricular block, gingival hypertrophy	High-grade sinoatrial or atrioventricular block, bradycardia, severe left ventricular dysfunction (LV ejection fraction <40%), constipation	First line[b]
Diuretics	Thiazide and thiazide-like	Hyperuricemia, hyperglycemia, hyperlipidemia, hypokalemia, dyslipidemia, metabolic alkalosis	Gout, metabolic syndrome glucose intolerance, hypercalcemia, hypokalemia, pregnancy	First line
Secondary agents				
Diuretics	Loop diuretics	Ototoxicity, hypovolemia, hyperuricemia, hypomagnesemia	Gout, metabolic syndrome glucose intolerance, pregnancy	If GFR < 30 ml/min/1.73 m^2
Potassium-sparing diuretics	MRA	Hyperkalemia, gynecomastia (spironolactone > eplerenone)	Severe renal impairment (GFR < 30 mL/min/1.73 m^2), hyperkalemia	Resistant hypertension[c]
	ENaC inhibitors	Hyperkalemia, metabolic acidosis	Severe renal impairment (GFR < 30 mL/min/1.73 m^2), hyperkalemia	Hypokalemia, resistant hypertension (amiloride)
Alpha-blockers		Orthostatic hypotension, rapid drop of blood pressure after first dose, dizziness, fluid retention, incontinence	History of orthostatic hypotension	Resistant hypertension, men with prostatic disease
Centrally acting sympatholytics	α_2-receptor agonists	Somnolence, dry mouth, rebound hypertension	Severe depression	Resistant hypertension, last line
	Imidazoline-receptor agonists

Antihypertensive Drugs, Fig. 1 Site of action of different classes of antihypertensive drugs. Antihypertensive drugs are directed against a variety of pharmacological targets in various cell types in different organs involved in blood pressure control. The most important targets in the brain, heart, vasculature (vascular smooth muscle cells), and the kidney (nephron) are shown. Non-ACE-dependent conversion of angiotensin I (Ang I) to angiotensin II (Ang II) may occur independent from ACE due to the activity of other enzymes in different tissues such as chymase in the heart; (−) indicates inhibition. *ACEi* ACE inhibitors, *ANP* atrial natriuretic peptide, *ARB* angiotensin receptor blocker, *ARNI* angiotensin receptor–neprilysin inhibitor, *BNP* B-type natriuretic peptide, *CCBs*, calcium channel blockers, *CCT* cortical collecting duct, *DCT* distal convoluted tubule, *ENaC* epithelial sodium channel, *MR* mineralocorticoid receptor, *MRA* mineralocorticoid receptor antagonist, *NEP* neprilysin, *TAL* thick ascending limb of the loop of Henle, *sGC* soluble guanylate cyclase. *Indicates targets for novel antihypertensive drug development

hemodynamic mechanisms may be important. The accumulation of kinins, including bradykinin, secondary to inhibition of ACE (known also as kininase II) that promotes vasodilation has been suggested to contribute to the overall antihypertensive effect of ACE inhibitors (Arendse et al. 2019). In addition, ACE is responsible for the degradation of angiotensin (1–7) which is an important part of

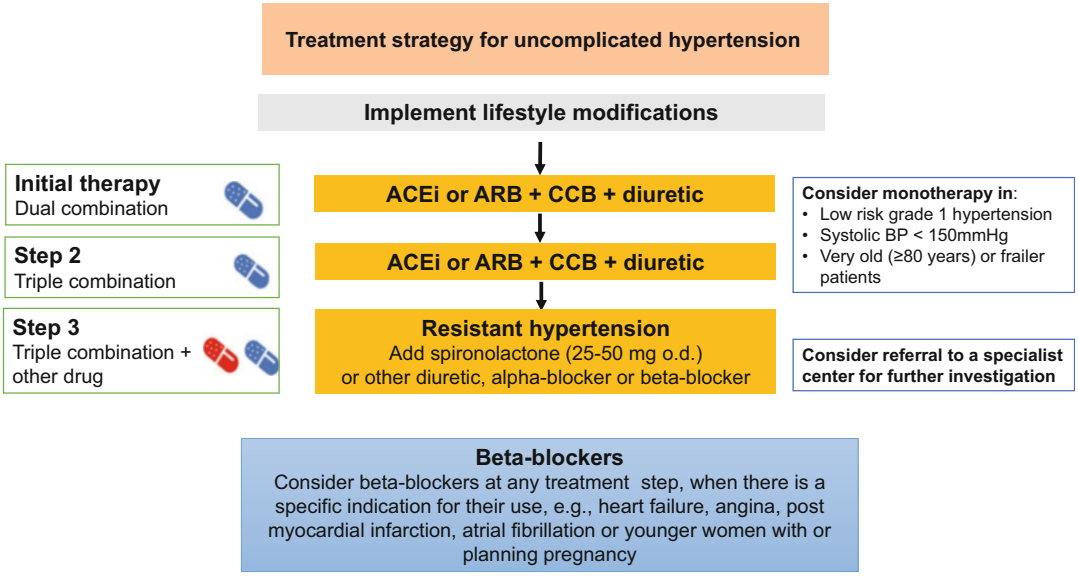
the counter regulatory pathway within the RAS. As a result, ACE inhibitors may increase the plasma concentration of the vasodilator peptide angiotensin (1–7) (Arendse et al. 2019). Independent of its hemodynamic effects, Ang II mediates a variety of adverse processes related to cell growth, inflammation, and vascular remodeling which contribute to hypertensive target organ damage. Consequently, the inhibition of tissue ACE (Paul et al. 2006) plays an important role for the prevention and regression of hypertension-mediated organ damage (Arendse et al. 2019).

Angiotensin Receptor Blockers (ARBs)

In contrast to ACE inhibitors, ARBs attenuate the effects of Ang II on vascular tone by directly blocking AT1 receptors, thereby promoting reduction in the total peripheral resistance with no effect on either the cardiac output or heart rate. At the same time, they exert the same favorable effects on cell proliferation and inflammation protecting against target organ damage. Their direct interaction at the receptor level overcomes some of the shortcomings of ACE inhibitors, namely, the reactive increase in renin and Ang I levels and the production of Ang II by non-ACE pathways (Arendse et al. 2019). The absence of accumulation of kinins that may be responsible for some of the beneficial effects of ACE inhibitors but also their side effects, especially cough as well as angioedema, is another difference. Due to their high selectivity, ARBs do not interact with AT2 receptors whose functions tend to oppose actions of the AT1 receptor and exhibit vasodilatory and antiproliferative effects upon stimulation by Ang II (Arendse et al. 2019; Paul et al. 2006). During chronic therapy with RAS blockers, the feedback inhibition of renin release is suppressed leading to reactivation of the RAS cascade and Ang II production. The latter may interact with unblocked AT2 receptors enhancing vasodilation and further blood pressure reduction. The combination of vasopeptidase inhibitors with ARBs is a novel approach to promote natriuresis in addition to vasodilation by simultaneous inhibition of neutral endopeptidase (NEP) and the RAS. This results in more pronounced blood pressure lowering than that exerted by either approach alone. NEP inhibitors increase the availability of vasodilatory peptides such as atrial (ANP), B-type (BNP), and C-type (CNP) natriuretic peptides (Volpe 2014). A novel antihypertensive agent LCZ696 is the first angiotensin receptor–neprilysin inhibitor (ARNI), consisting of the neprilysin inhibitor sacubitril in combination with valsartan, and has been shown effective in treatment of hypertension (Ruilope et al. 2010) although approval and market access for this compound was achieved for the treatment of heart failure (McMurray et al. 2014).

Beta-Blockers

Beta-blockers constitute a heterogeneous group of antihypertensive agents that competitively antagonize the effects of catecholamines at adrenergic beta-adrenoceptors. Beta-blockers differ in their receptor selectivity and the presence of additional intrinsic sympathomimetic activity (ISA) whereby an agent partially stimulates the receptor. Beta-blockers with ISA are generally not recommended anymore since partial agonism failed to prove significant clinical benefits (Benowitz 2015). The mechanisms by which beta-blockers lower blood pressure are still not fully elucidated, likely involving several modes of action. A short-term mechanism is the reduction of cardiac output through their negative chronotropic (heart rate lowering) and inotropic effects. However, this is not the primary blood pressure lowering mode of action because the ensuing baroreceptor stimulation would increase peripheral resistance. Cardiac output usually falls only acutely but returns to normal during chronic treatment, while long-term lowering of blood pressure occurs because of late lowering of peripheral vascular tone. Thus, the hemodynamic hallmark of chronic established hypertension, which is an increased peripheral resistance in the majority of cases, is also normalized by beta-blockers. Other possible mechanisms include inhibition of renin secretion from the kidneys, decrease in plasma Ang II and catecholamines levels, and central reduction in sympathetic outflow reducing vasomotor tone (Laurent 2017). In addition, prejunctional beta



Antihypertensive Drugs, Fig. 2 Synopsis of the treatment strategy for uncomplicated hypertension. The drug treatment strategy shown represents the core treatment strategy for patients with uncomplicated hypertension according to the 2018 European guidelines (Williams et al. 2018). This strategy is also appropriate for most patients with hypertension-mediated organ damage, cerebrovascular disease, diabetes, peripheral artery disease or the elderly

receptors may also be stimulated which leads to a decline in norepinephrine release and hence adrenergic drive. Currently used beta-blockers are usually classified into three different classes: (i) nonselective beta-blockers that block both beta-1 and beta-2 receptors (e.g., propranolol); (ii) beta-1 selective or *cardioselective* beta-blockers (e.g., atenolol, bisoprolol, and metoprolol) that preferentially block beta-1 receptors; and (iii) beta-blockers with additional vasodilatory effects (e.g., carvedilol and nebivolol). Of interest, beta-selectivity of the available beta-blockers for clinical use is poor (Baker 2005). Thus, when used in usual dosages, they block both beta-1 and beta-2 receptors. The additional vasodilatory effect elucidated by carvedilol is based on its capacity to block adrenergic alpha-1 receptors in the arteries, while the vasodilatory action of nebivolol results from nitric oxide release possibly due to activation of beta-3 receptors (Ignarro 2008). The latter two drugs could be therefore preferred as antihypertensive drugs, because of this vasodilatory effect and their improved tolerability and metabolic profile which has been also linked to this action (Ayers et al. 2012). Finally, beta-blockers exhibit a wide variation in their pharmacokinetics and their lipophilic or hydrophilic properties. Lipophilic agents such as labetalol, metoprolol, pindolol, and propranolol have relatively short plasma half-lives, cross blood–brain barrier, and exhibit wide interindividual variability compared to more hydrophilic agents, e.g., atenolol.

Calcium Channel Blockers

Calcium channel blockers (CCBs) inhibit the influx of extracellular calcium through binding to the L-type voltage-gated Ca^{2+} channels located on the vascular smooth muscle, cardiac myocytes, and cardiac nodal tissue (sinoatrial and atrioventricular nodes). The inhibition of inward calcium flux causes relaxation of vascular smooth muscle cells mainly in the arterial bed and promotes vasodilation and lowering of blood pressure. In cardiac muscle, they reduce cardiac contractility and slow conduction velocities in cardiac nodal tissue. All available CCBs are vasodilators acting primarily by reducing the total

peripheral resistance to reduce blood pressure (Laurent 2017). They are a heterogeneous group of compounds that vary in their structure as well as their vascular and cardiac selectivity. They can be divided into two different main classes (dihydropyridines and non-dihydropyridines) that work on different sites within the L-channel and hence produce different effects in the heart and vasculature. The dihydropyridine (DHP) (e.g., nifedipine and amlodipine) exhibit less cardiac depressant properties. Therefore, DHP CCB, particularly rapid- and short-acting agents, may induce unpredictable blood pressure decline and reflex tachycardia due to baroreflex stimulation. Short-acting dihydropyridine formulations have, therefore, been modified to slow-release formulations (in some cases, e.g., for nifedipine) or replaced by longer-acting ones to overcome these disadvantages and to improve the tolerability and safety of DHP CCBs.

The non-dihydropyridine (non-DHP) type, further subdivided into benzothiazepines, such as diltiazem, and phenylalkylamines, such as verapamil, attenuate the increase in heart rate in response to blood pressure lowering or exercise due to their negative chronotropic (verapamil > diltiazem) effects. In addition, they are in parallel to beta-blockers' negative dromotropic drugs and can be therefore used as alternatives to beta-blocker therapy when heart rate control is needed, e.g., in patients with atrial fibrillation (Williams et al. 2018). CCBs have a high first-pass effect, and all compounds are substrate of cytochrome P450 3A4 (CYP3A4) and p-glycoprotein (P-gp) (Algharably and Kreutz 2019). The non-DHP CCB verapamil and diltiazem are, in addition, moderate to strong inhibitors of CYP3A4 and P-gp (Algharably and Kreutz 2019). Hence, unlike most of the other antihypertensive drugs, verapamil and diltiazem have a potential to cause pharmacokinetic drug–drug interactions with drugs that are substrates of CYP3A4 and/or P-gp, e.g., simvastatin.

Diuretics

All diuretics act primarily by impairing sodium reabsorption in the renal tubules, thus increasing its excretion. They differ in their mode of action that relates to their major site of action within the nephron. These differences determine their relative efficacy, as expressed in the maximal percentage of filtered sodium excreted, and determine their pharmacological effects as well as clinical indications for each type of diuretic (Sarafidis et al. 2010).

Thiazide (e.g., hydrochlorothiazide or bendroflumethiazide) and thiazide-like (chlorthalidone or indapamide) diuretics that are functionally related compounds are referred to sometimes only as thiazide diuretics in the literature (Sarafidis et al. 2010). They act by inhibiting the Na^+/Cl^- cotransporter in the distal convoluted tubule of the kidney, where only ~5–10% of filtered NaCl is reabsorbed (Tamargo et al. 2014). The increased water loss is secondary to the increased excretion of NaCl. Thiazides are less potent than loop diuretics that act proximally at the ascending limb of the loop of Henle (Sarafidis et al. 2010). Thiazide diuretics lower blood pressure through a triphasic mechanism: (i) a short-term (i.e., first 2–4 weeks) reduction in extracellular fluid volume followed by reduction of cardiac output which is counteracted by reactive rise in sympathetic activity, plasma renin, and subsequent transient increase in peripheral resistance, thus opposing the blood pressure lowering effect; (ii) long-term effects, where gradual reduction in peripheral vascular resistance due to sodium loss occurs while cardiac output and plasma volume return to pretreatment levels; and (iii) chronic antihypertensive effect reached after about 2 months due to a persistent reduction in peripheral resistance, while a new steady state of reduced total body sodium and blood pressure is established. Hydrochlorothiazide, chlorthalidone, and indapamide represent the most frequently used thiazide/thiazide-like diuretics with chlorthalidone being the longest-acting agent.

Loop diuretics exert their effects at the thick ascending limb of the loop of Henle, where about 30% of filtered Na^+ is reabsorbed by inhibiting ►$Na^+/K^+/2Cl^-$ cotransport (►Na+/K+/$2Cl^-$ cotransporter). Loop diuretics are more potent diuretics than thiazides, but they have shorter half-lives and induce more pronounced reflex stimulation of the sympathetic nervous activity and RAS, which attenuates their blood pressure lowering efficacy (Laurent 2017). In the kidney, loop diuretics maintain or increase even the glomerular filtration rate (GFR) by prostaglandin-

mediated dilation of the afferent arteriole and by blocking of the tubuloglomerular feedback mechanism (Sarafidis et al. 2010). For all diuretics, active secretion via an organic acid transporter in the proximal tubule is important to reach their luminal site of action. Their concentration at the site of action determines the diuretic response. Unlike thiazide diuretics, loop diuretics present a sigmoidal relation between the natriuretic response and the amount of diuretic reaching their site of action. A maximally effective dose can therefore completely block Na^+ reabsorption. However, they have no place in the routine management of hypertension in patients with normal renal function due to their shorter duration and profound effects on natriuresis and diuresis. Their use is reserved to patients with severe renal impairment (e.g., when GFR is <30 mL/min/1.73 m^2) or in patients with severe edematous disorders (i.e., cardiac failure, nephrotic syndrome) when control of volume status is needed.

Potassium-Sparing Diuretics

Potassium-sparing diuretics act primarily at the cortical collecting duct, where about 3% of the filtered Na^+ load is reabsorbed, producing weaker natriuretic effects compared to loop diuretics and thiazide diuretics that act more proximally in the nephron (Sarafidis et al. 2010). They block the action of the epithelial Na^+ channel (ENaC) either directly (ENaC inhibitors) or indirectly (mineralocorticoid receptor antagonists; MRA). The ENaC inhibitors (amiloride, triamterene) block their target in the luminal membrane of the collecting duct, independently of aldosterone. They reduce aldosterone-sensitive sodium-potassium exchange and increase urinary sodium excretion coupled with relative potassium-sparing effect. Mineralocorticoid receptor antagonists (e.g., spironolactone and eplerenone) competitively inhibit the binding of aldosterone to the nuclear mineralocorticoid receptors in collecting duct cells and render them transcriptionally inactive for the synthesis of ENaC and subunits of the Na^+K^+-ATPase pump (Sarafidis et al. 2010).

Although ENaC accounts only for a minor fraction of sodium exertion, this channel plays a major role in maintaining sodium and potassium homeostasis as well as in blood pressure control.

Additional Antihypertensive Drugs

These agents are not generally recommended for the routine treatment of hypertension, but rather used as add-on therapy in patients with resistant hypertension or used in hypertensive patients with specific comorbid conditions responsive to them.

Alpha-Blockers

Prazosin, terazosin, and doxazosin are alpha-blockers available for the treatment of hypertension, although prazosin due to its short half-life (3–4 h) is no longer preferred. They selectively block α_1-adrenoceptors in the vasculature, leading to vasodilation in both resistance and capacitance vessels and lowering of blood pressure. By selective blocking of α_1-receptors, local feedback control mechanisms involving prejunctional α_2-receptors within the neurovascular junction are spared, thus reducing the risk of reflex sympathetic activation and cardiac stimulation during chronic treatment. Their effect on blood pressure is more prominent in the upright position or during exercise. On the long term, peripheral resistance is reduced with little or no change in cardiac output, heart rate, and cardiac index (Laurent 2017).

Centrally Acting Sympatholytic Agents

These agents interfere with sympathetic outflow from vasomotor centers in the brainstem but allow these centers to retain or even increase their sensitivity to baroreceptor control. This type of drugs can be classified according to their relative affinities to α_2- and/or imidazoline (I_1) receptors (Benowitz 2015). The most commonly used drugs are clonidine, moxonidine, and rilmenidine, all of which are considered as a mixed α_2- and I_1-agonist; clonidine has a higher affinity for α_2- and moxonidine/rilmenidine for I_1-receptors (Prichard and Graham 2000). Clonidine lowers blood pressure by decreasing both cardiac output and total peripheral resistance. Methyldopa, on the other hand, is a selective α_2-agonist. After metabolic conversion, methyldopa decreases sympathetic outflow and lowers blood pressure by reducing peripheral vascular resistance with a variable reduction in heart rate and cardiac output (Benowitz 2015).

Vasodilators

The direct vasodilator minoxidil works by opening potassium channels in vascular smooth muscle cells in arterioles, which leads to K^+ efflux and hyperpolarization. The latter inhibits Ca^{2+} influx through voltage-gated calcium channels. The mechanisms of action of hydralazine are not fully understood but may ultimately involve an altered calcium balance in vascular smooth muscles via an unidentified primary target (Knowles et al. 2004). Another possible mechanism may involve enhancing nitric oxide release from the vascular endothelium by increasing nitric oxide synthase expression (Xu et al. 2017). Blood pressure is lowered due to vasodilation but since the heart is not directly affected, direct vasodilators lead, when used alone, to a significant neurohumoral activation of both the sympathetic nervous system and RAS resulting in increases in heart rate and force of contraction as well as fluid retention.

In addition to these classes of antihypertensive drugs, several new drug classes involving targets inside and outside the RAS system are currently being developed at either the preclinical or clinical stage (Kreutz and Algharably 2016). Some additional novel drugs with blood pressure lowering potential are already in clinical use for the treatment of hypertension (esaxerenone; a novel nonsteroidal MRA) or other associated diseases such as pulmonary arterial hypertension (riociguat; a sGC activator) or heart failure (sacubitril; a neprilysin inhibitor).

Clinical Use

The mainstay in the management of arterial hypertension is the implementation of healthy lifestyle, and several lifestyle changes are recommended in current guidelines that may be sufficient to delay or prevent the need for drug therapy (Williams et al. 2018; Whelton et al. 2018). Nevertheless, most patients will require drug therapy in addition to lifestyle measures to achieve optimal blood pressure control. Despite subtle differences between international guideline recommendations, there are still five major (first line) drug classes that are recommended for drug treatment of hypertension (Williams et al. 2018; Whelton et al. 2018). These classes include ACE inhibitors, ARBs, beta-blockers, CCBs, and diuretics (thiazides and thiazide-like diuretics). This rationale is based on evidence from placebo-controlled studies that demonstrated their efficacy to reduce cardiovascular events, morbidity, and mortality (Williams et al. 2018). These studies also demonstrated that this benefit predominantly derives from their blood pressure lowering effect without significant differences among the five classes. However, when compared with other remaining four classes, beta-blockers are considered to be less effective in the prevention of stroke (Williams et al. 2018; Whelton et al. 2018; Wright et al. 2018). Consequently, in some guidelines they are not considered as first-line agents anymore. In the 2018 European guidelines of the European Society of Cardiology and European Society of Hypertension for the management of arterial hypertension, they are still considered as first-line agents, but their use in uncomplicated hypertension is limited. Accordingly, their use is preferred in patients with specific indications (Fig. 2). The backbone in the recommended core drug treatment strategy is the use of an ACE inhibitor or an ARB, while their combination is not recommended, because dual inhibition with both ACE inhibitors and ARB causes more harm than benefit. Thus, either RAS blocker in combination with a CCB or a thiazide/thiazide-like diuretic can be used as dual combination therapy for the initiation of treatment in the majority of patients. To increase adherence to therapy, the use of single-pill combinations is encouraged. A summary of important side effects and absolute or relative contraindications for the different antihypertensive drug classes is shown in Table 1. Although there is no consensus between treatment goals among guideline recommendations (Williams et al. 2018; Whelton et al. 2018), systolic and diastolic blood pressure should be lowered below systolic 140–130 and diastolic 80 mmHg in most patients. If blood pressure control is not achieved, the use of triple therapy by combining one RAS blocker with a CCB and diuretic is recommended. About 10% of patients exhibit resistant hypertension, i.e., they cannot be controlled with the recommended triple therapy. In this condition low-dose spironolactone is the

preferred drug for additional treatment, based on a randomized, double-blind, crossover trial (Williams et al. 2015).

As an alternative for drug treatment, interventional therapies such as renal denervation and baroreflex activation have been recently developed for the treatment of arterial hypertension (Williams et al. 2018; Schmieder et al. 2018). Additional novel non-pharmacologic interventional approaches include carotid body ablation and arteriovenous fistula placement, but renal denervation represents the most advanced approach (Schmieder et al. 2018). The long-term safety and efficacy of this method and its value on top or as an alternative for drug treatment therapy of hypertension remain to be established.

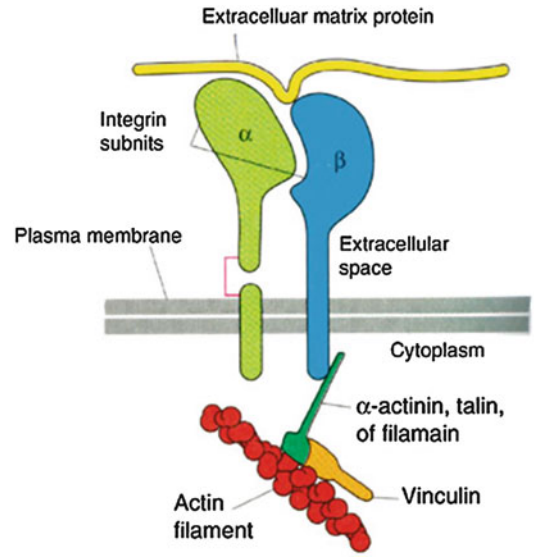
Definition of Integrin

Integrins are heterodimeric proteins of the plasma membrane that are critical to cell-cell interactions and to interactions of the cell with extracellular matrix (ECM) proteins. These physical interactions are critical to individual cell migration paths and multicellular tissue structure. There are 24 or more integrins, each composed of one of 18 monomeric alpha subunits and one of 8 beta subunits (Seguin et al. 2015). Each heterodimeric integrin binds to at least one ECM protein. Such interactions result in a conformational change in the integrin ("activation") (Arnout 2002; Arnaout et al. 2007; Ginsberg 2014). The physical changes in the extracellular integrin component generate intracellular signals via induced changes in the cytoplasmic components ("feet") of the integrins (Fig. 1). These cytoplasmic extensions in cancer cells of the integrin change their physical relationships with components of signal transduction pathways to regulate downstream functions such as the cell cycle and mechanisms of apoptosis (Davis et al. 2016). Specific integrins may act on blood vessel cells to modulate angiogenesis (Eliceiri and Cheresh 1998).

Alterations in the conformation of the large extracellular component of the integrin expose (or obscure) receptor sites for other large molecule ligands in the extracellular space or, as is now



Anti-integrins, Fig. 1 Diagrammatic representation of integrin inside-out signaling and integrin activation, which require conformational switch from bent-closed or extended-closed to extended-open confirmation

known, of extracellular small molecule ligands. As discussed below, such ligands include thyroid hormone analogues (Bergh et al. 2005; Davis et al. 2016) or steroid or steroid-like molecules (Lin et al. 2009).

Anti-integrin

The concept that the substantial extracellular domain of integrins may be manipulated by naturally occurring factors such as ECM proteins – for example, fibronectin, vitronectin, and von Willebrand factor – prompted investigators to search for pharmacologic ligands that might alter normal cell function or the functions of cancer and endothelial cells. Such protein ligands are designated **anti-integrins**. Protein ligands of integrins may contain similar short amino acid sequences, for example, Arg-Gly-Asp (RGD), and such short peptides can serve as anti-integrins (Danhier et al. 2012; Reardon et al. 2008). Another category of anti-integrins is antibodies developed to bind to specific regions of an integrin to modify its function, for example, interactions with the adjacent plasma membrane proteins (Byron et al. 2009). The interactions targeted by anti-integrins may be between integrins and extracellular matrix proteins or between integrins and cell surface proteins of adjacent cells (cell-cell interactions). Finally, anti-integrins may be small molecule integrin ligands, such as thyroid hormone analogues, that block the activity of the specific thyroid hormone (L-thyroxine, T4) at its discrete cell surface receptor on integrin αvβ3 (Cheng et al. 2010). In contrast, RGD peptides may bind to multiple integrins at sites of different overall structure that recognize the RGD sequence. Integrin antagonists demonstrated a wide range of therapeutic applications in thrombosis, vascular restenosis, cancer, asthma, allergy, and inflammatory diseases (Desgrosellier and Cheresh 2010; Dotan et al. 2020; Raab-Westphal et al. 2017).

In addition to affecting functions of integrins, anti-integrins may also serve as drug delivery tools (Li et al. 2016; Sudha et al. 2017a; Sun et al. 2017) or as imaging agents (Danhier et al. 2012) for cancers or inflamed tissues expressing integrins.

Basic Characteristics of Anti-integrins and Mechanisms of Anti-integrin Action

The protein-ligands of integrins, such as ECM proteins, often contain the RGD sequence, and RGD peptides have anti-integrin activity. Another strategic approach to the identification of anti-integrin ligands has been to determine whether naturally occurring small molecules, such as nonpeptide hormone analogues (Davis et al. 2013), might bind to specific sites on specific integrins under physiological circumstances to modify integrin-based cell functions. An example of the use of this strategy was the description of the pro-angiogenic action of thyroid hormone, T4 (Mousa et al. 2014; Davis et al. 2015), initiated at a previously unrecognized hormone receptor on integrin αvβ3. Removal of a single iodine from T4 occurs in vivo to yield tetraiodothyroacetic acid (tetrac) and resulted in an anti-angiogenic molecule that eradicated the pro-angiogenic activity of T4 in endothelial cells (Mousa et al. 2014; Stryker et al. 2019). This topic is reviewed in more detail in the specific anti-integrin section below on αvβ3.

Anti-integrin products may be directed at specific integrin monomers or at an intact heterodimer. The RGD peptide model and the thyroid hormone analogue and resveratrol anti-integrin molecules require heterodimeric integrin structure to construct the discrete receptor sites that may be formed at conjunctions of the specific monomers in a heterodimer. Antibody anti-integrins may be directed at specific facets of monomers.

As this chapter describes in more detail below, integrin αvβ3 also contains discrete sites that specifically bind dihydrotestosterone (DHT) and resveratrol that are unrelated to the thyroid hormone analogue receptor. DHT may act via its receptor on the integrin to stimulate the proliferation of breast cancer cells (Lin et al. 2009) and thus is not anti-integrin. In contrast, resveratrol is an anti-integrin, blocking the proliferation of a wide variety of cancer cells. Among the qualities of resveratrol in tumor cells is interference with the PD1/PD-L1 immune checkpoint (Lin et al. 2019).

In addition to αvβ3, several other integrins have been the foci of anti-integrin development. Integrin-focused drug development has been

substantial for possible application to inflammatory states, such as inflammatory bowel disease (Dotan et al. 2020; Park and Jeen 2018; Sabino et al. 2019; Shah et al. 2017). Integrins other than αvβ3 have also been linked to cancer (Seguin et al. 2015; Desgrosellier and Cheresh 2010; Raab-Westphal et al. 2017). Certain integrins have been implicated in ophthalmologic diseases and have been considered targets for anti-integrins (Gonzalez-Salinas et al. 2018). Finally, there are thrombotic conditions in which anti-integrins have been mentioned as possible therapeutic interventions (Mousa et al. 2010; Davis et al. 2018a; Mousa et al. 2018; Davis et al. 2018b). Because normal platelets bear αvβ3 that originated in the plasma membrane of the megakaryocyte, thyroid hormone action on platelet aggregation via αvβ3 might be a source of hypercoaguability (Mousa et al. 2010). Anti-integrin treatment might be a strategy in such patients.

Activity of anti-integrins may be modified by the state of the activation (conformation) of the highly plastic heterodimeric integrin (Ginsberg 2014). That is, activation state/conformation change may alter the accessibility of binding sites for ligands on the extracellular domain of integrins. Small molecules such as thyroid hormone analogues alter activation state (Leith et al. 2017) and physical factors may also modify the conformation of integrins. X-irradiation is an example of a factor that may rapidly activate integrin αvβ3 (Leith et al. 2018). Thyroid hormone analogues that interact with the same integrin will also affect the interactions of the integrin with ECM proteins, such as vitronectin (Davis et al. 2015) and thus change the motility of cells that anti-integrins may be designed to affect.

Therapeutic Potential of Anti-integrins

Integrins are involved in and modulate cell-cell interactions, interactions of ECM proteins and cells, motility of a large variety of cells, tissue structure, and the state of the cytoskeleton. Pharmaceutics directed at integrins are under study in a wide variety of clinical states. These include inflammation (Arnaout 2016; Kourtzelis et al. 2017) – such as that of the intestinal tract (Catalan-Serra and Brenna 2018), in the vascular system (Huang and Frangogiannis 2018; Edwards and Bix 2019) and joints (Morshed et al. 2019) – cancer biology (Lavergne et al. 2017; Raab-Westphal et al. 2017; Leith et al. 2018; Mousa et al. 2018; Davis et al. 2019) and angiogenesis (Mousa et al. 2014; Davis et al. 2015; Duro-Castano et al. 2017; Guerrero and McCarty 2018).

We have pointed out above that chemical modification of anti-integrin molecules to enable the transporting of anti-cancer drugs allows the anti-integrin, when bound to cancer cell integrin, to unload specific chemotherapeutic agents at the cancer site (Sudha et al. 2017a, b; Sun et al. 2017).

Against this background, it is understandable that a preclinical and limited clinical anti-integrin literature has emerged. The most substantial literature involves application of anti-integrins to inflammatory bowel disease, neuronal disorders, thrombosis, cancer, and cancer-associated complications, as discussed below.

Specific Anti-integrins

Alpha Integrins

Alpha 1 Beta 1 Integrin

Short chain disintegrin obustatin demonstrated high affinity and specificity for the α1 β1 Integrin with potent anti-angiogenesis activity (Marcinkiewicz et al. 2003).

Alpha 2 Beta 1 Integrin (Very Late Activating Antigen 2, VLA2)

A key role for α2β1 integrin in cell adhesion, cell motility, angiogenesis, stemness, and immune/blood cell regulations and its implication in cancer has been demonstrated (Adorno-Cruz and Liu 2018).

Alpha 3 Beta 1 Integrin

The α3β1 integrin expressed in human breast cancer cells and its participation in the degradation

and phagocytosis of the extracellular matrix has been shown (Coopman et al. 1996).

Alpha 4 Beta 1 Integrin (Very Late Activating Antigen 4, VLA4)

The α4 integrin-dependent leukocyte trafficking promotes cognitive impairment in multiple sclerosis (MS), Alzheimer's disease (AD), and other neuropathological disorders, which suggests that blocking α4 integrins might offer a new therapeutic strategy in MS, AD, and other neuronal diseases. The FDA-approved humanized monoclonal antibody against the cell adhesion molecule α4-integrin, namely natalizumab, is indicated for the improvement of disability and reduction of relapse rate in MS patients (Mazdeh et al. 2018; Engelhardt and Kappos 2008; Li et al. 2018; Manocha et al. 2018; Dattoli et al. 2018; Pietronigro et al. 2019).

Alpha 4 Beta 1/Beta 7 Integrin

Natalizumab is also FDA approved for inflammatory bowel disease (IBD), namely Crohn's disease, but has limited risk. In contrast, vedolizumab α4β7 integrin antagonist is approved for IBD with fewer systemic adverse effects versus natalizumab (Park and Jeen 2018).

Alpha 5 Beta 1 Integrin

Integrin subunit α5 (ITGA5) often combines with ITGB1 to form integrin α5β1, which serves as a receptor for cell differentiation, cell development, migration, angiogenesis, and invasion of cancer cells or bacteria (Kim et al. 2000; Cue et al. 2000; Mostafavi-Pour et al. 2018; Ren et al. 2009). The emergence of integrin α5β1 expression was found to be associated with tumor progression in lung cancer and other cancers (Rivera et al. 2017).

Beta 2-Integrin

Beta2-integrins are complex leukocyte-specific adhesion molecules, which are essential for leukocyte trafficking and immunological processes such as neutrophil phagocytosis, T cell activation, and ROS production and are implicated in various inflammatory and immune diseases (Fagerholm et al. 2019).

Beta 3 Anti-integrins

Alpha IIb/β3 Integrin – Integrin αIIbβ3, Glycoprotein IIb/IIIa (GPIIb/IIIa)

Platelet integrin αIIbβ3 (GPIIb-IIIa) binds to fibrinogen and fibrin, and novel antagonists were developed and evaluated as effective anti-thrombotic in various settings (Hantgan et al. 2007; Mousa et al. 1996; Mousa et al. 1998, 1999; Mousa and Ahmad 2007). There are already three FDA approved intravenous GPIIb/IIIa receptor inhibitors including eptifibatide, tirofiban, and abciximab used in patients with acute coronary syndrome undergoing percutaneous coronary intervention (Capodanno et al. 2019; Podolnikova et al. 2014). Eptifibatide and tirofiban are specific GPIIb/IIIa inhibitors, while abciximab cross-reacts with αvβ3 and α2β1 integrins. Hence, abciximab might reduce restenosis, myocardial infarct size, inhibit adhesion of monocytes, and impact the inflammatory response. In that regard, potent small molecule high affinity αvβ3 integrin antagonists demonstrated anti-restenosis efficacy in various preclinical models (Bishop et al. 2001; Srivatsa et al. 1997). Additionally, anti-angiogenesis efficacy was demonstrated in a retinal neovascularization model with small molecule αvβ3 antagonists (Luna et al. 1996; Santulli et al. 2008).

Alpha v Beta 3 Integrin

Tetrac blocks the actions of vascular growth factors, such as fibroblast growth factor (FGF2), vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF) (Mousa et al. 2014). Thus, tetrac can be designated a naturally occurring anti-integrin with anti-angiogenic properties.

Tetrac and chemically modified tetrac also have anti-cancer properties (Bharali et al. 2013; Mousa et al. 2018; Rajabi et al. 2019), but the growth of noncancer cells appears to be unaffected by tetrac (Davis et al. 2016). This reflects the generous expression of integrin αvβ3 by cancer cells compared with nonmalignant cells (except for endothelial cells). High affinity and specific αvβ3 antagonists were developed and evaluated in various settings (Helluin et al. 2000;

Kerr et al. 2000, 2001, 2002; Mousa 2005; Mousa and Mohamed 2005).

Alpha v Beta 6 Integrin

Integrin αvβ6 is exclusively expressed in epithelial cells and it activates transforming growth factor-β1 (TGF-β1) to modulate innate immune surveillance in lungs, skin, and gastrointestinal tract to maintain epithelial stem cell quiescence. The expression of αvβ6 integrin and its activation of TGF-β1 are associated with organ fibrosis and cancer. Therefore, αvβ6 integrin might serve as an attractive target for cancer therapy, imaging, and fibrosis (Koivisto et al. 2018). Additionally, β6 expression activates multiple systems involved in tumor lesions and cancer metastasis and its overexpression correlated with reduced patient survival in renal carcinoma and perhaps other cancer (Cantor et al. 2015).

Neurotransmitter Receptors and Integrin

Endothelial cells, as key cells for the angiogenesis process, express several nonneuronal nicotinic acetylcholine receptors (AChRs). In endothelial cells, alpha7 AChR stimulation indirectly triggers the activation of the integrin αvβ3 receptor and an intracellular MAP kinase (ERK) pathway that mediates angiogenesis. The intracellular mechanisms by which alpha7 AChR activation mediates angiogenesis were examined by our group (Arias et al. 2009).

Future directions should focus on these different interfaces between neurotransmitter receptors as well as hormones and integrins function, which might serve as novel therapeutics as highlighted in this brief overview.

Synonyms

Weight-loss therapies; Weight-management pharmacotherapy

Definition

Obesity is characterized by the accumulation of body fat resulting from excess energy intake over energy expenditure for a prolonged period of time. A commonly used assessment to define obesity is the body mass index (BMI), measured as a person's body weight in kilograms divided by the squared height in meters (kg/m^2). Obesity is defined by a BMI of $\geq$30 kg/m^2, and overweight is defined by a BMI of 25–29.9 kg/m^2. Obesity increases the risk for comorbidities such as type 2 **diabetes** and cardiovascular disease. Treatment with anti-obesity drugs is recommended for obese patients with BMI $\geq$30 kg/m^2 or BMI $\geq$27 kg/m^2 with existing comorbidities and aims to reduce body weight by $\geq$5%, an effect that was shown to be beneficial for reducing comorbidities and high glucose or high triglyceride profiles. The anti-obesity drugs currently approved for long-term weight management act primarily as appetite suppressants on the central nervous system, and one agent leads to reduced fat absorption from the intestines.

Mechanism of Action

In the healthy state, energy intake, driven by food consumption and nutrient intestinal absorption, counterbalances energy expenditure driven by thermogenesis, metabolism, and physical activity. Obesity results from an imbalance when energy intake exceeds energy expenditure over a prolonged period of time. The chronic surplus of energy is stored as triglycerides, the most condensed energy form, in adipose tissue. Environmental factors, such as the general availability of high-calorie food and limited need for physical exercise favor the development of obesity. Genetic factors that predispose to weight gain further contribute to it. While the different components affecting energy balance in theory give rise to various pharmacotherapy approaches, the development of an anti-obesity drug has yet to overcome the high hurdle of being efficacious and safe. It should result in a reduction of the fat mass while saving lean body mass and help to maintain the reduced weight. To account for counter-regulatory effects and the redundancy of mechanisms affecting energy intake and homeostasis, the concept of "polytherapies" – i.e., combination agents that are designed to target more than one biological mechanism – is becoming stronger.

Reflecting these challenges, there has been a long history of weight-loss therapies, and most of them had to be withdrawn from the market due to safety concerns. Those include sheep-derived thyroid hormone or 2,4-dinitrophenol, which reduce weight by increasing energy expenditure. Likewise, sibutramine, a combined **serotonin** and norepinephrine reuptake inhibitor, was more recently withdrawn from the market, as patients with preexisting cardiovascular conditions exhibited increased cardiovascular events. The currently approved anti-obesity drugs (or drug combinations) affect primarily energy intake as explained in more detail below.

Reduction of Energy Intake: Decreasing Fat Absorption

Inhibition of the absorption of fat (triglycerides) in the gastrointestinal lumen represents the most

efficient approach for reduction of caloric intake, as triglycerides are the most condensed energy stores. Ingested triglycerides are split by lipases into free fatty acids and monoglycerides in the intestinal lumen before crossing into the epithelial cells of the intestinal wall and resynthesis to triglycerides.

Orlistat

Orlistat is a hydrogenated derivative of lipstatin, a natural occurring lipase inhibitor of bacterial origin. The agent inhibits the activity of the pancreatic lipase by covalently binding to a serine residue in the active site of the enzyme, thereby the hydrolysis of triglycerides into absorbable free fatty acids and monoglycerides is reduced, which results in diminished fat absorption by ca. 30% (Table 1).

Reduction of Energy Intake: Decreasing Food Intake

Food intake and **appetite control** are influenced by complex mechanisms including central effects in the brain as well as cross talk with signals from the periphery. There are four drugs (or drug combinations), i.e., lorcaserin, phentermine/topiramate, naltrexone/bupropion, and liraglutide which promote weight loss primarily by mediating anorexigenic effects (reducing food intake) as explained in more detail below (and for review see Müller et al. 2018; Bray et al. 2018; Patel 2015).

Lorcaserin

Lorcaserin, a benzazepine derivative, is a selective **serotonin** (5-hydroxytryptamine [5-HT]-2C receptor agonist (Table 1). The 5-HT_{2C} receptor has been shown to be expressed (not exclusively)

Anti-obesity Drugs, Table 1 Drugs approved by the Food and Drug Administration (FDA) for long-term pharmacotherapy of obesity and their mechanism of action. EMA European Medicines Agency; 5-HT_{2C}-R = 5-hydroxytryptamine 2C receptor; GABA = γ-aminobutyric acid; GLP-1-R = glucagon-like peptide-1 receptor. ER extended release; SR sustained release. With the exception of liraglutide which is administered by subcutaneous (sc) injection, the drugs are administered as tablets

Generic name	Trade name (year of approval by FDA)	Mechanism of action	Dosage
Orlistat	Xenical® (1999) Alli® over-the-counter, (2007)	Inhibitor of pancreatic lipase reduces availability of fatty acids for absorption from intestinal lumen	120 mg, three times daily 60 mg, three times daily
Lorcaserin	Belviq® (2012) Not approved by EMA	Serotonin 5-HT_{2C}-receptor agonist acts centrally to reduce food intake	10 mg, twice daily (or 20 mg extended release)
Phentermine/ Topiramate ER	Qsymia® (2012) Not approved by EMA	Phentermine: sympathomimetic, increases norepinephrine levels in hypothalamus, resulting in anorexigenic effects Mechanism of topiramate to reduce body weight unclear may involve central GABA receptor modulation	3.75 mg/23 mg daily (14 days) 7.5 mg/46 mg (thereafter), max. 15 mg/92 mg
Naltrexone SR/ Bupropion SR	Contrave® (2014)	Naltrexone: antagonist of opioid receptors (μ-opioid receptor) that prevents the autoinhibition of hypothalamic POMC neurons which have anorexigenic effects Bupropion: agent that enhances the activity of POMC neurons	8 mg/90 mg daily
Liraglutide	Saxenda® (2014)	GLP-1 receptor agonist, acts on centrally expressed GLP-1 receptors	Up to 3 mg sc injection daily (starting with 0.6 mg/day)

in brain areas connected to eating behavior. Lorcaserin is assumed to reduce appetite and increase satiety by binding to $5HT_{2C}$ receptors on pro-opiomelanocortin (POMC) neurons in the hypothalamus which are known to promote anorexigenic effects. 5-HT_{2C}-deficient mice are hyperphagic and develop obesity, insulin resistance, and impaired glucose tolerance. Previous, unselective 5-HT agonists which were used as anti-obesity drugs, fenfluramine and dexfenfluramine, had been withdrawn due to cardiac valvulopathy likely mediated by their binding to $5HT_{2B}$ receptors expressed on the heart valve. Treatment with lorcaserin, also referred to as the third-generation 5HT agonist, did not show this issue over 2 years, in line with its selectivity profile.

Phentermine/Topiramate Extended Release (ER)

Phentermine/topiramate is a combination drug. Phentermine is a nonselective stimulator of synaptic norepinephrine (and of serotonin and dopamine) levels. This sympathomimetic drug is among the earliest pharmacological agents used for weight management. It is currently approved as monotherapy only for short-term (<12 week) treatment of obesity due to safety concerns about cardiovascular risk and abuse potential. The combination has lower dose of phentermine than usually prescribed for phentermine alone. It supposedly acts as an appetite suppressant by increasing norepinephrine levels in the central nervous system as the main mechanism (Table 1). The dopamine levels are only slightly increased, and their contribution to the anorectic effect is less clear.

Topiramate, a sulfamate-substituted monosaccharide derived from D-fructose, is commonly used to treat **epilepsy** and migraine, and was approved later on for weight management as the clinical trials showed effects on body weight. Topiramate is assumed to selectively decrease CNS neuronal activity by inhibiting certain neuronal calcium and sodium channels and modulating central glutamate and γ-aminobutyric acid (GABA) receptors to mediate the effects in epilepsy and migraine. The mechanism by which topiramate regulates body weight is not yet well understood, but may also involve modulation of GABA receptors (Table 1). The weight loss achieved with the combination is greater than treatment with the single agents alone.

Naltrexone Sustained-Release (SR)/Bupropion SR

This combination drug is a pairing of a known **opioid** receptor antagonist (naltrexone) with a known norepinephrine and dopamine reuptake inhibitor (bupropion) (Table 1). Bupropion alone is approved for depression and smoking cessation. This agent shares similar structural design and CNS actions as the sympathomimetic diethylpropion which is being used for short-term treatment of obesity. As an inhibitor of the reuptake of norepinephrine and dopamine, bupropion likely produces anorexigenic effect via combined dopaminergic and noradrenergic effects on POMC neurons in the arcuate nucleus of the hypothalamus. There is some evidence of additional centrally mediated effects on energy expenditure. Naltrexone alone is approved for treatment of alcohol and opioid dependence. It is an opioid receptor antagonist with high affinity for the μ-opioid receptor. It has appetite suppressant effects likely due to disrupting autoinhibition of POMC neurons. In combination with bupropion, it further enhances the activity of POMC neurons. Research suggests that the combination leads to improved food craving control and reduced overeating episodes.

Liraglutide

Liraglutide is a glucagon-like peptide (GLP-1) receptor agonist with 97% homology to human GLP-1. The peptide hormone GLP-1 is released by the small intestines in response to food ingestion and enhances pancreatic insulin production and secretion, while glucagon release is inhibited. While the natural GLP-1 has a very short half-life of 1–2 min and is cleaved by dipeptylpeptidase IV, modifications obtained for liraglutide resulted in extended circulating half-life of ca. 13 h. Liraglutide was originally approved for treatment of type 2 **diabetes** mellitus and was later on, since it showed ability to reduce body weight in the trials, approved for obesity treatment (at higher dose). Liraglutide exerts its effects to reduce body weight likely by a combination of influences on energy intake and

energy homeostasis. Consequences exerted on feeding behavior are likely mediated by acting on GLP-1R expressed in brain areas. In more detail, GLP-1 was shown to directly activate POMC/CART neurons and indirectly inhibit, via GABAergic transmission, the **neuropeptide Y**/agouti-related peptide (NPY/AgRP) neurons, which collectively results in signals that reduce food intake. It has been suggested that the delay in gastric emptying and the effect to slow gut motility comprises also part of the weight-loss mechanism of action of liraglutide.

Clinical Use

Obesity has reached an epidemic level not only in developed but also in developing countries. In 2016, the World Health Organization estimated that more than 1.9 billion adults were overweight and of these over 650 million were classified as obese (WHO 2018). Percentage wise, 39% of adults were overweight, and 13% were obese. The USA accounts for the highest global incidence, with a recent survey indicating that 35% of men and 40% of women in the USA were obese. Pharmacotherapy is generally recommended as the second-line treatment for obesity after lifestyle modifications. As obesity is a chronic disease, it requires long-term therapy. There are currently five drugs (with two combination) approved by the FDA for long-term (more than 6 months) anti-obesity therapy (Table 1). They are indicated for patients with a BMI $\geq$30 kg/m^2 or $\geq$27 kg/m^2 with an obesity-related comorbidity, such as type 2 **diabetes** mellitus, hypertension, or dyslipidemia, and they are used as an adjunct to lifestyle modifications. The treatment of obesity aims at a sustained loss of 5–10% of body weight, which has been shown to reduce the risk of obesity-associated comorbidities. It should be noted that, in addition, the FDA approved before 1960 the sympathomimetic agents benzphetamine, diethylpropion, phendimetrazine, and phentermine for short-term ($<$12 weeks) treatment of obesity. The clinical use and clinical trial data for the currently approved anti-obesity drugs as well as their side effects are summarized below and were compiled from Patel 2015, Bray et al. 2018, and Andrew et al. 2019.

Orlistat, marketed as Xenical®, has been approved by the FDA for obesity management already in 1999 (Table 1). There have been numerous clinical trials with orlistat. In a 4-year clinical trial in obese patients in conjunction with lifestyle intervention, the mean weight loss was significantly greater with orlistat (5.8 kg) than with placebo (3 kg). Orlistat was shown to have beneficial effects on associated comorbidities, as shown in clinical trials in obese patients with cardiovascular risks, where blood pressure was reduced. Lipid profiles were also improved, with an especially strong effect to reduce LDL-C levels that may be due to its mechanism of action. Furthermore, the XENDOS trial showed that glycemic control was ameliorated with orlistat. Of note, orlistat is the only drug approved by the FDA for weight management in obese adolescents.

While orlistat itself is minimally absorbed, the main unwanted effects of orlistat are attributable to its mode of action, as non-digested fat remains in the intestinal lumen and can cause steatorrhea (fatty stools), flatulence and fecal incontinence. These effects are associated with a high-fat meal, and therefore a low-fat diet is recommended. As absorption of fat-soluble vitamins may be hampered, supplementation of these vitamins is recommended.

Lorcaserin, marketed as Belviq®, has been approved in 2012 (Table 1). This agent has been investigated in three major phase 3 clinical trials. In the 1 year BLOOM trial, obese patients treated with lorcaserin lost a significantly greater percentage (5.8%) of body weight from baseline compared to placebo-treated patients (2.2%, $p > 0.001$) and achieved in absolute numbers a body weight reduction by 5.8 kg for the drug-treated versus 2.2 kg in the placebo-treated patients. Weight loss was similar in the other two clinical trials in obese and overweight adults. The trials also showed improvements in cardiovascular risk factors in line with the effect to reduce body weight. Furthermore, lorcaserin treatment of

obese or overweight patients with type 2 **diabetes** mellitus resulted in significant improvements in glycemic control.

The most common adverse events reported with lorcaserin are headache, dizziness, fatigue, and nausea. In contrast to the former unselective 5HT agonists, lorcaserin treatment did not show cardiac valvulopathy in clinical trials so far. This drug is not approved for treatment of obesity by the European health authority.

Phentermine/topiramate ER, marketed as Qsymia®, has been approved by the FDA in 2012 (Table 1). The efficacy of phentermine/topiramate ER in patients with overweight and obesity has been demonstrated in two phase 3 clinical trials and one extension trial. As an example, in the CONQUER trial, overweight or obese patients (BMI of 27–45 kg/m^2) with $\geq$2 comorbidities were treated with placebo, phentermine 7.5 mg/topiramate 46 mg, or phentermine 15 mg/topiramate 92 mg for 1 year. The patients lost 1.2% of baseline body weight in the placebo group, compared to 7.8% and 9.8% in the drug-treated groups, respectively ($p < 0.0001$ vs. placebo). There were significant improvements in cardiometabolic parameters for the combination treatment at the higher dose. In an extension trial, following 2 years of treatment, patients on the combination treatment lost body weight in a similar range, showed greater improvements in cardiometabolic parameters as well as reduced progression to type 2 **diabetes** mellitus compared with placebo.

The most common adverse reactions reported with phentermine/topiramate ER use include paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth. This combination drug is not approved for treatment of obesity by the European health authority.

Naltrexone SR/bupropion SR, marketed as Contrave®, is another combination drug (Table 1). Four one year trials were conducted to evaluate the safety and efficacy. In the COR-I and COR-II trials, obese patients or patients with BMI of $\geq$27 kg/m with one comorbidity were treated with naltrexone/bupropion at 360 mg/32 mg or placebo, resulting in placebo-adjusted weight loss between 2.5% and 5.2% of initial body weight. As weight loss occurred, glucose tolerance and lipid profiles improved.

The most common side effects are nausea, constipation, headache, dizziness, insomnia, and dry mouth. Abuse potential has not been reported. Slight effects to increase blood pressure and heart rate were observed, which may be due to the effect of bupropion. While they seem clinically insignificant, further studies are needed to assess the safety of naltrexone/bupropion in the cardiovascular disease population.

Liraglutide, trade name Saxenda®, is administered as a subcutaneous injection (Table 1). It is marketed at a lower dose under Victoza for treatment of type 2 **diabetes** mellitus. The effects of Liraglutide in the obese population were addressed in the SCALE program. In a clinical trial with 1-year treatment, the weight loss was 7.8 kg at the maximal dose of 3 mg daily liraglutide versus 2.0 kg in the placebo-treated group. Furthermore, in a different setup with an initial period of losing weight due to low-calorie diet, weight loss was 6.8 kg (and 6.2% weight loss relative to baseline weight) in the drug-treated patients, while placebo-treated patient did not show an additional significant weight reduction. Clinical trials in patients with cardiovascular comorbidities or type 2 **diabetes** mellitus showed an improvement of the respective parameters.

The most common adverse events reported included nausea, vomiting, diarrhea, constipation, and dyspepsia. Liraglutide as monotherapy has a low risk for hypoglycemia, but should not be taken with another antidiabetic agent.

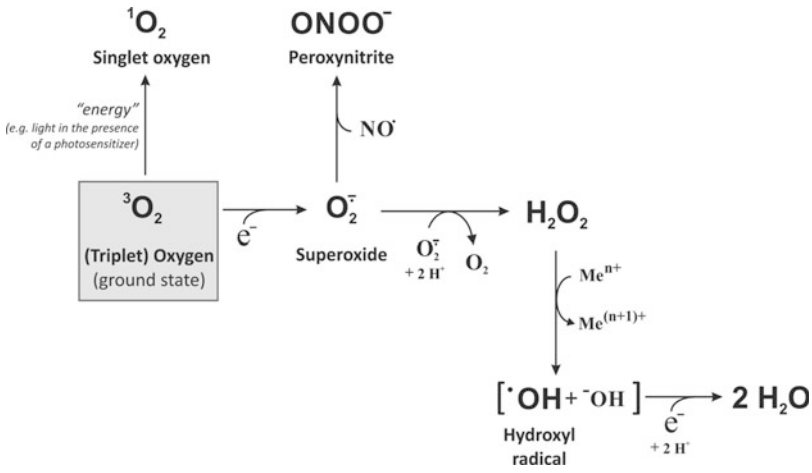
Introduction

Definitions: Oxidants, Antioxidants, Free Radicals, ROS

Antioxidants are molecules characterized by function rather than common structural motifs. Their common feature is the capability of acting "anti"-oxidants in biological systems. Owing to the exposure of tissues to high concentrations of physically dissolved molecular oxygen as well as to nitrogen-containing biomolecules, the oxidants, usually implied as being opposed by antioxidants, are oxygen- and/or nitrogen-derived reactive species generated in biological systems (Fig. 1). There is, of course, a plethora of other biologically relevant reactive species and oxidants, including sulfur-centered radicals or chlorinated species. Referring to all of these using the frequently employed acronym ROS ("reactive oxygen species"), as we will in this entry, is, therefore, strictly speaking, incorrect. It has, however, the advantage that two inconsistencies are being avoided: if the compounds shown in Fig. 1 were referred to simply as "oxidants" or "free radicals," this would neglect the fact that not all of these compounds are necessarily oxidants (such as the superoxide anion, which may act as reductant in biological systems) or radicals (such as the non-radical reactive species H_2O_2, $ONOO^-$, HOCl).

ROS may be generated endogenously and upon exposure to exogenous stimuli. Endogenous generation occurs wherever electrons are passed along in the presence of oxygen, such as in the mitochondrial respiratory chain or during xenobiotic metabolism (Klotz and Steinbrenner 2017; Kehrer and Klotz 2015). It may be catalyzed by dedicated enzymes, including oxidases that reduce oxygen to generate superoxide or hydrogen peroxide, and endogenous generation of ROS may occur as (by)product of an interaction of other ROS – such as peroxynitrite, which is generated through a combination of superoxide and nitrogen monoxide radicals, or hydroxyl radical, which may be generated by a metal ion-induced reduction of peroxides (Fenton reaction). Exogenous stimuli eliciting the endogenous generation of ROS include physical stimuli such as UV radiation or ionizing radiation and toxins.

Just as, chemically, ROS are not necessarily oxidants, the opposing antioxidants not necessarily act as reductants in a biological setting: in fact, oxidants can evoke an adaptive cellular response, for example, by stimulating transcription factors, and therefore serve one of the four commonly found antioxidative strategies (Sies 1993; Klotz 2015). These strategies include (i) the prevention of oxidant formation, (ii) interception of reactions between oxidants and their molecular targets, (iii) repair of molecules damaged by oxidants, and (iv) adaptation, through stress-induced signaling, by upregulating endogenous antioxidant defenses.



Antioxidants, Fig. 1 Reactive oxygen species derived from molecular oxygen by energy or electron transfer. Me, metal ion

Antioxidative Strategies: Endogenous Antioxidants and Pharmacological Approaches

Endogenous antioxidants may be categorized roughly by molecular mass. High-molecular-mass antioxidants would therefore include proteins, mostly enzymes, whereas low-molecular-mass (lmm) antioxidants would refer to widely known antioxidants such as vitamins C or E. A second level of distinction would be the extent to which the respective lmm compound is soluble in water. Examples of both proteins and hydrophilic as well as lipophilic lmm antioxidants are listed in Table 1.

Regarding the aforementioned antioxidative strategies, they can be illustrated using antioxidant proteins/enzymes as examples:

(i) *Prevention*: storage proteins, such as ferritin, or chelating proteins, such as metallothioneins or even serum albumin, may be considered antioxidants with respect to their capability of preventing the Fenton reaction from occurring: chelation of redox-active metal ions, such as copper ions, may prevent peroxide reduction to generate the hydroxyl radical. Prevention by enzyme inhibition is certainly another approach: oxidases such as xanthine oxidase or NADPH oxidase may be targeted by inhibitors, thereby attenuating superoxide and peroxide generation.

Pharmacologically, chelation therapy is treatment of choice in diseases accompanied by elevated transition metal ion levels, such as Wilson's disease (WD). Pathological copper accumulation in WD patients causes deterioration of tissues, in part due to oxidative reactions elicited by copper ions, resulting in membrane peroxidation and damage. Copper chelation therapy, employing chelators such as D-penicillamine, triethylenetetramine, or tetrathiomolybdate, is, therefore, standard therapy. In addition zinc salts sometimes are being used to induce endogenous metallothionein production, again to enhance copper chelation capacity. Oxidase inhibition would be achieved using pharmacologically active compounds such as the antihyperuricemic allopurinol, an inhibitor of xanthine oxidase.

(ii) *Interception*: Direct scavenging of ROS is achieved by dedicated enzymes. Superoxide and hydrogen peroxide as well as alkyl peroxides are substrates of enzymes (see Table 1), with superoxide disproportionation ("dismutation") being catalyzed by superoxide dismutases (SOD) and peroxide reduction to water or the respective alcohol catalyzed by peroxidases.

Pharmacologically, lmm enzyme mimetics have been synthesized and developed for decades, but only few have been successful beyond in vitro studies. In line

Antioxidants, Table 1 Categories of antioxidants and examples (not exhaustive)

Non-enzymatic	Enzymes
a) Low-molecular-mass (lmm)	Superoxide dismutases
Hydrophilic	Cytosolic Cu,Zn-SOD (SOD1)
Vitamin C (ascorbic acid)	Mitochondrial Mn-SOD (SOD2)
Urate/uric acid	Extracellular SOD (EC-SOD; Cu,Zn-dependent)
Glutathione	Peroxidases
Lipoic acid	Heme peroxidases (e.g., catalase)
	Glutathione peroxidases (GPx; selenium-containing and non-selenium-containing)
Lipophilic	Peroxiredoxins
Vitamin E (tocopherols, tocotrienols)	Reductases
	Glutathione disulfide reductase
Carotenoids	Glutaredoxins
Ubiquinone	Thioredoxins, thioredoxin reductases
	Phase I/phase II enzymes
b) Proteins	NAD(P)H:quinone oxidoreductase-1 (NQO1)
Metal ion-binding proteins	Glutathione S-transferases (GSTs)
Metallothioneins	Repair enzymes
Serum albumin	Methionine sulfoxide reductases
	8-Oxoguanine glycosylase-1 (OGG1)

with three types of SOD being present in humans (Cu, Zn-SOD, Mn-SOD, EC-SOD; see Table 1), with Cu or Mn ions at the active site, copper- or manganese-based SOD mimetics have been around for decades, yet only used in in vitro studies so far. Peroxidase-mimetic compounds were also developed, including Fe- or Se-based compounds, including the glutathione peroxidase mimetic, ebselen, which was developed after glutathione peroxidase was demonstrated to be a selenoenzyme. Ebselen, in the 1980s and 1990s, was tested as a drug candidate in the treatment of diseases associated with elevated ROS levels, such as brain ischemia and stroke. Although oral administration of ebselen was found to be safe for humans in a clinical trial with Japanese patients suffering from acute ischemic stroke, ebselen never progressed beyond clinical trials (for review, see Steinbrenner et al. 2016).

(iii) *Repair*: Oxidative damage elicited upon exposure of biomolecules to ROS (i.e., under condition of insufficient interception) may be reversed by dedicated enzymes, including methionine sulfoxide reductases (reducing oxidized protein-bound methionine sulfoxides), thioredoxins (reducing protein disulfide bonds), phospholipid-hydroperoxide glutathione peroxidase (GPx4, reducing oxidized lipids), and OGG1 (8-oxoguanine glycosylase-1, recognizing and excising oxidized guanine moieties in oxidatively damaged DNA, thereby initiating DNA base excision repair). Moreover, cellular structures damaged beyond repair, such as oxidized proteins and membrane components, are degraded in a targeted approach; this also constitutes a part of the cellular antioxidative defense (Grune et al. 1997; Jung et al. 2009; Korovila et al. 2017).

Pharmacologically, the repair of oxidative damage does not appear to be a major area of interest. As an exception, consumer products may be mentioned that use DNA repair enzymes in order to repair sun-induced DNA damage. In fact, liposomal preparations of DNA repair enzymes, including OGG1, were described as potent means of lowering the extent of skin cell DNA damage.

(iv) *Adaptation*: ROS may stimulate transcription factors, including Nrf2 or FOXO transcription factors (Gille et al. 2019), to elicit a transcriptional response that results in upregulation of antioxidant enzymes. Enzymes upregulated upon stimulation of Nrf2 include glutathione biosynthetic enzymes, quinone reductases, heme oxygenase-1 (resulting in production of bilirubin), and phase II enzymes, such as glutathione S-transferases (Klotz and Steinbrenner 2017). FOXO transcription factors also

regulate the expression of genes encoding superoxide dismutases, peroxidases (such as catalase), and others (for review, see Klotz et al. 2015).

Pharmacologically, compounds known to stimulate Nrf2 signaling are being used as drugs, including fumaric acid esters, such as dimethyl fumarate (DMF), which is approved for the treatment of certain forms of multiple sclerosis and for the treatment of psoriasis. DMF, as an electrophile and Michael acceptor, will stimulate Nrf2 signaling through interaction with cysteine residues of the Nrf2 interaction partner Keap-1. The same reaction will occur between DMF and glutathione, leading to glutathione depletion, which in vitro causes cell death and may be responsible for side effects of DMF use (Satoh and Lipton 2017). To what extent the therapeutic effect of DMF relies on its activating Nrf2 is not entirely resolved (Schulze-Topphoff et al. 2016). It should be mentioned that an adaptive response to ROS can also be stimulated by exercise and physical stimuli, including cold exposure (Siems et al. 1999; Powers et al. 2011).

Mechanism of Action of Low-Molecular-Mass Antioxidants

Following the above classification of antioxidative strategies and the ensuing broad definition of an antioxidant, the list of potential antioxidants seems overwhelming. Therefore, this entry will focus on pharmacologically relevant low-molecular-mass (lmm) antioxidants belonging to the second category, intercepting antioxidants. In fact, this is the category usually associated with an antioxidant: reacting with, scavenging, or quenching a reactive oxygen species.

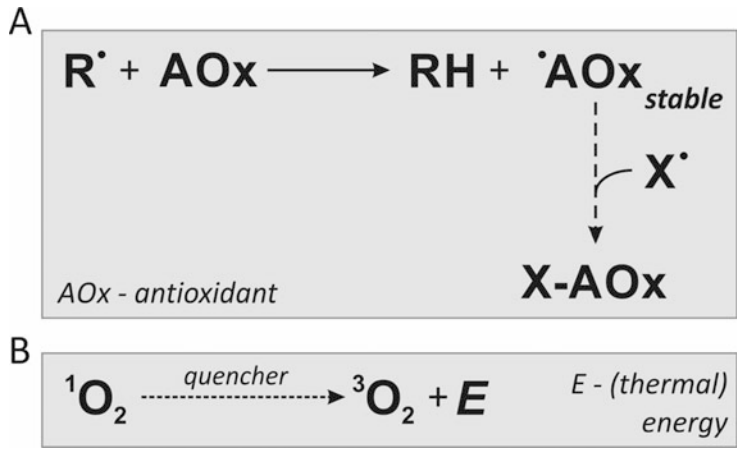
Endogenous and Exogenous lmm Antioxidants: Two Modes of Action

Numerous lmm antioxidants are endogenously formed, such as glutathione, uric acid, or bilirubin, breakdown products of purines and heme, respectively, or are both endogenously generated and provided from exogenous sources, such as lipoic acid or ubiquinone. Others are exclusively derived from exogenous sources, such as vitamins. These compounds are present in the relevant in vivo compartments at significant (at least micromolar) concentrations.

The first major mechanism of antioxidant action at the level of interception is reduction, i.e., the donation of (an) electron(s) to a recipient molecule. When interacting with a radicalic ROS (such as the hydroxyl radical or peroxyl radicals), transfer of a single electron would turn this radical into a non-radical, often stable, and less reactive compound. The remaining "antioxidant radical" is assumed to be a radical that is chemically relatively stable, providing time for selective reaction with a next antioxidant in a chain reaction, eventually leading to a stable radical molecule or a recombination of two radicals, forming an inert molecule (Fig. 2a). In the case of tocopherols, for example, the phenolic hydroxyl is the basis for the antioxidant activity of this molecule. Upon donation of an electron to a reaction partner, it forms the minimally reactive tocopheroxyl radical.

The potential of a chemical to reduce a prooxidant by electron transfer is governed by kinetic and thermodynamic parameters of the underlying redox equilibrium. Hence, redox potentials and concentrations of reaction partners in a given compartment define the likelihood of a successful scavenging reaction.

For example, melatonin (N-acetyl-5-methoxytryptamine) has been frequently suggested to be an effective antioxidant, avidly scavenging various ROS. Its reaction with the hydroxyl radical indeed occurs at a diffusion-controlled rate. However, considering the high reactivity of the hydroxyl radical, one is tempted to ask: which hydrogen-containing molecule's reaction with the hydroxyl radical does not occur at a considerable rate? And further considering the in vivo concentrations achieved by melatonin, which are usually not above nanomolar concentrations, and therefore several orders of magnitude lower than concentrations of other antioxidants in vivo, it is rather obvious that in vivo melatonin is unlikely to contribute to overall hydroxyl radical scavenging. Similar conclusions



Antioxidants, Fig. 2 Two modes of antioxidative action. (**a**) Reduction of a radical by an antioxidant, (**b**) quenching of an excited species, such as singlet oxygen

can be drawn with respect to the contribution of melatonin to scavenging of other ROS. So, whereas it seems unlikely that melatonin is an effective in vivo scavenger of ROS, it is indeed conceivable that it contributes to adaptive responses also at its nanomolar in vivo concentrations which are compatible with those of signaling molecules.

A second form of oxidant detoxification is through physical quenching, i.e., (stepwise) energy dissipation by reaction of a quencher molecule with an excited species. In essence, relaxation of electronically excited species will be induced, transferring energy to the quencher, which, in turn, dissipates this energy as vibrational (thermal) energy to the molecular environment (Fig. 2b). Among the lmm antioxidants found in vivo, carotenoids are prototypic quenchers, including provitamin A- (such as beta-carotene) and non-provitamin A-carotenoids (such as lycopene). They quench singlet oxygen ($^1O_2$) with very high efficiency in vitro. To what extent their quenching excited species such as $^1O_2$ significantly contributes to carotenoid antioxidative activity in humans is currently a matter of discussion (Bosio et al. 2013).

It should be mentioned here that, in principle, all antioxidants can also be pro-oxidants (as the reactions they are part of are redox equilibria). However, the demonstration of this effect is limited to in vitro test systems, since such concentration relations allowing for reversion of the reaction equilibrium can rarely be achieved in vivo.

Plant Secondary Metabolites

In addition to the abovementioned antioxidants, numerous plant secondary metabolites, such as plant polyphenols and many others, were reported as antioxidants. However, while indeed in vitro some of these act as scavengers of ROS, these compounds do not fulfill some important criteria that the above lmm antioxidants do. Not only is unmodified uptake unlikely in many of these compounds, as both microbiome and standard first-pass effect will lower concentrations of the original natural compound to be achieved in vivo. Also, a major advantage of the above lmm antioxidants is that many are constantly being recycled, including glutathione, as well as vitamins C and E, which may, to a certain extent, be recycled from their oxidized forms at the expense of cellular reducing equivalents. This is not always the case with plant secondary metabolites taken up by humans. Most importantly, however, at the concentrations usually achieved in vivo upon uptake of such compounds, and considering the much higher concentrations of well-known antioxidants in vivo, it is rather unlikely that interception of ROS-induced reactions contributes to any biological effect such plant secondary metabolites may have in humans. *NB*, the situation and significance of these metabolites in other biological materials, such as food products, juices, etc., is of course quite different from that in humans. There is (similar to the case made against and for melatonin above) a plethora of data suggesting that non-antioxidant activities are found with such compounds, including

interference with cellular signaling cascades (Klotz 2015). For example, several plant polyphenols act as kinase inhibitors, in part through competition with the ATP-binding site of kinases (Guerra and Issinger 2019).

Clinical Use (Incl. Side Effects)

The use of "antioxidants" in clinical practice is based upon the hypothesis that an underlying symptom, "oxidative stress," needs to be suppressed. Conceptually, "oxidative stress" is a situation in which the formation of ROS overwhelms the system's capacity of antioxidative defense, leading to cellular damage.

It is extremely difficult to determine whether a clinical situation is not only generally associated with but also mechanistically connected with oxidative stress in a concrete case. Therefore, antioxidants are sometimes used as a side therapy.

One of the major problems is, therefore, that the body's demand for antioxidants is not easy to assess (Grune and Berger 2007; Breusing and Grune 2010; Frijhoff et al. 2015). The determination of some vitamins has become standard clinical practice; however, conclusions as to the antioxidative capacity of the body cannot be drawn from that. For example, vitamin C levels could both reflect the antioxidative status or rather a nutritional habit. The same is true for other vitamins. The status of some trace elements, such as selenium, might give some insight into the endogenous levels of antioxidant selenoproteins, but such data have to be taken with a grain of salt as the distribution of trace elements is highly regulated and hierarchical. Many attempts have been made to assess oxidative tissue damage using various oxidation products, such as products of lipid peroxidation, protein, or DNA damage. However, none of these methods is currently suitable for use in clinical routine, predominantly owing to issues with pre-analysis stabilization of samples in clinical settings and the standardization between laboratories (Breusing et al. 2010; Weber et al. 2013; Augustyniak et al. 2015). Therefore, most of these methods are limited to single laboratory use and for clinical trials.

However, due to intensive research in this area, some diseases are now known to be likely connected with an increased demand on antioxidants. This includes atherosclerosis, some neurodegenerative diseases, chronic inflammation (e.g., rheumatoid diseases), and some cases of poisoning.

In general, most exogenous antioxidants are nutritional compounds, and even at pharmacological doses, they do not usually have serious side effects, often due to a very limited bioavailability.

More recently, however, the concept of "oxidative stress" was complemented by the concept of "oxidative eustress" (in contrast to the damaging "oxidative distress") (Sies et al. 2017). This is owing to the fact that a certain physiological steady-state ROS concentration, resulting from a steady flux of ROS generation and depletion, has signaling and regulatory effects in cellular metabolism and is required for normal cellular function and reactivity. Suppressing such redox regulation might result in dysregulation and cellular damage. Therefore, super-natural, high doses of oxidants might reduce the cellular response to physiological situations. The earlier belief that high doses of antioxidants (especially vitamins) are health promoting is, therefore, outdated. There are no indications that any high dosage of antioxidants in an otherwise healthy person has any positive effect. On the contrary, ongoing research and discussions suggest that consumption of super-natural, high antioxidant doses is not advisable.

Synonyms

Platelet aggregation inhibitors; Platelet inhibitors

Definition

Platelets play a central role in primary hemostasis. They are also important in pathological processes leading to thrombosis. Antiplatelet drugs are primarily directed against platelets and inhibit platelet activation by a number of different mechanisms. They are used for the prevention and treatment of thrombotic processes, especially in the arterial vascular system.

Mechanism of Action

Antiplatelet therapy is an important means in the prevention and treatment of thromboembolic artery occlusions in cardiovascular diseases. Platelets are discoid cell fragments, derived from megakaryocytes in the bone marrow that circulate freely in the blood. Under normal conditions they neither adhere to each other nor to other cellular surfaces. However, when blood vessels are damaged at their luminal side, platelets adhere to the exposed subendothelium. Adherent platelets release various factors (see below) that activate other nearby platelets resulting in the recruitment of more platelets at the site of vascular injury. The rapid formation of a "platelet plug" at sites of vascular injury is the main mechanism of primary hemostasis. This is followed by a strengthening of the primary thrombus due to the formation of fibrin fibrils by the coagulation cascade. Platelets also play an important role in pathological conditions since they can become activated on ruptured atherosclerotic plaques or in regions of disturbed blood flow. This in turn leads to thromboembolic complications that underlie common diseases such as myocardial infarction or thrombotic stroke.

Mechanisms of Platelet Activation

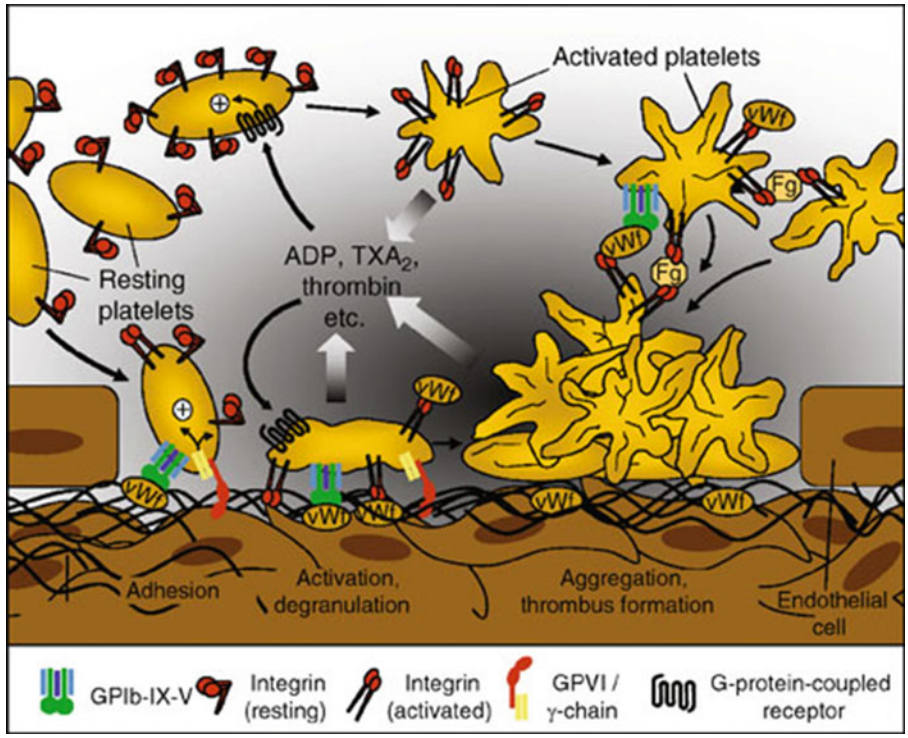
During the first phase of platelet activation, platelets adhere to extracellular matrix proteins of the subendothelium (see Fig. 1) (van der Meijden and Heemskerk 2019). Platelet adhesion is initially mediated by von Willebrand factor (vWf) which after binding to subendothelial collagen changes its conformation and interacts with the platelet receptor complex glycoprotein Ib-IX-V (GPIb-IX-V). This interaction brings platelets in contact with the subendothelium but does not result in a stable interaction. A stable adhesion of platelets is induced by the extracellular matrix protein collagen which via the platelet-specific receptor glycoprotein VI (GPVI) leads to an activation of platelets. This in turn results in the activation of several integrins like integrin α2β1 and αIIbβ3 which then mediate the firm adhesion of platelets to collagen, fibronectin, or laminin exposed at the subendothelial surface.

The formation of a platelet aggregate requires the recruitment of additional platelets from the bloodstream to the injured vessel wall. This process is executed through a variety of diffusible mediators which act through G-protein-coupled receptors. The main mediators involved in this process are adenosine diphosphate (ADP), thromboxane A_2 (TXA_2), and thrombin (factor IIa). These mediators of the second phase of platelet activation are formed in different ways. While ADP is secreted from platelets by exocytosis, the release of TXA_2 follows its new formation in activated platelets. Thrombin can be formed on the surface of activated platelets (see Fig. 2).

Initially, activated platelets change their shape, an event immediately followed by the secretion of platelet granule contents (including ADP, fibrinogen, and serotonin) as well as by platelet aggregation. Aggregation of platelets is mediated by fibrinogen or vWf. They connect platelets by bridging complexes of glycoprotein IIb/IIIa (integrin αIIbβ3) on adjacent platelets, forming a platelet aggregate. Each platelet contains about 50,000–80,000 glycoprotein IIb/IIIa (GPIIb/IIIa) molecules on its surface. In order to bind fibrinogen and vWf, GPIIb/IIIa has to be converted from low-affinity/low-avidity state to a high-affinity/high-avidity state by a process described as inside-out signaling that is initiated during platelet activation (Fig. 2).

Acetylsalicylic Acid (Aspirin)

TXA_2 is produced by activated platelets via the sequential conversion of arachidonic acid by phospholipase A_2, cyclooxygenase-1 (COX-1), and thromboxane synthase. Similar to ADP, TXA_2 acts as a positive feedback mediator. In vascular endothelial cells, COX-1 is involved in the generation of prostacyclin (PGI_2), which inhibits platelet activation and leads to vasodilation. Low doses of acetylsalicylic acid (aspirin) have an antiplatelet effect by inhibiting the TXA_2 production by irreversibly acetylating COX-1 at serine-530 close to the active site of the enzyme

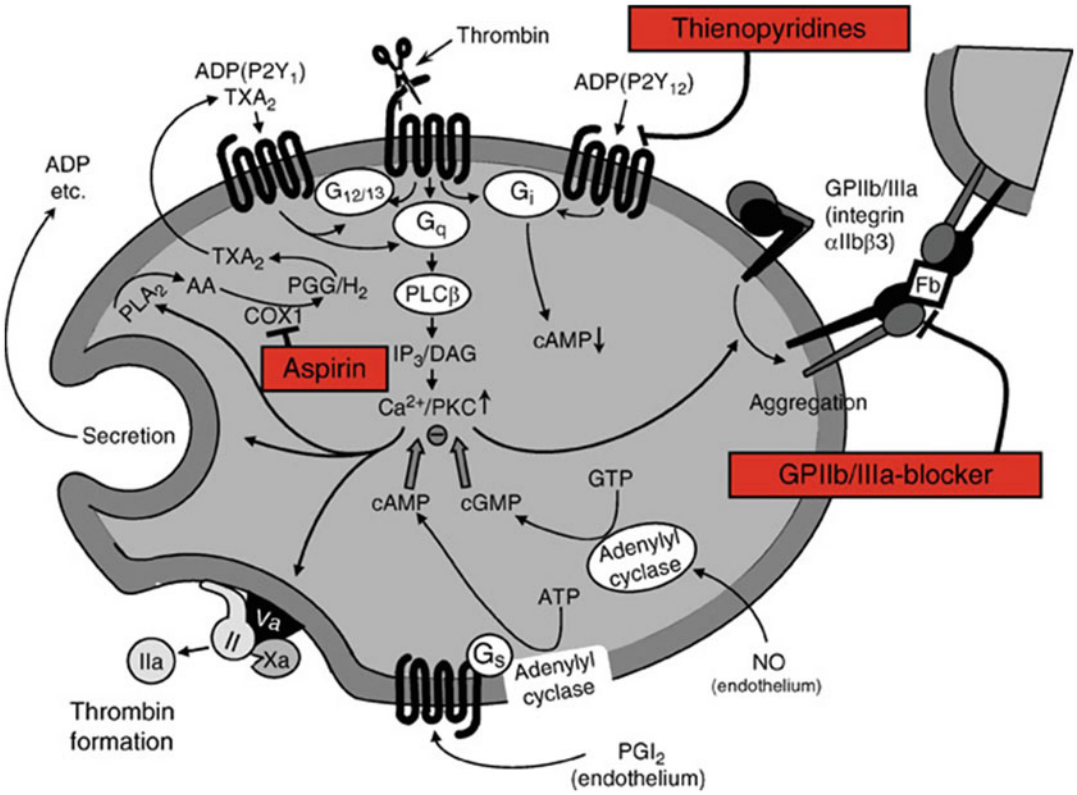


Antiplatelet Drugs, Fig. 1 Platelet adhesion, activation, aggregation, and thrombus formation on subendothelial surface at an injured blood vessel. After an injury of the vascular endothelium, the processes of primary hemostasis (platelet activation) as well as of secondary hemostasis (fibrin formation via the coagulation cascade) are triggered by a variety of stimuli. Shown are only the mechanisms of primary hemostasis. Platelets adhere via their receptor GPIb-IX-V and GPVI mediated by von Willebrand factor (vWf) or binding of extracellular matrix (especially collagen) to the subendothelium. Binding of collagen to GPVI initiates platelet activation resulting in integrin activation and the formation of a variety of diffusible mediators like ADP, thromboxane A_2 (TXA_2), as well as thrombin. These mediators initiate the second phase of platelet thrombus formation by recruiting platelets from the bloodstream into a growing platelet aggregate. The cross-linking of platelets primarily involves the activated integrin αIIbβ3 (GPIIb/IIIa) which can bind the bivalent ligands vWf and fibrinogen (Fb) resulting in the cross-linking of platelets

which interferes with the binding of the substrate arachidonic acid to the enzyme. This results in impaired platelet function for the rest of its life span (7–10 days). Anucleated platelets, in contrast to nucleated cells, are unable to de novo synthesize COX-1. The aspirin doses required for this antiplatelet effect are therefore considerably lower than those necessary to achieve inhibition of prostacyclin formation in endothelial cells or analgetic and antipyretic effects elsewhere in the body. Following oral administration of aspirin, platelets are exposed to a relatively high concentration of aspirin in the portal blood. This may further contribute to the relatively high sensitivity of platelets toward the action of aspirin. Most other tissues are partly protected from irreversible COX-1 inhibition by presystemic metabolization of aspirin to salicylate through esterases in the liver.

P2Y $_{12}$ Receptor Antagonists

ADP is released from activated platelets by the secretion of dense granules and acts through at least three receptors. These are the ionotropic purinoceptor $2X_1$ ($P2X_1$) and two G-protein-coupled receptors, the G_q-coupled purinoceptor $2Y_1$ ($P2Y_1$), and the G_i-coupled $P2Y_{12}$ receptor. The latter has also been termed $P2T_{AC}$ or $P2_{cyc}$ and is targeted by a group of antiplatelet agents. These include thienopyridines – such as clopidogrel and prasugrel. To become activated, clopidogrel and prasugrel require biotransformation by the hepatic CYP3A4 and CYP2C19



Antiplatelet Drugs, Fig. 2 Mechanisms of platelet activation, together with sites of drug action. Most platelet activators function directly or indirectly through G-protein-coupled receptors and induce several intracellular signaling pathways that eventually lead to secretion of granule contents, change of shape, inside-out activation of GPIIb/IIIa (integrin αIIbβ3), the exposure of factor Va, and subsequent formation of the prothrombinase complex which forms thrombin (factor IIa) as well as the activation of phospholipase A_2 (PLA_2). Activation of GPIIb/IIIa allows fibrinogen (Fb) or vWf to cross bridge adjacent platelets. The main pathway that leads to platelet activation involves the G_q/phospholipase C-β (PLC-β)-mediated formation of inositol 1,4,5 trisphosphate (IP_3) and diacyl glycerol (DAG). This in turn results in the release of Ca^{2+} from intracellular stores and the activation of protein kinase C (PKC) isoforms. Major inhibitors of platelet activation are the endothelium-derived mediators nitric oxide (NO) and prostacyclin (PGI_2). While NO via activation of guanylyl cyclase increases cGMP levels, PGI_2 via activation of a G_s-coupled receptor increases the levels of cAMP. Both cyclic nucleotides inhibit via different mechanism signaling processes involved in platelet activation. Aspirin blocks the conversion of arachidonic acid (AA) to prostaglandin G_2 and H_2 (PGG/H_2) by irreversibly inhibiting cyclooxygenase-1 (COX-1). Active metabolites of thienopyridines and other small molecules such as ticagrelor and cangrelor block ADP ($P2Y_{12}$) receptors on platelets, and GPIIb/IIIa blockers interfere with fibrinogen- and vWf-mediated platelet aggregation. TXA_2 stands for thromboxane A_2

enzymes into active metabolites. The active metabolites irreversibly modify the $P2Y_{12}$ receptor. Due to the requirement of the formation of active metabolites, thienopyridines have a delayed onset of action. Similar to the antiplatelet effects of aspirin, the effects of thienopyridines are long-lasting due to the irreversible inhibition of the $P2Y_{12}$ receptor. In contrast to thienopyridines, ticagrelor and cangrelor are no prodrugs, as they block the receptor directly in a reversible manner.

GPIIb/IIIa (Integrin-IIbβ3) Inhibitors

Most antiplatelet drugs only partially inhibit platelet activation. In contrast, blockers of GPIIb/IIIa interfere at the end of the pathway common to platelet aggregation. They prevent fibrinogen and vWf from binding to activated GPIIb/IIIa and can therefore completely inhibit platelet aggregation. The first GPIIb/IIIa antagonist developed was a hybrid human/murine monoclonal antibody. Its Fab fragment, termed abciximab, is clinically used and functions in a noncompetitive manner.

An alternative approach to block GPIIb/IIIa involves the use of peptides that mimic short protein sequences of fibrinogen or vWf. Several peptides (e.g., the cyclic heptapeptide eptifibatide) or nonpeptidic, low molecular weight compounds (e.g., tirofiban, lamifiban) have been developed and function as competitive antagonists (Table 1).

Others

The proteolytic enzyme thrombin is known to play a crucial role in the overall thrombotic event leading to both arterial and venous thrombosis by transforming fibrinogen into fibrin and by serving as a direct platelet activator. Thrombin exerts its effects on platelets via G-protein-coupled protease-activated receptors (PAR-1 and PAR-4 in human platelets). Thrombin-dependent receptor activation is achieved by cleaving an N-terminal extracellular peptide. Exposure of the newly generated N-terminal region functions as a tethered ligand for the receptor. Substances that directly bind to thrombin have been developed. The 65 amino acid long protein hirudin, originally isolated from the medical leech, *Hirudo medicinalis*, as well as related analogs have been recombinantly produced. They bind with the stoichiometry of 1:1 to thrombin and prevent its proteolytic action on fibrinogen as well as its binding to and the activation of PAR. The proteolytic activity of thrombin can be inhibited also by several small molecules such as argatroban and dabigatran. Since thrombin inhibitors primarily act by inhibiting thrombin-dependent fibrin formation, they are generally classified as anticoagulants.

Since platelets are the major source of TXA_2 production and action, inhibitors of thromboxane synthase and TXA_2 receptor (TP) antagonists are being developed. TXA_2 synthesis inhibitors may have some disadvantages as they lead to the accumulation of cyclic endoperoxides (e.g., PGH_2) that are themselves agonists at the TXA_2 receptor.

The major physiological inhibitors of platelet activation are endothelium-derived mediators like prostacyclin (PGI_2) which via a G_s-coupled receptor activates the formation of cAMP formation by adenylyl cyclase as well as nitric oxide (NO) which stimulates the formation of cGMP by activating guanylyl cyclase. NO-generating drugs like organic nitrates lead to platelet inhibition; however, their main effect is on the vascular smooth muscle. Dipyridamole can inhibit the degradation of cAMP by inhibition of cyclic nucleotide phosphodiesterase and has been used as an antiplatelet agent. However, its clinical usefulness is not clear.

Clinical Use

Due to the pivotal role of platelets in thrombus formation, especially in the arterial system, inhibition of platelet function has become a central pharmacological approach (Depta and Bhatt 2015; Franchi et al. 2015; McFadyen et al. 2018; Metharom et al. 2015). Antiplatelet drugs are given in order to prevent and treat thromboembolic diseases such as coronary heart disease, peripheral disease, and cerebrovascular disease. They have also revolutionized the procedures of invasive coronary interventions as they reduce the risk of restenosis and thrombosis.

Aspirin leads to maximal antithrombotic effects at doses much lower than required for other actions of the drug. Clinical trials have

Antiplatelet Drugs, Table 1 Pharmacological properties of GP IIb/IIIa inhibitors

	Abciximab	Eptifibatide	Tirofiban
Molecular weight (Da)	50,000	800	500
Integrin selectivity	αIIbβ3; αVβ3	αIIbβ3	αIIbβ3
Affinity for αIIbβ3 (K_D; nmol/l)	5	120	15
Plasma half life	0.5 h	2–2.5 h	2 h
Duration of action	12–24 h	2–2.5 h	2 h
Elimination	Proteolysis/renal	Mainly renal	Mainly renal

demonstrated that aspirin is maximally effective as an antithrombotic drug at daily doses of 75–160 mg. Higher doses have no advantage but increase the frequency of side effects, especially bleeding and upper gastrointestinal symptoms. Despite the development of various other compounds, aspirin has remained the gold standard for antiplatelet drugs due to its relative safety and extremely low cost. Several studies have demonstrated a beneficial role for aspirin as an adjunctive therapy in unstable angina and acute myocardial infarction. Mortality and disease progression were significantly reduced by low-dose aspirin treatment. Patients with a history of arterial thromboembolism including myocardial infarction, stroke, transient ischemic attack, or unstable angina were shown to benefit from low-dose aspirin treatment in several trials. The overall rate of mortality, as well as the occurrence of further vascular events, was reduced in these patients. The results of these studies led to the recommendation to use aspirin for secondary prevention of arterial thromboembolism. However, aspirin is not generally recommended for primary prevention of arterial thromboembolism. A possible beneficial effect, such as a decreased risk of nonfatal myocardial infarction, may outweigh the risk of hemorrhagic complications only in a population already at high risk of cardiovascular diseases but not in a population of average health. Aspirin may also be beneficial as a prophylactic agent to reduce the risk of deep venous thrombosis and pulmonary embolism. However, the effectiveness compared to existing therapies remains to be determined; anticoagulants are still the mainstay of treatment in these conditions.

$P2Y_{12}$ receptor antagonists are principally suited to treat conditions that respond to aspirin. In various trials, clopidogrel has been shown to be safe and similarly effective as aspirin. In patients at high risk for cerebrovascular events, thienopyridines seem to be somewhat more effective than aspirin in preventing serious vascular complications. $P2Y_{12}$ receptor antagonists may be used instead of aspirin when the latter is not tolerated. However, aspirin still remains the first choice in most cases due to its low cost, relative safety, and well-documented efficacy. $P2Y_{12}$ receptor antagonists can also be given in patients with acute coronary syndrome as well as during coronary interventions.

GPIIb/IIIa antagonists have to be administered parenterally. They can be used prophylactically during intracoronary interventions such as percutaneous transluminal revascularization with balloon angioplasty or intracoronary stenting, as well as to treat acute coronary syndromes like unstable angina and acute myocardial infarction. They are, however, usually not the first-choice therapy. The main complications are bleeding and thrombocytopenia. The bleeding risk appears to increase further with concomitant therapy with heparin at standard doses.

Synonyms

Antiprotozoan chemotherapeutics; Protocidal drugs

Definition

Protozoa are unicellular eukaryotes and a subregnum of the animal kingdom. Some protozoa exhibit a parasitic life style and are pathogenic to humans, animals, and plants. An estimated 1.5 billion people suffer from protozoal infections, with malaria (*Plasmodium* spp.) alone causing an estimated 219 million clinical cases each year. Other examples of important human infectious diseases with protozoan etiology include toxoplasmosis (*Toxoplasma gondii*), African sleeping sickness (*Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*), Chagas disease (*Trypanosoma cruzi*), visceral, mucocutaneous, and cutaneous leishmaniasis (*Leishmania* spp.), amoebic colitis and liver abscess (*Entamoeba histolytica*), and lamblic enteritis (*Giardia lamblia*). Although there is a huge demand for antiprotozoal drugs, particularly drugs affordable by people living in developing countries, the incentives to develop such drugs are low because of an uncertain return of investments. Accordingly, there is a dearth of efficacious and safe drugs. Only in recent years has this problem been addressed through several private-public partnerships (Aerts et al. 2017). For instance, in 2012 a joint initiative by pharmaceutical companies, donors, endemic countries, and nongovernment organizations signed the London declaration on Neglected Tropical Diseases with the objective of controlling the 10 most important neglected infectious diseases of the tropics and subtropics. Another example includes the Drugs for Neglected Disease Initiative (http://www.dndi.org/), which has had a major impact on the treatment of African trypanosomiasis by fostering the development of nifurtimox-eflornithine combination therapy, fexinidazol as the first all-oral treatment (which was approved by the European Medicines Agency in 2018), and acoziborole as a single dose oral treatment (Drugs for Neglected Diseases Initiative (DNDi) 2018; Pierce et al. 2017). In the following chapter, important antiprotozoal drugs, including their modes of action, will be discussed.

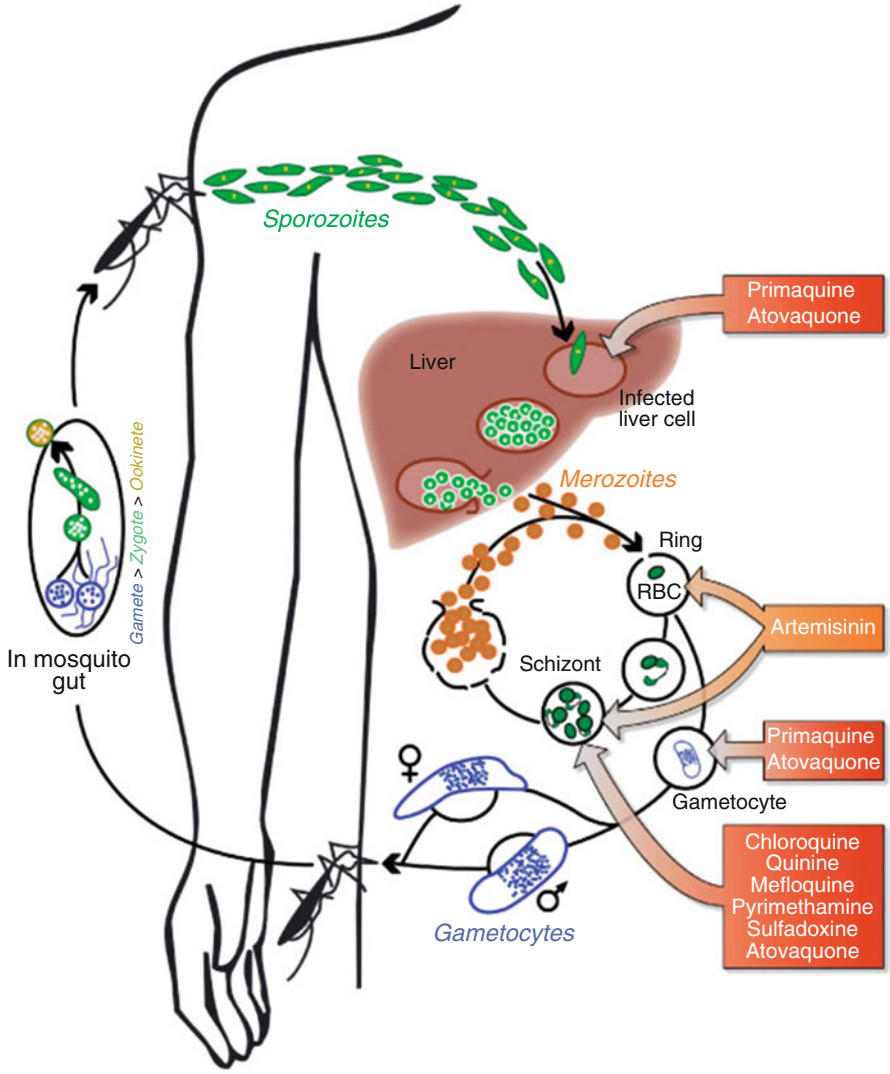
Antimalarial Drugs

Five different protozoa of the genus *Plasmodium* – *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi* – can cause malaria in humans. *P. falciparum* is the most virulent, being responsible for virtually all fatal malaria cases. Humans are infected by a feeding female Anopheles mosquito (Fig. 1). The clinical symptoms of malaria are associated with the development of the parasite within human red blood cells, whereas the liver stages remain asymptomatic. The following drugs (in alphabetical order) are currently in use for the treatment of malaria (Fig. 2) (White et al. 2014; World Health Organization (WHO) 2015).

Mechanism of Action

Amodiaquine, a Mannich base 4-aminoquinoline, eliminates blood stage parasites. Its mode of action is similar to that of chloroquine (see below) and there is some cross-resistance (Martin et al. 2018).

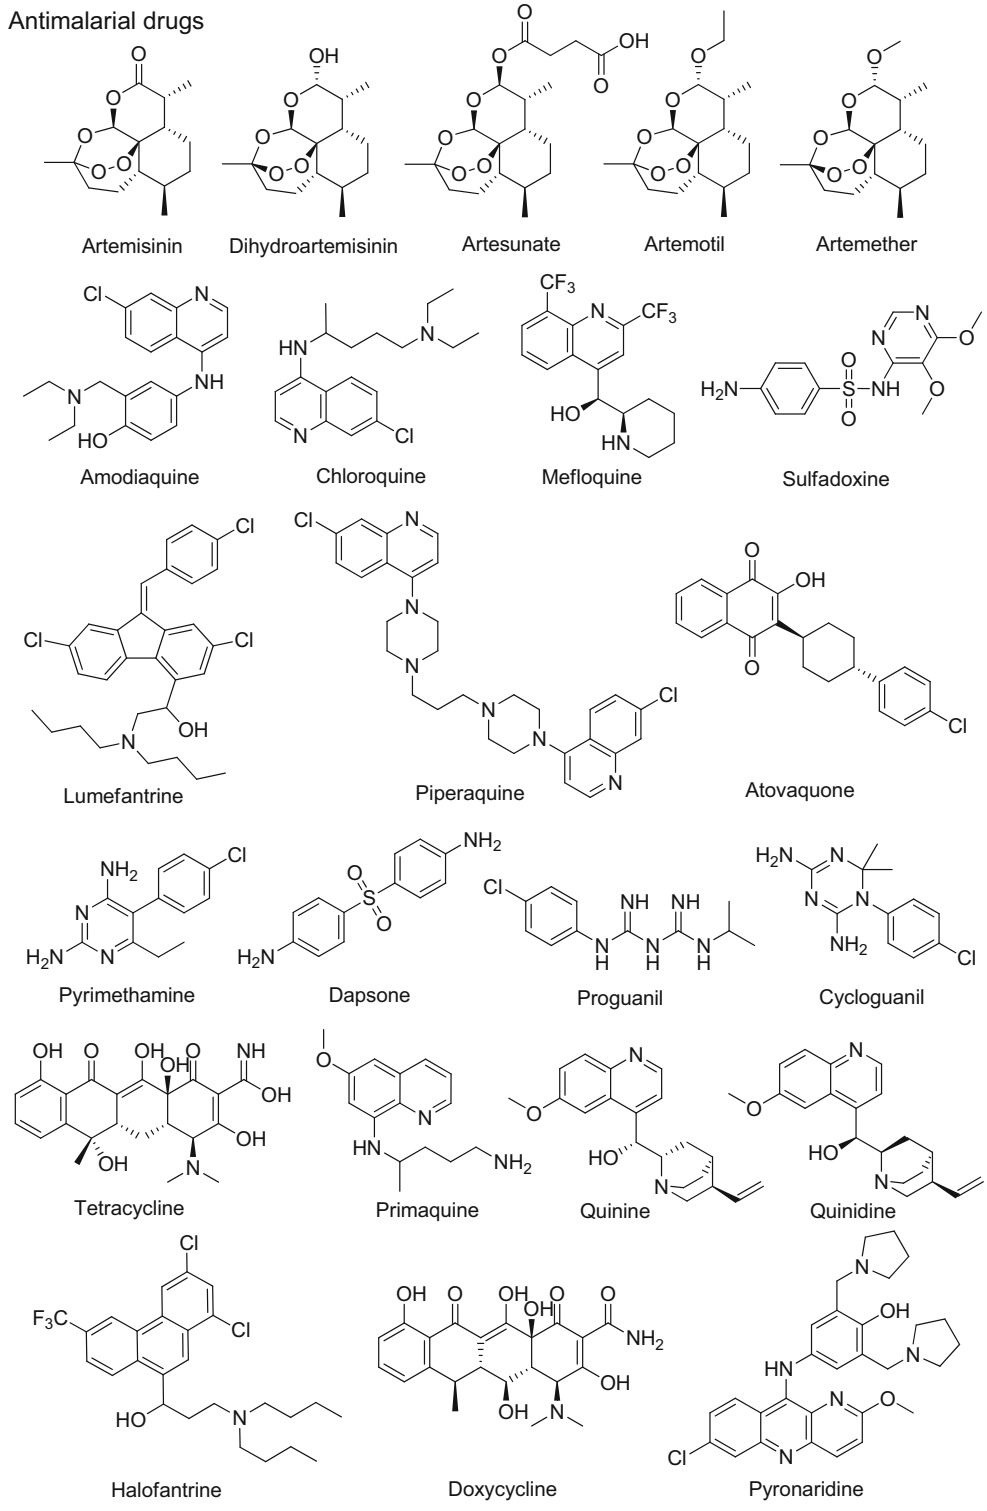
Artemisinin and its derivatives – artesunate, dihydroartemisinin, and arthemether – kill both asexual and sexual blood stages (Fig. 1). However, artemisinins are quickly eliminated from the body, resulting in parasite recrudescence, and are therefore combined with schizontocides that have a longer biological half-life, such as amodiaquine, lumefantrine, mefloquine, piperaquine, and sulfadoxine/pyrimethamine (White et al. 2014; World Health Organization (WHO) 2015). Artemisinin is a sesquiterpene lactone extracted from the leaves of *Artemisia annua*. Also known as qinghaosu, artemisinin has been used in China for the treatment of fever for more than 1000 years. Artemisinins are activated in the parasite via a mechanism that involves iron-catalyzed breakage of their endoperoxide bridge, resulting in carbon centered radicals that subsequently alkylate proteins and other biomolecules (Fig. 3). Damaged proteins are usually polyubiquitinated and targeted for degradation via the proteasome. However, the build-up of damaged and polyubiquitinated proteins during artemisinin exposure overextends the proteasome capacity, which, together with an ensuing stress response, leads to parasite death (Ross and Fidock 2019; Tilley et al. 2016). Artemisinin resistance has emerged at the Thai/Cambodian border in form of a delayed parasite clearance rate. Artemisinin resistance is associated with mutations in the kelch



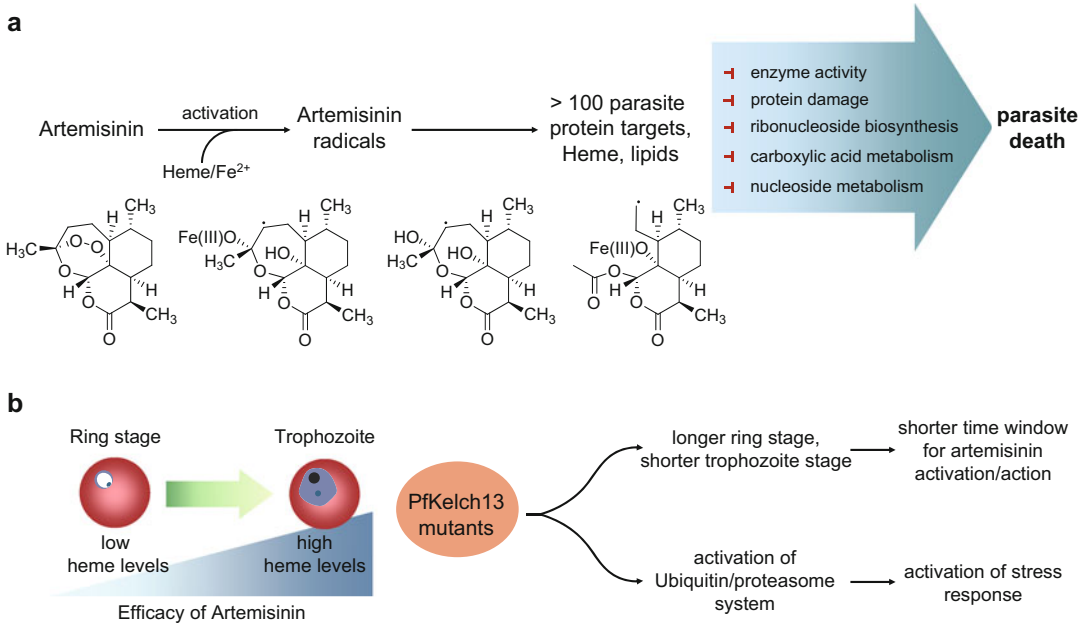
Antiprotozoal Drugs, Fig. 1 Life cycle of malaria parasites and site of action of different antimalarial drugs. Malaria is caused by protozoan parasites of the genus *Plasmodium.* Infected *Anopheles* mosquitoes transmit the parasite to humans during blood feeding. The infective stages are the sporozoites, which invade liver cells where they replicate to form merozoites. Upon rupture of the infected hepatocyte, merozoites are released into the blood stream where they infect erythrocytes. Within the erythrocyte, the parasites develop from ring stages to trophozoits and then to schizonts. When the infected erythrocyte finally ruptures, merozoites are released, which again invade erythrocytes. Some intraerythocytic ring stages develop to sexual stages (gametocytes). Gametocytes are taken up by feeding *Anophelines.* Within the mosquito, the parasites develop into gametes, zygotes, ookinets, and finally sporozoites. Primaquine and atovaquone are effective against liver forms of all *Plasmodia* including dormant stages of *P. vivax* and *P. ovale.* Primaquine also acts against gametocytes. Artemisinin destroys intraerythrocytic ring stage parasites and schizonts. The so-called schizonticidal drugs, chloroquine, quinine, mefloquine, pyrimethamine, and sulfadoxine, act against intraerythrocytic schizonts

propeller domain protein 13, which seems to play a role in ubiquitin-mediated protein degradation and oxidative stress response (Fig. 3) (Ross and Fidock 2019; Tilley et al. 2016).

Atovaquone, a hydroxynaphthoquinone, selectively inhibits the respiratory chain of protozoan mitochondria at the cytochrome bc1 complex (complex III) by mimicking the natural substrate,



Antiprotozoal Drugs, Fig. 2 Chemical structure of relevant antimalarial drugs



Antiprotozoal Drugs, Fig. 3 Proposed mode of action and mechanism of resistance of artemisinins. (**a**) Artemisinins are activated via reaction with ferrous iron, yielding carbon-centered radicals that subsequently alkylate proteins and other biomolecules. As a result, the intracellular processes that degrade damaged proteins via the proteasome are overpowered, leading to a break-down of metabolic pathways. (**b**) Artemisinins act on all asexual blood stages, although the efficacy increases with increasing amounts of heme levels. Artemisinin resistance is associated with mutations in the kelch propeller domain protein 13, which seems to play a role in ubiquitin-mediated protein degradation and oxidative stress response. In addition, artemisinin resistance involves a quiescence mechanism by which parasites remain in a ring-lake stage to outwait toxic drug concentration

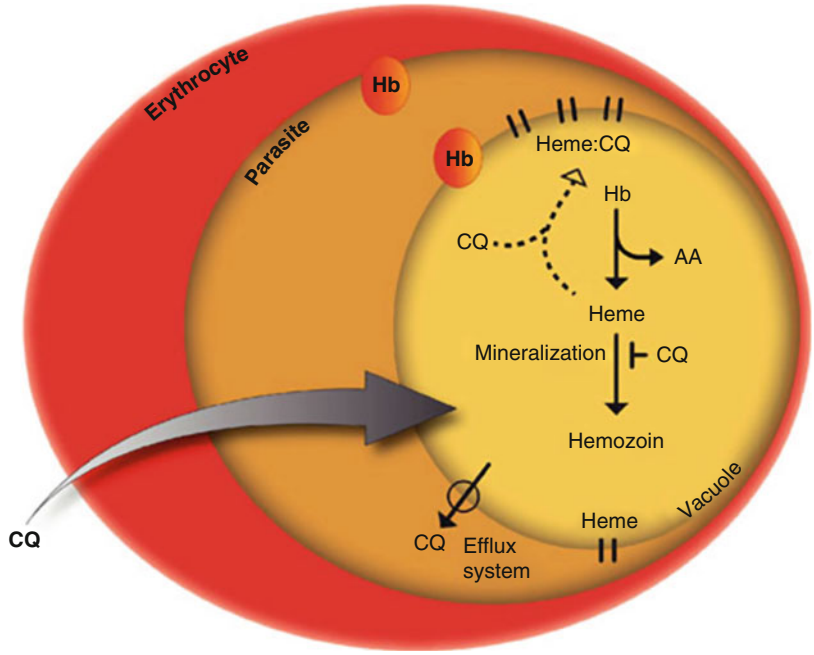
ubiquinone. Inhibition of cytochrome bc1 disrupts the mitochondrial electron transfer chain and leads to a breakdown of the mitochondrial membrane potential. Atovaquone is effective against all parasite stages in humans, including the liver stages.

Chloroquine, a 4-aminoquinoline, targets the intraerythrocytic stages of malarial parasites (Fig. 1). Its mode of action is intricately linked with the plasmodial heme metabolism (Fig. 4). During development within erythrocytes, *Plasmodia* feed on the host cell's hemoglobin, which is digested within an acidic food vacuole. Heme released during hemoglobin proteolysis is highly cytotoxic and perforates cellular membranes. Malaria parasites detoxify heme through biomineralization within their food vacuoles to insoluble and inert hemozoin (malaria pigment). Chloroquine, which accumulates in the food vacuole, prevents heme biomineralization by capping the growing biomineral and by forming complexes with heme, resulting in a build-up of heme and heme–chloroquine complexes. Chloroquine resistance is conferred by mutations in a food vacuolar transporter, termed the *P. falciparum* chloroquine resistance transporter (PfCRT), that expels drugs from the food vacuolar lumen (Fig. 4) (Ross and Fidock 2019).

Dapsone, an aromatic sulfone, is administered in combination with a proguanil derivative. Dapsone inhibits the plasmodial dihydropteroate synthase (DHPS) (Fig. 5).

Tetracycline and its derivative doxycycline are antibiotics widely used in the treatment of bacterial infections. They also exert an antimalarial activity. Tetracyclines inhibit the binding of aminoacyl-tRNA to the ribosome during protein synthesis.

Piperaquine, a bisquinoline, is a rapid acting blood schizontocide. It inhibits the heme



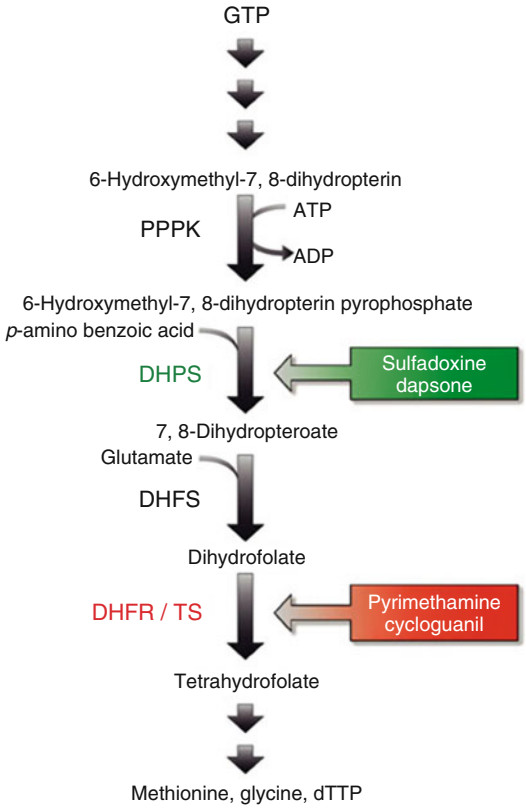
Antiprotozoal Drugs, Fig. 4 The antimalarial activity of chloroquine. Chloroquine's mode of action is associated with heme detoxification. During intraerythrocytic development, *P. falciparum* degrades hemoglobin down to amino acids (AA) in its acidic food vacuole. Heme released from hemoglobin (Hb) is toxic and destroys cellular membranes unless it is converted to an inert biomineral, termed hemozoin or malaria pigment. Chloroquine (CQ) binds to heme, thereby preventing its biomineralization. The build-up of membrane-lytic heme/chloroquine complexes kills the parasite. Chloroquine resistant parasites have acquired an efflux system that expels the drug from the food vacuole

detoxification pathway. Resistance to piperaquine is associated with distinct mutations in the chloroquine resistance transporter PfCRT (Ross and Fidock 2019).

Primaquine, an 8-aminoquinoline, eradicates the dormant stages (hypnozoites) of *P. vivax* and *P. ovale* from the liver. Its mode of action remains obscure.

Proguanil appears to have a dual activity. Part of it is metabolized to cycloguanil, which subsequently inhibits the protozaon dihydrofolate reductase/thymidylate synthase (DHFR/TS) (Fig. 5). Proguanil acts synergistically in combination with atovaquone by lowering the atovaquone concentration required to disrupt the mitochondrial membrane potential.

Pyrimethamine, cycloguanil, and sulfadoxine (sulfadiazine) are folate antagonists that interfere with the folic acid biosynthesis pathway in malarial parasites and other protozoa, including *T. gondii* (Fig. 5) (Ross and Fidock 2019). Folate is an essential precursor of the pyrimidine deoxythymidintriphosphate (dTTP) and the amino acids serine and methionine. Both protozoa and mammalian cells require folate for DNA and protein synthesis. However, protozoa can either synthesize dihydrofolate de novo or salvage folate precursors, whereas mammalian cells have no de novo dihydrofolate synthesis and must rely on dietary sources. By acting as an analogue of *p*-aminobenzoic acid, sulfadoxine (sulfadiazine) inhibits the DHPS, which then fails to convert dihydropteroate to hydroxymethyldihydropterin, resulting in a lack of dihydrofolate in the parasite. This mechanism does not affect the mammalian cells. Pyrimethamine and cycloguanil, the active metabolite of proguanil, act further down in the folic acid pathway by inhibiting the DHFR/TS enzyme complex. In mammalian cells, the DHFR and the TS are two independent enzymes.



Antiprotozoal Drugs, Fig. 5 Mode of action of folate antagonists in protozoa. Protozoa are capable of de novo synthesis of dihydrofolate, a precursor of thymidine, serine, and methionine. The 6-hydroxymethyl-7,8-dihydropterin pyrophosphate pyrophosphokinase (PPPK) and DHPS form one enzyme complex with two distinct active sites. The PPPK transforms GTP to 6-hydroxymethyl-7,8-dihydropterin and then to 6-hydroxymethyl-7,8-dihydropterin pyrophosphate. The product is linked to p-aminobenzoic acid (PABA) by DHPS, forming 7,8-dihydropteroate. Sulfadoxine exerts its activity by acting as a substrate analogue of PABA in this reaction. Glutamate is added to 7,8-dihydropterate by dihydrofolate synthase (DHFS) resulting in dihydrofolate. Dihydrofolate reductase (DHFR) and thymidylate synthase (TS) form a single enzyme complex with two enzymatically active sites. The catalytic site responsible for DHFR activity converts dihydrofolate into tetrahydrofolate. Pyrimethamine and cycloguanil exert their antimalarial activity by inhibiting the protozoal DHFR. The site of DHFR/TS responsible for TS activity converts tetrahydrofolate into deoxythymidintriphosphate (dTTP)

The protozoal DHFR/TS enzyme complex has a higher affinity for pyrimethamine and cycloguanil than does the human DHFR, which explains their high antiprotozoal activity. To avoid deficiency of folic acid in patients treated with antifolate antagonists, folinic acid should be administered. Pyrimethamine is a blood schizontocide and further acts against the liver stages (Fig. 1). Since resistance to pyrimethamine occurs rapidly due to single-point mutations within the DHFR/TS enzyme complex, pyrimethamine is only used in combination with sulfonamides for curative treatment (World Health Organization (WHO) 2015).

Quinine, an arylaminoalcohol, was the first antimalarial known to the Western world. It was originally produced from the bark of the cinchona tree and distributed as a powdery substance, which became known as Jesuits powder. Several potent antimalarials are derived from quinine, including lumefantrine, mefloquine, halofantrine, and quinidine, the dextrarotatory diastereoisomer of quinine. All arylaminoalcohols are believed to kill asexual blood stages by inhibiting heme detoxification in the parasite's food vacuole (Fig. 4), although the mechanism of action is not well understood.

Clinical Use

Malaria treatment has relied on a small number of drug classes: the aminoquinolines (such as chloroquine, amodiaquine, piperaquine); the aminoalcohols (mefloquine, halofantrine, lumefantrine); antifolates (sulfadoxine, pyrimethamine, proguanil); endoperoxides (e.g., artemisinin and derivatives); and the hydroxynaphtoquinone, atovaquone. Various degrees of resistance and geographic distributions of resistance phenotypes have developed for all classes of antimalarials (Martin et al. 2018; Ross and Fidock 2019). Chloroquine now fails in the treatment of falciparum malaria almost everywhere. Even resistance to artemisinin derivatives and artemisinin combination therapies have emerged and are threatening the efficacy of the current mainstay of malaria chemotherapy (Tilley et al. 2016). To prevent, or at least slow down, the emergence of resistance, compounds with different modes of action are being combined. The choice of drug, the route of drug application, and the

dose regimen depend on the type of infection and the severity of the disease. The primary objective of treating uncomplicated malaria is to cure the infection, whereas in severe malaria it is to prevent death.

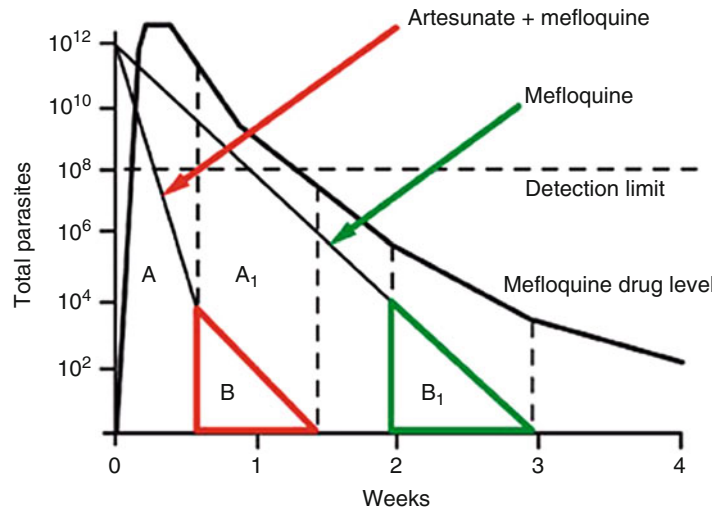
Severe Malaria

Artesunate is the treatment of choice for severe malaria in adults and children (World Health Organization (WHO) 2015). In severe malaria, rapid clearance of parasites is vital. Artesunate achieves this by damaging circulating ring stages, which are subsequently removed from circulation by the spleen. As a consequence, the parasite load rapidly declines by approximately four orders of magnitude within 48 h. Moreover, as the development of ring stages to the trophozoites is disrupted by artesunate, the progression of the disease is stopped. Trophozoites are the main pathological cause of falciparum malaria as they acquire cytoadhesive properties and sequester in the deep vascular bed of inner organs, including the brain, lung, and placenta, where they can cause hypoxia, impaired tissue perfusion, and the syndromes associated with cerebral and maternal malaria (White et al. 2014). Artesunate is water-soluble and is given by intravenous or intramuscular injection. In case artesunate is unavailable, artemether is preferred over quinine (World Health Organization (WHO) 2015). Artemether is applied intramuscularly.

Uncomplicated Malaria

The treatment of uncomplicated malaria seeks to prevent recrudescence and, at the same time, tries to prevent the development of resistance. This is the rationale behind artemisinin-based combination therapies (ACT). Artemisinin and its derivates (artesunate, artemether, artemotil, dihydroartemisinin) are clearing both parasitaemia and symptoms rapidly (White et al. 2014; World Health Organization (WHO) 2015). There is little difference in absorption and bioavailability among the different artemisinin derivatives. Due to the extraordinary high parasite clearance rate, artemisinin and its derivates quickly reduce the total burden of parasites to very low levels (Fig. 6). Thereafter, the eradication of the remaining parasites relies on the partner drug (Fig. 6). The partner drug needs to be effective and parasiticidal concentrations have to be sustained until all parasites have been killed. A slowly eliminated drug is ideal. The artemisinin derivatives are well tolerated, although type 1 hypersensitivity reactions have been reported in a few rare cases.

ACTs with amodiaquine, atovaquone–proguanil, chloroquine, clindamycin, doxycycline, lumefantrine, mefloquine, piperaquine, pyronaridine, proguanil–dapsone, sulfadoxine–pyrimethamine, and tetracycline have been evaluated in trials. The following ACTs are currently recommended for all cases of uncomplicated



Antiprotozoal Drugs, Fig. 6 Artemisinin combination therapy (ACT): Adding a 3-days artesunate course to mefloquine clears the parasitaemia much more rapidly ($A_1 \rightarrow A$). The remaining parasites are exposed to higher mefloquine levels in ACT (B) compared to mefloquine monotherapy (B_1) (with permission White, 1997 Antimicrob Agents Chemother 41:1413–1422)

falciparum malaria: artemether–lumefantrine, artesunate-mefloquine, dihydroartemisinin-piperaquine (White et al. 2014; World Health Organization (WHO) 2015). In regions of low antifolate and amodiaquine resistance, artesunate-sulfadoxine-pyrimethamine or atresunate amodiaquine can also be used (White et al. 2014; World Health Organization (WHO) 2015). In South-East Asia particularly in western Cambodia and the Thailand-Myanmar border, artemisinin-resistant *P. falciparum* has emerged, limiting the use of ACTs. Resistant parasites show delayed parasite clearance rated of more than 3 days (White et al. 2014). Amodiaquine, sulfadoxine–pyrimethamine, and, to a lesser extent, mefloquine resistance is also present with a prevalence of approximately 20% in this region. The Worldwide Antimalarial Resistance Network (http://www.wwarn.org) provides up-to-date information regarding the prevalence and distribution of antimalarial drug resistance.

Malaria Treatment and Chemoprophylaxis in Nonimmune People

Travelers treated for malaria after returning to non-endemic regions are treated along the same lines as above regarding uncomplicated and severe forms of the disease. Considerations with respect to development of resistance can be neglected. The following drugs are recommended: artemether–lumefantrine, dihydroartemisinin-piperaquine, atovaquone–proguanil, for uncomplicated malaria and intravenous artesunate for severe malaria or, if artesunate is not available quinine plus doxycycline or clindamycin (World Health Organization (WHO) 2015). For the millions of nonimmune travelers to malaria-endemic areas, chemoprophylaxis (high-risk areas) and stand-by treatment (low-risk areas) are the corner stones of malaria prevention (World Health Organization (WHO) 2015), along with exposition prophylaxis using repellent and insecticide-impregnated bednets.

Intermittent Preventive Therapy in Pregnant Women and Infants

In endemic areas, chemoprophylaxis has been abandoned for a variety of reasons, mainly due to sustainability problems and the risk of contributing to the development of resistance. Intermittent preventive therapy (IPT), however, appears to be an alternative to protect pregnant women (IPT_p) and children during the first year of their life (IPT_i) (World Health Organization (WHO) 2015).

Antimalarial Drugs (*P. vivax, P. ovale, P. malariae*)

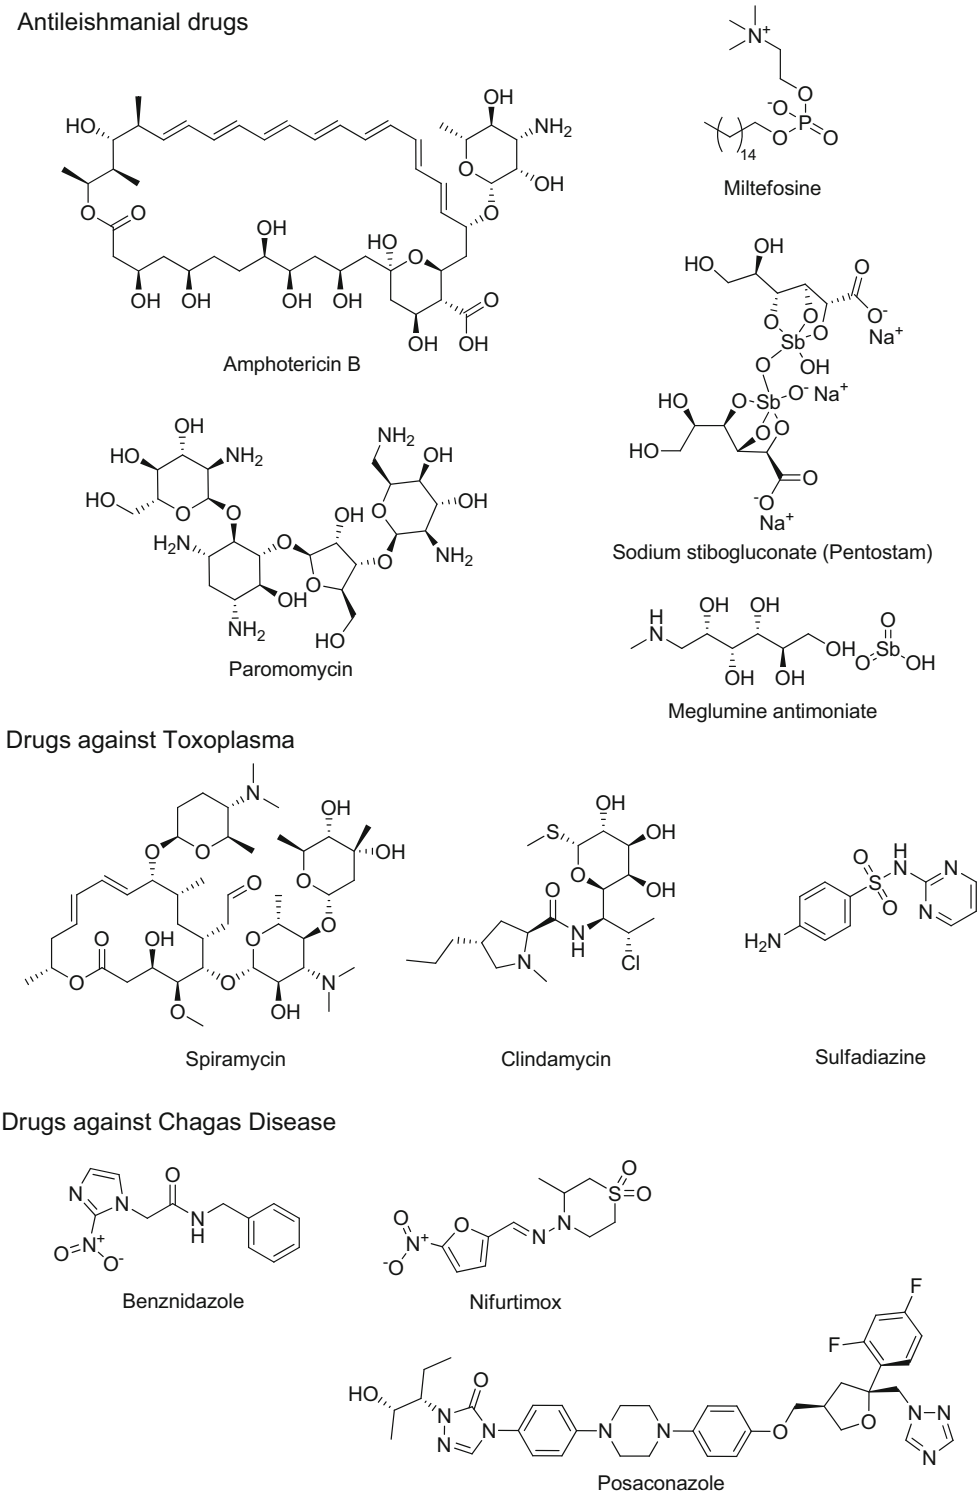
Resistance of *P. vivax* to chloroquine occurs, but it is geographically limited. Chloroquine is recommended for the treatment of chloroquine sensitive *P. vivax*, *P. ovale*, and *P. malariae* infections. Alternatively artemisinin-combination treatment can be prescribed. *P. vivax* and *P. ovale* produce hypnozoites, parasite stages in the liver that can produce multiple relapses. To achieve radical cure of *P. vivax* and *P. ovale* infection, treatment with schizonticidal drugs must be followed by treatment with primaquine to eliminate the dormant liver stages (White et al. 2014; World Health Organization (WHO) 2015).

Antileishmanial Drugs

Leishmaniasis is a disease complex caused by different species of *Leishmania*. The parasite, which is transmitted to humans by the bite of phlebotomine sandflies, multiplies within human macrophages. There are an estimated one million cases in approximately 97 countries each year and every year there are 60,000–90,000 new cases of visceral leishmaniasis.

Mechanism of Action

Amphotericin B is a polyene antibiotic (Fig. 7), used also in the therapy of systemic fungal infections. Its mode of action exploits differences in membrane composition between the pathogen and the human host. Ergosterol, the predominant sterol of fungi, plants, and some protozoan parasites, interacts with Amphotericin B, resulting in an increased ion permeability of the membrane (Ghorbani and Farhoudi 2018; Ponte-Sucre et al. 2017). Human membranes contain cholesterol, which has a low affinity for amphotericin B.



Antiprotozoal Drugs, Fig. 7 Chemical structure of relevant drugs for the treatment of Leishmaniasis, Toxoplasmosis, and Chagas disease

Miltefosine (Fig. 7), an alkylphosphocholine derivative, is a new antileishmanial drug and the first effective oral treatment of visceral leishmaniasis. However, there are concerns regarding teratogenicity, rapid emergence of resistance, and variable cure rates, possibly due to species differences in drug sensitivity. The mechanism of action of miltefosine seems to be complex, by interfering with intracellular Ca^{2+} homoeostasis, phosphatidylcholine synthesis, and mitochondrial cytochrome c oxidase (Ghorbani and Farhoudi 2018).

The pentavalent antimonial drugs, sodium stibogluconate and meglumine antimonate (Fig. 7), are prodrugs that require biological reduction to the trivalent form Sb(III) for antileishmanial activity. Sb(III) seems to inhibit the leishmanial trypanothione reductase, which, together with a depletion of thiols, results in a breakdown of the cellular thiol redox potential (Ponte-Sucre et al. 2017). *Leishmania* and other kinetoplastidae possess an unusual antioxidant termed trypanothione, which is composed of two molecules of glutathione joined by a spermidine linker. Trypanothione protects the cell from oxidative stress by reducing disulfide bonds formed within proteins. The trypanothione reductase regenerates oxidated trypanothione.

Clinical Use

Management of the disease varies with clinical presentation, host, geographic area, species, availability of drugs, and costs of treatment.

Pentavalent antimonial drugs have been the cornerstone of antileishmanial therapy for decades, in spite of their general toxicity (Burza et al. 2018; Ponte-Sucre et al. 2017). Pentavalent antimonial drugs are available in two formulations: sodium stibogluconate and meglumine antimoniate. Antimonials are cardiotoxic and painful when administered by intramuscular injection. Resistance to pentavalent antimonial drugs is widespread in India and is no longer recommended in this part of the world. They are, however, still used elsewhere, particularly in East Africa where resistance has remained low. Liposomal Amphotericin B is the drug of choice in the Indian subcontinent (Burza et al. 2018).

Liposomal Amphotericin B (LAMB) is a highly effective drug against visceral leishmaniasis with remarkably few side effects. Short treatment courses over a period of 3–5 days are recommended by the WHO in the Indian subcontinent. In some instances combination treatment is used (see below).

Amphotericin B: This second line drug has is poorly tolerated due to hypokalemia and nephrotoxicity. Prolonged treatment is necessary.

Paromomycin (PM), an oral aminoglycoside, is effective as a topical treatment for cutaneous leishmaniasis and, as a parenteral drug, against visceral leishmaniasis (Ponte-Sucre et al. 2017). Injectable paromomycin has been registered in India in 2006. It can be given in combination with LAMB or miltefosine (MF).

Miltefosine (MF): The antileishmanial activity of this anticancer drug was discovered in the mid-1980s. It has been used as an oral drug against visceral and cutaneous/mucocutaeous leishmaniasis in India in 2002. After more than a decade of use, there is evidence of reduced effectiveness. Treatment combinations with LAMB and PM exist.

Pentavalent antimonials (SbV) are the treatment of choice in combination with intramuscular PM in East Africa.

Antitoxoplasma Drugs

Infection with the obligatory intracellular parasite *T. gondii* is mainly acquired by ingestion of contaminated food or water. Approximately a third of the world's human population is infected.

Mechanism of Action

Clindamycin (Fig. 7), a lincosamide derivative, inhibits protein biosynthesis within a unique organelle of the parasite, termed apicoplast. Its mode of action is similar to that of spiramycin.

The folate antagonists, pyrimethamine and sulfadiazine, inhibit the parasite's DHFR/TS synthase enzyme complex and the DHPS, respectively (Figs. 2, 5, and 7) (see antimalarial drugs). To avoid deficiency of folic acid in patients treated with antifolate antagonists, folinic

acid supplementation is recommended to reduce bone-marrow suppression.

Spiramycin (Fig. 7) is a macrolide that inhibits protein biosynthesis by blocking transfer of the aminoacyl-tRNA along the ribosome in a unique organelle of the parasite, termed apicoplast (Dunay et al. 2018). The apicoplast is a remnant of a secondary endosymbiosis of a red algae and is only found in the phylum sporozoa.

Clinical Use

Toxoplasmosis remains a challenge to clinicians. *T. gondii* is one of the most prevalent parasites worldwide and it persists in the body for a lifetime. The infection passes unnoticed or with little signs and symptoms in immunocompetent children and adults. However, the parasite poses a major threat when acquired during pregnancy and transmitted to the fetus, and in immunocompromised patients with or without AIDS, due to a reactivation of latent disease or newly acquired infection. The major clinical conditions are congenital toxoplasmosis, ocular toxoplasmosis, and toxoplasmic encephalitis. Current treatment options are confined to the acute stage, but do not eradicate the parasite from the patient. The most commonly used treatment, and currently probably the most effective, is the combination of pyrimethamine and sulfadiazine, supplemented by folinic acid to prevent bone marrow suppression (Dunay et al. 2018; Montoya and Liesenfeld 2004). In maternal infection during pregnancy, the primary goal is to prevent transmission to the fetus, and the secondary goal, to treat the infected fetus at the earliest time possible to reduce damage. Due to the specific requirements during pregnancy, spiramycin is recommended for the first and early second trimester and pyrimethamine/sulfadiazine for the late second and third trimester (Dunay et al. 2018; Montoya and Liesenfeld 2004). In most countries, treatment is continued in the newborn for various lengths of time. The efficacy of this regimen, however, has still to await confirmation by appropriately designed studies, and different drug regimens and strategies need to be tested for different clinical settings. In the immunocompromised patients, recrudescence after successful treatment of acute toxoplasmosis is a problem. If restitution of the immune response cannot be achieved or is, for therapeutic purposes, not desired, chemoprophylaxis needs to be installed.

Drugs Against Chagas Disease

Chagas disease is a serious public health problem in Latin America, where an estimated 700,000–800,000 people are infected (Perez-Molina and Molina 2018). The causative agent is *Trypanosoma cruzi*, which is transmitted to humans by reduviid vectors (such as triatomines). During acute disease, the parasite develops intracellularly in many tissues, including nervous and muscular tissue. Focal parasite-induced degeneration of infected organs, particularly the heart and the gastrointestinal tract, characterizes the chronic form.

Mechanism of Action

Benznidazole (Fig. 7), a nitroimidazole derivative, has a mode of action that seems to involve covalent modification of macromolecules by nitroreduction intermediates.

Nifurtimox (Fig. 7), a nitrofuran, is a prodrug that is reduced to unstable nitroanion radicals, which react to produce highly toxic oxygen metabolites, such as superoxide and peroxide. Oxidative stress subsequently kills the parasite, which seems to lack effective enzymatic pathways to detoxify oxygen metabolites.

Clinical Use

Benznidazole and nifurtimox, which have been developed in the 1960s and 1970s, have remained the only two drugs available for the acute stage of the disease (Perez-Molina and Molina 2018). There is no proven effect on the chronic stage. The specific treatment of the chronic stage has gained renewed interest with recent findings where persisting parasites may play a role in the development of irreversible lesions. The side

effect of the two available compounds can be severe. The development and testing of new drugs has been slow. Recently, posaconazole, one of the most promising new drug candidates failed to cure Chagas patients (Bermudez et al. 2016).

Drugs Against African Sleeping Sickness

African sleeping sickness has reached a historical low due to sustained efforts to control the spread of this disease over the past 15 years. 2804 cases were reported by the WHO in 2015 of which 2733 were caused by *T. brucei gambiense*. The etiological agents, *T. brucei gambiense* and *T. brucei rhodesiense*, are transmitted to humans by the bite of Tsetse flies.

Mechanism of Action

Eflornithine (difluoromethylornithine, DFMO) (Fig. 8) enters the parasite via an amino acid transporter. It inhibits the ornithine decarboxylase of the polyamine pathway, in both the trypanosome and the mammalian cell, by acting as an irreversible competitor of the natural substrate ornithine. Inhibition of ornithine decarboxylase results in depletion of the polyamines, putrescine, spermidine, and spermine, which are essential for cell proliferation. Eflornithine selectively harms the parasite and not the mammalian cells, despite acting as an ornithine decarboxylase inhibitor in both cell types. This selectivity is explained by the lower rate of ornithine decarboxylase production in the parasite, as compared to mammalian cells. Due to the high turnover rate, mammalian cells are capable of quickly replenishing inhibited ornithine decarboxylase by newly synthesized enzyme. Eflornithine is only effective against *T. brucei gambiense* (Buscher et al. 2017; Hedley et al. 2016).

Melarsoprol (Fig. 8), a trivalent organic melaminophenyl arsenic compound, kills intracerebral parasites of both *T. brucei gambiense* and *T. brucei rhodesiense* via rapid cell lysis (Fairlamb and Horn 2018). Melarsoprol enters trypanosomes via an adenosine/adenine transporter and via aquaglyceroporin 2. The mode of action of melarsoprol is largely unclear. Initial evidence suggests that melarsoprol interferes with redox homoeostasis by forming a complex with the antioxidant trypanothione. The complex, termed MelT, inhibits the antioxidant enzyme trypanothione reductase. Resistance to melarsoprol is associated with mutations in aquaglyceroporin 2, leading to reduced drug uptake. Melarsoprol is highly toxic to humans.

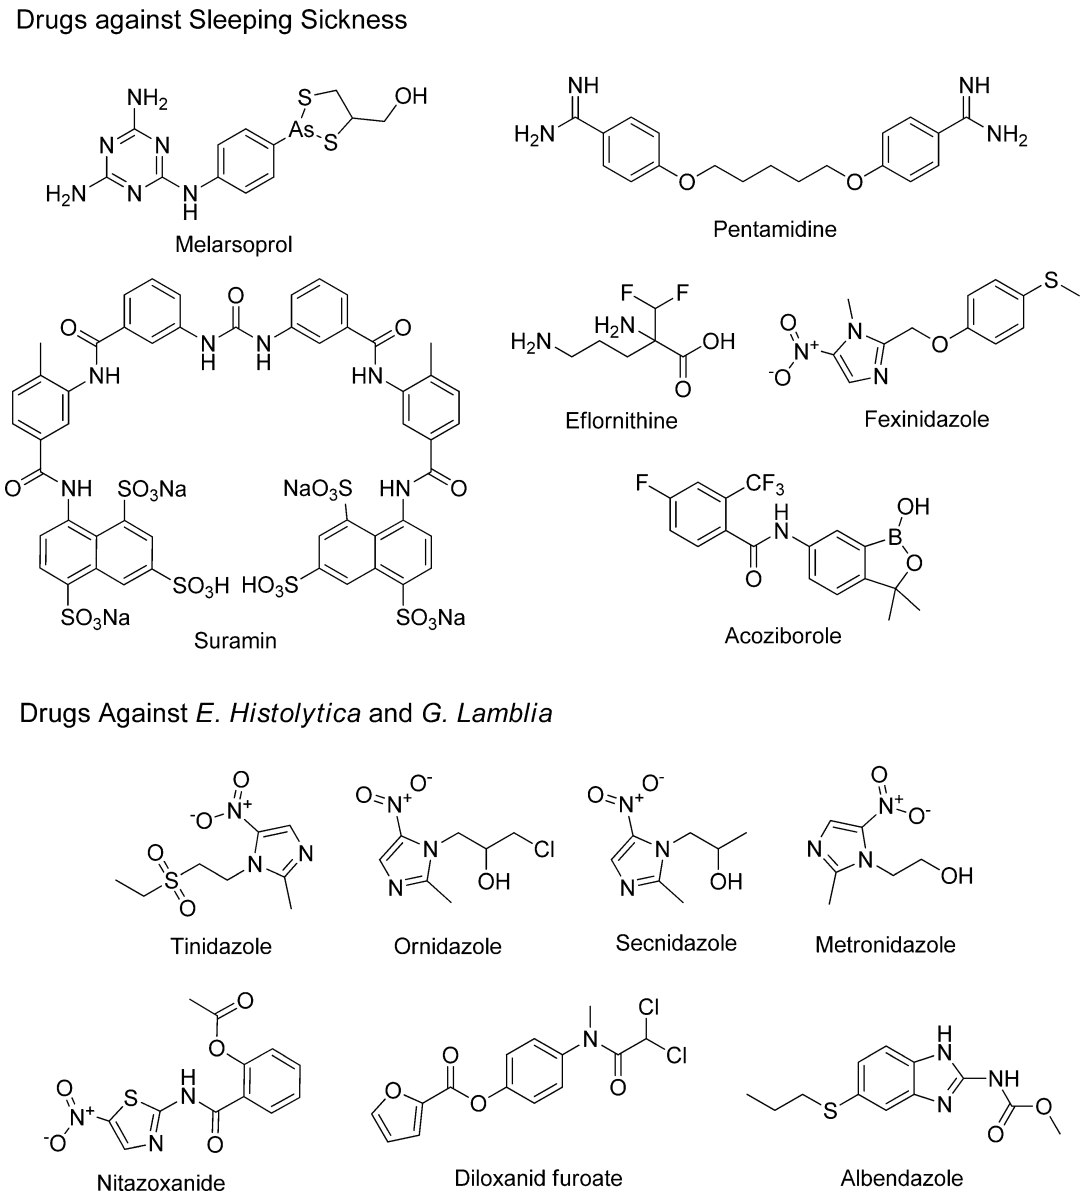
Nifurtimox and fexinidazole (Figs. 7 and 8) are nitro pro-drugs that are activated by a ubiquinone nitroreductase in the mitochondrion of the parasite. Their mode of action is unclear, but may involve disruption of mitochondrial functions.

Pentamidine is an aromatic diamidine (Fig. 8). Pentamidine uptake by the parasite is mediated by several different adenosine transporters. The mode of action is unclear. There is, however, evidence suggesting that pentamidine inhibits DNA, RNA, and protein synthesis.

Suramin (Fig. 8), a symmetrical, polysulfonated naphthylamine, is selectively taken up by the parasite via receptor-mediated endocytosis. It inhibits a number of trypanosomal enzymes, including pyruvate kinase, leading to an inhibition of energy production.

Clinical Use

There has been substantial progress in the treatment of African sleeping sickness in recent years (Buscher et al. 2017; Hedley et al. 2016). The first line treatments for the acute hemolymphatic stage are pentamidine *(T. brucei gambiense)* and suramin *(T. brucei rhodesiense)* (Buscher et al. 2017). The late central nervous system stage is treated using nifurtimox-eflornithine combination therapy in the case of *gambiense* African trypanosomiasis. The efficacy of nifurtimox-eflornithine against *T. brucei rhodesiense* has not yet been explored and melarsopol remains the treatment of first choice. Melarsoprol is highly toxic and can causes reactive encephalopathy, a lethal complication in 2–10% of treated patients.



Antiprotozoal Drugs, Fig. 8 Chemical structure of relevant drugs for the treatment of Sleeping Sickness, Amoebiasis, and Lambliasis

A cumbersome dosing schedule, used for decades, has recently been shortened to a 10-days course based on pharmacokinetic studies and controlled clinical trials. This certainly will improve patient compliance and costs. Fexinidazole has received a positive scientific review by the European Medicine's Agency in November 2018 for the treatment of *T. bucei gambiense*. WHO treatment guidelines are currently being updated to define the role of fexinidazole. Fexinidazole is registered in the Democratic Republic of Kongo (Buscher et al. 2017).

Drugs Against *E. Histolytica* and *G. Lamblia*

Entamoeba histolytica and *Giardia lamblia* are waterborne infectious diseases that cause colitis and liver abscess, and enteritis, respectively (Hemphill et al. 2019).

Mechanism of Action

5-Nitroimidazoles derivatives (Fig. 8), such as metronidazole, tinidazole, ornidazole, and secnidazole, are the drugs of choice in the treatment of anaerobic protozoa. All 5-nitroimidazoles share the same mode of action. Anaerobic microorganisms reduce 5-nitroimidazoles to their active forms. This process only occurs under strongly reducing conditions. In some anaerobic protozoa and bacteria, such conditions are achieved when ferredoxin is reduced by the fermentation enzyme pyruvate ferredoxin oxidoreductase (POR). Ferredoxin can transfer one electron to 5-nitroimidazole, resulting in the reduction of the nitro group. POR does not occur in mammalian cells. The corresponding enzyme to POR in mammalian cells is pyruvate decarboxylase, which is not able to establish a reducing potential high enough for the reduction of 5-nitroimidazoles. The reduced products of 5-nitroimidazoles disrupt the DNA structure, thereby interfering with transcription and replication.

Clinical Use

Entamoeba histolytica colonization of the large intestine is eradicated using a luminal agent such as diloxanid furoate or paromomycine (Figs. 7 and 8). Invasive amoebiasis (colitis, liver abscess) is treated with one of the 5-nitroimidazole derivatives (Leder and Weller 2019), followed by a luminal agent to prevent relapses from remaining cysts in the intestine.

Giardia lamblia is treated with 5-nitroimidazole derivatives. Albendazole, paromomycine, and nitazoxanide (Figs. 7 and 8) are second line treatments. Antimicrobial resistance is estimated at 20% and repeated treatment courses may be necessary. Patients who are repeatedly treated by monotherapy may benefit from combination treatment, that is, metronidazole plus albendazole (Bartelet 2018).

Synonyms

Thionamides

Definition

Antithyroid drugs are defined as drugs that inhibit thyroid hormone synthesis. Clinically, these drugs were developed for the treatment of hyperthyroidism (Burch and Cooper 2018). The mainstay of current antithyroid drugs is thionamides, sulfur-containing derivatives of thiourea. Second-line drugs known to negatively impact thyroid production at the level of the thyroid gland include iodine, perchlorate, and cholestyramine. Drugs such as β-blockers and glucocorticoids may inhibit thyroid hormone function in peripheral tissue. Among β-blockers, propranolol has been demonstrated to impair peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). Though in its preliminary stages, a selective thyrotropin receptor (TSHR) antagonist has been shown to have antithyroid properties in an animal model (Neumann et al. 2014). This may be a promising and novel therapeutic target in the treatment of Graves' disease; however, its clinical use has yet to be determined. The focus of this entry will be on the mechanism of action, pharmacokinetics, and clinical use of thionamides.

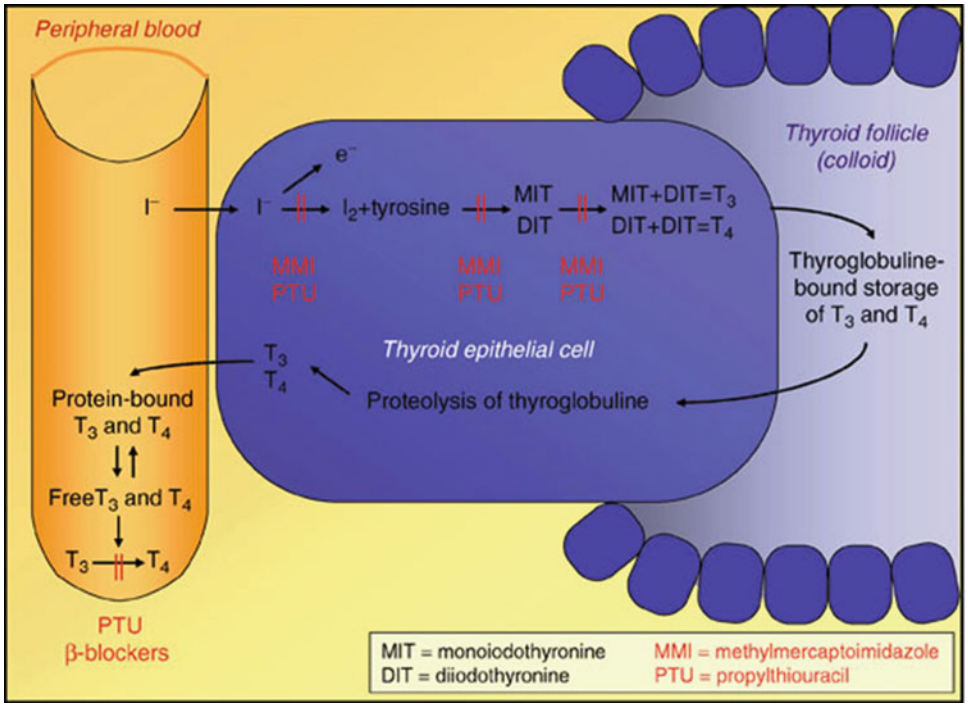
The antithyroid properties of thionamides were first noted in the early 1940s by three independent groups (Mackenzie, Richter, and Kennedy)

(Kennedy 1942; Mackenzie et al. 1941; Richter and Clisby 1942). These groups each observed goitrogenic effects of sulfaguanidine and/or thiourea in animal models. In 1942, Professor Edwin B. Astwood unified the results of these studies and proposed a novel therapy for hyperthyroidism using thiourea. Further purification of 2-thiouracil as a potent antithyroid drug led the first documentation of successful hyperthyroidism treatment (Astwood 1984). The search for more potent and less toxic agents led to the discovery of 6-*n*-propylthiouracil (PTU) in 1946, methimazole (MMI) in 1949, and carbimazole (CBM) in 1956. These antithyroid drugs remain the cornerstone of hyperthyroid treatment today, over 60 years later (Burch and Cooper 2018).

Thionamides are heterocyclic thiocarbamide compounds that are derivatives from thiourea. Thiouracil and PTU belong to the pyrimidines subgroup, whereas MMI and CBM belong to the thioglyoxalines subgroup. CBM is an MMI prodrug that was developed with the unachieved goal of less toxicity. CBM is used predominantly in the United Kingdom, whereas MMI is favored in North America, most of Europe and Asia.

Mechanism of Action

The mechanism of thionamide action is incompletely elucidated; however, our current understanding involves multiple actions within the thyroid hormone production pathway (Fig. 1). Biologically active thyroid hormones, triiodothyronine (T_3) or thyroxine (T_4), are synthesized within the thyroid in five sequential steps. First,



Antithyroid Drugs, Fig. 1 Synthesis and secretion of thyroid hormones and mechanisms of action of antithyroid drugs. Iodine is actively concentrated by the thyroid gland (sodium-iodide transporter). After oxidation it is bound to thyrosine residues, thus forming monoiodothyronine (MIT) or diiodothyronine (DIT). MIT and DIT are coupled to triiodothyronine (T_3) or thyroxine (T_4) and are stored in thyroid follicles bound to thyroglobulin. Thyroid hormones are released by proteolysis. In the thyroid and in peripheral tissue, T_4 is converted to T_3. Antithyroid drugs act by inhibiting the thyroid peroxidase-mediated formation of T_3 and T_4 and compete with iodothyronine residues for oxidized iodine. Moreover, they inhibit iodine oxidation. Propylthiouracil (PTU), but not methimazole (MMI), inhibits the monodeiodination of thyroxine to triiodothyronine

inorganic iodide is actively transported into the basement membrane of thyrocyte via the sodium-iodide symporter, a process known as trapping. Second, organification occurs at the apical-colloid interface with the oxidation of iodide to iodine (iodination) and binding of iodine to tyrosyl residues of thyroglobulin (Tg) to form monoiodothyronine (MIT) or diiodothyronine (DIT). Third, MIT and DIT are coupled (appropriately termed coupling) to form T_3 and T_4. Iodination and coupling are catalyzed by thyroid peroxidase (TPO) with hydrogen peroxide. Fourth, T_3 and T_4 are stored in the follicular lumen until the reentry of Tg in a pinocytosis process forming lysosomes. The fusion of lysosomes with colloid vesicle releases T_3 and T_4 into the circulation. Lastly, two deiodination processes occur within the thyroid cell: deiodination of MIT and DIT by intrathyroidal deiodinase releasing useable iodide and deiodination of T_4 to T_3 through Type I and Type II 5′-deiodinases (Miehle and Paschke 2003). The majority of T_4 to T_3 deiodination occurs in peripheral tissue (Fig. 1).

The predominant mechanism of thionamides as antithyroid drugs is mediated through TPO inhibition during iodine organification (Davidson et al. 1978; Taurog 1976). Specifically, the heme residues of TPO are bound to oxidized iodide prior to its subsequent iodination to thyroglobulin. In the presence of iodine, thionamides act as competitive inhibitors to TPO and become iodinated themselves thus reducing MIT and DIT levels. These inhibition rates depend mainly on the iodine to drug concentration ratio. At high iodine to drug ratio, the inhibition of iodination is reversible and TPO is only partially inactivated. Under these conditions extensive drug oxidation occurs. When the iodine to drug ratio is low, iodination is irreversibly inhibited. This is associated with rapid and complete inactivation of TPO (Miehle and Paschke 2003). Furthermore, thionamides have also been shown to a lesser degree to impair coupling and thyroglobulin synthesis and function (Engler et al. 1983; Monaco et al. 1980).

PTU has distinct inhibitory properties on Type I 5′-deiodinases, properties not shared by MMI or CBM. This results in reduction of T_4 to T_3 conversion, which theoretically results in reduced biologically active thyroid hormone action.

Lastly, thionamides have been associated with decreased thyroid-stimulating antibody titers (Fenzi et al. 1979). Antithyroid drugs have both direct and indirect immune effects that result in reduced thyrotropin receptor antibodies (TRAbs) (Hesarghatta Shyamasunder and Abraham 2017). Similar results have been noted following thyroidectomy and gradually (6–12 months) following radioactive iodine therapy. The degree of TRAb reduction associated with therapy is important in three areas: (1) prediction of Graves' disease remission (Hesarghatta Shyamasunder and Abraham 2017), (2) management of Graves' orbitopathy (Kahaly et al. 2019), and (3) risk of fetal hyperthyroidism in pregnancy (Abeillon-du Payrat et al. 2014).

Pharmacokinetics

MMI and CBM are well absorbed in the gastrointestinal tract. After oral ingestion of 15 mg MMI, peak serum concentrations increase linearly and are in the range of 300 ng/ml at 1–2 h. In vitro, CBM is an effective inhibitor of iodination without prior hydrolysis to MMI. This is contrasted in vivo, where CBM is biologically inactive prior to conversion to MMI. In human serum, CBM is almost completely converted to MMI. Ten milligram CBM is equivalent to 6.7 mg MMI (Miehle and Paschke 2003). MMI is minimally protein bound. The total volume distribution is approximately 40 L and the serum half-life is 4–6 h. MMI can be applied parenterally (Wu et al. 2013). MMI and CBM are likely metabolized by the liver as patients with hepatic disease have prolonged plasma levels, whereas the levels are unchanged in chronic kidney disease and is minimally excreted in urine (Cooper 2005).

PTU is also well absorbed in the gastrointestinal tract. After a 150 mg oral dose, peak serum concentrations are in the range of 3 μg/ml at 1 h. PTU is 80–90% protein bound. The total volume distribution is around 30 L and the serum half-life of PTU is 75 min. Drug levels are not impacted in patients with thyrotoxicosis, renal disease, or liver

disease. PTU is mostly excreted in the urine after hepatic conjugation with glucuronide (Cooper 2005). Biotransformation of PTU primarily occurs at the S group. It results in substantial loss of antiperoxidase activity. The metabolites, 6-*n*-propyluracil, *S*-methyl-PTU, PTU disulfide, and PTU glucuronide, are only weakly active or completely inactive as TPO inhibitors.

For peri- and postpartum women, the lipophilic character of MMI allows for transplacental passage and for relatively elevated levels in breast milk. While PTU also crosses the blood-placenta barrier, PTU is excreted in breast milk to a lesser degree than MMI due to its the high protein binding and ionization at a physiologic pH (Cooper 2005).

Both drugs, MMI and PTU, are actively concentrated by the thyroid gland. Intrathyroidal concentrations of MMI are in the range of 5×10^5 M. There is no difference in intrathyroidal concentrations of MMI 3–6 and 17–20 h after ingestion of 10 mg of CBM. Little is known about intrathyroidal concentrations of PTU. After a single dose of 10 mg of MMI or 100 mg of PTU, inhibition of intrathyroidal organification of iodide is about 90% and 60%, respectively, at 8 h. Thus MMI can be administered once daily, whereas PTU is dosed thrice daily.

Metabolism of the drugs by TPO is largely iodine dependent. Under conditions of reversible inhibition of iodination, the drugs are rapidly metabolized to higher oxidation products such as sulfonate and sulfate, with disulfide as an intermediate. If there is irreversible inhibition of iodination (higher drug to iodide ratio), some of the drug is oxidized only to the disulfide stage, but the TPO is simultaneously inactivated, and no iodination is observed (Miehle and Paschke 2003).

Clinical Use

Thionamide use in the treatment of hyperthyroidism is well summarized in the 2016 American Thyroid Association (ATA) Guidelines for Diagnosis and Management of Hyperthyroidism and Other Causes of Thyrotoxicosis and in the 2018 European Thyroid Association (ETA) Guidelines for the Management of Graves' Hyperthyroidism (Kahaly et al. 2018; Ross et al. 2016). Graves' disease, caused by unregulated thyroid hormone production and secretion precipitated by autoantibodies to thyrotropin receptor (TRAbs), is the most common cause of hyperthyroidism in iodine-sufficient countries. Other causes of hyperthyroidism include autonomous hormone production caused by somatic (toxic adenoma or toxic multinodular goiter) or less frequently germline activating TSH-receptor gene mutations sometimes precipitated by iodine contamination or by passive release of preformed thyroid hormone due to thyroid tissue destruction (subacute or painless thyroiditis). Less common causes include exposure to endogenous or exogenous sources of extrathyroidal thyroid hormone or rarely excessive production of thyrotropin causing unregulated thyroid hormone production and release. The consequences of untreated or undertreated hyperthyroidism include atrial fibrillation, osteoporosis, weight loss, tremor, proximal muscle weakness, mood symptoms, and at its extreme thyroid storm and cardiovascular collapse. This emphasizes the importance of effective and persistent hyperthyroid treatment.

Thionamides are used as first-line treatment for Graves' disease (Table 1). Specifically, the ETA guidelines recommend MMI or CBM for at least 12–18 months in the treatment of nonpregnant patients choosing antithyroid drugs (Kahaly et al. 2018). In North America, the trend has shifted toward increased use of antithyroid drugs over radioactive iodine therapy (Ross et al. 2016). Radioactive iodine therapy (RAI) and thyroidectomy are the other first-line therapies that should be discussed with patients. MMI or CBM is preferred over PTU in most patients except during the first trimester of pregnancy or during treatment of thyroid storm due to once-daily dosing, more potent efficacy, and less toxicity. The starting dose of MMI as per ATA task force is 5–10 mg daily if free T_4 is 1–1.5 times the upper limit of normal (ULN), 10–20 mg if free T_4 is 1.5–2 times ULN, and 30–40 mg if free T_4 is 2–3 times ULN (Ross et al. 2016). Due to its shorter duration of action, the starting dose of PTU is 50–150 mg three times daily.

Antithyroid Drugs, Table 1 Different treatment strategies depending on the cause of hyperthyroidism

	Graves' disease	Toxic adenoma and toxic multinodular goiter
Etiology	Organ-specific autoimmune disease	Constitutively activating somatic mutation in TSH receptor or in Gsα
	TSH receptor antibody production	
Remission after antithyroid drug treatment	In 30–70% of patients 1 year after treatment withdrawal	No remission
Antithyroid drug treatment	12–18 months	Until euthyroid
Treatment with radioiodine or surgery	If relapse after cessation of antithyroid drug	After euthyroidism is achieved

Remission from Graves' disease ranges from 30% to 70% following cessation of antithyroid drugs for at least 1 year (Burch and Cooper 2018). Remission occurs most frequently during the first 12 months (Paschke and Ludgate 1997). Unfortunately, Graves' disease recurs in one-third of patients, whereas one-third of patients achieve permanent remission. Antithyroid drugs are particularly favored in patients with high likelihood of remission, including women, those with mild disease, small goiters, and low-to-negative TRAb titers. Factors negatively impacting remission include tobacco smoking, age <30, increased thyroid volume and postpartum. The optimal duration of therapy is 12–18 months as there is no added benefit with respect to recurrence rate and there is an increased risk of adverse effects (Abraham et al. 2010). However, a recent study suggested that longer-term MMI use (60–120 months) in select patient populations with Graves' disease may increase remission rates (Azizi et al. 2019). Nonetheless, thyrotropin, and free T_4 (free T_3) should be monitored closely until doses are stabilized. Thionamide doses should be gradually decreased to the minimal maintenance dose as the serum thyroid hormone levels fall. The aim is to restore clinical and biochemical euthyroidism within 1–2 months.

In thyroid autonomy caused by somatic TSH receptor or Gsα mutations, a spontaneous remission (e.g., by nodule apoplexy) is very uncommon. Therefore, antithyroid drug treatment is used to render patients euthyroid before ablative RAI or surgery (Table 1). Similar to Graves' disease, MMI is favored over PTU as PTU increases the failure risk of RAI though its ability to neutralize iodinated free radicals (Cooper 2005). This effect can be overcome by increasing the radioiodine dose. Continuous MMI use up to radioiodine therapy can reduce its success rates, thus MMI should be discontinued 2–3 days prior to RAI. In patients at increased risk of complications of hyperthyroidism, MMI can be resumed 3–7 days post RAI (Ross et al. 2016).

Iodine intake impacts the responsiveness of hyperthyroid patients to thionamides. Combined iodide and antithyroid drug therapy short term has been demonstrated to reduce gland vascularity and to reduce complications of transient hypoparathyroidism and voice hoarseness following thyroidectomy (Randle et al. 2018). Response to thionamides are increased in countries with moderately low iodine intake compared with iodine-sufficient countries (Miehle and Paschke 2003).

The "block-and-replace" regiment with simultaneous administration of an antithyroid drug and L-thyroxine is used in individual cases. The initial hypothesis was that combined therapy may result in higher remission rates. This hypothesis has now been disproven with an increased propensity of adverse effects with this regiment due to the higher antithyroid drug doses used in this approach (Burch and Cooper 2018).

Use of MMI and PTU during pregnancy and postpartum is discussed in the 2017 Guidelines of the ATA for the Diagnosis and Management of Thyroid Disease During Pregnancy and the Postpartum (Alexander et al. 2017). While moderate-severe hyperthyroidism poses fetal and maternal risks, MMI and PTU both have potential teratogenic effects. Specifically, MMI exposure has been associated with aplasia cutis. Other defects associated with MMI use include choanal or

esophageal atresia and abdominal wall, eye, urinary system, and ventricular septal defects. In contrast, PTU exposure has been associated with face and neck cysts and urinary tract abnormalities in male fetuses. Due to the less severe teratogenic effects of PTU, the current guidelines recommend PTU as the first-line treatment of moderate-severe maternal hyperthyroidism until 16 weeks of gestation. After 16 weeks, MMI or PTU are both reasonable options. Small levels of PTU and MMI are detected within the breast milk; thus, the lowest effective doses should be utilized.

Side Effects

Antithyroid drugs have several notable adverse effects that should be discussed with patients prior to initiation of therapy. The most frequent side effects are allergic cutaneous reactions including skin rash, pruritus, and urticaria, which occur in up to 6% of patients (Burch and Cooper 2018). In patients with minor skin rashes, the ATA guidelines recommend consideration of antihistamine therapy without cessation of antithyroid drugs (Ross et al. 2016). The alternative is to switch to the other thionamide (i.e., MMI to PTU or vice versa), which may result in two-thirds of patients having improved minor reactions. Other common adverse effects reported for thionamides include arthralgias. In this case, switching to the alternative thionamide is also an option.

The two rare, but severe, adverse effects of thionamides are agranulocytosis and hepatotoxicity (Burch and Cooper 2018; Cooper 2005). The prevalence of agranulocytosis is reported at 0.2–0.5% of patients taking thionamides. The mechanism of thionamide-induced agranulocytosis is still unclear; however immune-medicated bone marrow suppression is likely involved. Risk of agranulocytosis is dose-dependent for MMI but not for PTU. Most reports of agranulocytosis occur within the first 3 months of treatment. It is critical that patients be advised to discontinue the offending drug immediately if sore throat, pharyngitis, or fever occur and immediately seek medical attention. Most patients recover from agranulocytosis after discontinuation of the antithyroid drug. Given that specific HLA types may be at increased susceptibilities and the severity of the effect, it is not advised to switch to alternative thionamides.

Thionamides have been associated with mild and severe hepatic dysfunction in up to 0.3% of patients. PTU, MMI, and CBM are not recommended in patients with transaminase elevation greater than five times ULN. Rates of hepatic failure were observed to be higher with PTU compared with MMI (Wang et al. 2014). Patients should be advised to discontinue the offending drug and seek immediate medical attention with new onset of jaundice, sudden abdominal pain, or dark urine. Historically, PTU was associated with hepatocellular dysfunction and MMI/CBM with cholestasis. Recent studies have challenged this notion, and caution must be applied to both classes of thionamides particularly within the first 12 weeks of therapy (Ross et al. 2016).

Lastly, antithyroid drug-induced vasculitis, associated with perinuclear anti-cytoplasmic neutrophil antibody, has been reported following years of therapy (Burch and Cooper 2018). Patient may present with cutaneous, pulmonary, and renal involvement, and the offending drug should be immediately discontinued. Persistent antithyroid drug use may require immunosuppressive therapy or even hemodialysis. Fortunately, the drug-induced vasculitis generally resolves following cessation of the offending drug.

Antitussive Drugs

Clive P. Page
Sackler Institute of Pulmonary Pharmacology, King's College London, London, UK

Definitions

Cough is an essential protective reflex response to irritating stimuli in the respiratory tract. It involves the sudden, usually involuntary,

expulsion of air from the lungs. Cough can prevent foreign bodies from entering the lungs or aid the removal of mucus and irritants from the lungs. Cough is a common symptom in upper respiratory tract infections and more chronically in asthma, chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis (IPF), and lung cancer or may also indicate some other underlying disorders such as gastroesophageal reflux disease. It is also frequently caused by smoking. Conversely, in certain conditions such as Parkinson's disease, stroke, and motor neuron disease, cough may be severely affected, and the patient loses this protective function. Cough is useful if it is aiding the expulsion of foreign substances, but chronic cough is an unpleasant, difficult symptom for patients to live with and maybe debilitating.

Basic Mechanisms

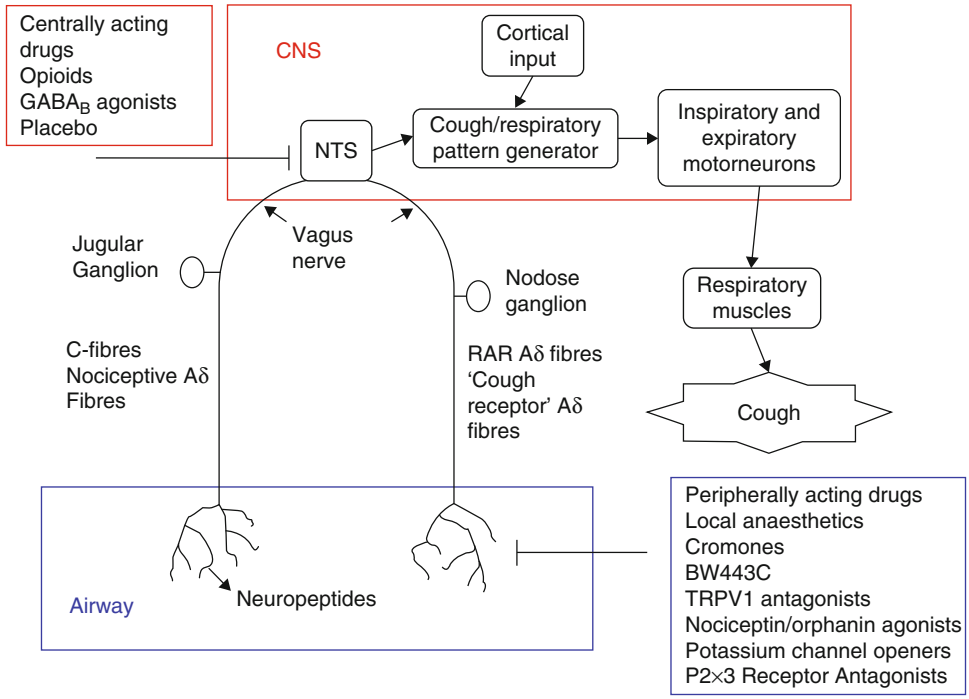
Physically, cough results from a series of events starting with the patient inhaling, often to near maximum levels. Secondly, the glottis closes, and the breathing muscles cause compression of the air in the lungs, leading to high pressure in the pleural space and alveoli. The expulsive phase occurs when the glottis reopens allowing the compressed air to escape. It is at this point that the cough sound is heard and also that foreign materials which may have been deposited in the lungs are removed. Coughing often occurs in bouts, or epochs, rather than as discrete events. *Cough* may be voluntary or involuntary – subthreshold stimuli may evoke the urge to cough, but not the reflex itself.

Airway irritation is detected by sensory nerves which are found within the walls of the airways. Various nerve endings are found in this area, but it is thought that the rapidly adapting receptors (RARs) are the predominant sensors of *cough*. RARs rapidly adapt to a maintained stimulus and have thin myelinated Aδ fibers. Slowly adapting receptors and C-fibers (C-fibers are sensory nerves with unmyelinated axons and can have a modulatory role on the cough reflex). Several different types of sensory nerves have been identified, and more than one type of fiber is involved – it is possible that the combination of fibers and the nature of the discharge regulate *cough* as much as the quantity of action potentials.

These primary afferents project from the airway into the CNS exclusively via the vagus nerve, via the nodose or jugular ganglia. These neurons enter the brainstem and terminate in the nucleus tractus solitarius. Here they synapse with other neurons which determine the various motor components of *cough*. At these central synapses, there are many neurotransmitter receptors present (e.g., tachykinins, glutamate, 5-HT, GABA, NMDA, dopamine, opioids, and nociceptin), which may be the site of action of centrally acting antitussive drugs (see below). It is also here that other sensory afferents terminate and may modulate the synaptic signalling. If there are disorders in other organs which also have sensory neurons carried in the vagus, it is here that these nerves may interact with airway neurons to cause *cough*. In contrast, in diseases where *cough* is reduced, it is generally due to problems in the efferent part of the reflex loop.

Previously it was thought that there was a central "cough center" in the CNS, but current research suggests that this is an oversimplification. The ability to coordinate a combination of a variety of motor outputs is essential for *cough*. For example, outputs go to control airway structures such as the glottis and a wide range of breathing muscles such as the diaphragm and intercostal muscles. In addition, synchronization with the respiratory rhythm is required as it is not possible to *cough* and breathe concurrently. Finally, the CNS is thought to contain a gating mechanism by which the brain determines whether the arriving stimuli are of sufficient magnitude for a cough to occur. The cortex is not necessary for cough, but it can exert descending control on the reflex (Fig. 1).

The sensory nervous system which governs cough is subject to plasticity (nerve plasticity) –



Antitussive Drugs, Fig. 1 Schematic diagram of the cough reflex and sites of action of some tussive agents. Airway sensory nerves activated in response to a tussive stimulus travel though the vagus nerve to the medulla, where they terminate in the nucleus tractus solitarius (nTS). Second-order neurons relay the message to the respiratory pattern generator, which modifies the activity of the inspiratory and expiratory motor neurons and leads to cough. Tussive agents can activate a variety of airway receptors to cause cough. Many nerve types (both peripherally and centrally) undergo phenotypic changes and have increased responses to tussive stimuli following inflammation. The sites of action of antitussive drugs are shown. Abbreviations: *RAR* rapidly adapting receptor, *CNS* central nervous system. (Figure adapted from Reynolds et al. 2004)

such that there may be an enhancement of this cough pathway, either by changes in the receptors on sensory nerve endings, the ganglia, or within the CNS which can increase the activity of these neurons leading to a hypertussive state.

Pharmacological Interventions

Cough is currently a huge unmet clinical need, as none of the currently available treatments are reliably effective (Dicpinigaitis et al. 2014). However, there are many treatments which are currently used, with variable levels of success. In addition, if it is caused by another condition, such as gastroesophageal reflux disease, then treatment of that may reduce cough.

Drugs

Centrally Acting Drugs

Opioids Opioids (opioid systems) are thought to exert their antitussive effects by acting as agonists at μ- and κ-opioid receptors in the CNS. Activation of these receptors activates various G-proteins and leads to the inhibition of the activity of most neurons, but the activity of a few is increased. Recent evidence suggests that morphine may also interact with TRPV1 receptors to explain some of its antitussive activity.

Centrally acting drugs include dextromethorphan and codeine. However the possibility that there may also be peripheral effects of these drugs has led to the development of BW443C (see below).

Opioid drugs are often more effective than other nonnarcotic treatments, but they are also associated with more side effects making them less suitable for many patients. Higher doses which are more effective are also associated with undesirable effects such as sedation.

Peripherally Acting Drugs

Local Anesthetics Local anesthetics are more consistently effective than other therapies, but they cannot be used routinely for this purpose. High concentrations are needed for therapeutic benefit, but this also increases the amount crossing the blood-brain barrier and entering the brain producing unwanted effects. Topical administration to the airways can reduce this.

Patients who do not obtain sufficient symptomatic relief from other treatments may use lidocaine, benzonatate, bupivacaine topically, or mexiletine orally.

Cromones Both disodium cromoglycate and nedocromil sodium have antitussive effects in humans, particularly against ACE inhibitor-induced cough. This suggests an effect on bradykinin-induced changes in sensory nerve function. Antitussive activity of these drugs is thought to occur by increasing the depolarization of sensory nerves, which increases the threshold for an action potential and therefore inhibits the activity of these neurons. A recent study has provided evidence of cromoglycate being effective in reducing cough in patients with IPF (Birring et al. 2017).

GABAB Receptor Agonists GABA is the predominant inhibitory neurotransmitter in the CNS. Baclofen acts centrally as an agonist at the $GABA_B$ receptor, which increases inhibition of nerves. 3-Aminopropylphosphinic acid (3-APPi) has been shown experimentally to act as an antitussive at peripheral nerves, and preclinical evidence suggests that baclofen indeed has antitussive actions clinically (Dicpinigaitis 2006).

Novel Drugs

Tachykinin Antagonists (Tachykinins) C-fiber afferents from the airways contain peptide tachykinin transmitters such as substance P (SP) and neurokinins A and B (NKA and NKB). Stimulation of these nerves can also cause local release of these mediators at their peripheral terminal, allowing them to enhance the activity of the *RARs*. SP, NKA, and NKB act at the tachykinin receptors (NK_1–NK_3), and so understandably, antagonists for NK_2 in particular are being investigated as novel treatments for cough (Dicpinigaitis et al. 2015).

BW443C BW443C is a novel opioid used for the treatment of cough, but which does not enter the brain and so exerts its effects only on peripheral nerves. It has not been tested as an antitussive in humans due to its rapid metabolism in the lungs, but the concept of a peripheral opioid is still possible.

Nociceptin/Orphanin Receptor Agonists Nociceptin and orphanin are synonyms for the peptide that acts at an opioid-like receptor. Nociceptin may act by inhibiting tachykinin release from sensory C-fibers, and a clinical trial has started to test its effects on *cough*.

TRPV1 Receptor Antagonists Capsaicin, the pungent chemical from chili peppers, induces cough. Capsaicin is an agonist at the transient receptor potential vanilloid receptor 1 (TRPV1) – a polymodal receptor which integrates several harmful stimuli such as noxious heat, low pH, and various possible endogenous mediators to mediate pain and cough. TRPV1 receptors have been demonstrated to be upregulated in patients with chronic cough (Chung 2007).

Capsaicin is used to cause cough experimentally and clinically, and the TRPV1 antagonist capsazepine can inhibit cough elicited by both capsaicin and citric acid. This suggests that other TRPV1 antagonists could be effective treatments for cough (reviewed in Dicpinigaitis et al. 2014). However, capsazepine does not block hypertonic saline-

induced cough, suggesting that other tussive receptors are also important (Birring et al. 2017) and several studies with $TRPV_1$ antagonists have failed to show clinical benefit in patients with chronic cough.

TRPA1 Receptor Antagonists TRPA1 receptors are activated by known pro-tussive agents such as cinnamaldehyde and acrolein (found in tobacco smoke) which have led to the development of novel TRPA1 antagonists as possible treatments for cough (Dicpinigaitis et al. 2015).

Potassium Channel Openers An effect of opening K^+ channels is to hyperpolarize the primary sensory neurons. Similar to local anesthetics, this makes the cell less likely to produce an action potential because more depolarizing stimuli are needed to overcome the block. NS1619 is an example of this type of drug which has initially shown antitussive activity in a variety of experimental systems.

Quaternary Ammonium Salts Quaternary ammonium salts such as carcainium chloride (RSD 931) have been shown to be antitussive while having much reduced local anesthetic activity (Dicpinigaitis et al. 2015). While the molecular mechanisms underlying this antitussive activity are not understood, RSD 931 appears to be Aδ fiber-selective and may represent a novel class of antitussive drug. More recently JMF2-1 a lidocaine derivative that blocks Na^+ channels has had beneficial effects in the airways without significant local anesthetic activity.

P2x3 Receptor Antagonists ATP is known to be an agonist of P2x3 receptor found on sensory nerves in the lung. Gefapixant is a novel P2x3 receptor antagonist that has shown promise in early clinical trials in patients with idiopathic cough and is now undergoing phase 3 clinical trials (Dicpinigaitis et al. 2014).

Definition

Apelin (APLN) is a small adipokine released primarily by adipose tissue. It is also expressed in many organs, including the brain, heart, lung, kidney, and stomach. It is a ligand for the G-protein-coupled receptor APJ. Apelin is involved in many physiological processes, such as regulation of blood pressure, body fluid homeostasis, the endocrine stress response, cardiac contractility, angiogenesis, and energy metabolism. It may also participate in pathological processes, including heart failure, obesity, diabetes, cancer, and neurodegenerative diseases.

Basic Characteristic

Apelinergic System

Apelin is an endogenous peptide first isolated from the bovine stomach in 1998, encoded by the apelin gene *APLN* located on chromosome Xq25-26.1. Its receptor APJ (APLNR) belongs to the family of seven-transmembrane proteins and is closely related to the angiotensin receptor. Apelin is secreted by adipose tissue as a 77-amino acid prepropeptide called preproapelin, which can be cleaved to produce a mature 36-amino acid apelin peptide, apelin-36, and shorter peptides, apelin-17 and apelin-13, and its modified pyroglutamyl form [Pyr1]apelin-13 (Fig. 1) (Tatemoto et al. 1998).

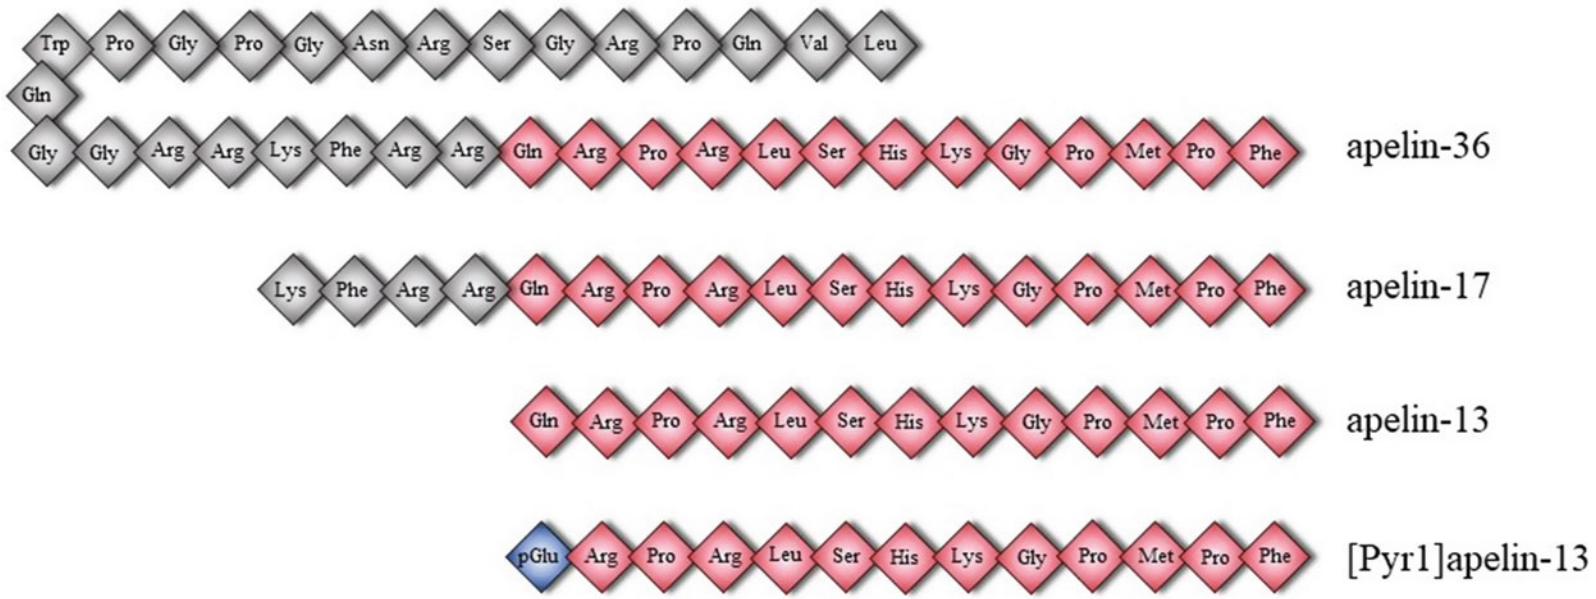
Tissue distribution of apelin prepropeptide and APJ is similar, and in humans it was found in the heart, lung, kidney, spleen, stomach, and central nervous system. This extensive expression suggests that apelin/APJ, also known as the apelinergic system, may be involved in many physiological processes, such as regulation of cardiovascular system homeostasis, angiogenesis, and carbohydrate metabolism. The role of apelin in various processes is probably mediated through several signalling pathways: the AMP-activated protein kinase/nitric oxide synthase (AMPK/eNOS), phosphatidylinositol 3-kinase/protein kinase B (PI3K/Akt), and mitogen-activated protein kinase (MAPK) pathways mediate angiogenesis and ischemia and reperfusion (I/R) protection. Processes leading to metastasis are mediated through the peroxisome proliferator-activated receptor (PPAR), PI3K/Akt/mechanistic target of rapamycin (mTOR), MAPK, and PAK1/cofilin pathways. The apelinergic system also has an influence on processes connected with energy metabolism, including glucose uptake, lipolysis, and fatty acid oxidation via the AMPK/eNOS and PI3K/Akt pathways (Fig. 2) (Wysocka et al. 2018).

Apelin in the Cardiovascular System

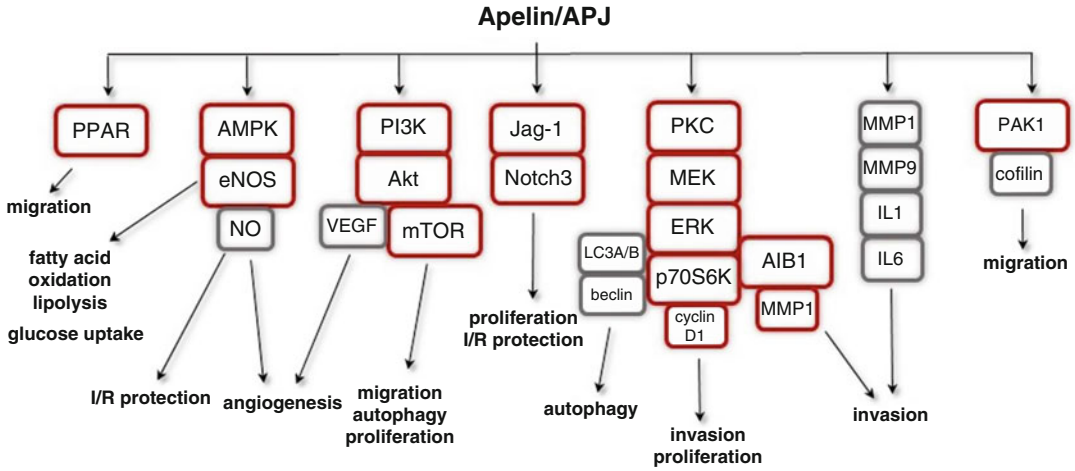
Due to the high expression level of apelin in the heart, the apelinergic system was considered to have an impact on cardiac system regulation. In humans, it can induce peripheral and coronary vasodilation, lower arterial blood pressure, and increase cardiac output. Apelin also stimulates a positive inotropic effect and upregulates the Ca^{2+} sensitivity of myofilaments in heart muscle (Kuba et al. 2019). Moreover, this peptide is also involved in physiological process of forming new blood vessels, called angiogenesis, that is crucial for supplying tissue in oxygen. Apelin upregulates hypoxia-inducible factor (HIF-1), vascular endothelial growth factor (VEGF), and vascular endothelial growth factor receptor 2 (VEGFR), as well as activates the AMPK/eNOS and PI3K/Akt/eNOS pathways.

In hypertension, a cardiovascular condition characterized by increased arterial blood pressure, apelin reduces blood pressure, which is mediated through the Akt/eNOS signalling pathway.

Under hypoxia, a pathological condition characterized by restriction of blood delivery to organs and tissues that is often caused by ischemia and reperfusion, apelin displays a protective effect. This protection is possible through activation of antioxidant enzymes reducing oxidative stress. In different cardiovascular pathologies, such as coronary artery disease and ventricular hypertrophy, the apelin level is altered, suggesting that it could be successfully used as a biomarker of cardiovascular system pathologies (Table 1) (Wysocka et al. 2018).



Apelin, Fig. 1 Amino acid sequences of apelin peptides



Apelin, Fig. 2 An overview of the apelin-induced signalling pathways

Apelin in Obesity and Diabetes

Apelin belongs to the family of adipokines, biologically active molecules secreted by adipose tissue. Therefore, this peptide was suggested to be involved in some obesity-related disorders, but its role remains unclear. In several studies, apelin plasma level was increased in obese individuals in comparison to nonobese patients (Table 1). It can also mediate angiogenesis regulation correlated with adipose tissue growth (Wysocka et al. 2018). Moreover, apelin plays a beneficial role in carbohydrate metabolism by increasing glucose uptake and insulin sensitivity through translocation of glucose transporter type 4 (GLUT-4) in a PI3K/Akt-dependent manner. Several investigations have demonstrated involvement of this peptide in the regulation of diabetic complications, including cardiomyopathy, retinopathy, and nephropathy, where apelin acts as a protector against oxidative stress and apoptosis through the mTOR pathway (Cheng et al. 2019; Wysocka et al. 2018).

Apelin in Cancer

In many cancer types, the level of apelin is upregulated (Table 1), suggesting a beneficial role of apelinergic system in cancer progression. It has a potential to stimulate tumor growth, cancer cell migration, and metastasis through several mechanisms, including AMPK, PI3K/Akt, PPAR, MAPK, and p-21-activated kinase (PAK1)/cofilin pathways. Under tumor hypoxia, the angiogenic balance is shifted to pro-angiogenic conditions, connected with upregulation of apelin and its receptor. During cancer development, this peptide can also suppress apoptosis, programmed cell death, by decreasing the level of caspase-3 activity, which is a crucial apoptotic executor. Interestingly, apelin is especially involved in progression of obesity-related cancer. Numerous studies have revealed that increased body mass index (BMI) is correlated with the risk of developing tumors, such as prostate cancer, breast cancer, and esophageal adenocarcinoma. Several investigations have demonstrated that in obese individuals with cancer, the apelin peptide level was elevated compared to nonobese patients and positively correlated with BMI, fasting insulin level, hyperinflammation, metabolic changes in adipose tissue, and neovascularization (Table 1) (Wysocka et al. 2018).

Apelin in Neurodegenerative Diseases

Apelin is widely expressed in the central nervous system, and hence it was suggested to be involved in development and progression of neurodegenerative disorders. It can inhibit Alzheimer's disease (AD) by regulating neuron apoptosis, inflammatory mediators, Tau activation, as well as amyloid-β accumulation. Tau and amyloid-β are molecules

crucially involved in Alzheimer's disease as the microtubule stabilizer and main component of amyloid plaques found in AD patients' brains, respectively. Apelin is able to suppress Tau activation via PI3K/AKT/glycogen synthase kinase-3β (GSK-3β) signalling pathway regulation. Furthermore, in Parkinson's disease (PD) apelin plays a protective role, although the mechanism is still unknown. Activation of the apelin receptor has a neuroprotective and antiapoptotic effect in PD. Additionally, apelin is connected with progression of Huntington disease (HD). It can delay HD progression through inhibition of the tumor necrosis factor/nuclear factor kappa B (TNF/NF-κB) pathway connected with increased neurodegeneration induced by mutant huntingtin protein (Luo et al. 2019).

Drugs

Apelin as a Therapeutic Target

Despite the fact that no clinical trials focusing on apelin have been conducted, many scientists still focus on the possible application of this peptide in pathological disorders. Apelin has an inhibitory effect against atherosclerosis, which is a chronic inflammatory disease. It can reduce lipid accumulation of foam cells through autophagy activation via PI3K/Beclin-1 pathways. Moreover, apelin signalling blocks angiotensin II-induced atherosclerosis, which is probably caused by eNOS pathway activation.

Under hypertension, exogenous peptide injected into rats decreased systolic and diastolic blood pressure immediately. Apelin also reduced the mean arterial pressure in rats, and this mechanism is probably connected with nitric oxide production. Moreover, in patients with hypertension, the level of serum apelin was lower than in healthy controls. The same results were obtained in patients with left ventricular hypertrophy or hemodialysis patients with pulmonary arterial hypertension.

The main feature of myocardial infarction is left ventricular enlargement and reduced capillary density. Several studies have indicated that the concentration of serum apelin was lower in patients with acute myocardial infarction in comparison to healthy individuals. Furthermore, exogenous administration of apelin reduced infarct size and improved heart muscle functions after ischemia through phosphorylation of PI3K/Akt and extracellular signal-regulated kinase (ERK) pathways. Additionally, apelin treatment

led to an increase in myocardial capillary density and formation of new blood vessels.

In diabetes mellitus, more evidence suggests that apelin can lower blood glucose level and improve insulin sensitivity. It stimulates glucose uptake via the PI3K/Akt pathway. This peptide also plays a protective role in the regulation of diabetic complications. It inhibited the progression of diabetic nephropathy in the model of diabetic mice. Moreover, apelin suppressed hypoxia-induced apoptosis of pericytes, cells involved in normal vascular structures, by downregulating the expression of caspase-3 in diabetic retinopathy (Cheng et al. 2019).

Drugs Targeting Apelin/APJ

At present, there are several apelin receptor antagonists that have been described and used to examine therapeutic effects in cell cultures, animal models, and patients. F13A is one of the natural antagonist isoforms of APJ that is highly selective and exhibits similar binding affinity but opposite functions to those of natural apelin-13. It can inhibit tumor growth and dilation of arteries in a hepatocellular carcinoma model. It also promotes hepatocyte proliferation and liver regeneration after hepatectomy. The first synthetic peptidic compound described as an APJ antagonist is ALX40-4C. It was first used in phase I/II clinical trials to investigate its therapeutic effects against HIV-1 virus. Several studies suggested that it could also block ligand-induced APJ internalization and intracellular calcium mobilization. There are also several cyclic peptides synthesized as APJ antagonists that are more protected from proteolytic degradation and have a long half-life. Several nonpeptidic small molecule compounds also target the APJ receptor. Well-known ML221 is described as the first reported APJ functional antagonist in cell-based assays. It could inhibit migration and invasion, as well as proteolytic activities of colon cancer cells. It also inhibits pathological angiogenesis and at the same time accelerates the recovery of normal vessels in the ischemic regions in the retina of oxygen-induced retinopathy model mice. To conclude, every drug targeting the apelin receptor has therapeutic potential, but further research is necessary (Huang et al. 2018).

Synonyms

Control of food intake; Regulation of ingestive behavior

Definition

Appetite control is a complex function of the brain that regulates feeding behavior. This function integrates cognitive and emotional factors with a complex array of peripheral signals originated from the gastrointestinal tract, adipose tissue.

Basic Mechanisms

Feeding behavior is subjected to both short-term regulation during a single meal and long-term regulation related to the maintenance of body weight and fat content. As a complex function of the brain, ingestive behavior is controlled by psychological and cognitive factors such as sociocultural context (e.g., eating habits), experience (sensory preferences), or emotional status (mood). Appetite control is regulated by the nutritional status, which can be sensed in the brain by glucose-sensing neuronal and non-neuronal cells to elicit an adaptive response. Appetite control also integrates information about the status of peripheral organs, particularly the gastrointestinal tract and adipose tissue (Morton et al. 2006). Two main groups of signals can be distinguished: (i) satiety signals (short term) secreted from gastrointestinal organs and (ii) adiposity-related signals (long term) that are proportionate to body fat stores (Morton et al. 2014). A key factor of this control system is that energy intake is primarily controlled by adjustment of the meal size rather than the meal onset, allowing the organism to initiate meals at times that are convenient and to adapt eating patterns to individual constraints (food availability) and activities (circadian rhythm).

Satiety Signals

Satiety-inducing signals are conveyed to the brain by afferent nerve fibers that are sensitive to mechanical or chemical stimulation of the stomach and small intestine during food ingestion. In addition, humoral signals such as cholecystokinin (CCK) are released upon nutrient stimulation of neuroendocrine cells located in the gastrointestinal wall. These satiety signals converge in the nucleus tractus solitarii in the brainstem and induce meal termination in the absence of hypothalamic control, as demonstrated in decerebrated rats. CCK is the paradigmatic humoral satiety signal, and its action has been studied extensively in multiple species including humans. Exogenous administration of CCK dose dependently reduces meal size. This effect is synergistically enhanced by other factors that limit meal size, such as gastric distension. Specific CCK-A receptor antagonists stimulate food intake in rats, indicating that endogenous CCK contributes to the termination of meals. However, repeated administration of CCK before each meal does not reduce caloric intake of free-feeding mice or rats, because the animals compensate the reduced meal size by increasing the number of meals. In obesity there is CCK resistance, a phenomenon where the body does not react to physiological concentrations of CCK.

Adiposity Signals

Insulin as a Satiety/Adiposity Signal

The first hormonal signal found to comply with the characteristics of both a satiety and an

adiposity signal was insulin (Morton et al. 2006). Insulin levels reflect substrate (carbohydrate) intake and stores, as they rise with blood glucose levels and fall with starvation. Increased insulin secretion in obesity can be explained by reduced insulin sensitivity of the liver, muscle, adipose tissue, and brain. Insulin is known to enter the brain via a receptor-mediated transport, and direct administration of insulin to the brain reduces food intake. The adipostatic role of insulin is supported by the observation that mutant mice lacking the neuronal insulin receptor (NIRKO mice) develop obesity. Further, sole brain insulin signaling activation in men by administering intranasal insulin reduces food intake confirming insulin's suppressing effect on appetite. Insulin resistance occurs in obese conditions attenuating the effect of insulin on food intake and causing hyperglycemia and impaired lipid storage.

Leptin as an Adiposity Signal

Leptin is a cytokine produced and secreted by adipose tissue in proportion to the body fat content (Friedman and Halaas 1998). Overall leptin synthesis is higher in subcutaneous than in visceral adipocytes. Mice lacking leptin receptor in the brain develop a severe hyperphagia and a dramatic degree of obesity which is considerably more pronounced than that of the NIRKO mouse. Thus, leptin is the key adiposity signal in rodents and humans. Leptin secretion reflects the metabolic status of the adipocyte rather than the sheer size of triglyceride deposits, and leptin levels may transiently be dissociated from total body fat. Nonetheless, over the course of a day with unrestricted food supply, plasma leptin levels reliably reflect the amount of total body fat. Local administration of leptin into the brain results in reduced food intake. The vast majority of patients with obesity have elevated serum levels of leptin. Thus, it is believed that the polygenic obesity is due to leptin resistance. Data are emerging that reducing leptin secretion in obesity improves leptin resistance and insulin sensitivity, suggesting that primary hyperleptinemia might be causal for altered leptin signaling in the long term (Zhao et al. 2019).

Appetite-Regulating Pathways in the Arcuate Nucleus of the Hypothalamus

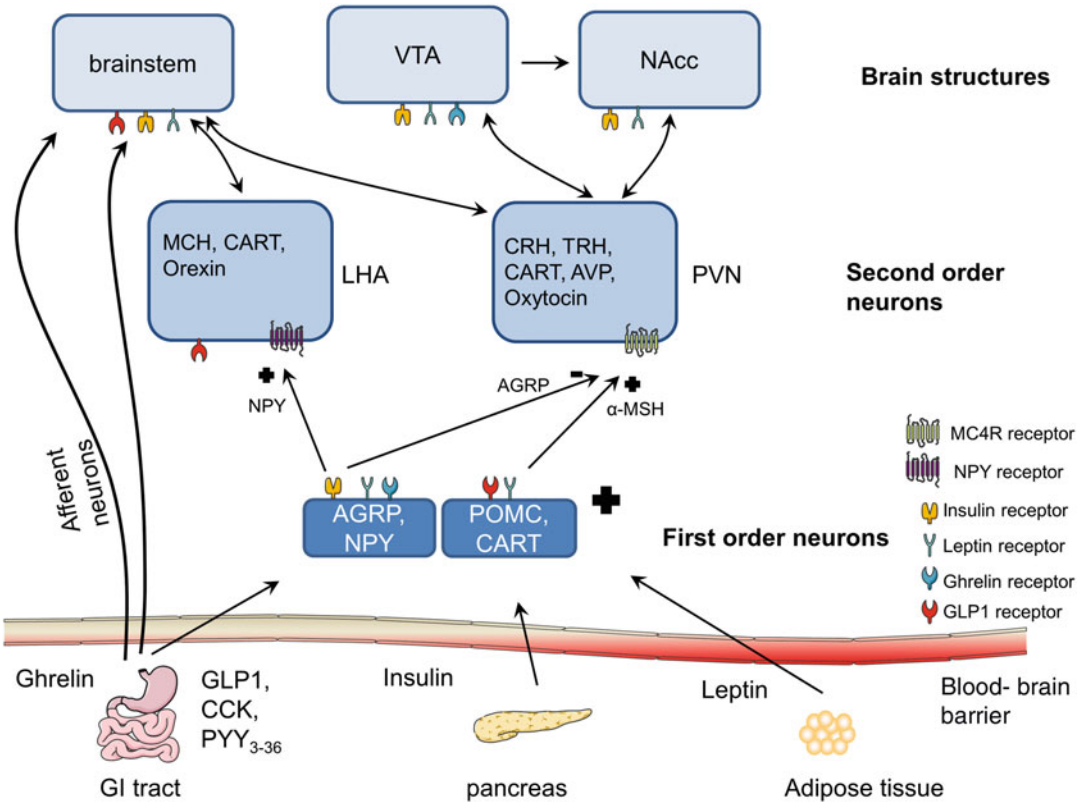
Two distinct populations of neurons in the arcuate nucleus have been identified as the most relevant target cells of leptin (Fig. 1) (Timper and Bruning 2017). Leptin inhibits expression of the orexigenic peptides NPY (neuropeptide Y) and AgRP (agouti-related protein) in one subset of neurons and stimulates production of the anorexigenic peptides α-MSH (α-melanocyte-stimulating hormone) and CART (cocaine- and amphetamine-regulated transcript) in the other. Insulin receptors are also highly concentrated in the arcuate nucleus, and insulin appears to elicit similar changes in these neuropeptides as leptin. Further insulin and leptin signaling can cross activate each other in the hypothalamus, suggesting a high degree of functional overlap. Nevertheless, recent studies reveal heterogeneity in these hypothalamic neuronal populations highlighting the importance of further detailed investigation to gain better insights into the complex interplay of hormonal control of appetite control.

The Melanocortin Signaling System

Considerable evidence indicates that the molecules of the melanocortin system are key mediators of the response to leptin. AgRP and α-MSH are antagonistic ligands for a common receptor, the melanocortin-4 receptor (MC4R). α-MSH is an anorexigenic neuropeptide that activates MC4R and thereby reduces appetite, whereas AgRP is an orexigen that acts as an endogenous antagonist of the receptor and suppresses its activation by α-MSH. The critical role of the melanocortin system in appetite regulation is supported by the effects of spontaneous and experimental mutations of AgRP, α-MSH, and MC4R in mice. Moreover, patients with complete loss of proopiomelanocortin (POMC), the precursor molecule of α-MSH, develop severe hyperphagia and overweight, and 4–5% of all cases of severe human obesity appear to be due to mutations in the *MC4R* gene.

Role of NPY/AGRP Neurons

NPY has long been known to be a potent orexigen when directly injected into the hypothalamus.



Appetite Control, Fig. 1 Diagram of pathways integrating appetite control. Satiety is the net output from brainstem centers that leads to the termination of an individual meal. Satiety is primarily determined by neural and humoral inputs from the gastrointestinal tract (short-term satiety signals). Response to satiety signals is modulated by descending anabolic or catabolic pathways originating in the hypothalamus. Appetite-regulating hormones are released in proportion to total body fat (leptin), glucose levels (insulin), or changes in food intake (ghrelin). Leptin and insulin stimulate secretion of anorexigenic peptides (α-MSH, CART) and inhibit expression of orexigenic ones (NPY, AgRP) in the arcuate nucleus (ARC), whereas ghrelin exerts opposite effects. Secondary target neurons in the paraventricular nucleus (PVN) and the lateral hypothalamic area (LHA) integrate signals from neurons in the ARC and connect them with satiety centers in the brainstem. In addition, recent evidence shows that afferent signals such as leptin and ghrelin also directly target brain centers known to play a key role in reward and addiction. Areas where such neurocircuitry is located include the ventral tegmental area (VTA) or the nucleus accumbens and appear to control mostly the hedonic components of feeding behavior

Hyperphagia of the leptin-deficient ob/ob mice is attenuated by knockout of NPY, supporting the role of NPY as a downstream effector of leptin. The effects of NPY on appetite regulation are mediated by different receptor subtypes (NPY1R and NPY5R). However, the neuropeptide is not an indispensable transmitter of adiposity signals, since lean mice which lack NPY show a normal feeding behavior. On the other hand, it has been shown that the NPY/AGRP neurons play an essential role for basal orexigenic drive. Ablation of these neurons from the arcuate nucleus in adult mice reduces drastically food intake with a substantial loss of body fat. In conclusion, NPY/AGRP neurons likely play an essential role in the control of feeding behavior, but their function cannot be easily explained solely based on the expression of the neuropeptides NPY and AGRP.

Second-Order Hypothalamic Targets in Adiposity Signaling

Lesions of the lateral hypothalamic area (LHA) cause anorexia, whereas ablation of the paraventricular nucleus (PVN) causes a hyperphagic

obesity syndrome. Consistent with these results, LHA neurons express the orexigenic neuropeptides MCH and orexin. PVN neurons produce several neuropeptides that are anorexigenic when administered directly into the brain (CRH, TRH, oxytocin), in addition to their better known roles as endocrine regulators. LHA and PVN receive rich inputs from axons of NPY/AgRP and α-MSH/CART-producing neurons in the arcuate nucleus.

Other Hormones, Peptides, and Neurotransmitters Involved in Appetite Control

Many other peptides including galanin, ghrelin, and glucagon-like peptide-1 and glucagon-like peptide-2 (GLP-1 and GLP-2) have been described to participate in appetite control (Table 1). In addition, the neurotransmitters norepinephrine, dopamine, and serotonin are known to be involved in appetite regulation. The role of the monoamines in energy homeostasis is illustrated by effects of drugs (see below). Agonists of α_1 adrenoceptors, 5-HT_{2C} serotonin receptors, and dopamine receptors (D1 and/or D2) suppress appetite. The relevant neural circuits that use these transmitters are complex but include projections to the arcuate nucleus. A control system mediating appetite-stimulating effects is the cannabinoid signaling. Endocannabinoids have been added to the list of signals that act downstream of leptin. Leptin reduces levels of the endocannabinoid anandamide in the hypothalamus of normal rats, and mice that lack the cannabinoid receptor 1 (CB1) showed reduced food intake under conditions of low leptin levels (after fasting).

Pharmacological Intervention

Appetite-Suppressing Drugs

The increasing prevalence of obesity and its consequences has stimulated the search for appetite-suppressing drugs as anti-obesity agents (Timper and Bruning 2017). Therapy based on nutritional and behavioral counseling produces almost always only a temporary weight loss. Past anti-obesity drugs targeted predominantly adrenergic and serotonergic pathways (e.g., fenfluramine, sibutramine), and many had been withdrawn from the market because of side effects (e.g., rimonabant, sibutramine). The recent insights in appetite control as outlined above have provided new candidate targets for the search of appetite-suppressing drugs. New existing drugs target various centrally acting pathways (e.g., serotonergic, dopaminergic, GLP-1 signaling) but have common negative side effects such as nausea or dry mouth. Due to novel insights into neuronal control of food intake, combination therapies are now present such as bupropion/naltrexone, which improve metabolic outcome and can reduce adverse effects. Since obesity is usually a chronic disorder which requires lifelong therapy, anti-obesity drugs need to meet high safety standards.

Incretin Mimetics

Liraglutide, a GLP-1 receptor agonist, has been initially prescribed as treatment option for type 2 diabetes but has now been also approved for the treatment of obesity. At a dose of 3 mg/day and a half-life of 13 h, liraglutide – in addition to peripheral actions – reduces food intake by modulating the reward and the homeostatic system in the brain. It activates the reward system in the ventral tegmental area in addition to POMC stimulation in the hypothalamus resulting in reduced appetite.

Exenatide, a 39-amino-acid peptide from the Gila monster (*Heloderma suspectum*), is an incretin mimetic, a functional analog of human glucagon-like peptide-1 (GLP-1). Because of its resistance to degradation, *in vivo* potency of exenatide is much greater than that of GLP-1. Exenatide improves glycemic control through glucose-dependent secretion of insulin and suppression of high glucagon levels in patients with type 2 diabetes, delays gastric emptying, and reduces of food intake. Exenatide is administered at doses of 5 and 10 μg twice daily; its most frequent adverse effects were nausea and hypoglycemia.

Phentermine

Phentermine is a sympathomimetic and enhances neurotransmitter release, primarily the release of norepinephrine with minor dopamine release. It is

Appetite Control, Table 1 Hormones, peptides, and neurotransmitters implicated in appetite control

an appetite suppressant by reducing the perception of hunger. Weight loss is about 5% of initial body weight. Adverse effects include elevated heartbeat, high blood pressure and restlessness but may also include pulmonary hypertension and valvular heart disease in severe cases. Due to severe adverse effects, phentermine has been withdrawn from the market in Germany.

Weight was regained when the drug was stopped, indicating that a continuous therapy would be necessary to achieve the useful but limited therapeutic effect. This general limitation is likely to apply for any novel drug that targets central pathways. Phentermine is currently available as a combinational therapy with topiramate, a sulfamate derivative of fructose, which decreases neuronal activation and may enhance thermogenesis. This combination exhibits beneficial effects on body weight reduction, in addition to improved blood pressure, HbA1c levels, and quality of life. However, topiramate causes a marked impairment of cognitive functions that outweighs its therapeutic benefit.

Bupropion/Naltrexone

Bupropion is a monoamine reuptake inhibitor and increases dopamine and norepinephrine action. Further bupropion activates POMC neurons resulting in reduced appetite and energy expenditure. Naltrexone represents an opioid antagonist and blocks the orexigenic effects of β-endorphin, which is co-spliced with α-MSH upon POMC activation. Thus this combination causes a more profound activation of the appetite-suppressing effects due to POMC activation. A weight loss about 5% is achieved after a year of treatment. A common side effect is nausea.

Lorcaserin

Lorcaserin is a selective 5-Ht_{2c} receptor agonist and causes weight loss by improving satiety, reducing food craving and impulsivity, and reducing overall the activity in the reward system. A common dose is 10 mg/day and results in average in a 4% body weight loss compared to control subjects. Adverse effects are headache, back pain, and nausea.

Tesofensine

Tesofensine is a serotonin-noradrenaline-dopamine reuptake inhibitor and was initially developed as a potential medication for the treatment of Alzheimer's and Parkinson's disease. The efficacy criteria were not met, but an unexpected side effect of profound weight loss in these patients was identified. Tesofensine is currently in phase III clinical trials for obesity and at an oral dose of 0.5 mg/day reduces body weight by up to 10% in obese patients. Rodent data suggest that tesofensine reduces food intake by activating α1 adrenoreceptors and also D1 dopamine receptors. Common side effects in obese patients are dry mouth, headache, and nausea. Elevations in blood pressure and pulse rate have also been reported.

Leptin and Leptin Sensitizers

Leptin has been shown to markedly reduce appetite and weight in extremely rare individuals who lack leptin. In contrast, in the first clinical study of patients with polygenic obesity and elevated leptin levels, weight loss was variable and relatively small. This disappointing result may be explained by the leptin resistance consistently observed in obese humans and rodents and novel data showing that hyperleptinemia per se might be a cause of leptin resistance (Zhao et al. 2019). Leptin is used for the treatment of generalized lipodystrophy. Celastrol, a pentacyclic triterpene and major component of *Tripterygium wilfordii*, reduces body weight up to 45% due to suppression of food intake in leptin-resistant animal models. In particular, celastrol enhances leptin sensitivity independent of the melanocortin system but via activation of IL-1 receptor, suggesting that activation of inflammatory processes can be beneficial (Feng et al. 2019). Clinical trials are currently in early phase I.

Drugs with Appetite-Stimulating Effects

Psychotropic Drugs

Stimulation of appetite and weight gain has frequently been observed as a side effect of long-term therapy with various psychoactive drugs. Prominent examples not only are the tricyclic (e.g.,

imipramine) and heterocyclic (e.g., mirtazapine) antidepressants but also selective serotonin reuptake inhibitors (e.g., paroxetine), neuroleptic drugs altering dopamine or histamine signaling (e.g., olanzapine), and lithium. These drugs modulate central monoamine signaling by, e.g., altering serotonin, dopamine, or histamine receptor activation, which is believed to explain their appetite-stimulating effect. Stimulation of appetite by cyproheptadine, a nonselective serotonin receptor antagonist and histamine receptor blocker, is presumably caused by mainly inhibiting serotonin receptor activation.

Treatment of Cachexia and Anorexia

In the palliative treatment of cachexia and anorexia in advanced cancer and AIDS patients, modest relief can be achieved with appetite-stimulating drugs. Various pharmacologic strategies have been tested, including corticosteroids, anabolic steroids, megestrol acetate, cyproheptadine, melatonin, and dronabinol (delta-9-tetrahydrocannabinol). The cannabinoid receptor agonist dronabinol is approved in the USA for stimulation of appetite in AIDS patients. Thalidomide also improves appetite and progressive weight gain in AIDS patients. Cyproheptadine improves appetite in patients with cystic fibrosis. Megestrol has been successfully used to increase appetite and weight gain in patients with cancer.

Definition

An aptamer is a short 20–100 nucleotide-long polymer of single-stranded DNA or RNA that binds specifically to a molecular or cellular target, such as a protein, small molecule, or even a whole cell (e.g., lysozyme, thrombin, vascular endothelial growth factor, ATP, IgE, nucleolin, ochratoxin A, among others). Although aptamers tend to be synthetically derived, there are examples of naturally existing riboswitches, which contain an aptamer-like region and, upon binding a small molecule, induce a structural change. Analogous to antibodies, aptamers act as molecular recognition elements, binding tightly to their intended target (Nimjee et al. 2017).

In the consideration of aptamer utility, aptamer structure and nucleic acid composition play a critical role. Watson-Crick base pairing creates the secondary structure (e.g., stems, hairpins, bulges, etc.) with additional non-covalent interactions forming the tertiary structures (e.g., pseudoknots, G-quadruplexes, etc.). Secondary

structures may be computationally predicted (e.g., MFold program), which provide aptamers with a unique versatility that permits the design and creation of aptamer constructs by simple adjustments of the oligonucleotide sequence. For example, the stability of the hairpin structure can be increased through the addition of complementary nucleotides on the 5′ and 3′ ends of the oligonucleotide or an oligonucleotide sequence may be inserted to link together aptamer sequences. Further, aptamers may be predictably denatured, rendering them inactive, and refolded into their native, functional structures. The versatility of aptamers allows for optimization in diagnostic assays, molecular sensing, therapeutics, and drug delivery, allowing for a single aptamer to serve multiple purposes.

Aptamers are typically isolated through a process known as SELEX (*Systematic Evolution of Ligands by EXponential enrichment)*. In general, oligonucleotides that bind the target are isolated and amplified, thus enriched in an iterative process that is repeated until oligonucleotide species that bind with high affinity are enriched and identified using sequencing and binding assay analyses.

Basic Mechanisms

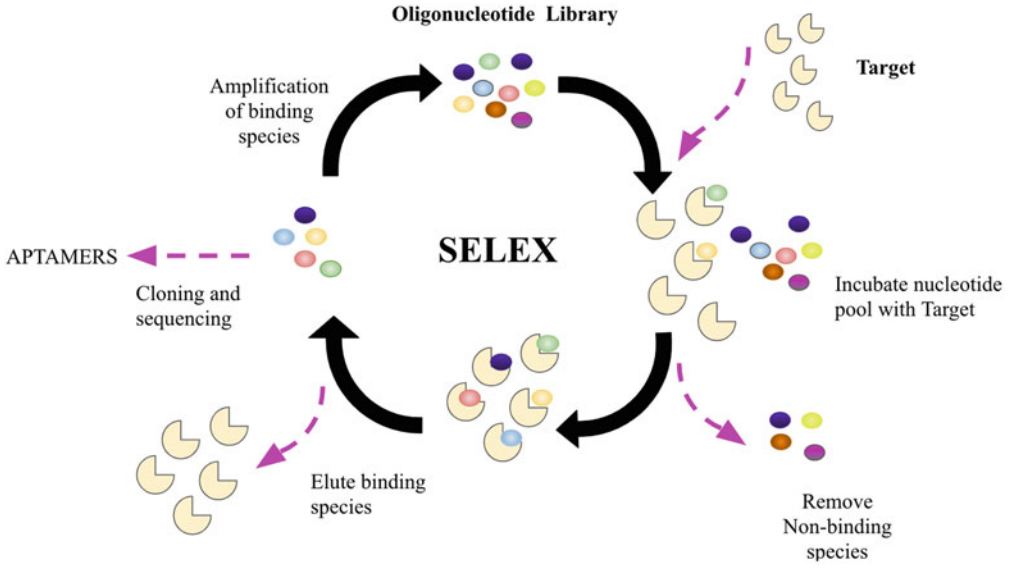
Aptamer Selection

Aptamers are typically isolated in a process known as the *Systematic Evolution of Ligands by EXponential enrichment* (SELEX) or in vitro aptamer selection. In SELEX, a nucleic acid library, containing 10^{14}–10^{15} random species, is enriched for species that bind to the target. In practice, the library is designed with each oligonucleotide species containing a variable or random region flanked by static regions that include PCR primer binding sites. The design of the nucleic acid library includes consideration of the length of the randomized region, nucleic acid type (i.e., canonical A, C, G, T/U, modified, or a combination thereof), flanking static regions (e.g., PCR primer design, inclusion of an RNA polymerase start site/promoter, etc.), and potentially the target (e.g., hydrophobic/hydrophilic, positively/negatively charged, etc.) (Stovall et al. 2014).

The enrichment of target-binding species is accomplished via iterative cycles of the following: target and oligonucleotide pool incubation, selection, and amplification of the target-bound oligonucleotide species (see protocol in Stovall et al. 2014). First, random nucleic acid libraries are incubated with targets. The selection step partitions target-bound oligonucleotide species from unbound species, using a physical partitioning methodology (e.g., nitrocellulose filter-based, magnetic bead-based, affinity chromatography, gel-shift selections, etc.). In the final step, isolated target-binding species are amplified, typically by polymerase chain reaction (PCR) (Fig. 1).

After target-pool incubation and application of selection pressure in an RNA aptamer selection, amplification of target-bound RNA occurs through conversion to cDNA via reverse transcription and subsequent PCR amplification. During PCR, a primer with an RNA polymerase promoter sequence is reappended to enable subsequent regeneration of RNA. Upon completion of PCR, a transcription reaction generates the selected RNA pool for additional rounds of in vitro aptamer selection. Typically, 6–20 rounds are performed with increasing stringency of selection conditions (e.g., pH, temperature, pool/target ratio, monovalent/divalent salt concentrations) to enrich the nucleotide pool, reducing the complexity of the original library (Stovall et al. 2014).

The efficacy of the selection can be assessed by sequencing clones in the selected pool (Stovall et al. 2014). The increased abundance of short sequence motifs (e.g., 4–10 nucleotide-long recurring sequences) or even full-length clones across rounds is evidence that a selection occurred, although a binding assay is necessary to confirm an aptamer selection. Binding assays, such as radioactive binding assays, microscale thermophoresis, surface plasmon resonance (SPR), etc., determine the affinity and specificity of the selected pool and aptamer candidates to bind their target (Plach and Schubert 2019). Further, identified aptamers can be truncated and assayed to determine the minimized variant or



Aptamers, Fig. 1 Schematic illustration of the SELEX process for the generation of aptamers. The procedure consists of multiple rounds of three major steps: (I) binding/incubation of the aptamer target with the nucleotide library, (II) elution of binding oligonucleotide species, and (III) amplification of collected oligonucleotides (i.e., selected pool)

minimum sequence/region required to preserve binding and specificity (Stovall et al. 2014).

The SELEX procedure has been modified in a number of ways to both improve efficacy and to cater to a diverse set of applications. Some commonly utilized examples include negative SELEX, toggle SELEX, and in vivo SELEX (for more examples of SELEX methodologies, see table in Darmostuk et al. 2014).

Interactions Between the Target and Aptamer

The aptamer's folded structure and the subsequent binding interactions with the target play a key role in formulating the intended application. Single-stranded aptamers, primarily via Watson-Crick base pairing and other non-covalent interactions, form structural motifs such as hairpins, pseudoknots, stems, bulges, and G-quadruplexes. The stability and secondary structures of the aptamers can be computationally predicted using programs such as MFold. Binding interactions between the target and aptamer are driven by hydrogen bonding, electrostatic interactions, hydrophobic interactions, π-π stacking, and van der Waals forces (Sakamoto et al. 2018). The specific structural characterization of these interactions may be ascertained through nuclear magnetic resonance spectroscopy (NMR), X-ray crystallography, and electron microscopy.

Quantifying the affinity of the aptamer to the target can be found through a number of techniques, generally referred to as binding assays. Common binding assay techniques include surface plasmon resonance (SPR), biolayer interferometry (BLI), microscale thermophoresis (MST), fluorescence polarization (FP), flow cytometry, filter binding assay, and electromobility shift assay (EMSA) (Plach and Schubert 2019).

Aptamer to target binding affinity is typically expressed by the dissociation constant (K_d), the rate of dissociation between the aptamer and the target. A smaller K_d reflects a higher binding affinity between the aptamer and the target. The K_d is related to Gibbs free energy (ΔG) by the following equation: $\Delta G = -RT\ln(1/K_d)$.

Observing the thermodynamic properties of the aptamer-target interaction is another approach of assessing the binding affinity. For example, isothermal titration calorimetry (ITC) is a label-free method frequently used to quantify

aptamer-target thermodynamic parameters (ΔG, ΔH, and ΔS) and K_d by measuring the enthalpic change between the bound and unbound aptamer-target species. An ITC binding assay is typically performed by maintaining one interacting partner at constant concentration and volume and incrementally titrating the other interacting partner into the system (Plach and Schubert 2019).

Pharmacological Relevance

Aptamers as Diagnostic Agents

Due to their molecular recognition properties as well as their structural versatility (including computationally predicted structures, ability to refold, etc.), aptamers are well suited as diagnostic and sensing reagents. The hairpin structure of aptamers allows for conjugation of molecules to the 5′ and/or 3′ terminal site or intercalation within the stem without impacting the structure or binding. From binding the target, a conformational change can result in observable changes in fluorescence, electrochemistry, or colorimetry. Widely used methodologies that are coupled with aptamers to suit these observable changes include optical sensing, electrochemistry techniques to create "aptasensors", and nanotechnology.

Aptamer-Fluorophore Conjugates and Optical Sensing

Aptamers are advantageous in optical imaging techniques due to the ease of fluorescent labeling and the availability of a variety of fluorophores and quenchers. There are several methods for optical detection using aptamers, two of which will be highlighted here. Both approaches are based on the flexible structure of the unbound aptamer and the more rigid structure of the target-bound aptamer. In one approach, fluorophore and quencher are conjugated to opposing termini (5′ and 3′) of a destabilized hairpin structure. Upon binding of the analyte, the conformation of the aptamer is altered, thereby altering the distance of the fluorophore and quencher and resulting in a change in fluorescence. The other approach involves strand displacement. In this example, the system contains an optically labeled aptamer recognition element (i.e., something to bind the target) and an oligonucleotide that is complementary to that aptamer (which is it attached at a distance from the aptamer or a different strand altogether). The complementary strand is labeled with a quencher and bound to the linearized aptamer. Upon the aptamer binding the target, the complementary quencher strand is displaced through a competitive binding interaction, resulting in a colorimetric response (Ilgu and Nilsen-Hamilton 2016).

Electrochemical Sensing

Electrochemical sensing with aptamers involves the use of an electrode to measure changes in impedance, current, or resistance and detect the presence of the analyte. The mechanisms underlying electrochemical sensing are diverse. One method relies on changes in the aptamer-target interaction that can alter the catalytic activity of an oxidative or reductive enzyme resulting in signal detection. Another method, dubbed "strand displacement," involves the displacement of a complementary strand with a redox reporter or the sole displacement of a redox reporter. For example, in a complementary strand and redox reporter displacement system, when the target binds to the aptamer, the release of the complementary strand results in the displacement of the redox reporter to generate the electrochemical signal (Ilgu and Nilsen-Hamilton 2016).

Nanomaterials, Aptamers, and Sensing

The stability, controllable chemical and physical properties, and large surface areas of nanomaterials can be coupled with the high selectivity of aptamers enabling for the design of highly selective and sensitive sensors. The common aptasensors utilizing nanomaterials include colorimetric detection using gold nanoparticles (AuNPs). The AuNPs adsorb the aptamers onto the surface. Through competitive displacement, target binds the aptamer. When the aptamer is displaced, the AuNPs aggregate resulting in a change in color from red (disaggregated) to purple (aggregated). The change in color is attributed to the change in the interparticle distance between the AuNPs (Jo and Ban 2016). Other examples of

nanomaterials employed in aptasensors include quantum dots, magnetic nanoparticles, gold nanorods, and graphenes.

Aptamers as Therapeutic Agents

Aptamers can be used directly as therapeutic agents. Acting primarily as antagonists, aptamers can competitively inhibit their molecular targets in vivo (e.g., enzymes, receptors, etc.). A comprehensive list of aptamer therapeutics that have undergone clinical testing can be found in the Haßel and Mayer (2019) review.

The only currently FDA-approved aptamer therapeutic Macugen® (pegaptanib) is a treatment for wet, age-related macular degeneration. Approved in 2004, the Macugen aptamer binds a 165 amino acid-long isoform of the vascular endothelial growth factor (VEGF) protein and inhibits its function, thereby suppressing angiogenesis and decreasing swelling and bleeding. The aptamer is constructed from a 2′-fluoro modified pyrimidine and 2′-methoxy modified purine library and contains a PEG addition and 3′ inverted dideoxythymidine cap for enhanced in vivo stability (Haßel and Mayer 2019).

Despite their limited translation to clinical use, aptamers are well suited to the therapeutic space, as they exhibit high tissue and cell penetration, allowing for efficient and differential take-up by the target cells (Hori et al. 2018). The use of covalent and non-covalent conjugation strategies allows for different aptamers to serve as easily exchangeable building blocks for functionalization of other therapeutic agents, such as liposomes and gold nanoparticles (Hori et al. 2018). Several optimizations can be made to aptamer therapeutics, which include functional regulation via aptamer antidotes and chemical modifications to improve longevity and specificity in vivo.

Functional Therapeutic Designs Using Antidotes

Because of the nature of oligonucleotides, Watson-Crick base pairing, and solved secondary structures, functional aptamer therapeutic designs are common, as in the development of "antidotes." In instances in which an aptamer's activity needs to be neutralized quickly, an oligonucleotide antidote, with a sequence complementary to the aptamer, may be employed. In vivo, the antidote oligonucleotide binds the aptamer and prevents secondary structure formation, thus quenching the functional aptamer. This methodology has been successfully employed in the delivery of an anti-coagulation factor IXa aptamer and its antidote, thus dosing the clotting response (Nimjee et al. 2017). Aside for this point, the aptamer REG1 developed for this coagulation factor IXa target failed Phase III clinical trials in 2014, because of adverse anaphylactic effects which were likely the result of the PEG addition and not the aptamer itself (Haßel and Mayer 2019).

Modifications in the Therapeutic Space

Due to their small size and hydrophilicity, aptamers are susceptible to clearance from the bloodstream via renal filtration and degradation by nucleases. There are several strategies to mitigate these effects. Conjugation of moieties such as PEG, zwitterionic poly(carboxybetaine) (PCB), or poly(2-methacryloyloxyethy phosphorylcholine) (PMPC) slows renal or hepatic clearance. Recent studies have found, however, that PEGylation elicits an immune response that inhibits binding and anaphylactic effects while PCB and PMPC exhibit low to non-immunogenicity. Further, the use of chemical modifications of the phosphor-sugar backbone of RNA aptamers (such as replacing 2′OH with 2′F or 2′-*O*-methyl, locked nucleic acids, xeno nucleic acids, or phosphorothioates) introduces resistance to nuclease degradation improving half-life and stability in vivo. Similarly, spiegelmers, which are a class of aptamers whose sugars are the enantiomer of those present in living systems, confer resistance to nuclease degradation due to the stereoselective nature of enzymatic processes. Further, three of such spiegelmer aptamers are currently in or completed Phase II clinical trials (Haßel and Mayer 2019).

Introduced by the company SomaLogic, another class of molecules known as SOMAmers (slow off-rate modified aptamers) optimize binding affinities and lower dissociation rates by using oligonucleotide libraries containing deoxyuridine bases with five-position modifications that

contain functional groups akin to amino acids. The addition of the modified uridines potentially increased the diversity nucleic acid libraries and, subsequently, improved selection hit rates to identify aptamers (Nimjee et al. 2017).

Aptamers as Drug Delivery Agents

In addition to being used as direct therapies, aptamers can be adapted for targeted drug delivery. They can bind to cell surface targets, delivering therapeutic payloads to a particular cell or tissue type. For example, aptamers may deliver small compound drugs, oligonucleotide-based drugs, or nanoparticles.

Aptamers Conjugated to Small Compounds

The conjugation of aptamers to small compounds, such as drugs, toxins, etc., allow for targeted delivery and thus a reduction of systemic exposure and toxicity. This aptamer-targeted drug delivery is particularly promising in the development and refinement of anticancer drugs such as doxorubicin, which induces cancer cell death by intercalating into DNA. The drug cargo (i.e., anthracycline drugs, doxorubicin, daunorubicin, etc.) can be linked to the aptamer by intercalation in GC-rich regions of the aptamer, conjugation of a CG-cargo structure containing the intercalated payload, or creation of a dimeric aptamer complex with CpG sequences containing the intercalated payload (Hori et al. 2018). GC regions are typically used in designs implementing doxorubicin because it is known to bind preferentially to 5′-CG-3′ and 5′-GC-3′ regions. Additionally, the high GC content provides added stability (Hori et al. 2018). Other conjugation strategies include direct conjugation via amine coupling utilizing N-hydroxysuccinimide and crosslinking the payload and aptamer with formaldehyde.

Aptamer-Oligonucleotide-Based Drug Conjugates

In addition to conjugation to drugs and toxins, aptamers can deliver oligonucleotide therapeutics (i.e., siRNAs, anti-miRNA, or miRNA), targeting undruggable oncogenes at the level of protein expression. Importantly, because oligonucleotide-based therapeutics function inside the cell, the therapeutic requires targeted delivery. Delivery is achieved through the covalent conjugation of the aptamer to the oligonucleotide therapeutic. Aptamer-siRNA chimeras using anti-epithelial cell adhesion molecule (EpCAM) aptamers are widely used for epithelial cancers and cancer stem cells (Hori et al. 2018). For example, Judy Lieberman received a patent in 2019 for a novel aptamer-siRNA molecule (AsiCs) targeting breast cancer using EpCAM (patent number, 10385343). An overview of aptamer-oligonucleotide therapeutic approaches can be found in the Hori et al. (2018) review.

Aptamer-Nanoparticle Conjugates

Aptamers can be used to deliver or functionalize nanoparticles including liposomes, gold nanoparticles (AuNPs), polymers, and dendrimers by covalent or non-covalent conjugation to these constructs, decreasing systemic toxicity. Liposomes show promise as carriers for anticancer drugs due to their ability to target tumor tissue. Recent work has shown reduced systemic toxicity and increased cellular uptake and cytotoxicity of Doxil, a PEGylated liposomal doxorubicin, by conjugating AS1411, a nucleolin-targeting aptamer. AuNPs also show promise as constructs for targeted drug delivery due to their biocompatibility, low toxicity, and large surface area. Aptamers conjugated to AuNPs carrying drug payloads such as doxorubicin increased cellular intake and cytotoxicity in several cancer cell lines (Hori et al. 2018). A full review of approach to functionalizing nanoparticles for increased efficacy can be found in the Hori et al. (2018) review.

Future of Aptamers

Challenges to Widespread Use in Clinical Diagnostics

Despite their promise in clinical diagnostics, there are few clinical aptamer-based diagnostics currently in use due to what has been coined the "thrombin problem." The "thrombin problem" refers to the predominant focus on creating novel

clinical diagnostic techniques using the most well-characterized aptamers, such as the anti-thrombin aptamer, rather than discovering new clinically relevant aptamers against new biomarkers (Famulok and Mayer 2011). Thus, the generation of aptamers for clinically relevant biomarkers for which alternatives are not available could increase use in a clinical setting.

In addition to the limited number of clinically relevant aptamers, aptamer-based sensors (i.e., aptasensors) often fail to detect the analyte in "real" patient samples. Preanalytical handling and processing of patient samples, which can potentially denature proteins and hence alter the ability of the aptamer sensor to detect the analyte with a high degree of reliability and sensitivity, hinder translation to the clinic. Recent work, however, has successfully employed protease inhibitors and bivalent aptamers (i.e., a construct of two or more aptamers) to allow for the detection of thrombin in patient samples (Famulok and Mayer 2011).

Challenges to Widespread Use in Therapeutics

A limited number of aptamers have reached late-stage clinical trials, with only one aptamer-based drug having received FDA approval, Macugen®, an anti-VEGF aptamer used to treat age-related wet macular degeneration. There are several impediments to in vivo application of aptamers including their short half-life due to nuclease-mediated degradation, rapid renal filtration, unknown and variable immunogenicity and toxicity with systemic administration, and entrapment in cellular organelles (Haßel and Mayer 2019). In addition to recent advancements in the stability and longevity of aptamers in vivo, the use of deep sequencing, live-animal-based SELEX, and high-throughput SELEX has increased efficiency while increasing the likelihood of identifying aptamers (Hori et al. 2018).

Though aptamers show great promise as therapeutics, the lack of commercial infrastructure, the high cost of modified oligonucleotides, and the previous failures of aptamer therapeutics to attain FDA approval hinder their widespread use in a clinical setting. Anti-nucleolin aptamer AS1411, for example, showed antitumor activity in patients with metastatic renal cell carcinoma and acute myeloid leukemia without exhibiting systemic toxicity but failed in Phase I (2009) and Phase II (2011) clinical trials respectively. The failure of these clinical trials was largely due to the lack of characterization of the fate of the AS1411 aptamer within the cell. Undoubtedly, expanding the use of aptamers in a biochemical and clinical setting will require thorough characterization of the fate of aptamers within their target cells and in the body (e.g., pharmacokinetic-pharmacodynamic (PK/PD) profiles), optimal pharmacological formulation, immunogenicity and toxicity profiles, as well as increased funding by biopharmaceutical companies for pre-clinical and clinical trials (Haßel and Mayer 2019).

Despite these hurdles to effective implementation of aptamer-based therapeutics, the funding of other RNA-based therapeutics by biopharmaceutical companies has increased, resulting in the approval of six oligonucleotide-based (non-aptamer) therapies. This financial support indicates a push in recent years toward the use of RNA-based therapeutic intervention and perhaps positively foreshadowing the emergence of additional aptamer thereapeutics in the future (Haßel and Mayer 2019).

AQP

► Aquaporins

Aquaporins

Eric Beitz
Pharmaceutical and Medicinal Chemistry, Christian-Albrechts-University of Kiel, Kiel, Germany

Synonyms

AQP; Water channels

Definition

Aquaporins, AQP, are cellular channel proteins that are permeated by water and small, uncharged solutes. The AQP protein family is functionally divided into water-specific channels, often referred to as "orthodox aquaporins," and solute channels that mainly conduct glycerol, termed "aquaglyceroporins." Besides glycerol, other similar or smaller sized solutes, such as urea, hydrogen peroxide, and gases including ammonia and carbon dioxide pass certain AQP isoforms. As passive channel elements of cellular membranes, water and solute passage via AQPs is driven solely by osmotic or chemical concentration gradients, respectively.

Basic Mechanisms

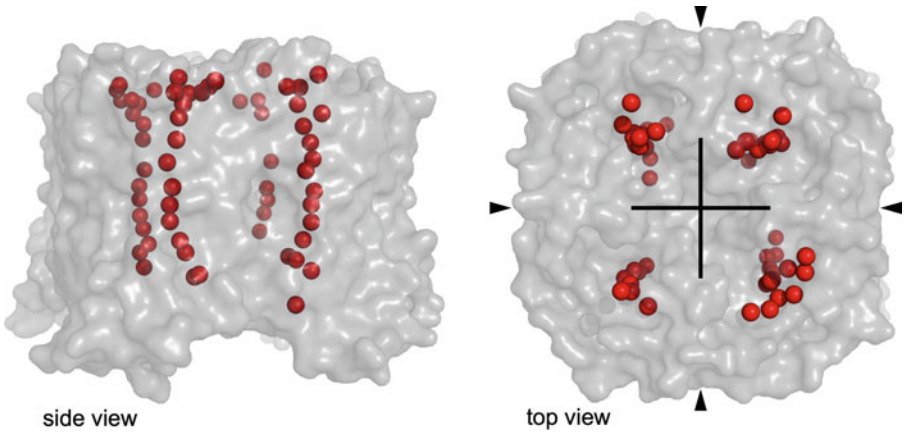
Aquaporin Structure-Function Relationships

The human AQP protein family comprises 13 isoforms, see Table 1 (Day et al. 2014). All share the same general fold and quaternary protein structure consisting of homotetramers with one individual water/solute pore in each protomer (Fig. 1). About four fifths of the volume of the AQP tetramer are buried in the lipid bilayer with the extra- and intracellular protein surfaces exposed and accessible for water and solute substrate molecules. The transduction channels are narrow allowing water or solute molecules to pass only in single files. Substrate selection occurs by two principles: (1) size and (2) exclusion of charged compounds and ions (Beitz et al. 2006). Consequently, water-specific, orthodox AQPs exhibit pore entry sites with a small diameter of 2.4 Å matching the diameter of a water molecule, whereas the filter region of aquaglyceroporins is wider at around 3.4 Å accommodating passage of glycerol in a longitudinal orientation. The channel interior provides suitably spaced hydrogen bond interaction sites for passing water or solute molecules, and an electrostatic environment that prohibits entry of charged entities due to a high energetic barrier. With respect to the handling of ions, AQP6 is rather special because it functions as a chloride (and nitrite, nitrate) channel in intracellular vesicles of intercalated cells of the kidney collecting duct. It accompanies the vacuolar proton ATPase permitting accumulation of hydrochloric acid in the vesicles, which release upon signaling their acid load into the primary urine for body pH regulation.

AQP water permeability is characterized by three hallmarks, which even before the discovery of the AQPs in 1992 (Preston et al. 1992) led to the assumption that proteinaceous water channels must exist in the cell membrane. First, water

Aquaporins, Table 1 Aquaporin isoform tissue localization and function

Isoform	Tissue (selection)	Functions (selection)
AQP0	Eye lens	Cell–cell contact, transparency
AQP1	Erythrocytes, kidney proximal tubule, lung, brain choroid plexus, eye	Colton blood group, primary urine concentration, lung moistening, cerebrospinal fluid regulation, intraocular pressure regulation
AQP2	Kidney collecting duct principal cells	Vasopressin-dependent body water homeostasis
AQP3	Erythrocytes, kidney, adipocytes, skin	Gill blood group, body water homeostasis, lipolysis, skin moistening
AQP4	Kidney, brain, neuronal tissue	Body water homeostasis, cerebrospinal fluid regulation, target of autoantibodies causing NMO
AQP5	Sweat and salivary glands	Sweat and saliva production
AQP6	Kidney collecting duct intercalated cells	Vesicular chloride channel, body pH regulation
AQP7	Adipocytes, intestine	Lipolysis, intestinal water facilitation
AQP8	Mitochondrial	Highly ammonia permeable
AQP9	Liver	Lipogenesis, gluconeogenesis
AQP10	Adipocytes, intestine	Lipolysis, intestinal water facilitation
AQP11	Kidney	Deletion causes polycystic kidney disease
AQP12	Pancreas	Unknown



Aquaporins, Fig. 1 Aquaporin structure and single-file water passage

permeation via AQP channels is at least one order of magnitude faster than simple transmembrane diffusion; in fact, it can be as fast as the unhindered mobility of water molecules in free aqueous solution. Second, at < 5 kcal mol^{-1}, the Arrhenius activation energy of AQP water permeability is lower than that of transmembrane diffusion (> 10 kcal mol^{-1}); as a consequence, the AQP water channel function is largely temperature independent. Third, AQP water permeability is inhibitable, e.g., by organic mercurials (isoform-dependent), whereas transmembrane water diffusion is not (Agre 2004).

The permeability properties of AQPs for solutes largely adhere to the above-described characteristics. Yet, the discrimination between solute passage via an aquaglyceroporin and transmembrane diffusion is sometimes less clear in particular for small, lipophilic gas molecules, e.g., ammonia, NH_3, or carbon dioxide,

CO_2, which directly penetrate the lipid bilayer quite easily.

The driving force for diffusion in general, irrespective of passing an AQP channel or a cell membrane, is entropy. Particles will move along an existing gradient towards establishment of an equilibrium. For orthodox AQPs, this means specifically, that a net water movement will occur only when a transmembrane osmotic gradient exists. In this case, water molecules will pass the AQP in the direction towards the compartment holding the higher particle concentration (Fig. 2). This occurs prominently in the salt-laden tissue surrounding the nephron (up to 1200 mM salt compared to 300 mM in the remaining body) driving the concentration process of the primary urine by a transcellular water movement of more than 150 l per day. Yet, also local intracellular changes in particle concentrations will initiate AQP-carried water fluxes across the membrane. Ion channels in neuronal cells and the ubiquitous sodium-potassium ATPase, Na^+/K^+-ATPase, transiently disturb the equimolar transmembrane ion distribution and trigger an equilibrating water movement into or out of a single cell. Likewise, a local breakdown of polymerized filamentous actin into individual soluble actin molecules will locally increase the osmolarity and lead to water influx. This mechanism promotes local cell-swelling and protrusion of lamellipodia ("cell-feet") that are central to cell motility, e.g., of cells of the immune system but also of migrating tumor cells. Aquaglyceroporin solute channels will permit a net flux of a specific solute when its concentration is uneven at both sides of a membrane leading, for example, to an efflux of glycerol from adipocytes during lipolysis.

Aquaporin Regulation

Almost all human AQPs appear not to be gated, i.e., contrary to certain plant AQPs, there are no molecular closing mechanisms contained in the AQP protein itself sensing, for instance, pH conditions or ion concentrations, so that the channels remain open at all times. AQP10 of the intestine and adipose cells poses an exception in that it is activated by acidic pH conditions (Gotfryd et al. 2018). It is further rather typical that AQPs are constitutively present at the cell plasma membrane as permanent water and solute pore elements (Fig. 3). Regulation occurs, however, on the transcriptional level, e.g., in the lung, hypoxia induces the expression of the AQP1 gene (Agre 2004), and glucocorticoids via nuclear receptors that of AQP4. By this long-term regulation mechanism, more AQP channels will be inserted into the plasma membrane increasing water permeability. In the case of the mentioned hypoxia-induced orthodox AQP1, this facilitates lung moistening at conditions of low air pressure, e.g., at high altitudes. A second, short-term regulation mechanism exists for specific human AQP isoforms. Here, AQP protein is stored in intracellular vesicles that will traffic to and fuse with the plasma membrane upon a signal. A prominent example for this mechanism is the vasopressin-dependent body water homeostasis (Tamma et al. 2005): vasopressin secreted from the posterior pituitary activates the G-protein-coupled receptor type 2 for vasopressin of principal cells in the kidney collecting duct, adenylyl cyclase/cAMP-signaling will lead to phosphorylation of water-specific AQP2 residing in perinuclear vesicles and initiate transport and insertion into the apical plasma membrane. As a result, the cells are rendered more water permeable increasing concentration of the primary urine by water reabsorption. When the vasopressin signal ceases, AQP2 will be dephosphorylated by protein phosphatases initiating internalization back into the pool of intracellular vesicles. Vasopressin has an additional long-term effect on AQP2-facilitated water permeability via gene induction by the cAMP-dependent transcription factor cAMP response element-binding protein, CREB.

Aquaporins as Surface Antigens and Cell–Cell Contact Proteins

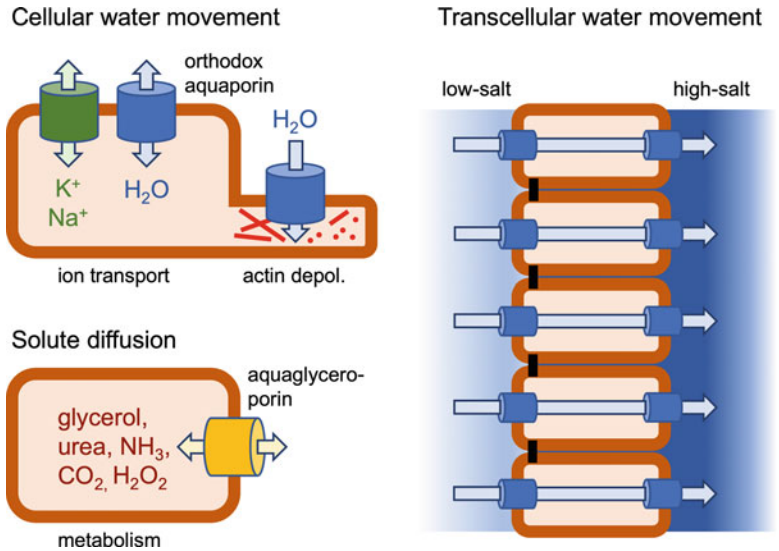
Independent from their channel function, AQP surface structures act as antigens (Agre 2004). Human erythrocytes carry AQP1 and the aquaglyceroporin AQP3 in their plasma membranes, and both AQPs represent antigens in the blood group system. The Colton blood group is due to an alanine versus valine variation of AQP1, and the Gill blood group to AQP3. The orthodox

AQP4 is strongly expressed in neuronal tissue including the optic nerves. In rare cases, individuals produce autoantibodies against AQP4 resulting in neuromyelitis optica, NMO, characterized by demyelination and inflammation that damage neuronal tissue and functionality. AQP4 autoantibodies are used as diagnostic marker for NMO. The extracellular surfaces of AQP0, which is exclusively expressed in the eye lens, interact with each other facilitating cell–cell contacts of lens fiber cells. Their proper alignment is responsible for the transparency of the lens. Certain polymorphisms of the AQP0 gene that result in alterations of the cell–cell contact sites on the AQP0 protein cause early-onset cataract.

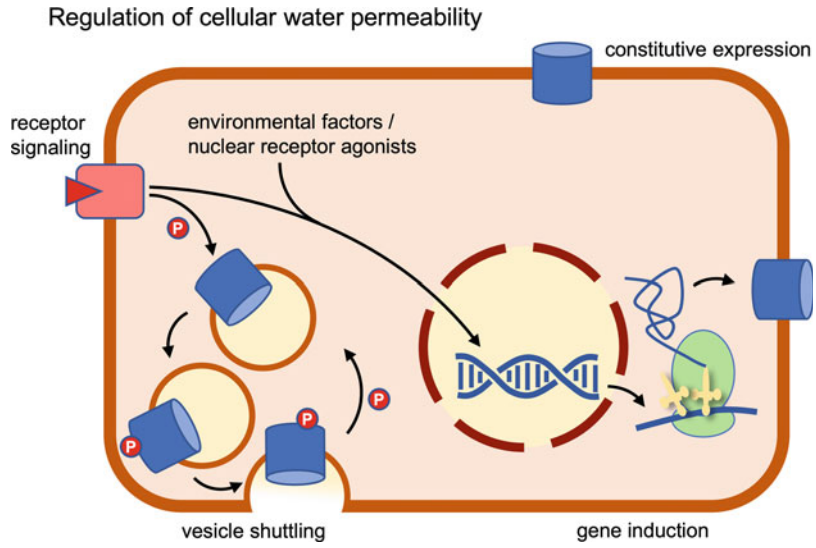
Physiological Functions of Aquaporin Water Permeability

Transmembrane water facilitation is a main task of the AQPs (Day et al. 2014). Since water makes up two-thirds of the body weight and all organs and tissues are exposed to and regulate aqueous interstitial, serum, or surface fluids, AQP water permeability is ubiquitously relevant. Their functionality is intricately connected to the transport of ions or osmotically active compounds (Fig. 2) that drive transmembrane water movement. Such mechanisms are specific to individual tissues and cells. The kidney is the central organ maintaining the body water homeostasis. Several AQP isoforms are expressed in the various kidney cell types. Eighty percentage of the filtrated primary urine volume are reabsorbed in the proximal tubule and Henle loop of the nephron. This transcellular water flow (Fig. 2) is almost exclusively carried by AQP1. The fine-tuned urine volume regulation takes place in the collecting duct. It involves the vasopressin-regulated, apical AQP2 of the principal cells via vesicle shuttling, and long-term AQP2 gene induction via CREB (Fig. 3), as well as the constitutively expressed AQP3 and AQP4 at the basolateral membranes. This way the blood osmolarity is kept even within $<1\%$ accuracy. Accordingly, erythrocytes usually experience a highly constant osmotic environment in the blood stream; however, 20–30 times per day, they will pass the high-salt tissue of the kidney and are subjected to a volume decrease by more than 20%. AQP1 and AQP3 of the erythrocyte membrane are thought to preserve membrane integrity by letting water pass swiftly and in an ordered way.

Water regulation in the brain is particularly critical due to the inflexible bone-enclosed compartment. Any overpressure, edema, will immediately inflict cell stress and ultimately cell damage. AQP4 and AQP1 are relevant isoforms in the production and release, respectively, of the cerebrospinal fluid. Similar situations, although at a smaller volume scale, are present and regulated by



Aquaporins, Fig. 2 Driving forces of cellular and transcellular water and solute movement



Aquaporins, Fig. 3 Regulation of cellular water permeability via aquaporins

AQPs in the enclosed eye and inner ear compartments. Here as well, diseases are linked to dysregulated fluids, i.e., glaucoma and Menière's disease, respectively.

AQP water permeability is further required in cells that are exposed to external body surfaces present in the lung (AQP1, AQP4), mucosal tissues (various AQPs), and secretory glands, e.g., for sweat and saliva (AQP5). In this encyclopedia entry, a listing of physiologically relevant situations of AQP-driven water permeability cannot be conclusive; it is referred to the cited literature and reference therein for further details.

Role of Aquaporins in Glycerol Metabolism, Gas Transport, and Redox Signaling

Solute-permeable aquaglyceroporins assume key functions in the adipocyte and liver glycerolipid metabolism and glucose neogenesis pathways (Gotfryd et al. 2018). During lipolysis in adipocytes, lipase enzymes catalyze the chemical hydrolysis of the ester bonds between fatty acids or cholesterol and the glycerol hydroxyl moieties. The freed fatty acid portion will be used mainly in the same cell for the energy metabolism process of β-oxidation, whereas glycerol will be released from the cell via aquaglyceroporins, predominantly AQP7 and AQP10. Accumulation of glycerol in the adipocytes due to malfunction or absence of AQP7 causes adipocyte swelling by increased glycerolipid storage resulting from product-inhibition of the catabolic lipase reaction. Glycerol will travel with the blood to the liver where AQP9 facilitates uptake into hepatocytes for gluconeogenesis or glycerolipid synthesis and storage depending on the energy metabolic state. Cells of the intestine also express the aquaglyceroporins AQP7 and AQP10. Glycerol further fulfills a moistening function in the skin via AQP3 and contributes to wound healing (Agre 2004).

Other permeants of aquaglyceroporins are produced by metabolic degradation of amino acids, namely urea from the conversion of arginine to ornithine by arginase, and ammonia from the oxidative deamination of glutamate to α-ketoglutarate or the deamination of glutamine to glutamate. Ammonia is also a product of purine and pyrimidine metabolism. There are, however, dedicated transporters for urea (solute carrier family members SLC14A1 and SLC14A2) and ammonia (Rhesus proteins, Rh) encoded in the human genome that are probably of higher relevance than AQPs.

Ammonia, NH_3, is the neutral form of positively charged ammonium, NH_4^+, and both molecules are linked by a pH-dependent protonation equilibrium. At neutral pH, 99% are present as protonated NH_4^+ leaving only 1% of neutral NH_3. As a small, not too polar molecule, NH_3 exhibits substantial background diffusion across lipid bilayers even in the absence of a suitable channel or transporter. This property is even more pronounced in the permanently neutral and more lipophilic gas molecule carbon dioxide, CO_2. Nevertheless, a role of AQPs in CO_2 transmembrane permeability has been proposed for lipid bilayers with high membrane protein content, e.g., urothelial cells mainly of the bladder expressing uroplakins (Endeward et al. 2017).

Hydrogen peroxide, H_2O_2, is quite similar to the water molecule in terms size, polarity, and hydrogen bonding capability (Almasalmeh et al. 2014). Accordingly, several AQPs conduct hydrogen peroxide, which is produced during aerobic energy metabolism by chemical reduction of oxygen. Recently, a role as a signaling molecule has been attributed to hydrogen peroxide affecting many cellular processes such as proliferation, differentiation, inflammation, circadian rhythm, and aging (Sies 2004).

Pharmacological Intervention

The many basic physiological functions of orthodox aquaporins and aquaglyceroporins, and their roles in diseases render AQPs attractive drug targets (Beitz et al. 2015). One can think of brain and lung edema, glaucoma, Menière's disease, tumors, fatty liver disease (steatosis) to name a few. However, direct modulation of AQP functionality by drug-like small molecules is difficult due to the narrow transport path in which inhibitors would need to bind to gain sufficient affinity (Beitz et al. 2015). Until today, there are experimental, preclinical compounds that block aquaglyceroporin permeability; however, suitable inhibitors of orthodox aquaporins are still to be found.

There are two pharmacological scenarios in which AQPs are indirectly involved in pharmacotherapy. First, the aquaglyceroporin AQP9 serves as an entry pathway for arsenic trioxide, As_2O_3, which is used as an antineoplastic agent in acute promyelocytic leukemia. Arsenic trioxide, when dissolved and absorbed into body fluids, forms very weak arsenous acid, $As(OH)_3$. In its mostly protonated form, it resembles glycerol in shape and size, and therefore is a permeant of AQP9. Once inside the cytosol, arsenic drives the malignant promyelocytes into apoptosis (Beitz et al. 2015). Second, inhibition of the kidney vasopressin receptor by the "vaptan" drug class act as "aquaretics" that selectively increase the secreted water volume (Beitz et al. 2015). Different from "diuretics," salt secretion remains unaffected. Consequently, vaptans are used to treat euvolemic and hypervolemic hyponatremia. Other clinical conditions associated with water retention accompanying congestive heart failure or liver cirrhosis can be addressed as well. Vaptans have further been beneficial in animal models of surgically induced inner ear volume increase, which is responsible for the symptoms of Menière's disease, hearing loss, and severe vertigo attacks.

Definition

Ah receptor complex: The AhR is a basic helix-loop-helix transcription factor that forms an active complex with the AhR nuclear translocator (Arnt) protein. The AhR-Arnt complex binds dioxins/xenobiotic response elements in target gene promoters to activate transcription. In addition to this classical mechanism, other AhR-mediated pathways have been identified. AhR-mediated downstream responses are dependent on multiple factors including ligand structure and cell context.

Basic Characteristics

AhR-Mediated Toxicity

The toxicities associated with exposures to the herbicide 2,4,5-trichlorophenoxy acetic acid were linked to a contaminant in the production of the herbicide which was identified as 2,3,7,8-tetrachlordibenzo-p-dioxin (TCDD) (Hites 2011). Early studies on TCDD and structurally related polychlorinated dibenzo-p-dioxins (PCDDs) dibenzofurans (PCDFs) and biphenyls (PCBs) showed that these compounds caused a familiar pattern of biochemical and toxic responses that were age, sex, organ, animal species, and strain dependent (Poland and Knutson 1982). Well-characterized effects caused by TCDD included a rabbit ear chloracnegenic response which is also observed in human skin and induction of cytochrome P4501A1 (CYP1A1) and other drug-metabolizing enzymes (Poland and Knutson 1982). It was also observed that the potency of individual PCDD and PCDF and PCB congeners was structure dependent, and maximal activities/toxicities were observed for compound such as TCDD which contained four

laterals (2, 3, 7, and 8) chloro substituents and potency decreased with increasing chlorination and loss of one or more lateral chlorine substituents (Poland and Knutson 1982). These observations led to the hypothesis that the toxicity of TCDD and structurally related chlorinated aromatic industrial by-products was due to an intracellular receptor protein since a hallmark characteristic of most receptors is their structure-dependent effects of ligands. In a landmark publication, Poland and coworkers identified an intracellular protein called the aryl hydrocarbon receptor (AhR) that bound TCDD with high affinity (K_D-sub nM) and exhibited structure-dependent binding affinities with other chlorinated aromatics and polynuclear aromatic hydrocarbons (PAHs) (Poland et al. 1976). Moreover, there was a rank order correlation between the receptor binding affinities versus response potencies (e.g., CYP1A1 induction) for the compounds suggesting that the AhR was necessary for mediating the toxicities of toxic chlorinated aromatics and some of the effects induced by PAHs (Poland et al. 1976).

The AhR Nuclear Translocator: A Partner for the AhR

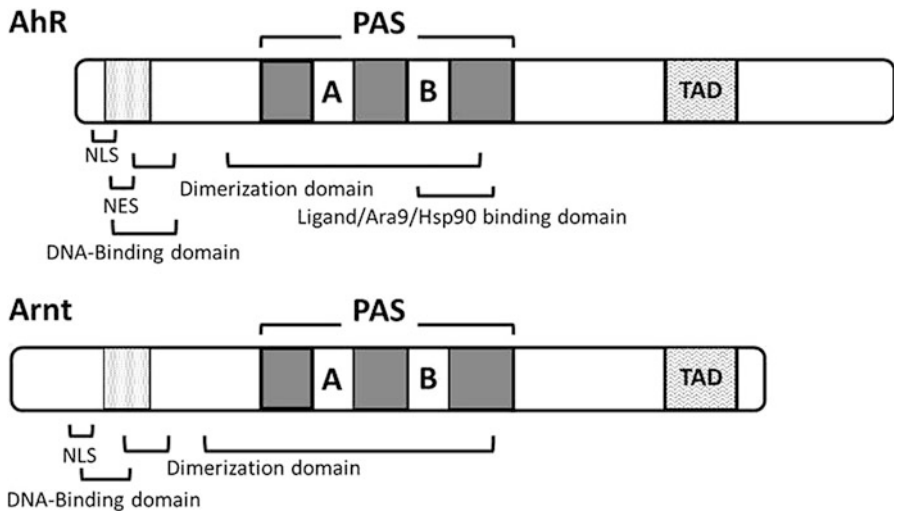
The molecular biology of AhR-mediated response was initially investigated using multiple approaches which included ligand-induced effects on receptor interactions and cellular location molecular weight studies, and the use of genetically modified cells, and identification of nuclear/gene target sites (i.e., cis-elements) (Probst et al. 1993). It was observed that in many cell lines, TCDD and related compounds induced cytosol to nuclear translocation of the AhR complex, and the estimated molecular weight of the complex indicated that at least one other protein was associated with the AhR. Moreover, the nuclear AhR complex exhibited increased DNA-binding affinity to putative dioxin or xenobiotic response elements (DREs/XREs) identified in promoter regions of AhR-responsive genes such as CYP1A1. Pioneering work by Hankinson and coworkers (Hoffman et al. 1991; Probst et al. 1993; Hankinson 1995) used genetic approaches to identify the AhR nuclear translocation (Arnt) protein which was necessary for nuclear uptake and DNA binding of the AhR-Arnt complex. The identification of Arnt as the AhR partner protein (Hoffman et al. 1991) led to the subsequent discovery that Arnt or hypoxia-inducible factor β (HIF1β) was also a partner for HIFs and other proteins that play integral roles in maintaining cellular homeostasis.

The AhR: Knockout Mice and Cloning

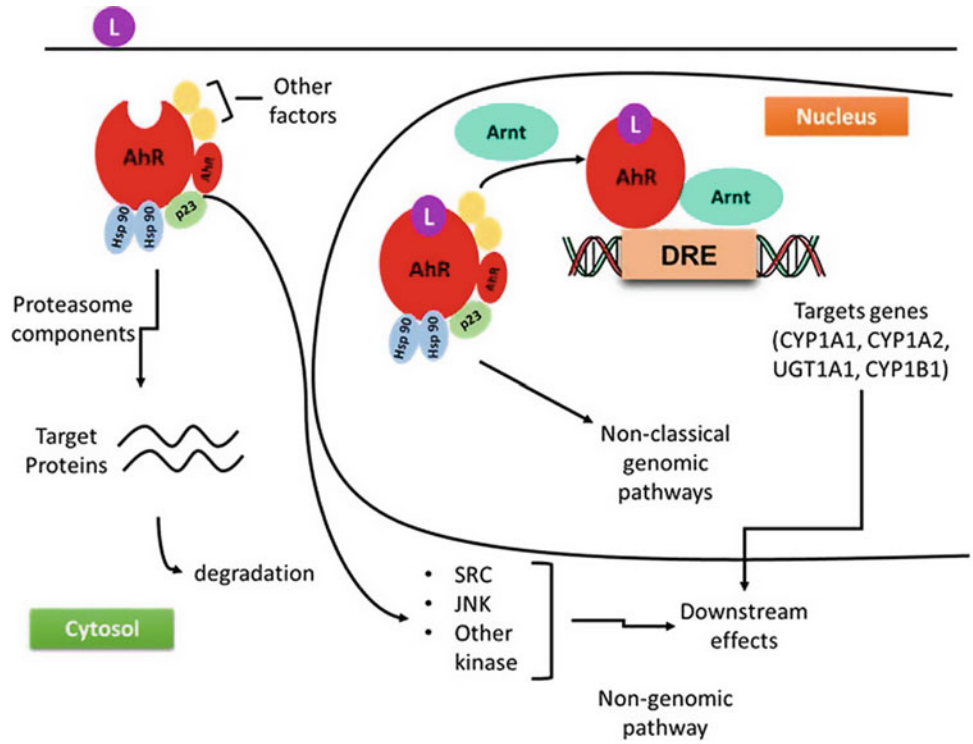
The next advance in understanding the function and structure of the AhR was dependent on molecular advances in gene cloning and development of knockout mouse models. The AhR knockout (AhRKO) mice were generated in three different laboratories and although their phenotypes varied, in all cases treatment with TCDD and related toxic compounds did not induce CYP1A1 and the typical AhR-mediated toxic responses (Schmidt et al. 1993; Fernandez-Salguero et al. 1995; Mimura et al. 1997). These results confirmed that the toxicity of TCDD was mediated through the AhR. The AhRKO mice were viable; however, comparable studies could not be performed with Arnt since Arnt knockout mice are embryolethal, and this is not surprising since Arnt interacts with and is necessary for the function of multiple members of the Per-Arnt-Sim (PAS) family of proteins. The AhR and Arnt genes were also cloned and sequenced and shown to be basic-helix-loop-helix (bHLH)-PAS proteins (Fig. 1) (McIntosh et al. 2010). The structural organization includes bHLH (DNA binding), PAS, and transactivation domains; an acidic D/E region (for AhR), Q and P/S/T regions within the transactivation domains of the AhR and Arnt gene, and a nuclear localization signal (Arnt). The bHLH-PAS genes are members of the PAS superfamily which encompasses genes that act as environmental sensors that play an increasingly broad role in biology (McIntosh et al. 2010) and the AhR-Arnt complex senses and responds not only to TCDD and related toxicants but many other endogenous and dietary AhR ligands.

AhR: Classical and Non-classical Mechanisms of Action

Figure 2 illustrates the classical mechanism of action of the AhR which is bound in the inactive



Aryl Hydrocarbon Receptor, Fig. 1 Domain structure of the human AhR and Arnt genes



Aryl Hydrocarbon Receptor, Fig. 2 Mechanisms of action of the ligand-activated AhR complex

form in the cytosol with Hsp90, ARA9, p23, and other proteins. Addition of ligand induces nuclear uptake of the complex, formation of a nuclear AhR-Arnt heterodimer which interacts with cis elements (DRE/XRE) in target gene promoters to activate gene transcription. However, there is also evidence for non-classical pathways in which the AhR can act independent of Arnt and also function outside the nucleus (Fig. 2). For example, there is evidence for ligand-induced functions of the cytosolic AhR which activates Src, JNK, and other kinase pathways (Enan and Matsumura 1996); AhR also acts as an E3 ubiquitin ligase (Ohtake et al. 2007). The ligand-activated nuclear receptor interacts with proteins other than Arnt and also binds cis-promoter elements that are not DREs. For example, TCDD suppresses liver regeneration, and this is due, in part, to induction of p21 by the AhR-KLF6 complex bound to a non-consensus DRE in the p21 gene promoter (Jackson et al. 2014). Thus, the AhR can function in both classical and multiple non-classical pathways in modulating genotypic and phenotypic changes in target cells/tissues.

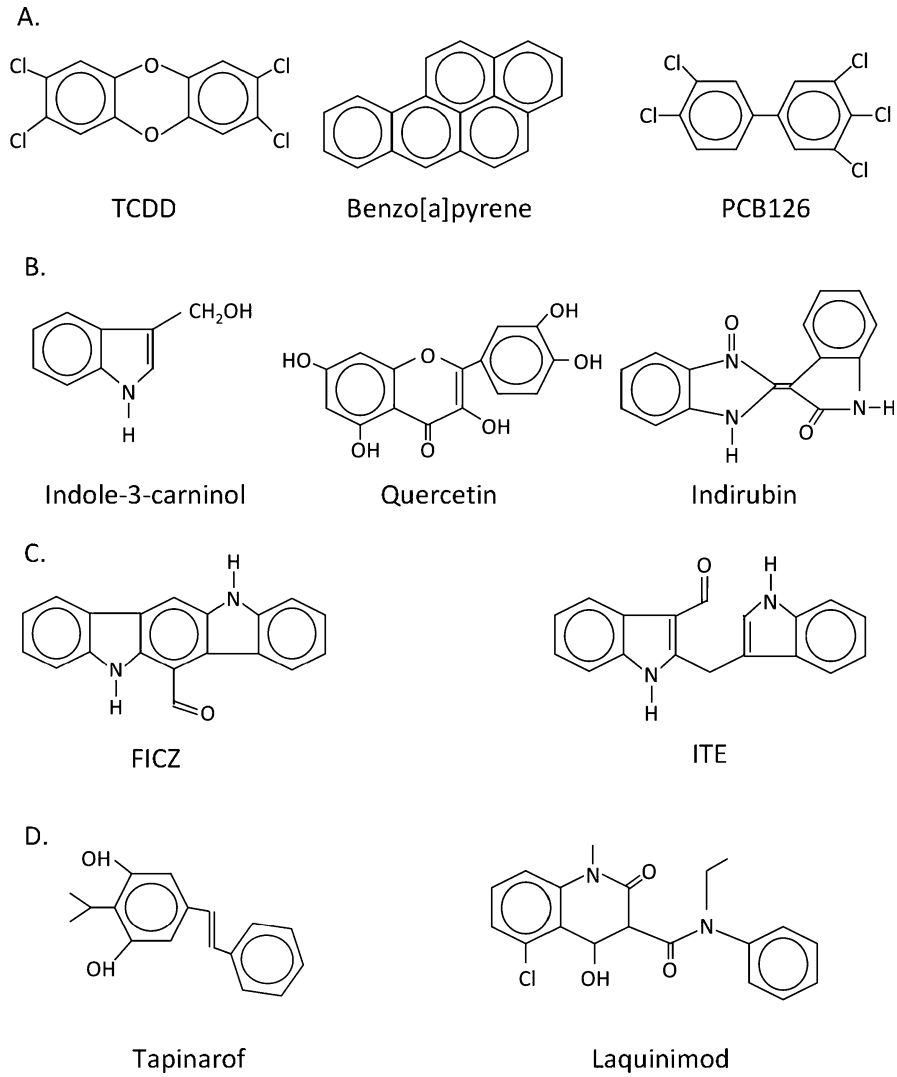
AhR: Role in Multiple Endogenous Functions

After generation of AhRKO mice, it became evident that although loss of the AhR was not embryolethal the mice exhibited multiple abnormalities indicating that the AhR was required for important physiological roles which were independent of the effects of AhR "toxic" ligands. For example, AhRKO mice exhibit some of the following differences from their wild-type counterparts; decreased liver size due, in part, to defects in fetal vascular structure and failure of ductus venosis closure, cardiovascular and reproductive deficits immune response problems, and many other tissue specific effects (Esser and Rannug 2015; Rothhammer and Quintana 2019). Many of these responses were observed during the initial generation of AhRKO mice; however, in the last 10–15 years the linkage of the AhR with tissue-/organ-specific phenotypic effects has expanded significantly. The AhR plays an important role in immune responses, infection autoimmune diseases, stem cell development cancer, inflammation, and antimicrobial resistance and mediates ligand-dependent crosstalk between the gut and distal organs including the brain (Esser and Rannug 2015; Rothhammer and Quintana 2019). The functions of the AhR in cancer are highly complex and tumor specific, and for some tumor types the results are contradictory. Studies in head and neck cancer clearly show that the AhR play a pro-oncogenic role, whereas for intestinal cancers the AhR acts as a tumor suppressor (Safe et al. 2013; Murray et al. 2014).

Drug

AhR: Ligand Multiplicity and Selectivity

The AhR was initially identified as the receptor that binds and mediates the toxic effects induced by TCDD and related compounds. Early studies also showed that PAH also bound the AhR, and like TCDD, PAHs induced CYP1A1 but did not induce the typical pattern of TCDD-induced toxic responses including chloracne dysregulation of the immune system, porphyria, bodyweight loss, cleft palate, and other developmental reproductive toxicities, and this may be due, in part, to their rapid metabolism. In addition, AhR ligands such as 6-methyl-1,3,8-trichlorodibenzofuran MCDF) and 3-methoxy-4-nitroflavone which exhibit partial antagonist/agonist activities (Astroff et al. 1988) were identified, and although these compounds inhibited some tissue/species-specific TCDD-induced responses, they also induced some TCDD-like activities. Subsequent and ongoing studies have identified several different structural classes of compounds that bind the AhR and activate/inhibit AhR-dependent effect, and these compounds include diverse aromatic industrial and non-industrial compounds, endogenous biochemicals including bilirubin, tryptophan-derived metabolites and photoproducts, plant extracts and phytochemicals, and diverse pharmaceuticals (rev. in Denison and Nagy 2003). Figure 3 illustrates some examples of the structurally diverse AhR ligand which include the highly toxic TCDD which binds the AhR with high affinity and other diverse structural classes of AhR ligands which exhibit lower AhR binding affinity. This pattern of structurally diverse



Aryl Hydrocarbon Receptor, Fig. 3 Structurally diverse AhR ligands including, (**a**) toxic [TCDD, benzo [a]pyrene and 3,3′,4,4′,5-pentachlorophenyl (PCB126)], (**b**) phytochemical derived (indole-3-carbinol, quercetin and indirubin), (**c**) endogenous (FICZ and ITE), and (**d**) pharmaceutical (Tapinarof and Laquinimod) ligands

compounds binding the AhR is paralleled by similar binding data for other receptors including estrogen receptor α which binds 17β-estradiol (E2) and diethylstilbestrol with high affinity as well as structurally diverse ligands with lower binding affinity (Kuiper et al. 1998). The structural diversity of ER ligands is paralleled by their functional diversity, and this has led to development of selective ER modulators (SERMs) such as tamoxifen which is an ER antagonist (breast) and agonist (uterus) and has been extensively used as an antiestrogen for treating ER-positive breast cancer patients**.** There is also AhR binding, genomic and functional data indicating that AhR ligands are selective AhR modulators (SAhRMs) and exhibit tissue-specific AhR agonist or antagonist activities (Astroff et al. 1988; Denison and Nagy 2003). There are an increasing number of examples where SAhRMs have been used to target the AhR to provide health benefits in animal models of disease, and this include phytochemicals such as indole-3-carbinol for inhibiting colon cancer and tryptophan-rich diets for enhancing immune cell function (Esser and Rannug 2015).

The realization that the AhR is a potential target for therapeutics has been hindered in the past by the linkage of this receptor to TCDD. However, AhR ligand such as laquinimod and tapinarof are being developed for treating autoimmune disease and dermatitis, respectively (Kaye et al. 2016; Smith et al. 2017), and due to the expression and functions of the AhR in multiple diseases, there are many exciting opportunities for future development of SAhRMs as therapeutics.

Arteriosclerosis (see Definition)

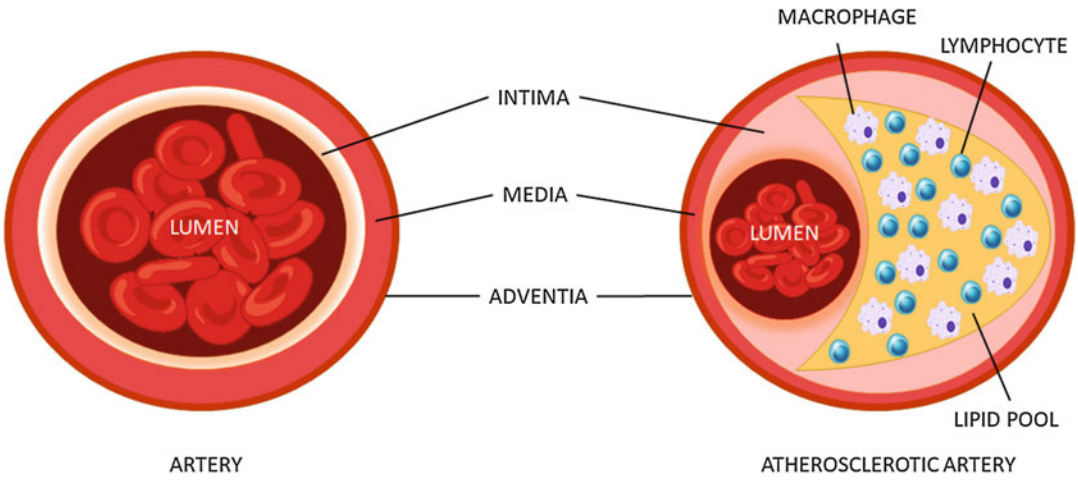
Definition

Atherosclerosis is an arterial disorder that comes from Greek words *athera* which means porridge and *sclereni* which means hardening of arteries. It is an inflammatory disorder, in which the lipid plaques along with inflammatory responses accumulate inside the arteries resulting in hardening and narrowing of the arteries and therefore restricting blood flow. Plaques are waxy substances that consist of lipids and oxidized lipids along with many inflammasomes. Plaques are complex, heterogenous composition which include fibrous caps, necrotic cells, and inflammatory responses (Barrett et al. 2019). Blockade of coronary artery (that supplies blood to the heart) with plaques hampers the blood flow to the heart, and the cardiac cells become deprived of oxygen. Symptoms of atherosclerosis in coronary artery include angina, vomiting, coughing, and anxiety, which eventually leads to myocardial ischemia. Plaques causing atherosclerosis of carotid artery eventually leads to brain stroke and cause symptoms like weakness, headache, facial numbness, and paralysis.

Basic Mechanisms

Atherosclerosis is a chronic condition that progresses silently for decades. The progression of the lesion initiates with the formation of thrombus which obstructs the blood flow (Bentzon et al. 2014) (Fig. 1).

Atherosclerosis grows in specific regions of artery. The initial changes that take place are morphological changes in the intima where the lipoproteins aggregate. The aggregated lipoproteins influence chemotaxis of leukocytes and other inflammasomes through multiple mechanisms which include oxidation and enzymatic and non-enzymatic proteolysis. At the initial stage, the monocytes or the macrophages adhere to the arterial endothelium which is accompanied by accumulation of macrophages in the intima (Ardies and Roberts 2014). More macrophages adhere to the area and these cells that modify the lipoproteins into lipid droplets which are filled with

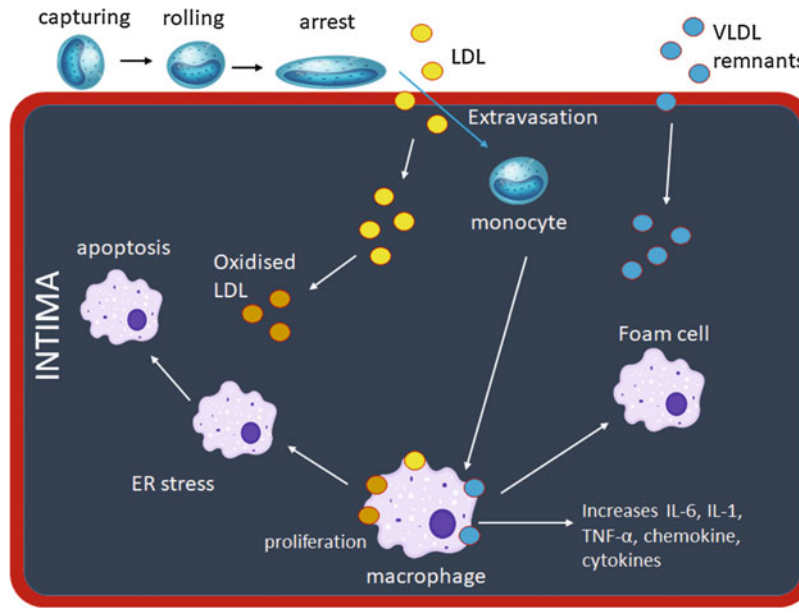


Atherosclerosis, Fig. 1 Nonatherosclerotic artery and atherosclerotic artery

cholesteryl ester; this entire process is known as foam cell formation. The disturbed metabolism of lipid alters the functioning of the cells. The foam cell that is aggregated in the lesion decreases the migration from the lesion that results in chronic inflammation and lesion progression. These complex plaques comprise of immune cells and vascular smooth muscle, and the macrophages within it secrete proinflammatory mediators, nitrogen species, reactive oxygen, and matrix-degrading proteases leading to apoptosis or necrosis of the cells. The dead macrophages secrete lipid and form prothrombotic necrotic core and form unstable plaques. Thin fibrous cap of these unstable plaques may get ruptured, forms thrombus which results in acute myocardial infarction or stroke. The formation of foam cells is the major and the central cause for the pathophysiology of atherosclerosis.

Cells Involved in Atherosclerotic Lesions

Multiple cell types along with various signalling pathways are involved in inflammation and atherosclerosis. Modified lipoproteins activate endothelial cells which secrete adhesion molecules like vascular cell adhesion molecule 1 (VCAM-1), intracellular adhesion molecule 1 (ICAM-1), and selectins. These molecules with chemoattractant mediators along with complement factors and MCP-1 help monocyte adhesion to the impaired endothelial into the intima. Monocytes are activated by macrophages that modify the lipoprotein to form foam cells. Macrophages are the major cell types that contribute to progression of atherosclerotic lesion. Lipoproteins that are accumulated in the intima release various cytokines like IL-1, IL-6, and TNF-α (Fig. 2). T lymphocytes are found in the atherosclerotic lesion and get accumulated in early lesion (Libby 2012). LDL stimulates T lymphocytes and produces interferon-γ. Atherosclerotic lesions contain minimal B lymphocytes. Oxidized LDL produces antibodies from B lymphocytes that get accumulated in atherosclerotic lesions. T lymphocytes are known to increase the progression of atherosclerosis, whereas antibodies secreted by B lymphocytes called as B1 cells protect against formation and development of atherosclerosis. Neutrophils are the most abundant leukocyte type in blood and are present for only 1–2 days. Neutrophils are the first line in acute inflammatory responses. The neutrophils get activated and reach to the area of lesions, but the mechanisms are still unknown (Weber and Noels 2011). VSMCs (vascular smooth muscle cells) are the most abundant cell type in arteries. Inflammation leads to VSMC



Atherosclerosis, Fig. 2 Process of formation of foam cells

proliferation and gets migrated into the atherosclerotic lesion. VSMCs stabilize the lesion by secreting extracellular matrix which forms a fibrous cap and transforms them into foam cells. VSMC foam cells lose its capacity of secreting extracellular matrix. Oxidized LDL increase the smooth muscle cell proliferation.

Process of Formation of Foam Cells

Recruitment of Circulating Monocytes

Endothelium dysfunction leads to recruitment of circulating monocytes to the site of injury (Moore et al. 2013) (Fig. 2). Monocytes in atherosclerotic lesions undergo processes like capture, rolling, and transmigration. The surface molecules of activated endothelial cells capture and roll the monocytes. This process depends on their immobilization by chemokines, p-selectin, VCAM1, and ICAM1 and interacts with chemokine receptor and integrins. The monocyte chemokines interact with chemokine PECAM1 or VCAM1 and facilitate the removal of monocytes across the endothelium and into plaque. PECAM1 or VCAM1 are secreted by endothelial cells, macrophages, and smooth muscle cells.

Foam Cell Formation

Macrophages forming foam cell are one of the earliest stage in progression of lesion and continue throughout its progression (Moore and Tabas 2011) (Fig. 2). Even though macrophages take apoB-containing lipoprotein from the LDL receptor, the receptor gets downregulated by increased cellular cholesterol. Scavenger receptors take up the modified lipoprotein and help in foam cell formation. Pathways related to foam cell formation are still unknown. The oxidative stress in the intima modifies the lipoprotein and produces damaged signals; these signals are then identified by the scavenger receptor. This scavenger receptor includes SR-A1, SR-A2, SR-B1, CD36, LOX1, SREC1, and CXCL16, and majorly SR-A1 and CD36 help in uptake of the oxidized LDL. These all receptors bind to oxidized LDL and help in formation of foam cell. During oxidation, various lipoprotein mediators like 12/15-lipoxygenase, myeloperoxidase, and free radicals including superoxide, hydrogen peroxide, and nitric oxide had been found in the walls of artery. The lipoproteins get attributed by these receptors into the late endosome and lysosomes. The lysosomal acid lipase hydrolyzes the lipoprotein cholesteryl ester into fatty acids and cholesterol. Cholesterol undergoes

reesterification and gets converted to cholesteryl ester and forms foam. Proteases and lipases in the intima modify the lipoproteins and accumulate LDL (Moore et al. 2013). Extracellular matrix glycoproteins in the intima retain apoB-containing lipoproteins and modulate the activity of enzymes. These enzymes include group IIA secretory phospholipase A2 (PLA2G2A), PLA2G5, and PLA2G10 and secretory sphingomyelinase and produce modified forms of LDL which are taken up by macrophages. Cholesterol gets delivered to the endolysosomal compartment and stimulates ACAT1-mediated cholesterol via receptor-independent endocytic pathway. They stimulate ACAT1-mediated cholesterol esterification. LDL and other apoB-containing lipoproteins form foam cell by multiple pathways. Excessive lipoprotein uptake results in defective lipid metabolism within macrophages and leads to increased lesion complexity. Cholesteryl ester in lipids is inert, but cholesterol inside the cell membrane can be toxic. Macrophages enriched with cholesterol suppress the esterification of lipoprotein by ACAT1 which results in increased accumulation of cholesterol, and the plasma membranes become enriched with cholesterol that increases the inflammatory signalling through Toll-like receptors. Macrophage cholesterol export gets hampered due to trafficking of cholesterol from lysosomes and further increases the inflammatory response. This dysregulated lipid metabolism, if prolonged, can lead to apoptosis and cell death. Clearance of apoptotic cells from lesions is known as efferocytosis that engulfs the cells to metabolize lipids inside the apoptotic cells. Excessive lipoprotein uptake by macrophages affects the cellular lipid metabolism and increases apoptosis and suppresses efferocytosis that leads to secondary necrosis and a necrotic core; this necrotic core with thinned fibrous cap is more prone to rupture.

Macrophage Polarization

Monocytes when entering intima get polarized to M1 macrophages (classically activated inflammatory cells) or M2 macrophages (alternately activated cells) that are known to resolve inflammation (Moore et al. 2013). M1 macrophages are derived from Ly6Chi monocytes, and M2 macrophages are from Lys6Clow monocyte precursors. The factors in lesion microenvironments that promote macrophage polarization remain incompletely defined. M1 macrophages are known as foam cell precursors, and in plaques they are enriched in lipids and localized to areas distinct from the less inflammatory M2 macrophages.

Inflammatory Responses

Activation of innate immunity is known to be the main system in progression of atherosclerosis and is mainly affected due to dysregulated lipid metabolism that causes accumulation of lipids and oxidized lipid in the lesion (Moore et al. 2013). This triggers various receptors like scavenger receptor, TLR, and nucleotide-binding oligomerization domain (NOD)-like receptors which results in activation of various inflammatory responses. In early and advanced lesions, cholesterol crystals are found in the extracellular spaces and in macrophages; these cholesterol crystals activate the NLRP3 inflammasome which secretes many proinflammatory cytokines. The remnant of VLDL and fatty acid also activates pro-inflammatory cytokines, independent of TLRs, which are a class of membrane-spanning, non-catalytic receptors that have a significant role in innate immune responses. Oxidized LDL along with oxidized phospholipids activate TLR2- and/or TLR4-related signalling cascades and increase inflammation. The lipid ligands along with CD36 and SRA react with TLRs and activate myeloid differentiation factor (MyD) 88 and c-Jun N-terminal kinases (JNK) and are responsible for apoptosis.

Macrophage Retention and Emigration

In the pathogenesis of atherosclerosis, macrophages aggregate in the lesion and are

accompanied by monocyte recruitment, proliferation of macrophages, formation of foam cell, and finally macrophage emigration and death (Moore et al. 2013) (Fig. 2). Lipoproteins in the intima causing pathogenesis of atherosclerosis are responsible for the recruitment of macrophages. Macrophage emigration occurs in the early stage of the plaques formation, but its rate of withdrawal decreases with the progression of lesion. The macrophages in the lesion do both retention and emigration of signals. Macrophage foam cells formed due to an increased expression of the neuro-immune guidance cues, netrin 1 and semaphorin 3E on macrophages, which promote its chemostasis. Deficiency of netrin 1 decreases the progression of lesion and increases emigration of macrophages. The CC-chemokine receptor CCR7 and CC-chemokine ligands CCL19 and CCL21 are responsible for the signalling of macrophage emigration from the endothelium to the lumen. As the progression of lesion continues, the foam cells enriched with lipid cause cytotoxicity induced by cholesterol and saturated fatty acid, which further causes ER stress and therefore increases apoptosis (Fig. 2). Tyrosine protein kinase MER (MERTK) and LRP1 are the receptors involved in efferocytosis that removes the apoptotic cells, but as these receptors get damaged due to accumulation of cholesterol, they continue as secondary necrosis and increase the lipid-enriched necrotic core that causes the lesion to rupture.

Pharmacotherapy for Atherosclerosis

Dyslipidemia is one of the common reasons that promote the progression of atherosclerosis; the lifestyle changes have increased the risk for atherosclerosis (Chan et al. 2014). Statins are considered as first-line lipid regulator. Patients resistant to statin are advised for alternative drugs like cholesterol absorption inhibitor or bile acid sequestrant. Various other approaches like targeting other lipid-regulating agents can be opted to treat dyslipidemia and ultimately for the treatment of atherosclerosis.

Statins (3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitor)

It is a lipid-lowering class of drugs that lowers the LDL levels by inhibiting HMG-CoA reductase. HMG-CoA is a rate-controlling enzyme that produces cholesterol. Inhibitors of HMG-CoA induce LDL expression which results in the reduction of intracellular cholesterol that induces an increase in SREBP-2-mediated hepatic LDL receptor synthesis (Sahebkar and Watts 2013). This results in increased clearance of LDL along with remnants of VLDL and chylomicron (Fig. 2). They lower the plasma concentration of LDL and apoB100 and increase HDL level. Clinical trials have consistently demonstrated that statin therapy reduces cardiovascular events. They also inhibit the mevalonic acid formation which shows anti-inflammatory activity. It reduces leukocyte adhesion, macrophage aggregation, and various other inflammasomes.

Fibrates (Peroxisome Proliferator-Activated Receptor-α Agonist)

Fibrates are nuclear hormone receptor agonists and activate PPAR-α, which decreases plasma TAG, LDL, and small-dense LDL particles and increases HDL levels (Do et al. 2014). They increase the oxidation of fatty acid due to which VLDL secretion decreases in the liver and decreases the availability of TAG substrate. They also increase the lipolysis of VLDL by LPL (lipoprotein lipase) activation and by decreasing the gene expression of apoc-III. They increase the reverse cholesterol transport by increasing apoA1 and ABCA1 expression by LXR activation. They repress the VCAM1 expression and inhibit inflammatory activation of vascular SMCs. Hence, several trials show that fibrates decrease atherosclerosis.

Niacin

Niacin has shown theoretical potential for treating atherosclerotic diseases (Do et al. 2014). It

decreases the TAG and LDL cholesterol levels in plasma and increases HDL cholesterol level. It also decreases lipoprotein a level in plasma. It decreases the secretion of VLDL TAG in the liver by inhibiting fatty acid mobilization and also decreases IDL and LDL. It decreases the clearance of HDL and apoA1 thereby increasing its plasma level. Despite of having these many desirable properties, yet it's not proven to be beneficial in cardiovascular disease.

Cholesterol Absorption Inhibitors

Ezetimibe is used to decrease the amount of cholesterol and other fatty substances in the blood. It also decreases the LDL cholesterol levels in the blood (Do et al. 2014). It works by inhibiting the function of Niemann-Pick C1-Like 1 protein (NPC1L1) and decreases the intestinal cholesterol absorption, its transport, and cholesterol content in liver (Fig. 2). It decreases the LDL particle number but does not affect the particle size of LDL. It decreases TAG in the liver and is not affected by body weight, visceral fats, and sensitivity of insulin. Ezetimibe when combined with statin shows beneficial effects and inhibits the absorption of cholesterol and shows fractional catabolism of apoB-containing lipoprotein. Ezetimibe when combined with low dose of statin decreases LDL cholesterol level more effectively as compared to higher dose of statin itself.

ω-3 Polyunsaturated Fatty Acids

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are ω-3 polyunsaturated fatty acids that are mostly found in fish oils. These fish oils reduce VLDL TAG levels (Rached et al. 2014). Its supplementation reduces VLDL production in the liver and reduces VLDL TAG levels accordingly. It inhibits the activity of diacylglycerol acyltransferase, fatty acid synthase, and acyl-CoA carboxylase enzyme which decreases the TAG levels and inhibits synthesis of fatty acid. It induces PPAR-α which enhances β-oxidation of fatty acids, but these are less effective than fibrates.

Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors

PCSK9 was found to be involved in autosomal dominant hypercholesterolemia and is known to degrade the LDL. Few mutations of this target increase hypercholesterolemia, but some loss of mutation shows hypocholesterolemia which decreases the risks related to CVS. PCSK9 increases LDL levels in plasma by degrading the LDL in the liver. Statins reduce LDL cholesterol in plasma and upregulate PCSK9 via SREBP2 which limits the efficacy of statin in reducing plasma LDL cholesterol level. Antibodies against PCSK9 increase the numbers of LDL receptors at the cell surface and reduce plasma LDL cholesterol (Rached et al. 2014). Antibodies like monoclonal or humanized antibodies are injected intravenously or subcutaneously. Other approaches to inhibit PCSK9 also include ASO therapies, and this target can be promising new approach for treatment of hypercholesterolemia and potentially atherosclerosis.

Antisense Oligonucleotide (ASO) Therapies

ASO sequences, when injected, bind to the mRNA and promote selective complex degradation by endogenous nucleases and also inhibit the functioning and processing of mRNA. These are short, single-stranded, synthetic analogues of natural nucleic acids that bind to mRNA in a specific manner. Mipomersen, an advanced ASO, inhibits apoB100 in the liver (Rached et al. 2014; Do et al. 2014) (Fig. 2). It reduces apoB, LDL, non-HDL, and TAG levels in plasma in different types of dyslipidemia. It decreases lipoprotein a levels by inhibiting its synthesis. It also targets other apoC-III and lipoprotein a, in which apoC-III blocks LPL-mediated lipolysis of VLDL and chylomicrons and reduces clearance of their remnant from the liver (Fig. 2). Decrease in apoC-III levels

in plasma decreases TAG concentration and reduces the risk of cardiovascular events.

Microsomal Triacylglyceride Transfer Protein (MTP) Inhibitors

This protein is useful in formation and helps in secreting apoB-containing lipoprotein from the liver and intestine (Do et al. 2014). It helps in transferring TAG, cholesteryl ester, and phospholipid to apoB in the cell during the lipoprotein assembly process. Abetalipoproteinemia is a disorder of lipoprotein assembly and is a rare condition that occurs due to mutation of this protein, in which apoB-containing lipoproteins become undetectable in plasma. Lomitapide is a MTP inhibitor that reduces LDL level in condition like hypercholesterolemia and can be given alone or in combination with ezetimibe, which is a cholesterol absorption inhibitor. Side effects like minor elevation in transaminase level in the liver, side effects in GIT, and increases in fats in the liver were reported. This drug is approved for treating homozygous FH as this drug is proven to be beneficial for cardiovascular disorders. MPT inhibitors that target the intestine promote weight loss without elevating enzymes in the liver or increases in fats in the liver and are suggested for treating broader range of lipid disorder (Rached et al. 2014).

ACAT and DGAT Inhibitors

Esterification of cholesterol in macrophages helps in formation of foam cells and is an important step in pathogenesis of atherosclerosis due to which there is accumulation of cholesterol in the intima which on esterification forms foam cells; this can be prevented by targeting ACAT (Acyl-CoA/cholesterol acyltransferase) using ACAT inhibitors. Early versions inhibited both ACAT isoforms like ACAT-1 and ACAT-2 (Rached et al. 2014). K-604 is an ACAT-1 selective inhibitor which is under development by Kowa Pharmaceuticals. ACAT-2 is an isoform that esterifies hepatic and intestinal cholesterol along with cholesteryl ester for the synthesis of lipoprotein. Inhibiting ACAT-2 using ASOs was found to inhibit secretion of VLDL and chylomicron in plasma and reduces atherosclerosis in mice. Therefore, inhibitors of ACAT-2 are under development. Diacylglycerol acyltransferase (DGAT) esterifies the third fatty acid to DAG to form TAG in hepatic, intestinal, and adipose tissue. In mice DGAT-1 inhibitor reduces TAG levels in plasma, steatosis in the liver, and obesity. Studies in mice with DGAT-1 deficiency or mice treated with DGAT-1 inhibitors demonstrated reduced plasma TAGs, hepatic steatosis, and obesity. It also improved insulin resistance. DGAT-1 inhibitor decreased fasting TAG levels in plasma in patients with hypertriglyceridemia. DGAT-2 isoform helps in synthesis of TAG in the intestine and liver and the provision of CE for lipoprotein synthesis. Specific DGAT-2 inhibitors reduce the TAG levels in the liver and in plasma and are under development for clinical use.

ATP-sensitive potassium channels

Definition

ATP-dependent potassium (K_{ATP}) channels are potassium selective ion channels present in a range of tissues. The defining property of K_{ATP} channels is their sensitivity to intracellular nucleotides. The channels are inhibited by ATP and activated by ADP and thus couple cellular metabolism to membrane excitability. The opening of K_{ATP} channels results in membrane hyperpolarization and reduces cellular excitability. The channel is a member of the inwardly rectifying family of potassium channels though the rectification it displays is relatively weak and thus K_{ATP} channels can significantly influence excitability whatever the resting membrane potential. The channels were first described in cardiac tissue (Noma 1983) but subsequently isolated in pancreatic β cells, neurons, and skeletal and smooth muscle (Tinker et al. 2018). In this essay we consider only those channels unequivocally constituted of Kir6.0 subunits; a large number of other ion channels are ATP-responsive, but we will not review these. We also do not discuss the mitochondrial K_{ATP} channel given the controversy over its molecular composition. The following is based on a number of recent and historical reviews, and the citation to the primary literature can be found in those (Ashcroft and Rorsman 2013; Ashcroft and Ashcroft 1990; Babenko et al. 1998; Flagg et al. 2010; Foster and Coetzee 2016; Nichols 2016; Seino and Miki 2004; Tinker et al. 2014, 2018).

Basic Characteristics

Subtypes Defined by Functional Properties

K_{ATP} channels were first recognized by their electrophysiological and pharmacological properties. The channel has a single-channel conductance of 60–80 pS depending on the ionic conditions and is selective for potassium over sodium (permeability ratio P_{Na}/P_K~0.01). The nucleotide regulation of K_{ATP} channels can be characterized in inside-out patch clamp recordings. ATP inhibits K_{ATP} channels with a K_i (the concentration required to bring half maximal inhibition) of 10–500 μM and a Hill coefficient between 1 and 2. There are variations with differences between channels from one tissue to another: for example, pancreatic and neuronal channels are thought to be more metabolically sensitive than cardiac channels with a lower numerical Ki for ATP inhibition. The inhibition is not dependent on ATP hydrolysis, and non-hydrolyzable derivatives can substitute for ATP.

In solutions containing magnesium, MgADP is able to activate the channels generally in the low mM range and relieve the inhibition by ATP. There is another important property related to ATP provision: the activity of K_{ATP} channels progressively declines in ATP-free solutions, and this activity can be restored by the addition of low μM concentrations of MgATP. This phenomenon is present in a number of potassium channels and results from an unqualified dependence on phosphatidylinositol (4,5) bisphosphate in the membrane. Thus phosphatidylinositol (4,5) bisphosphate is an essential cofactor for K_{ATP} channel activity, but it is less clear if this is an important pathway for cell regulation. Thus K_{ATP} channels respond to metabolic perturbations within the physiological range: a process that may be tuned by anionic phospholipid regulation.

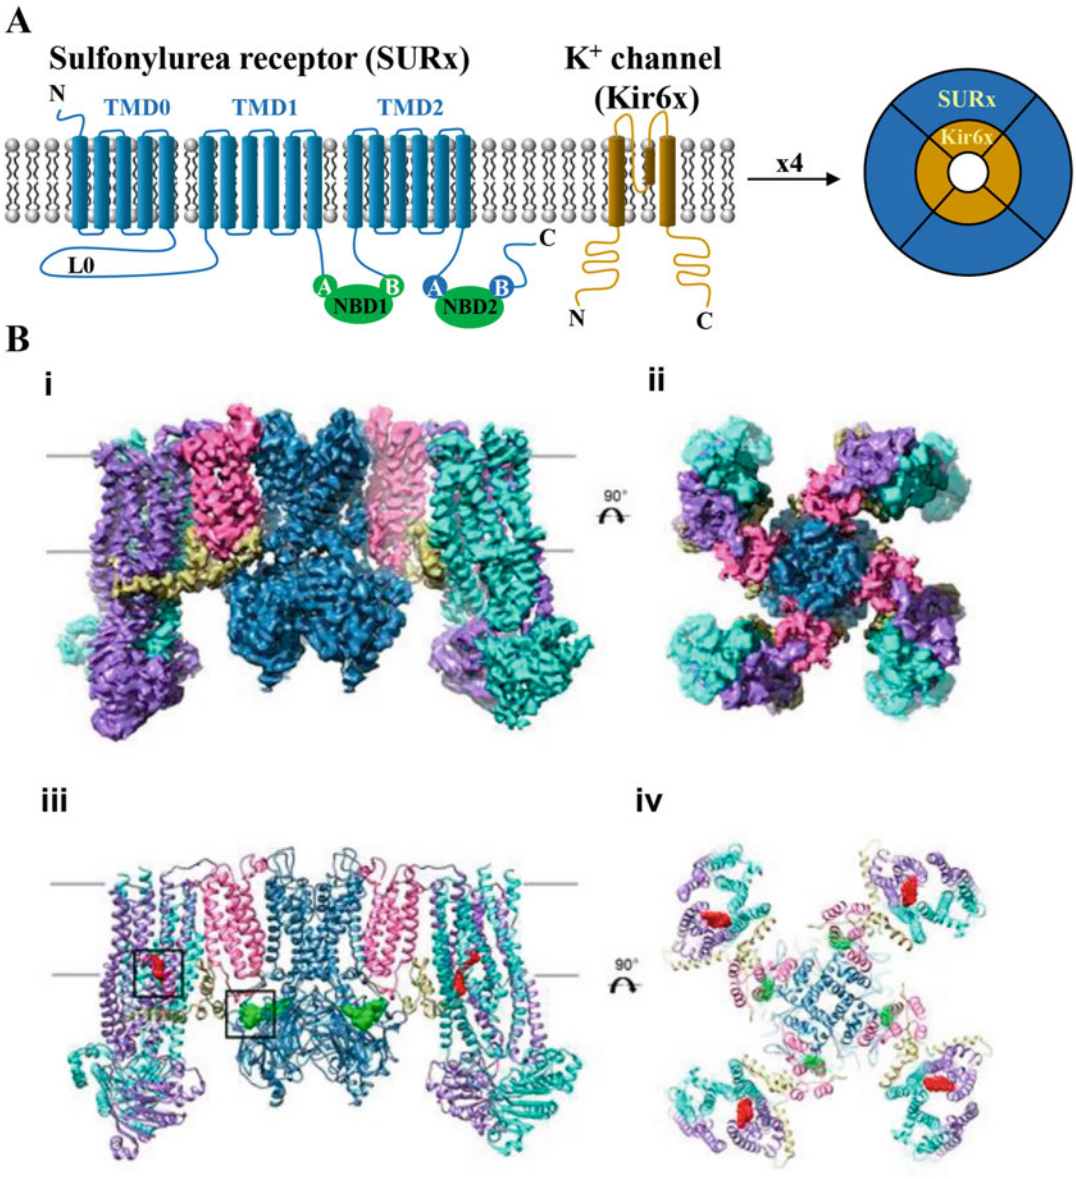
The above description defines the "classical" K_{ATP} channel; however particularly in smooth muscle, there exist channels with similar but also some distinct properties. These channels have a lower single-channel conductance (30–35 pS), and channel activity is absolutely dependent on cytosolic nucleotide diphosphates. The current is more aptly described as a "K_{NDP}" current. This is accompanied by reduced sensitivity to ATP and prominent regulation by cell signalling pathways particularly involving protein kinase A and protein kinase C.

K_{ATP} channels have a distinctive pharmacology: they are inhibited by sulfonylureas including the earlier low-affinity reagents such as tolbutamide and chlorpropamide and a second-generation group including glibenclamide, gliclazide, and glipizide. Newer agents which are based on the non-sulfonylurea component of glibenclamide ("glinides") include meglitinide, mitiglinide, and repaglinide. In general these agents show selectivity for the K_{ATP} channel present in the pancreatic β cell, but at higher concentrations they can inhibit channel populations in other tissues. Synthetic efforts have also led to the development of drugs with a different pattern of selectivity. For example, HMR-1098 preferentially inhibits cardiac over pancreatic beta cell K_{ATP} channels. Furthermore, PNU99963 and PNU37883A are non-sulfonylureas and selectively block the vascular K_{ATP} channel. They were initially developed as potentially selective agents for the vascular channel.

K_{ATP} channels can be activated by a number of drugs with a variety of chemical structures. These include diazoxide, minoxidil, cromakalim, nicorandil, pinacidil, aprikalim (and analogues such as rilmakalim), WAY-151616, ZM-244085, and ZD-6169. Initially these drugs were developed for their selective actions on smooth muscle and in particular hypotensive effects. However diazoxide is more potent in activity for the pancreatic channel and can cause hypoglycemia. Diazoxide, minoxidil, cromakalim, nicorandil, pinacidil, and aprikalim all have significant additional activity toward the cardiac channel, while WAY-151616, ZM-244085 and ZD-6169 seem to be more smooth muscle specific.

Subtypes Defined by Molecular Cloning

A major advance in understanding of the molecular physiology of K_{ATP} channels came with the cloning of their component subunits. The channel is an octameric complex consisting of four Kir6.0 subunits and four sulfonylurea receptors (Fig. 1a). The coexpression of both proteins is necessary for the expression of membrane currents, and only correctly folded and assembled octamers are exported from the endoplasmic reticulum to the plasma membrane. Incorrectly folded subunits are recognized in the Golgi and retro-translocated to the endoplasmic reticulum for degradation. There are two Kir6.0 subunits, Kir6.1 and Kir6.2, encoded by the genes *KCNJ8* and *KCNJ11*. There are two sulfonylurea receptor genes, *ABCC8* and *ABCC9*, and these generate the proteins SUR1 and splice variants of *ABCC9*, SUR2A, and SUR2B. Other splice variants have been suggested, but their significance is debated. Kir6.0 subunits are a member of the inwardly rectifying family of potassium channel and have two transmembrane segments, a pore-forming H5 domain and an intracellular N and C-terminus. SURs belongs to the superfamily of ATP-binding cassette (ABC) proteins with 17 transmembrane segments grouped into 3 domains comprised of 5,



ATP-Dependent K^+ Channels, Fig. 1 Molecular composition and structure of a K_{ATP} channel. (**a**) Schematic of the molecular composition of a K_{ATP} channel. K_{ATP} channels are an octameric complex consisting of four pore-forming Kir6.x subunits and four regulatory sulfonylurea receptor (SUR) subunits. Kir6.x belongs to the inward-rectifying K^+ channel family (Kir); it is composed of two transmembrane domains (M1 and M2), a pore-forming region (H5) with the K^+ selectivity sequence and intracellular N and C termini. SUR belongs to the ATP-binding cassette (ABC) family of proteins. It consists of three transmembrane domains (TMDs) composed of five, six and six transmembrane segments, respectively. Two nucleotide-binding domains (NBD1 and NDB2) comprised of Walker A and B nucleotide-binding motifs provide the binding sites for magnesium-complexed adenine nucleotides. (**b**) The high-resolution structure of the pancreatic K_{ATP} channel. (i) Cryo-EM density map (side view) of the K_{ATP} channel (3.63 Å resolution). Gray lines indicate the position of the membrane. (ii) The K_{ATP} channel complex when viewed extracellularly. (iii) A model of the K_{ATP} channel complex with various ligands bound as indicated (ATP in green and glibenclamide in red). (iv) The model viewed from the extracellular side of membrane. This figure is reproduced from Martin et al. (Martin et al. 2017)

6, and 6 transmembrane helices (TMD0, TMD1, and TMD2, respectively). The N-terminus is extracellular with cytoplasmic linkers connecting the other domains to one another and nucleotide-binding domains in the second linker (NBD1) and C-terminus (NBD2). As the name suggests, the nucleotide-binding domain protein modules bind and hydrolyze adenine nucleotides.

The specific combinations of Kir6.0 and SUR subunits determine the particulars of the current in each tissue. In pancreatic β cells, SUR1 and Kir6.2 underlie the current and lead to 70 pS single-channel conductance, a high sensitivity to ATP inhibition (Ki ~ 10–30 μM), inhibition by tolbutamide, and activation by diazoxide. In many smooth muscles, SUR2B and Kir6.1 constitute the channel with a 35 pS single-channel conductance, an absolute prerequisite for provision of nucleotide diphosphates for activity, low-affinity inhibition by glibenclamide, and activation by levcromakalim. The contents of this section are summarized in Table 1.

The Relationship of Structure to Function

A great deal is understood about how modulators of K_{ATP} channel function from mutagenesis studies and recent high-resolution cryo-EM structures (Fig. 1b). The channel, in the closed state, assembles with four SUR1 subunits attached at the periphery of the tetramer of Kir6.2 subunit. The N-terminus and proximal C-terminus of Kir6.2 link to the SUR1 TMD0 and linker L0, and TMD1 and TMD2 lie away from the channel subunit. The inhibition of the channel by ATP is governed by amino acids in the pore-forming Kir6.0 subunit: a horseshoe-shaped binding pocket is defined by adjacent N and C domains from separate Kir6.2 subunits, and the complex can bind up to four molecules of ATP. Activation by MgADP is determined by the sulfonylurea subunit in particular interaction with residues in the NBDs. The binding site is made up of residues from both NBD1 and NBD2, and the two binding sites formed in an individual SUR are asymmetrical with respect to structure and function with only one able to hydrolyze ATP rapidly. However ATP hydrolysis is not key for activation as MgADP readily modulates the channel. In other ABC transporters, the NBDs dimerize on activation though this has not yet been unequivocally demonstrated for SUR. Sulfonylureas bind to SUR, but at high concentrations some may also directly interact with the pore. The binding site is defined by the transmembrane segments in TMD2, particularly the transmembrane domains 15 and 16, though the cryo-EM structures also indicate interaction with the linker between TMD0 and TMD1 and TMD1. There are indications from the structures that glibenclamide might affect the ability of the NBDs to align and potentially dimerize. The binding site for potassium channel openers is present on the SUR subunit but is less well defined, but the cytoplasmic linker between TM13 and TM14 and the last TM helices, TM16 and TM17, may be involved in activation by pinacidil. It is also plausible that different potassium channel openers may have different binding sites and it is clear that the sites don't overlap with that for sulfonylureas.

Physiology, Pathophysiology, and Therapeutic Potential

Insulin Secretion in Pancreatic β Cells

Insulin is synthesized, stored, and released from the β cells present in the islets of Langerhans in the pancreas. Insulin is key to maintaining blood glucose within the normal range by promoting glucose uptake in peripheral tissues and switching off glucose production. The process by which the blood glucose concentration is coupled to insulin secretion is known as stimulus-secretion coupling, and K_{ATP} channels are centrally involved. When blood glucose increases, pancreatic β cells depolarize and initiate increased firing of action potentials. The metabolism of glucose by β cells is tightly coupled to ATP production via mitochondrial oxidative metabolism. This increase in ATP leads to inhibition of K_{ATP} channels and is the main reason for membrane depolarization. The increased action potential firing leads to calcium entry into the β cell via voltage-dependent calcium channels which in turn promotes the exocytosis of insulin containing vesicles. This

vCMs, ventricular cardiomyocytes; aCMs, atrial cardiomyocytes; CCS, cardiac conduction system; ATP, adenosine triphosphate

process is mimicked by the application of sulfonylureas and their derivatives and is why they are used to treat type II diabetes mellitus. It is worth bearing in mind that they are prescribed less frequently due to issues with weight gain and as result drugs such as metformin are usually the

first-line therapy. Stimulus-secretion coupling in pancreatic β cells is shown in Fig. 2a.

Mutations in K_{ATP} channel subunits occur in rare hereditary diseases of insulin handling. Congenital hyperinsulinism is one such syndrome and refers to high and inappropriate secretion of insulin resulting in life-threatening hypoglycemia. The disease is rare and occurs in 1 in 50,000 births but is more common in areas where there are high levels of consanguinity. The commonest cause is missense mutations in ABCC8 and KCNJ11, and these lead to loss-of-function properties in the channel. The disease can be treated with K_{ATP} channel openers specifically diazoxide. Diabetes mellitus occurring in the neonatal population (up to 9 months) is rare occurring in 1 in 100,000 births but has a unique genetic basis. Mutations in ABCC8 and KCNJ11 are the commonest but not the only causes of neonatal diabetes mellitus. ABCC8 and KCNJ11 mutations are heterozygotic and generally occur de novo. In general, these result in quite subtle gain-of-function phenotypes with channels being less sensitive to ATP inhibition and thus inappropriately active at a given blood glucose concentration resulting in impaired insulin secretion. The patients used to be treated with insulin, but with these advances in understanding the pathogenesis of the disease, they are now given sulfonylureas often with dramatic responses.

The ability of K_{ATP} channels to act as metabolic sensors has led to studies in a number of related areas. Thus, K_{ATP} channels have been suggested to have a role in glucagon release from α cells in the islets of Langerhans and in secretion of various incretins from the enteroendocrine system in the gut. Furthermore, Kir6.2 and SUR1 are expressed in central neurons that are thought to influence feeding behavior and satiety. Thus there is active research in these areas with suggestive data, but there isn't a prevailing consensus yet.

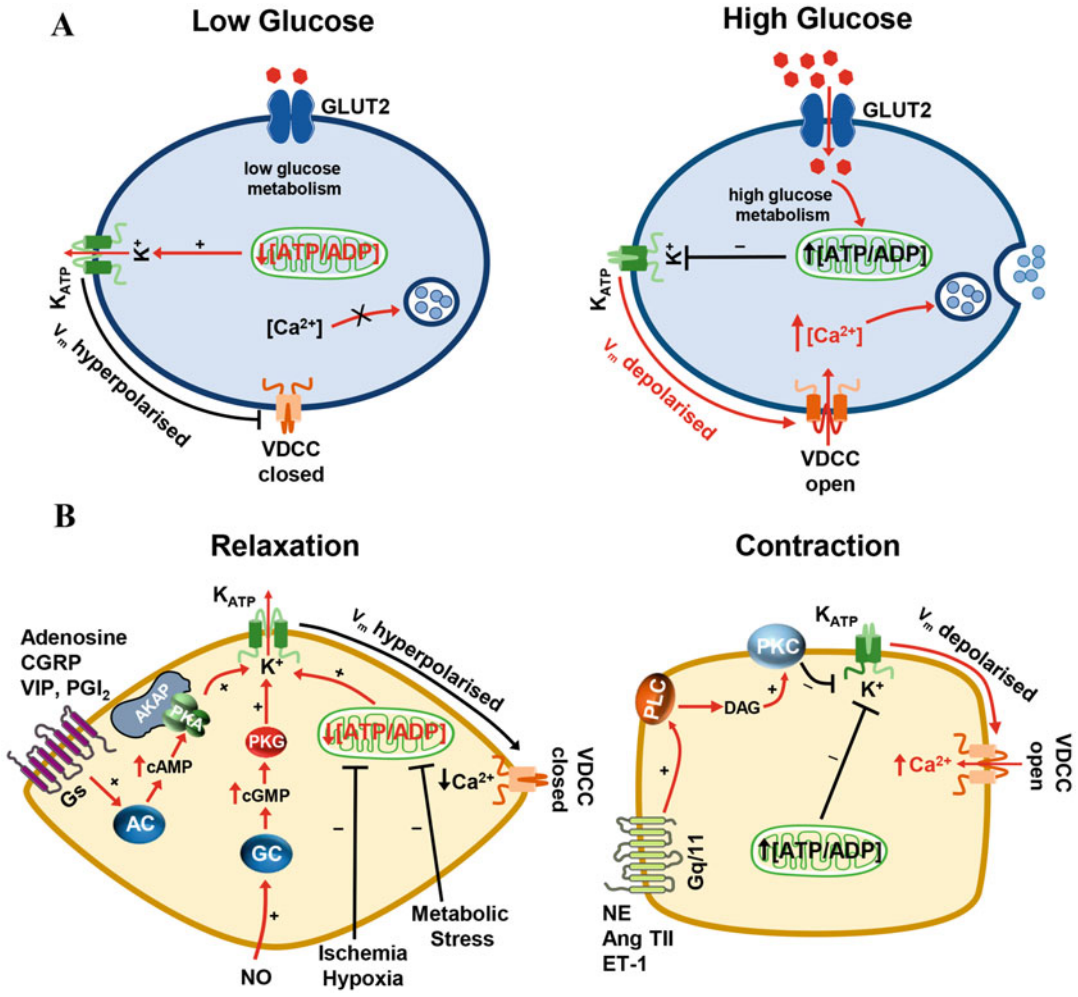
Cardiac Function

The expression of K_{ATP} currents in cardiac myocytes is robust and substantial though under resting metabolic conditions they are not active. Though the focus is usually on ventricular cells, these currents are present in atrial cells and cells of the conduction system. The most heavily investigated area is the role of K_{ATP} channels in cardiac protection which includes phenomena such as resistance to ischemic cell death, ischemia-reperfusion injury, and preconditioning, i.e., the ability to promote myocyte survival by prior application of short sublethal episodes of ischemia. The central idea is that opening of K_{ATP} channels shortens the cardiac action potential, reducing calcium entry through voltage-dependent calcium channels and reducing contractile work. This attenuates calcium overload, metabolic demands, and ultimately cell death. There is a substantial body of evidence supporting this which has been accrued in animals and humans based on pharmacological and more recently studies in genetically modified mice. There has been interest in exploiting this therapeutically, but to date no approach has been established in clinical practice.

The focus with cardiac K_{ATP} channels is usually on pathological scenarios in which channel opening may be protective. However this doesn't address the question of what physiological role the channel may play. For example, the channel contributes little to the cardiac action potential in the absence of metabolic challenge. The most convincing hypothesis, supported by work in genetically modified mice, is that the channel prevents myocardial damage under high workloads and accompanying adrenergic drive.

Control of Smooth Muscle Tone

The channel in smooth muscles has distinct properties as discussed above, and this is consistent with the channel being constituted of Kir6.1 and SUR2B. K_{ATP} currents are widely expressed in many vascular beds in both conduit and resistance vessels. Endothelial cells also express a K_{ATP} current; however this is much less studied. It may be that they perform complementary roles in regulation of vascular function. K_{ATP} channels are centrally involved in blood pressure control. If K_{ATP} channels open, then calcium entry through



ATP-Dependent K^+ Channels, Fig. 2 The role of K_{ATP} channels in pancreatic β cells and vascular smooth muscle. (**a**) K_{ATP} channels regulate insulin release by coupling cellular metabolism to electrical activity. ATP production is reduced when blood glucose is low, allowing K_{ATP} channels to open leading to membrane hyperpolarization thus preventing an increase intracellular Ca^{2+} and subsequent insulin release (left). Cellular metabolism increases when blood glucose is high, and ATP production increases leading to K_{ATP} channel inhibition and an increase in intracellular Ca^{2+} and insulin release (right). (**b**) Modulation of vascular smooth muscle K_{ATP} channels via vasodilators and vasoconstrictors regulates smooth muscle tone. The membrane potential of vascular smooth muscle (VSM) cells is determined by the opening/closing of K_{ATP} channels. Activation of K_{ATP} channels either directly or indirectly cause membrane hyperpolarization resulting in closure of voltage-dependent calcium channels (VDCC), reduced intracellular Ca^{2+}, and relaxation. Conversely, K_{ATP} channel inhibition causes depolarization of the membrane, opening of VDCC, increased intracellular Ca^{2+}, and contraction. Left, K_{ATP} channel activation initiated by vasodilators such as adenosine, calcitonin gene-related peptide (CGRP), vasoactive intestinal peptide (VIP), and PGI_2 via the G-protein (Gs)/adenylate cyclase (AC)/protein kinase A (PKA) signalling pathway leads to the relaxation of VSM. Hypoxia, ischemia, and metabolic stress inhibit oxidative phosphorylation and therefore decrease the ATP/ADP ratio leading to activation of K_{ATP} channels. Right, endogenous mediators such as norepinephrine (NE), angiotensin II (ang II), and endothelin-1 (ET-1) inhibit K_{ATP} channels via the G-protein (Gq/11)/PKC signalling pathway leading to VSM contraction

voltage-dependent calcium channels is reduced, and cytosolic calcium falls leading to vascular relaxation. Furthermore, a number of vasodilators including adenosine, calcitonin gene-related peptide, vasoactive intestinal polypeptide, and prostacyclin can activate the channel. This occurs through activation of the relevant G-protein-coupled receptor, activation of the stimulatory G-protein, and then engagement of the adenylate cyclase, cAMP, and the protein kinase A pathway. Protein kinase A directly phosphorylates residues on both Kir6.1 and SUR2B, and this leads to an increase in channel open probability. Vasoconstrictors such as angiotensin II, endothelin, and norepinephrine acting via $G_{q\backslash 11}$ coupled receptors and protein kinase C can inhibit the K_{ATP} channel. Evidence from genetically modified mice lacking the Kir6.1 subunit in vascular smooth muscle shows that the K_{ATP} channel is predominantly involved in vasorelaxation as the mice are hypertensive. Furthermore, administration of many potassium channel openers leads to significant falls in blood pressure. Vascular K_{ATP} channels are also involved in local vascular reactivity to increase blood flow to tissues and cells with high metabolic demand. This occurs through their direct metabolic sensitivity but also and probably more critically via adenosine-mediated signalling. The role of the channel in vascular smooth muscle is illustrated in Fig. 2b.

K_{ATP} channels are also present in nonvascular smooth muscles such as the gastrointestinal tract and bladder. In a similar vein, the application of potassium channel openers can lead to muscle relaxation. There has been interest, for example, in developing such drugs to treat bladder instability.

Other Roles

The areas described above are those where the role of K_{ATP} channels has been best defined, and there is largely a scientific consensus. However K_{ATP} currents are prominent in a range of other tissues, and we discuss those here with suggestions about their functional role. There are prominent K_{ATP} currents in skeletal muscle which have similar properties to those in cardiac muscle. Their exact physiological role is not clearly defined, but they have been proposed to be involved in preventing muscle fatigue with exercise. However they may also have a broader metabolic function by influencing glucose uptake and cellular metabolism. K_{ATP} channels are present in a number of neuronal populations including peripheral nerves. In addition to influencing feeding behavior, they have also been proposed to have roles in regulating neuronal excitability and cellular protection. Specifically, they have been suggested to be involved in pain, Parkinson's disease, and epilepsy.

There is rare disease called Cantu syndrome. This is a multisystem disease and has a number of features including increased hair growth, dysmorphic facial features, skeletal abnormalities, cardiac hypertrophy, and heart failure. Novel sporadic missense mutations have been found in ABCC9 and KCNJ8 and result in increased K_{ATP} channel activity. Despite its rarity this disease suggests a role for K_{ATP} channels during development.

Drugs

The relevant drugs are discussed in prior sections and also listed in the table; however it is worth briefly reviewing the current use in clinical practice. In some of the rare genetic syndromes, specific agents targeting the channels are being used in a precision-based fashion to target the underlying defect. More broadly, sulfonylureas and derivatives are used to treat type II diabetes mellitus though they are now a second-line agent. Nicorandil is used to treat angina but again only as a second-line agent as it causes gastrointestinal and skin ulcers, and diazoxide and minoxidil are still available to use in hypertensive emergencies. Minoxidil is associated with increased hair growth possibly by increasing blood flow to the hair follicle and is used in a topical preparation for male pattern baldness (395).

Atrial natriuretic factor/B-type natriuretic peptide

Definition

Atrial natriuretic peptide (ANP) and brain (also known as B-type) natriuretic peptide (BNP) are biologically active molecules that belong to the natriuretic peptide family, which also includes a third member, C-type natriuretic peptide (CNP). ANP was first isolated from human atrial tissue and its complete amino acid sequence was determined in 1984 (Kangawa and Matsuo 1984). BNP was first identified in porcine brain tissue in 1988. It is now known, however, that both ANP and BNP are secreted by the heart and act as cardiac hormones. In response to stretching of the myocardium, the two peptides are secreted from cardiomyocytes into the circulation. Both ANP and BNP preferentially bind to natriuretic peptide receptor-A (NPR-A or guanylyl cyclase-A) and exert similar effects through increases in intracellular cyclic guanosine monophosphate (cGMP) within target tissues. Through this action, they induce a decrease in vascular tone, an immediate increase in electrolyte and water excretion via the kidney and antifibrotic and antihypertrophic effects in the heart, all of which functionally antagonize the renin-angiotensin-aldosterone system (RAAS) (Nishikimi et al. 2006).

Basic Characteristics

Characteristics of ANP and BNP Genes and Peptides and Their Regulation of Gene Expression and Secretion

The *Nppa* gene encoding human ANP contains three exons and its transcript is translated into a 151-amino acid precursor, preproANP. A 25-amino acid signal peptide is then removed, yielding 126-amino acid proANP, which is the tissue form of the hormone. ProANP is stored in secretory granules in the atrium and is thought to be proteolytically converted to the 28-amino acid peptide ANP (α-ANP) and 98-amino acid N-terminal proANP (NT-proANP) by the transmembrane enzyme corin during its secretion (Nishikimi et al. 2011). The major molecular form of circulating human ANP is α-ANP, which contains a ring structure with a disulfide linkage (Nishikimi et al. 2011). β-ANP, which is an antiparallel dimer of α-ANP, and proANP (γ-ANP) have also been isolated from the human failing heart, and plasma levels of both β-ANP and proANP are increased in cases of severe heart failure, though the precise mechanism regulating the formation of β-ANP remains unclear.

The *Nppb* gene encoding human BNP also contains three exons. Within the endoplasmic reticulum in ventricular myocytes, BNP mRNA is initially translated into a 134-amino acid precursor, preproBNP, and then converted to 108-amino acid proBNP through removal of a 26-amino acid signal peptide (Nishikimi et al. 2006, 2011). The N-terminal region of proBNP is glycosylated within the Golgi apparatus and then cleaved, presumably by the proteolytic enzyme furin, yielding 32-amino acid BNP and 76-amino acid N-terminal proBNP (NT-proBNP), which are secreted from the heart in equimolar fashion. Not all proBNP is cleaved into BNP and NT-proBNP, and the remaining proBNP is also secreted into the circulation, though it is less active than BNP. Whereas the amino acid sequence of ANP is well conserved among species, the amino acid sequences of BNP are diverse. The predominant circulating form of BNP is composed of 26-, 45-, or 32-amino acids in pig, rat, and human, respectively (Nishikimi et al. 2011).

In normal conditions, most all of ANP in the circulation are secreted from the atrium, whereas most of BNP in the circulation are derived from the ventricle. Within the atrium, ANP is stored in granules and is immediately secreted in response to a secretory stimulus. Within the ventricle, by contrast, BNP secretion is controlled through gene expression via the so-called constitutive pathway. It therefore takes time for blood BNP levels to increase, even in response to a strong stimulus.

Expression and secretion of ANP and BNP are increased under pathological conditions in the heart. Mechanical stress, for example, stimulates the synthesis and secretion of both peptides in atrial and ventricular cells. Neurohumoral factors, such as endothelin-1, α-adrenergic agonists, and angiotensin-II, as well as various growth factors and cytokines, including interleukin (IL)-1β, IL-18, leukemia inhibitory factor (LIF), cardiotrophin (CT) -1, tumor necrosis factor (TNF) α, and transforming growth factor (TGF) -β, all stimulate ANP and/or BNP synthesis in cultured cardiomyocytes. ER stress also induces BNP gene expression in cardiomyocytes (reviewed in Nakagawa et al. 2019).

Characteristics of Action

The natriuretic peptide system also includes three membrane-bound natriuretic peptide receptors: NPR-A (or guanylyl cyclase-A), NPR-B (or guanylyl cyclase-B), and NPR-C (or clearance receptor). The three natriuretic peptides preferentially bind to NPR-A with a rank order potency of ANP $\geq$ BNP $>>$ CNP. NPR-A is linked to guanylyl cyclase, leading to production of the intracellular messenger cGMP in target cells. By contrast, the three peptides bind to NPR-B with a rank order potency of CNP $>$ ANP $\geq$ BNP. The three peptides also bind to NPR-C, or clearance receptor, which possesses no known intrinsic enzymatic activity, with a rank order potency of ANP=CNP>BNP.

The physiological actions of ANP and BNP at target cells and organs are similar and commonly mediated via NPR-A. Binding to NPR-C ultimately leads to internalization and lysosomal

degradation of the peptides and their clearance from the circulation. Another important mechanism by which natriuretic peptides are cleared is via membrane-bound metalloendopeptidase, also known as neprilysin, which is broadly distributed among tissues, including the lung and kidney, and acts on a variety of peptides (Volpe et al. 2016).

The effects of ANP/BNP include diuresis, natriuresis, vasodilation, and inhibition of aldosterone synthesis and renin secretion, which enable these hormones to play key roles in regulating blood pressure and fluid volume (reviewed in Nishikimi et al. 2006). After secretion from the heart, ANP/BNP immediately affect electrolyte and water excretion by the kidney and functionally antagonize the renal actions of the RAAS. ANP/BNP affect blood pressure acutely by acting on vascular smooth muscle cells and chronically by affecting vascular endothelial permeability. They also reportedly prevent vascular smooth muscle cell growth and proliferation and vascular fibrosis. In addition, ANP/BNP act on the heart itself to suppress cardiac hypertrophy and pathological cardiac remodeling at least in part by antagonizing signaling from the RAAS (Nishikimi et al. 2006). Like cardiomyocytes, cardiac fibroblasts also express NPR-A, NPR-B, and NPR-C; in fact, cardiac fibroblasts show larger increases in intracellular cGMP in response to NPR-A or NPR-B stimulation than do cardiomyocytes. Moreover, ANP/BNP-NPR-A signaling is an important regulator of the growth and proliferation in cardiac fibroblasts (Volpe et al. 2016).

Genetically modified animals have proven to be highly useful for studying ANP/BNP-NPR-A signaling. Marked cardiac hypertrophy with interstitial fibrosis is observed in NPR-A knockout mice (Oliver et al. 1997), and pressure overload in these mice leads to reduced left ventricular systolic function (Knowles et al. 2001). On the other hand, although ANP knockout mice exhibit salt-sensitive hypertension, there is no obvious cardiac hypertrophy under basal conditions (John et al. 1995). However, pressure overload leads to robust interstitial and perivascular fibrosis with cardiac hypertrophy and reduced fractional shortening in ANP knockout mice (Franco et al. 2004). BNP knockout mice exhibit multifocal fibrotic lesions within the cardiac ventricles with no signs of systemic hypertension or ventricular hypertrophy (Tamura et al. 2000). In response to ventricular pressure overload, the focal fibrotic lesions are worsened in BNP knockout mice than those in wild-type mice, despite similar increases in ventricular weights in the two groups (Tamura et al. 2000). These results indicate that ANP and BNP exert anti-fibrotic effects in vivo and serve as important local regulators of ventricular remodeling. The difference in the phenotypes of ANP and BNP knockout mice may highlight the predominant paracrine effects of BNP within the ventricles.

Drugs

ANP and BNP as Diagnostic Agents

Listed in guidelines published worldwide, BNP and NT-proBNP are diagnostic indicators for patients with heart failure (Yancy et al. 2017; Ponikowski et al. 2016; Tsutsui et al. 2019). Plasma BNP and NT-proBNP levels are established biomarkers that increase in proportion to disease severity and are used for diagnosis and estimation of prognosis, and for evaluating treatment efficacy in patients for heart failure (Yancy et al. 2017; Ponikowski et al. 2016; Tsutsui et al. 2019). Meta-analyses have shown that BNP- or NT-proBNP-guided therapy reduces all-cause mortality in patients with chronic heart failure, as compared to usual clinical care, especially in patients <75 years of age (Porapakkham et al. 2010). As mentioned above, proANP is enzymatically converted to ANP and NT-proANP. Because NT-proANP is further cleaved into smaller fragments in vivo, the mid-region of proANP (amino acids 53–90; MR-proANP) is the preferred detection site of this peptide, and it too is available for diagnosis of heart failure. However, there are also noncardiovascular conditions that can affect plasma levels of natriuretic peptides, including age, renal failure, and obesity, which may affect their diagnostic utility in heart failure (Yancy et al. 2017).

According to the ACC/AHA/HFSA guidelines in the USA, measurement of BNP or NT-proBNP is useful for diagnosis of heart failure and for establishing prognosis or disease severity in cases of chronic heart failure (recommended class I, level of evidence A). BNP- or NT-proBNP-guided heart failure therapy can be useful to achieve optimal dosing of guideline-directed medical therapy (recommended class IIa, level of evidence B) (Yancy et al. 2017). In the ESC European guidelines, measurement of plasma BNP, NT-proBNP, or MR-proANP is recommended for diagnosis in all patients with acute dyspnea or suspected acute heart failure as a means of differentiating acute heart failure from noncardiac causes of acute dyspnea (recommended class I, level of evidence A) (Ponikowski et al. 2016). In the JCS/JHFS guidelines in Japan, measurement of plasma BNP or NT-proBNP is recommended for diagnosis in acute heart failure and for evaluating the severity and prognosis of heart failure (recommended class I, level of evidence A), for screening (recommended class IIa, level of evidence C) and for evaluating the therapeutic effect of treatment (recommended class IIa, level of evidence B) (Tsutsui et al. 2019).

ANP/BNP System as a Therapeutic Target

Natriuretic peptides themselves or drugs that enhance their actions are being used for treatment of heart failure and other cardiovascular conditions.

Carperitide is a recombinantly produced intravenous formulation of human ANP, which is administered to patients with acute decompensated heart failure to improve their hemodynamic condition. Several studies have reported its beneficial effects in a variety of contexts. For example, continuous infusion of low-dose carperitide from the start of cardiopulmonary bypass effectively maintains postoperative renal function (Sezai et al. 2009). In addition, patients with acute myocardial infarction administered carperitide had smaller infarcts, fewer reperfusion injuries, and better outcomes than controls (Kitakaze et al. 2007). Finally, low-dose carperitide infusion for 72 h as the initial treatment improved the long-term prognosis of patients with acute decompensated heart failure (Hata et al. 2008). Carperitide is now available in Japan.

Nesiritide is an intravenous formulation of recombinant human BNP. The US Food and Drug Administration approved nesiritide for use in acute decompensated heart failure in 2001. Nesiritide reduces LV filling pressure, but has variable effects on cardiac output, urinary output, and sodium excretion. Several clinical trials have reported beneficial effects of nesiritide, which reduces the severity of dyspnea more rapidly than diuretics alone (Colucci et al. 2000). Nesiritide was associated with significantly lower in-hospital mortality than positive inotropic therapy (milrinone and dobutamine) in patients with acute decompensated heart failure listed in the ADHERE registry (Abraham et al. 2005). The NAPA trial showed that nesiritide improves postoperative renal function and may improve survival (Mentzer et al. 2007). However, the ASCEND-HF study, a large randomized trial in patients with acute decompensated heart failure, reported that nesiritide had no impact on mortality, rehospitalization, or renal function, and it increased the risk of hypotension, though it showed a small but statistically significant impact on dyspnea (O'Connor et al. 2011). Because nesiritide has a longer effective half-life than nitroglycerin or nitroprusside, two vasodilating agents, adverse effects such as hypotension may persist longer (Yancy et al. 2017). The effective half-life of nesiritide is also longer than that of carperitide. On February 5, 2018, the US Food and Drag Administration reported that pharmaceutical companies were discontinuing the manufacture of nesiritide.

Neprilysin, or neutral endopeptidase 24.11, degrades vasodilating peptides such as natriuretic peptides, adrenomedullin, and bradykinin as well as vasoconstrictors such as angiotensin II and endothelin-1, among others. Neprilysin cleaves ANP and CNP, breaking the ring and inactivating the peptides. In contrast to ANP or CNP, the primary cleavage site of human BNP is within

the N-terminal region, making BNP relatively resistant to degradation by neprilysin in humans (Bayes-Genis et al. 2016). By inhibiting neprilysin, degradation of natriuretic peptides is slowed. The resultant increases in ANP and BNP levels would be expected to enhance their physiologic effects by increasing binding to NPR-A and generation of cGMP, thereby enhancing their beneficial cardiovascular effects (Ponikowski et al. 2016). Moreover, because neprilysin is reportedly elevated in heart failure (Bayes-Genis et al. 2016), its inhibition may be an effective therapeutic strategy for heart failure and other cardiovascular conditions.

Candoxatril is a pure neprilysin inhibitor that was shown to elevate plasma ANP concentrations in patients with essential hypertension, though levels of angiotensin II and aldosterone were also significantly increased (Richards et al. 1993). Moreover, candoxatril failed to exert favorable clinical effects in patients with hypertension or heart failure (Bevan et al. 1992; Kentsch et al. 1996). These results suggest that although neprilysin inhibition suppresses the degradation of natriuretic peptides, it also suppresses degradation of angiotensin-II, resulting in RAAS activation. Thus, to produce the clinical benefits of neprilysin inhibition, it is necessary to also suppress the RAAS.

Omapatrilat is an inhibitor of both neprilysin and angiotensin converting enzyme (ACE), a so-called vasopeptidase. In the IMPRESS trial of 573 patients with NYHA class II to III heart failure, omapatrilat decreased the rate of a composite endpoint (death, hospitalization, or discontinuation of treatment for worsening heart failure) as compared with lisinopril, an ACE inhibitor (Bayes-Genis et al. 2016). However, in the OVERTURE trial of 5770 patients with NYHA II to IV heart failure and LVEF$\leq$30%, omaptrilat did not show superiority to enalapril with respect to a primary endpoint (death from any cause or admission for heart failure). In addition, angioedema was reported in 24 (0.8%) omapatrilat-treated patients by only 14 (0.5%) enalapril-treated patients (Bayes-Genis et al. 2016). And in the OCTAVE trial of 25,302 patients with hypertension, angioedema was reported in 2.2% of omapatrilat-treated patients but only 0.7% of enalapril-treated patients. The high rate of angioedema in patients with hypertension and the nonsuperiority of omaptrilat compared to an ACE inhibitor in patients with heart failure led to interruption of the clinical development of omapatrilat and cessation of further development of this class of drugs (Volpe et al. 2016). The increased incidence of angioedema is possibly due to the presence of excess bradykinin caused by dual inhibition of neprilysin and ACE, both of which degrade bradykinin.

Angiotensin receptor neprilysin inhibitors (ARNIs) have been developed as a therapeutic class of agents acting on the RAAS and neprilysin. The first in this class is LCZ696 (sacubitril/valsartan), which is a molecule that combines moieties of valsartan, an angiotensin II receptor type 1 blocker (ARB), and sacubitril, a neprilysin inhibitor, in a single substance. By inhibiting angiotensin II type 1 receptors with valsartan, ARNIs inhibit the action of angiotensin II without affecting bradykinin degradation. A randomized double-blind clinical trial showed that LCZ696 significantly reduced death from cardiovascular causes and hospitalization for heart failure as compared to enalapril, an ACE inhibitor, in patients with NYHA class II to IV heat failure and ejection fractions of 40% or less (PARADIGM-HF) (McMurray et al. 2014). Thus, according to the ESC guidelines, LCZ696 is recommended as a replacement for an ACE inhibitor to further reduce the risk of heart failure hospitalization and death in ambulatory patients with heart failure with reduced ejection fractions who remain symptomatic despite optimal treatment with an ACE inhibitor, a beta-blocker, and a mineralocorticoid receptor antagonist (Ponikowski et al. 2016). Similarly, the AHA/ACC guidelines recommend an ARNI as an alternative to ACE inhibitors or ARB to reduce morbidity and mortality in patients with chronic heart failure with reduced ejection fraction and as replacement of an ACE inhibitor or ARB in

patients with chronic symptomatic NYHA class II or III heart failure with reduced ejection fraction to further reduce morbidity or mortality (Yancy et al. 2017).

Synonyms

Second-generation antipsychotics

Definition

The introduction of atypical antipsychotics (AAPs), since the discovery of its prototypical drug clozapine in the 1970s, has been a milestone in psychopharmacology for treating schizophrenia, bipolar disorder, and other brain diseases that are characterized by psychotic features, as these drugs allow a significant recovery not only in terms of hospitalization and reduction in symptoms severity, but also in terms of safety, socialization, and better rehabilitation in the society. Compared to typical antipsychotics (TAPs), AAPs produce minimal motor side effects, such as parkinsonism and tardive dyskinesia, and seem to be more effective in improving cognitive symptoms (Meltzer 2013). Unfortunately, AAPs may cause weight gain and metabolic adverse reactions; hence, patients should be constantly monitored. Besides, each AAP has a unique pharmacological profile, which explains the clinical diversity between them.

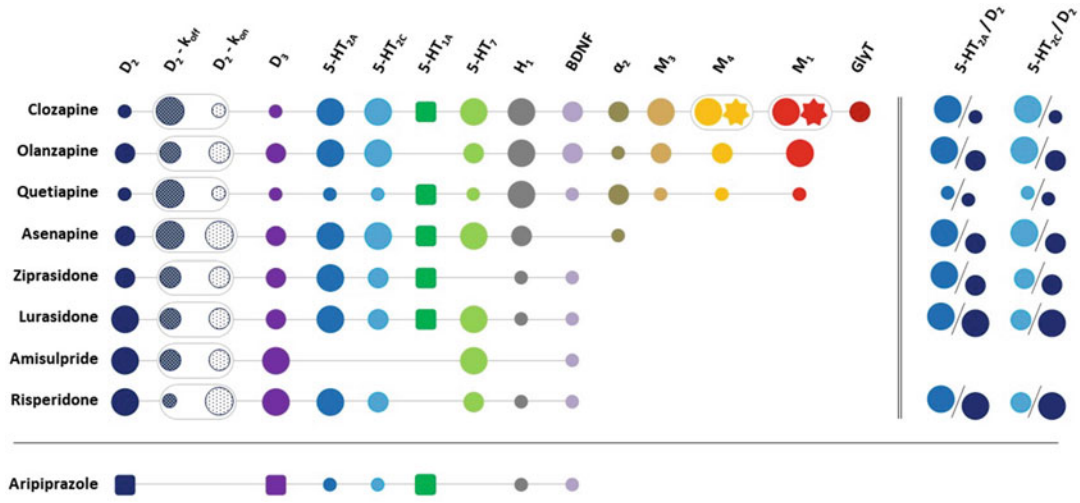
Mechanism of Action

AAPs are characterized by a wide array of receptor and molecular targets (Fig. 1).

Dopaminergic system and dopamine receptors. The dopaminergic hypothesis for schizophrenia is still the leading theory of the disease, and this is confirmed by the fact that the vast majority of APs are antagonists at D_2 dopamine receptors. However, if D_2 blockage is the only mechanism of action of TAPs, AAPs are weak D_2 antagonists, and they act beyond this target involving other receptors that can regulate the dopaminergic system. Regarding TAPs, it was shown that D_2 receptor occupancy between 65% and 80% seems optimal for clinical efficacy, while above 80% the occurrence of EPS increases. Conversely, D_2 occupancy is low for clozapine and quetiapine and never reaches the 80% threshold. In respect to clozapine, higher level of occupancy can be found for olanzapine and risperidone, particularly at higher doses, with the possible occurrence of EPS. New AAPs such as brexpiprazole and cariprazine act as D_2 receptor partial agonists, similar to aripiprazole.

In addition, AAPs have fast dissociation kinetics (K_{off}) from the D_2 receptor, and this is believed to contribute to their low propensity to EPS. Recently, it was also underlined the importance of the association constant (K_{on}) together with the K_{off} for determining EPS, while K_{off} seems predominant for inducing increase of prolactin secretion.

D_3 receptor is another important target of AAPs, and it is not easy to differentiate the effect of these drugs on D_2 versus D_3. Selective D_3 antagonists seem to enhance dopamine and acetylcholine secretion in the PFC, and this could



Atypical Antipsychotics, Fig. 1 Molecular targets of AAPs. List of the most relevant targets involved in the mechanism of action of AAPs based on receptor occupancy. Values are reported as high (●), medium (●), and low (●). ●, ■ and ✹ represent receptor antagonism, partial agonism, and positive allosterism, respectively. ◉ and ◉ represent K_{off} and K_{on} values for the D_2 receptor and ● represents BDNF production, while ✹ represents positive allosterism by the clozapine metabolite, norclozapine, at M_1 and M_4 receptors. Aripiprazole is shown at the bottom for its different mechanism of action. Finally, the 5-HT_{2A}/D_2 and 5-HT_{2C}/D_2 receptor affinity ratios are included on the right. Clozapine covers a wide range of molecular targets among all AAPs, while risperidone and amisulpride are mostly limited to just a few, and this might explain clozapine's superiority among AAPs

have a pro-cognitive effect (Aringhieri et al. 2018).

Regarding D_4 receptors, recently, Cardozo et al. (2017) employed an innovative in silico approach and demonstrated that the D_4 receptors in the pineal gland can be a unique target for clozapine.

Serotoninergic (5-HT) system and serotonin receptors. Serotonin, via its 15 receptors, is capable of having a profound impact on dopaminergic, glutamatergic, and GABAergic neurons and other neurotransmitters in the human brain. Besides the hypothesized 5-HT_{2A}/D_2 ratio-based mechanism of AAPs, other serotonin receptors have also been considered as potential targets of different AAPs. In fact, today it is clear that receptors such as 5-HT_{2C} and 5-HT_{1A} have an important role similar to that of 5-HT_{2A} in the mechanism of action of AAPs. In addition, other serotonin receptors such as 5-HT_6 and 5-HT_7 seem potential targets for old and new AAPs such as amisulpride and others. The general idea is that the dopamine efflux in the mesolimbic and mesocortical pathways is regulated by 5-HT_{2A} and 5-HT_{2C} receptors, mostly expressed in the glutamatergic and GABAergic cortical neurons. 5-HT_{2A} receptor antagonism seems relevant to reduce the dopamine release in the mesolimbic areas, while blockade of 5-HT_{2C} should increase dopamine efflux in the cortex. Besides improving negative symptoms of schizophrenia, 5-HT_{2C} antagonism might be responsible for some antidepressant activity, and this is shared with some atypical antidepressants like mirtazapine, trazodone and nefazodone.

In addition, clozapine, quetiapine, aripiprazole, and ziprasidone also act as 5-HT_{1A} partial agonists, and this in turn determines the increase in dopamine release in the PFC and hippocampus. Intriguingly, the modulation of the serotoninergic receptors alone is not sufficient to exert a full antipsychotic activity, while combined with other receptor targets (e.g., D_2 receptors), it finds its optimal therapeutic effect.

Glutamatergic system and glutamate receptors. The glutamatergic system has a prominent role in the pathogenesis of schizophrenia and other psychoses. In fact, in drug-resistant schizophrenic patients or in patients with very limited

response, abnormalities in the glutamatergic system may be particularly relevant and the use of NMDA antagonists in animals mimics some aspects of the human schizophrenic disease. Importantly, in non-responders, only clozapine seems to be effective, at least to a certain degree, while in few cases, olanzapine shows partial efficacy at higher doses. This evidence suggests that the superiority of clozapine is partially explained by its activity on the glutamatergic system. It is also true that the glutamatergic, dopaminergic, and serotoninergic systems are strongly interconnected, which further complicates the analysis of the mechanism of action of AAPs on the glutamatergic system. Noteworthy, the activity of serotonin 5-HT_{2A} and 5-HT_{1A} receptors seems to be relevant for controlling the glutamatergic system, and this may explain the superiority of AAPs over TAPs. In addition, effects on NMDA receptors and glycine transporters (GlyTs) that contribute to homeostasis in the glutamatergic system seem important for controlling glutamate hyperactivity, a feature which may be relevant particularly for clozapine's action. Interestingly, agonists at the glycine site or glycine transporter inhibitors, in monotherapy or in association with AAPs, have demonstrated some promising results in schizophrenic patients.

Cholinergic system and muscarinic receptors. Decreased M_1 receptor signaling has been linked to cognitive impairment associated with schizophrenia (CIAS), and, thus, enhancement of M_1 receptor signaling has been postulated to be a therapeutic target for CIAS. Clozapine was the first AAP reported to improve CIAS in schizophrenia. Notably, even though clozapine is an antagonist at M_1, M_3, and M_5 receptors, its principal metabolite norclozapine behaves as positive allosteric modulator of the M_1 receptor. Patients under clozapine treatment with high norclozapine/clozapine ratio showed higher improvement in memory tasks and reduced learning impairment. Notably, clozapine therapy usually lacks the traditional anticholinergic side effects like dry mouth, and it could instead promote sialorrhea.

A recent preclinical work suggests that the M_4 receptor also has an important role in cognitive function. Regarding AAPs, clozapine behaves as M_4 receptor antagonist in the rat striatum, while its metabolite norclozapine behaves as M_4 receptor agonist, an effect that can be relevant in the human neocortex. Olanzapine appears to be a weak partial agonist at the M_4 receptor, but in some experimental conditions, it behaves as an antagonist instead.

Histaminergic system and histamine receptors. Clozapine, olanzapine, quetiapine, and asenapine show high occupancy values for the H_1 receptors in human brain at minimum clinical doses. In fact, weight gain is one of the major side effects of these AAPs. Instead, risperidone and ziprasidone have low to medium affinity for this receptor, and this might explain the reduced weight gain in patients treated with them. H_1 receptor antagonism is also responsible for sedation, a side effect that may be helpful in acute psychoses, particularly in agitated patients. The H_3 receptor is mainly a presynaptic autoreceptor, and it acts as a presynaptic heteroreceptor on non-histaminergic neural systems (such as ACh, noradrenaline, dopamine, or glutamate). Some preclinical studies have highlighted the possible role of H_3 receptor antagonism in treating schizophrenia, particularly its role in cognition, which was confirmed in schizophrenic patients by a mild effect to improve cognition. Thus, AAPs acting on the H_3 auto- and heteroreceptor, such as clozapine, facilitate the release of histamine, noradrenaline, ACh, and serotonin, and these neurochemical changes might be responsible for increase in food intake and improved cognition.

Noradrenergic system and noradrenergic receptors. Many AAPs have an affinity for the noradrenergic α_1 and α_2 receptors as antagonists, and in spite of limited clinical evidence, a role for the noradrenergic system has been proposed in schizophrenia. The antagonism of many AAPs and in particular clozapine on α_1 receptor might contribute to the control of positive symptoms and modulate the correct firing of mesolimbic dopaminergic neurons. The concomitant block of α_1 and D_2 receptor may synergistically contribute to clinical efficacy. Clozapine and norquetiapine also act as α_2 receptor antagonists, and this can be important for their antidepressive characteristics. α_2 receptors modulate the firing of

noradrenergic and dopaminergic neurons, and a strong α_2 antagonism with a moderate D_2 antagonism could contribute to a good receptor profile for an ideal antipsychotic.

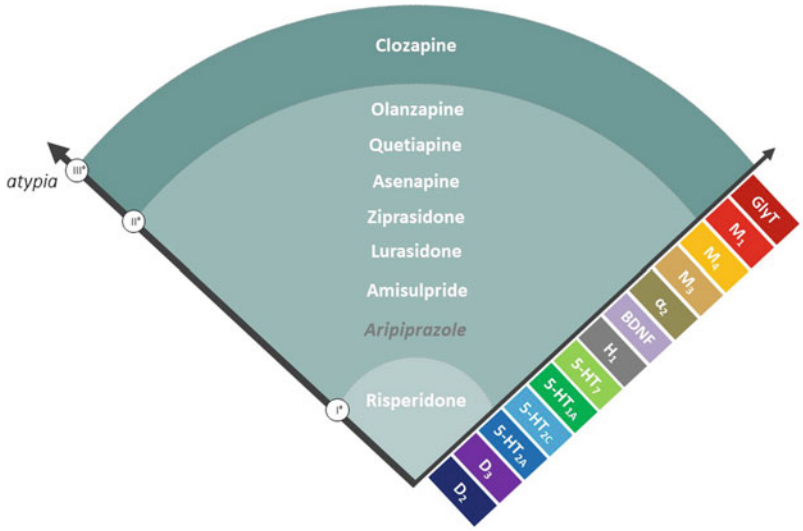
Neurotrophic factors, synaptogenesis, and neurogenesis. AAPs can increase neurotrophic factors production in many areas with relevant consequences in the long-term treatment of schizophrenia. Different studies reported an increase in BDNF, NGF, and FGF2 levels in preclinical models following the treatment with different AAPs, particularly with clozapine, olanzapine, risperidone, and lurasidone. However, olanzapine and risperidone lose this property at higher doses. As a consequence, AAPs seem to induce neurogenesis, synaptogenesis, and neuroplasticity, a peculiar characteristic that distinguish them from TAPs.

Biased agonism. The capacity of a ligand to preferentially activate either G protein-dependent signaling or G protein-independent signaling (e.g., β-arrestin pathway) is called "biased agonism" or "functional selectivity." This innovative new concept reflects the heterogeneity and complexity of the different receptor conformations in the active state depending from the stimulant (Kenakin 2013). In addition, recent data have demonstrated how receptor functional selectivity is a dynamic and adaptable process, which can also be modified by physiopathological conditions. Apparently, downstream D_2 receptor signaling, AAPs antagonize strongly β-arrestin pathway, while TAPs are strong antagonists on both G_i and β-arrestin pathways. This difference could be important even if the clinical implications are still unknown. In addition, some β-arrestin biased agonists derived from aripiprazole have been synthetized, and they have shown antipsychotic activity in vivo with fewer adverse events. Recently, it has been found that clozapine, which is classically considered an antagonist on 5-HT_{2A} receptor, can activate this receptor and promote ERK and Akt kinases phosphorylation via a G protein-independent pathway (Aringhieri et al. 2017). Olanzapine and quetiapine showed a similar effect but with less intensity.

Receptor dimers. There is a large amount of evidence that shows how GPCRs, apart from being monomers, form homo- and heterodimers. The action of AAPs on several receptor dimeric complexes has been demonstrated especially in vitro; however the confirmation in vivo in animal models or humans is still lacking. Among the many receptor dimers analyzed, the most convincing evidence refers to 5-HT_{2A}/$mGlu_2R$ heteromer in the somatosensory cortex in mice (Fribourg et al. 2011). In normal conditions, this receptor complex enhances 5-HT_{2A} activity toward G_i, while in animal models of schizophrenia, this complex switches mostly toward a G_q activity. In these pathological conditions, clozapine can restore the physiologic equilibrium in favor of G_i coupling. Importantly, in schizophrenic patients, it has been found a downregulation of $mGlu_2R$ and 5-HT_{2A} upregulation that may lead to an increase of a G_q signaling.

Clinical Use

AAPs are generally used in several mental disorders such as schizophrenia, bipolar disorder, obsessive-compulsive disorder, dementia with agitated patients, and autism spectrum disorder. Schizophrenic patients should be treated with AAPs in the acute phase and in the long-term maintenance. Bipolar mania as well benefits from the use of these drugs together with mood stabilizers. With the discovery of AAPs, great expectations raised on their claimed superiority in treating positive, negative, and mood symptoms of schizophrenia compared to TAPs. Several reviews on this topic and few meta-analysis have systematically compared TAPs and AAPs, and they have found data supporting AAPs superiority for certain aspects, where clozapine, olanzapine, risperidone, and amisulpride have resulted better than TAPs in terms of efficacy, quality of life, tolerability, dropout, and side effects (Huhn et al. 2019). However, the clinical differences are less evident when TAPs are used at lower doses, particularly in comparison with risperidone. For these reasons, it has been proposed a continuum spectrum of atypia that ranges from risperidone, the least atypical, to clozapine, the most atypical, while all other



Atypical Antipsychotics, Fig. 2 Continuum spectrum of atypia: the three levels of atypicality. Classification of AAPs in three categories, where risperidone is least atypical (Level I) and clozapine is most atypical (Level III), while all others fall within these two extremes of the spectrum (Level II). The molecular targets shown on the right add up, beginning with the D_2 and 5-HT_{2A} receptors that are common targets for all AAPs, extending to additional mechanisms such as M_1 positive allosterism and GlyT activity that seem specific to clozapine. Further targets, such as H_1 and α_2 receptors and BDNF, are relevant to both Level II and III of atypia. The clinical characteristics of each AAP are well explained according to their molecular profile on different targets

AAPs fall within these extremes of the spectrum (Fig. 2).

In the first episode of psychosis, generally AAPs and TAPs have similar efficacy. However, as it has been demonstrated in several clinical studies, in terms of relapse and treatment discontinuation, AAPs seem more successful since they show a better tolerability profile.

On negative symptoms (apathy, anhedonia, asociality) of schizophrenia, AAPs perform better than TAPs for two main reasons in relation to their different mechanism of action: (1) TAPs strongly antagonize D_2 receptors in the prefrontal cortex (PFC), and this may worsen these symptoms; (2) AAPs improve dopamine, serotonin, and acetylcholine transmission in the PFC with positive clinical consequences. On this aspect, differences within the AAP family are small, with clozapine being the most effective. In addition, the reduction of negative symptoms may be influenced in part by elimination of positive symptoms, making the comparison among APs not so obvious.

On cognitive symptoms, AAPs may obtain a mild improvement apparently in specific domains. Clozapine seems to improve verbal fluency, while olanzapine and quetiapine show some effect on attention and processing speed. The cholinomimetic properties of the clozapine metabolite norclozapine on M_1 receptor may contribute to its cognitive activities.

Apart from clinical differences, AAPs have a more favorable profile compared to TAPs in terms of severe adverse reactions (Table 1). In fact, regarding motor side effects, AAPs have a strong reduction of extrapyramidal symptoms (EPS). On this topic, within the AAP family, there are differences where clozapine practically never shows parkinsonism, while risperidone sometimes can have this side effect, especially at higher dose. As clozapine, quetiapine also never induces EPS, and for olanzapine this adverse event is rare. A second motor adverse reaction that concerns psychiatrists in the long-term use of APs is the occurrence of tardive dyskinesia (TD). The prevalence of TD in patients treated with APs is about 20% after 1 year, with a cumulative increase of 5% per year during drug exposure. The introduction of AAPs has determined a strong

reduction of TD; however, TD can still be caused by AAPs, and this possibility should not be underestimated. The incidence of TD is about two to ten times lower for AAPs compared to TAPs, and for this reason, the second class should be preferred for long-term treatment. Among the AAPs, clozapine has the least propensity to induce TD and may have beneficial effects on patients who develop this long-term motor adverse reaction. In fact, clozapine should be considered for patients who develop TD caused by the other APs (Table 2).

Despite a better profile in terms of motor side effects, AAPs cause weight gain and other metabolic adverse reactions (Table 1). Olanzapine and clozapine treatments are associated with the greatest risk of weight gain, whereas quetiapine, risperidone, and amisulpride show low-to-moderate levels of this undesired effect. Interestingly, the new molecules such as ziprasidone, lurasidone, and asenapine seem more tolerable on the metabolic profile. However, this advantage in terms of adverse effects has to be combined with their therapeutic efficacy, as these new drugs need more data to show similar efficacy compared to the other AAPs. The mechanisms of action related to weight gain are complex, and many receptors may be involved such as H_1, 5-HT_{2C}, and D_2 receptors, either expressed in the hypothalamus or in the peripheral tissues. Nutritional intervention and psychoeducational programs are a good tool to minimize this tedious side effect caused by AAPs. In addition, clozapine, and especially olanzapine, are associated with hyperglycemia and dyslipidemia; hence patients receiving these treatments should be cautiously monitored.

Atypical Antipsychotics, Table 1 Principal side effects among AAPs. Most relevant side effects recurring in patients undergoing AAPs therapy. Values are reported as high (+++), medium (++), low (+), and very rare (+/−)

Drug	EPS	Hyperprolactinemia	Weight gain	Risk of diabetes	Hyperlipidemia	Sedation	QTc prolongation
Clozapine	+/−	+/−	+++	+++	+++	+++	+
Olanzapine	+/−	+	+++	+++	+++	+++	+
Quetiapine	+/−	+/−	++	++	++	+++	+
Asenapine	+	+	+	+	+	++	++
Ziprasidone	+	+	+	+	+	++	++
Lurasidone	+	+	+	+	+	+	+/−
Amisulpride	+	++	+	+	+	+	++
Risperidone	++	+++	++	+	+	+	+
Aripiprazole	+	+	+	+	+	+	+/−

Atypical Antipsychotics, Table 2 Clozapine, the gold standard AAP: pros and cons

Pros	Cons
Efficacy in treatment-refractory schizophrenia	Agranulocytosis (0.7–1%)
Efficacy on negative and cognitive symptoms (improved verbal fluency)	Weight gain
Efficacy in psychoses associated with PD	Hyperglycemia, increase in triglycerides
Efficacy in patients who develop TD	Sialorrhea
Only FDA-approved AAP to lower suicide risk and to exert some antidepressant properties	Risk of epileptic seizure
Diminished aggressive behaviors	Risk of myocarditis
No EPS	Sedation
No TD	
No increase in serum prolactin	

These adverse reactions arise partly as a consequence of weight gain but also for AAP activity on different molecular targets present in different organs, such as pancreas, liver, and adipose tissue. Another possible adverse effect of AAPs, in particular for sertindole, is the alteration of the electrocardiogram, like QTc prolongation, requiring patients monitoring before and after AP introduction (Table 1).

Besides the overall effectiveness of APs in schizophrenia, about 30% of patients are pharmacoresistant, defined as an insufficient clinical response with at least two or more drugs. In this subset of individuals, clozapine is superior to all the other drugs and is considered the gold standard for treatment-refractory schizophrenia (Table 2). Clozapine superiority compared to the others is also evident for patients with violent behavior and with high suicide risk.

The benefits of clozapine are unfortunately outweighed by the risk of agranulocytosis, which is rare (0.7%), but potentially life-threatening, and patients should be monitored on white blood cell counts weekly for the first 6 months. For this reason, usually clozapine is not the first choice among AAPs, even if many authors have underlined how this drug is underused considering its clinical superiority in different medical conditions.

Macroautophagy

Definition

Cells are continuously recycling constituent materials. For this, they have available two degradative systems, the proteasome and the lysosome (Liebl and Hoppe 2016). Degradation through the ubiquitin-proteasome system (UPS) is mainly used for small and short-lived proteins, whose degradation in the 26S proteasome is highly selective. It is macroautophagy which is the high capacity degradative pathway, enabling a massive

catabolic switch in cell metabolism upon demand. Especially larger proteins and protein aggregates, as well as bulk "gulps" of cytoplasm, invading microorganisms and even whole cellular organelles such as dysfunctional mitochondria, go to the lysosome via macroautophagy after the formation of a double-membrane vesicle around the target or "cargo" (Yu et al. 2018). Autophagy can initiate large-scale degradation and can produce metabolic intermediates on a large scale (Mizushima and Komatsu 2011).

Common to both proteasomal and macroautophagic degradation is the process of ubiquitination which puts a tag on cargo, labeling it for disposal (Liebl and Hoppe 2016). The choice of appropriate cargos, small or large, random or selected, and their transport to lysosomes where they can be degraded, represents the domain of autophagy.

The broader term, autophagy (from the ancient Greek for "self-eating"), refers to three forms of vesicular transport ending with the incorporation of contents into the lysosome (Mizushima and Komatsu 2011): microautophagy, chaperone-mediated autophagy, and macroautophagy. With microautophagy, late endosomes invaginate and engulf small elements of the cytoplasm and then, by fusing their membranes, complete the enclosure; these vesicles then transport their contents to the lysosome. With chaperone-mediated autophagy, as is apparent from the name, cytoplasmic elements are selected by specific chaperones having affinity for their targets, which then are taken up into the lysosome for degradation (Mizushima and Komatsu 2011).

Macroautophagy, the main subject of this article, is the best investigated form of autophagy and, for simplicity, will be referred to hereafter just as autophagy. This major catabolic pathway exists in practically all cells, having been conserved in evolution back to the yeasts. Autophagy has essential roles in maintaining cell survival, in meeting nutritional needs, and responding to stresses, in selective degradation of particular macromolecules, but also for selective degradation of whole organelles and invading parasites. Peculiar to macroautophagy is the concentration of cargo on an isolation membrane which forms at modified regions of endoplasmic reticulum (ER). As indicated above, these cargos can be large. They can also be complex, containing proteins, lipids, and nucleic acids. Cargos can be very specifically selected, or they can be just neighboring cytosolic elements. The isolation membrane grows and closes around the cargos, forming the extended double-membrane autophagosome which then fuses with lysosomes, taking advantage of special proteins, called SNARES [soluble *N*-ethylmaleimide-sensitive factor attachment receptors (Yu et al. 2018)]. These bring the membranes into close proximity, thus promoting fusion events. In this way, a mature, actively degradative autolysosome is formed (Mizushima and Komatsu 2011; Yu et al. 2018).

Basic Characteristics

All forms of autophagy are essentially pathways leading to the lysosome. The lysosome must be seen not just a degradative organelle with numerous potential hydrolytic enzymes, but as a platform for the regulation of the metabolism required for cell survival, including the regulation of autophagy (Inpanathan and Botelho 2019). This means overseeing nutrient availability and supplying large amounts of amino acids which can be used as an energy source as well as for new protein synthesis. These same degradative processes allow for safe disposal of toxic cell materials such as misfolded proteins, for malfunctioning whole organelles, and for defense against microbial invasion. The garbage disposal role is essential; thus, basal autophagy at a low level is continuous in almost all cells (Mizushima and Komatsu 2011). Upregulation of autophagy in response to stresses leads to induction of genes required for increased autophagic and lysosomal activity. This induction is controlled by complex, multiple interacting networks acting mainly on two enzyme complexes, the mammalian target of rapamycin complex 1 (mTORC1) and the AMP-activated protein kinase (AMPK), both of which are located on the lysosome and are central for control of cell growth and proliferation (Inpanathan and Botelho 2019).

Autophagy Is Important

The Belgian scientist Christian de Duve was awarded the Nobel Prize in 1974, for the discovery of lysosomes and implicitly, the process of autophagy. An understanding of the molecular events in autophagy began to emerge through work of Ohsumi and colleagues, which led to his receiving the Nobel Prize finally in 2016. Working with yeast mutant screens, Ohsumi's laboratory was able to define numerous autophagy-related (*ATG*) genes encoding the so-called autophagy-related (ATG) proteins for which functions were gradually defined (Yang and Klionsky 2010). A pathway for the interactions of the different ATG proteins contributing to autophagy was worked out taking advantage of the unique opportunities provided by the yeast system. Mizushima, working in Ohsumi's laboratory, then proceeded to identify the mammalian autophagy genes encoding ATG5 and ATG12 and was able to demonstrate their conjugation to a complex (Yang and Klionsky 2010). This work was subsequently extended in a worldwide effort which now defines a collection of *Atg* genes numbering more than 35.

Serious diseases are associated with dysfunctional autophagy (Mizushima and Komatsu 2011). Mutations in autophagy-related genes are either causal or represent risk factors for development of numerous diseases. Prominent are the neurodegenerative diseases, for example, Parkinson's disease (van Beek et al. 2018), cancer (Byun et al. 2017), and diseases of innate immunity, leading to inadequate responses to infection (van Beek et al. 2018; Germic et al. 2019a), but also to autoimmune diseases such as Crohn's disease (van Beek et al. 2018). Natural processes such as ageing also exhibit a correlation with declining autophagic activity (Mizushima and Komatsu 2011). Thus, pharmacological targeting of autophagy may eventually lead to important therapeutic innovations.

Outline for a Canonical Autophagic Pathway

The stepwise events in the process of autophagy have been illustrated in excellent review articles (Yang and Klionsky 2010; Mizushima and Komatsu 2011; Simon et al. 2017; Yu et al. 2018). Thus, the pathway will be described here only briefly.

The most important, immediately proximal regulators of autophagy are two cellular regulatory enzyme complexes acting in opposition. These are mTORC1, a central regulator of cell growth, and AMPK, a kinase activated by declining energy charge, i.e., increasing AMP levels. Both AMPK and mTORC1 are serine/threonine protein kinases, and both are localized on the lysosome. The mTORC1 is bound to Ragulator in a complex with the Rag proteins, small GTPases serving jointly as sensors for amino acid levels, not just in the cytoplasm but also across the membrane in the lysosome. The mTORC1 is displaced from the lysosome and inactivated when stress conditions such as amino acid or glucose starvation, or hypoxia, mandate a shift to catabolism (Inpanathan and Botelho 2019). Under these conditions, AMPK may also be activated, phosphorylating ULK1 or ULK2 directly and initiating autophagy. Most of the more distal inducers of autophagy also act indirectly via mTORC1 or AMPK.

The initiation of autophagy represents a collaboration between two kinase complexes, the first a protein kinase and the second a class 3 phosphatidylinositol 3-kinase (PI3K). The protein kinase complex that initiates autophagy is made up of ULK1 or ULK2, ATG13, FIP200, and ATG101 (Galluzzi et al. 2017). Both the ULK proteins and ATG13, like mTORC1, are localized on the lysosomal surface, and both are maintained inactive owing to mTORC1-dependent phosphorylation (Inpanathan and Botelho 2019). As indicated above, declining proportions of ATP to AMP lead to an AMPK activation with subsequent ULK1 or ULK2 phosphorylation, overriding mTORC1 inhibition. Similarly, following any stress which leads to mTORC1 displacement and inactivation, the ULK protein kinase can activate by autophosphorylation, then phosphorylating ATG13, after which both translocate, and together with FIP200 and ATG101 assemble an autophagy initiating complex at special sites on the ER (Galluzzi et al. 2017; Yu et al. 2018). These sites are believed to be enriched for ATG9, the only ATG which is a membrane protein and is subject to

phosphorylation by the activated ULK protein. These will make up the phagophore, which is then elongated following continuing ATG9 and membrane enrichment, believed to be brought in by fusion with endosomes originating in the Golgi (Yu et al. 2018).

At this point, the second multiprotein kinase, the components of the class 3 phosphatidylinositol 3-kinase (PI3K) complex are recruited to the phagophore. This complex is composed of vps34 (the catalytic subunit), vps15 (the regulatory subunit), Beclin-1 (BECN1), ATG14, and the nuclear receptor-binding factor 2 (NRBF2). ULK kinases phosphorylate both BECN1 and ATG14, activating the local production of phosphatidylinositol 3-phosphate [PI3-P (Galluzzi et al. 2017; Simon et al. 2017)]. Important is the availability of BECN1, which exists in the cell in complexes, largely with BCL-2, an inhibitor of apoptosis. For PI3K function, BECN1 must be released from these complexes. This can be accomplished by phosphorylation with, among other kinases, the activated ULK kinase, thus freeing both partners to act, respectively, stimulating autophagy and potentially inhibiting apoptosis (Simon et al. 2017).

Further phagophore development requires recruitment of several additional ATG proteins which constitute two ubiquitin-like conjugation systems: the first producing complexes of ATG5-ATG12-ATG16L1 which localize at the phagophore; the other conjugation takes place with ATG8, which after its proteolytic processing by ATG4, is then conjugated to phosphatidylethanolamine (PE). There exist at least six mammalian orthologues of yeast ATG8, which owing their conjugation to PE, can localize at the phagophore membrane. Prominent among these is microtubule-associated protein 1 light chain 3 beta (LC3B), that after its lipidation is designated LC3-II in consequence of its altered electrophoretic mobility (Mizushima and Komatsu 2011; Galluzzi et al. 2017).

Initially, the phagophore represents two extended, neighboring protrusions of the ER, cargo must now be recognized and concentrated within the arms of these protrusions as they extend and enlarge.

As with a 26S proteasome, cargo recognition for autophagy depends on the presence of ubiquitin chains tagged onto targets. Ubiquitin, a 76-residue, highly conserved protein, can be conjugated to proteins using one of its seven lysines or N-terminal methionine (Liebl and Hoppe 2016). A large selection of more than 600 different E3 ubiquitin ligases provides a very high versatility as well as specificity in this ubiquitin conjugation process. Interestingly, almost all proteins, protein aggregates or organelles must be conjugated to ubiquitin at its Lys63 in order to undergo autophagy, whereas "for proteasomal degradation, all non-Lys63 ubiquitin linkages were found to facilitate proteasomal degradation in vivo" (Liebl and Hoppe 2016).

How are targets which have been conjugated with Lys63-polyubiquitin chains recognized? The prototype autophagy receptor or adaptor is the multifunctional sequestosome 1 protein (SQSTM1), more commonly designated simply p62. P62 binds to Lys63-polyubiquitin chains with its ubiquitin-binding (UBA) domain, and, by virtue of an LC3 interacting region (LIR domain), is able to bind lipidated LC3 on the membrane of the phagophore. In this way, the localization of cargos is achieved prior to membrane closure and the formation of the autophagosome. Just as there exist several LC3 orthologues [e.g., LC3 or γ-amino butyric acid receptor-associated proteins (GABARAP), etc.], there exist also several functionally analogous proteins which like p62 can serve to bridge Lys63-polyubiquitinated cargos to LC3 at the phagophore membrane [(examples, p62, NDP52, or optineurin) (Galluzzi et al. 2017)].

The choice of targets for autophagy is accomplished in a process of selective ubiquitination which is possible owing to the versatility of the huge number of selective E3 ubiquitin ligases. Appropriate levels of certain individual cellular regulatory proteins such as transcription factors and enzymes are maintained with the help of autophagy (Jiao et al. 2018; Flynn et al. 2019; Sánchez-Martin and Komatsu 2019). Recognition of and selective autophagic degradation of larger structures such as organelles [e.g., *mitophagy* (removal of mitochondria) or *pexophagy*

(targeting peroxisomes)], or *aggrephagy (*aimed at degradation of protein aggregates) or *lipophagy* (needed for lipid homeostasis)] are described in a comprehensive review (Galluzzi et al. 2017). The various processes are generally analogous to the canonical pathway described above, with additional highly specialized features associated with the recognition of dysfunctional organelles or threats like intracellular parasites.

Networks Regulating Autophagy

There are networks regulating autophagy activation in response to low ATP or amino acid levels, loss of growth factor receptor activation, hypoxia, oxidative stress, or DNA damage. These, through various intermediate signaling steps as indicated in Fig. 1, activate autophagy mainly through AMPK or mTORC1 (Inpanathan and Botelho 2019). Figure 1 illustrates these networks in a simplified form as well as others responding to DNA damage and furthermore indicates some of the overlaps. It is important to realize that the same regulatory enzymes can be activated by signals coming from many directions, many contradictory when they finally come to mTORC1 or AMPK.

Significantly increased demands on autophagy and lysosomal degradation also require increased gene expression in the nucleus to produce the proteins needed in autophagosome formation and lysosomal expansion. Thus, as shown in Fig. 1, several transcription factors may be activated; examples are tumor suppressor p53, involved in responding to DNA damage, or TFEB (transcription factor EB) regulating expression of many lysosomal proteins, or transcription factor Nrf2 (nuclear factor erythroid 2-related factor 2) which is important for the response to oxidative stress (Sánchez-Martin and Komatsu 2019). Another interesting example is transcription factor p73 which regulates the transcription of ATG5 at times when the whole organism is subjected to starvation. Livers of animals deficient in p73, but starved, show huge numbers of accumulated cytoplasmic lipid droplets, presumably owing to the blocked triglyceride hydrolysis into the fatty acids which would be needed to mobilize energy (He et al. 2013).

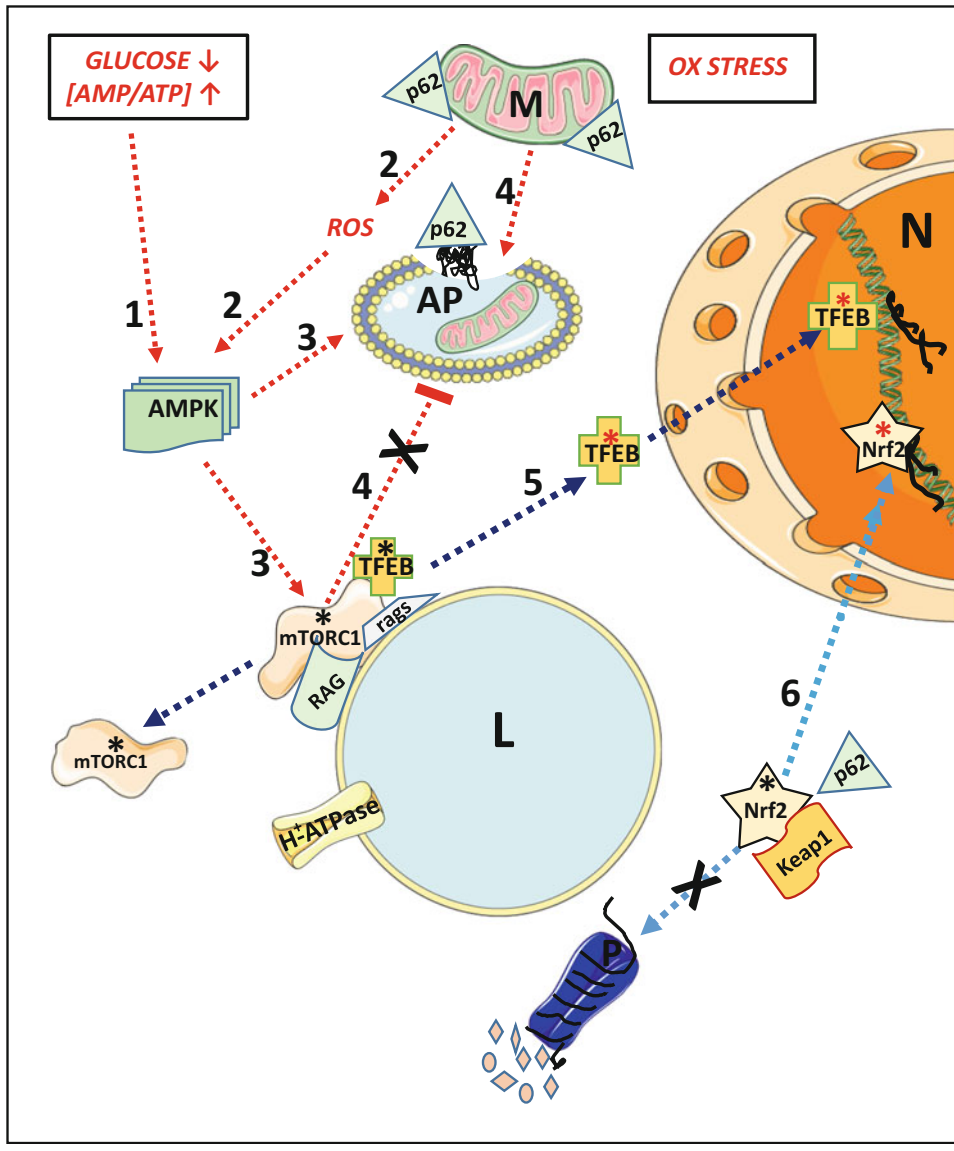
Drugs

Autophagy Activators Versus Inhibitors: Which and When, a Quandary

The regulation of autophagy is complicated, as can be seen from the examples presented in Fig. 1. While a pharmacological intervention with autophagy is clearly possible, our present knowledge is insufficient to predict all the potential side effects. Even so, empirical trials with different drugs are in progress. What are the predictable risks?

***Neurodegenerative diseases and ageing*:** These conditions seem to have in common an inadequate autophagy leading to the accumulation of misfolded proteins, protein aggregates, and damaged mitochondria. Apparently, these also slow the flow along the narrow axons of neurons. The accumulation of protein aggregates is toxic and dysfunctional mitochondria produce insupportable levels of reactive oxygen species (ROS); in consequence neurons die. Thus, one hopes that an additional activation of autophagy might be able to alleviate the progression of diseases like Parkinson or Alzheimer, or even, in principle, ageing. Experimental efforts to increase autophagic activity seem appropriate and in fact trials have been performed with impressive initial results (Byun et al. 2017; Moors et al. 2017; Thellung et al. 2019). Some of the relevant drugs and their targets are summarized in Tables 1 and 2 below. Because of the central roles which most of the targets play in the regulatory processes of the cell and because the drugs are still at an early stage of development, lacking the desired specificity, drugs (Tables 1 and 2) need to be evaluated empirically, under the closest clinical scrutiny. The greatest risk with all of these drugs is obviously the impact of such drugs on different organ systems.

***Cancer*:** Dysfunctional autophagy favors genomic instability, allowing the accumulation of p62 together with toxic protein aggregates and damaged mitochondria producing high ROS levels. Thus, a deficient autophagic response contributes to an accumulation of mutations, some of which are likely to be oncogenic. A widely held opinion is that a capability for an effective



Autophagy, Fig. 1 Pathways leading to the activation of autophagy are illustrated as simplified activation networks numbered from one to six. On the left side metabolic stresses like starvation, i.e., low glucose and a rising AMP/ATP quotient, are indicated. On the right are depicted the consequences of oxidative stress (OX) arising from excessive levels of reactive oxygen species (*ROS*) produced by a damaged mitochondrion (M). Both stresses lead to an activation of autophagy. A developing autophagosome (AP) is shown at midline, containing a dysfunctional mitochondrion and in the process of taking up protein aggregates (black squiggles) together with the SQSTM1 (p62) ubiquitin adaptor. P62 is shown acting as an adaptor at several points in this illustration. The numbered arrows indicate the several different networks activating autophagy. (**1** and **2**) show responses to starvation and oxidative stresses, both typically via activation of AMPK. The kinase activity of AMPK phosphorylates mTORC1, causing its inactivation and displacement from its binding to Ragulator on the lysosome (L), but in (**3**) AMPK also directly phosphorylates sites on ULK1 and 2, thereby initiating the first steps in the formation of an autophagosome. The black asterisk on mTORC1 designates an inactive kinase, ending its role in many anabolic functions together with its inhibitory role (**4**) on ULK1 and 2. The transcription factor TFEB, which is maintained inactive by phosphorylation via mTORC1, then translocates to the nucleus (**5**) and initiates transcription of several ATG genes and genes encoding lysosomal proteins. The activation of another transcription factor

autophagic response plays an early protective role, preventing tumor initiation (Byun et al. 2017; Moors et al. 2017). Moreover, in tumor progression, tumor cells showing deficient autophagy are common and probably very relevant for the course of the disease. The role of autophagy in cancer progression seems to be context dependent. While an active autophagy clearly can contribute positively to mobilization of the metabolic intermediates needed for rapid tumor cell growth (Byun et al. 2017; Moors et al. 2017), it is selective autophagy which is normally responsible for regulating levels of enzymes like phosphofructo-2-kinase/fructose-2,6-bisphosphatase 3 and hexokinase 2, which, if they accumulate because of deficient autophagy, provide a huge impetus to glycolysis, possibly explaining the famous "Warburg effect" (Jiao et al. 2018; Flynn et al. 2019). That would suggest that loss of functional autophagy could spur tumor progression. In fact, it is possible sensitize tumors to chemotherapy if at the same time, autophagy is inhibited. On the other hand, there are potential effects of autophagy on cell differentiation which could channel populations of tumor cells into an end-differentiated or dormant state. Thus, one must surmise that with different tumors, disease progression can potentially benefit either way, from active autophagy or from a deficiency of autophagy, presumably in a tumor type-dependent fashion. What will be needed in the future is a personalized molecular analysis of individual tumors in order to decide which, if any interventions in autophagy offer promise. Hence, for innovative cancer therapies with autophagy drugs, right now a real quandary exists, and concerns about risk are self-evident.

***Diseases of dysfunctional immunity*:** Autophagy is central for immunity for several reasons. Neutrophils, important as a first line of defense against microbial infection, depend on autophagy and certain ATG proteins for essential neutrophil functions including differentiation, phagocytosis, cytokine production, degranulation, and cell death (Germic et al. 2019a). Moreover, in some little understood way, autophagy is also able to limit inflammatory responses and to a degree to protect normal tissues (Byun et al. 2017; Germic et al. 2019b).

Some intracellular parasites are able to develop strategies to overcome phagocytic killing, achieving a release from phagocytic vacuoles into the cytoplasm. Recognition of such free, invading microbes by pathogen-recognition receptors such as Toll-like receptors or NOD-like receptors induces autophagy, stimulates their inclusion in autophagosomes, and facilitates finally their degradation in lysosomes (Byun et al. 2017).

Moreover, autophagy is involved in development, survival, and differentiation of T lymphocytes (Byun et al. 2017) and as a degradative pathway, autophagy also plays a significant role in antigen processing and presentation on MHC class II molecules (Byun et al. 2017; Germic et al. 2019b). This multiplicity of immune functions which show a dependence on the process pf autophagy suggests that autophagy modulation with inflammatory or autoimmune diseases must present therapeutic opportunities. Here again, the potential risks are self-evident.

Perspective

It is evident from Fig. 1 and Tables 1 and 2 that numerous potential drug targets suitable for modulating autophagy exist. In fact, many autophagy-inhibiting (Pasquier 2016) or activating drugs (Byun et al. 2017; Moors et al. 2017; Thellung et al. 2019) are known and have been subjects of investigation for years. Because most of these targets belong to networks that are central in

Autophagy, Fig. 1 (continued) (Nrf2) is illustrated in (**6**). Nrf2 is normally bound to the ubiquitin ligase Keap1, which targets it to the proteasome (P), thus maintaining Nrf2 levels very low. SQSTM1 (p62) binding to Keap1 targets its degradation via uptake into an autophagosome, freeing Nrf2 to translocate to the nucleus where it stimulates transcription of numerous antioxidative genes and, interestingly, also the SQSTM1 (p62) gene itself. Autophagy, Table 1 Some drugs inhibiting autophagic activity[a]

Drug	Network	Target	Specificity
3-Methyladenine	PI3K class 3 and autophagy	Vps34	Inhibits Vps34 and autophagy, but also PI3K class 1, hence indirectly mTORC1
Wortmannin	PI3K class 3 and autophagy	Vps34	Pan-PI3K inhibitor, inhibits autophagy, but also other kinases including mTORC1
LY294002	PI3K class 3 and autophagy	Vps34	Synthetic inhibitor for Vps34 and autophagy; inhibits also PI3K class 1 and mTORC1
Compound 31	PI3K class 3 and autophagy	Vps34	Optimized inhibitor for Vps34 and autophagy for oral application. Specific
Pepstatin A	Lysosomal proteases	Lysosomal cathepsins D, E, and BHL	Protease and autophagy inhibitor, blocking lysosomal degradation of cargos. Specific
Bafilomycin A1	Lysosomal acidification and hydrolase activation in the lysosome	Vacuolar lysosomal H^+-ATPase	Inhibits autophagy by preventing lysosomal acidification, hence lysosomal hydrolase activities. V-ATPases are present in endosomes and secretory vesicles. Unspecific
Chloroquine and hydroxychloroquine	Lysosomal acidification and hydrolase activation	Lysosomes	Lysosomotropic drugs inhibiting lysosomal acidification and autophagy. Relatively specific

[a]Modified from Pasquier (2016)

Autophagy, Table 2 Some drugs activating autophagic activity[a]

Drug	Previous applications in the clinic	Target	Mechanism
Rapamycin, tacrolimus, etc.	Antifungal, immunosuppressive, anticancer	*Raptor*	Prevents raptor assembly in mTORC1, hence inhibiting the mTOR kinase and allowing autophagy initiation
Torin	Anticancer	*Blockade of mTOR kinase ATP-binding site*	Blocks the ATP binding site of mTOR, hence allowing autophagy initiation
Lithium	Mood stabilizer	*Inositol mono-phosphatase inhibitor*; causes inositol depletion	Blocks inositol mono-phosphatase, reducing levels of free inositol, for example, needed for synthesis of phosphatidylinositol 3,4,5 trisphosphate
Valproic acid	Antiepileptic, mood stabilizer	*Inositol mono-phosphatase inhibitor*; causes inositol depletion	Acts like lithium; blocks inositol mono-phosphatase, limiting free inositol levels, for example, needed for phosphatidylinositol 3,4,5 trisphosphate synthesis
Metformin	Antidiabetic	*AMPK activation*, hence, UNK 1 and 2 activation	Activated AMPK phosphorylates ULK1 and 2, resulting in autophagy initiation and mTOR inactivation, blocking its anabolic kinase activity
Resveratrol	Antioxidant	*AMPK activation*, hence, UNK 1 and 2 activation	Activates AMPK (after targeting SIRT1) like metformin. It also activates transcription factors responsible for ATGs and antioxidant proteins
Verapamil	Anti-arrhythmic and antihypertensive	*Ca^{2+} channel blocker*; also calpain inhibitor	Protects cells from oxidative damage by inducing Keap1 degradation and activating transcription factor Nrf2 to transcribe antioxidant proteins. See Fig. 1

[a]Modified from Thellung et al. (2019)

regulating cellular homeostasis, the main concern at this early stage of clinical study and drug development for autophagy modulators is the lack of specificity.

As a fundamental housekeeping and survival program, autophagy modulation promises huge benefits for the management of several different diseases. What will be needed for therapeutic applications, however, will be drugs showing a fine, incremental impact allowing a favorable intervention in a specific setting, but without too many negative systemic side effects. As with practically all applications in pharmacology, future efforts will have to focus on the refinements in drug structure which can provide the increased specificity needed for treatment of different pathologies.

Bacterial Resistance to Antibiotics

Anke Heisig and Peter Heisig
Pharmaceutical Biology and Microbiology,
Institute of Biochemistry and Molecular Biology,
University of Hamburg, Hamburg, Germany

Introduction

Antibiotics have revolutionized the therapy of infectious diseases nearly a century ago. For the first time with penicillin, a selective therapy targeting the bacterial cell synthesis was available. However, concomitantly with the detection of the antibacterial activity of penicillin, Sir Alexander Fleming reported on the phenomenon of bacterial resistance to penicillin. Since then, several strategies have been applied to overcome this problem and conserve antibiotic activity for future therapeutic options:

Different strategies for the development of new antibiotics

- By isolation from natural sources antibiotics belonging to different molecular classes (e.g., aminoglycosides, tetracyclines, cephalosporins)
- By chemical modification known antibiotics (e.g., aminopenicillins, doxycycline, amikacin)
- By total chemical synthesis of novel drugs (e.g., sulfonamides, fluoroquinolones)
- By a combination of antibiotics with inhibitors of known resistance enzymes (e.g., amoxicillin with the β-lactamase inhibitor clavulanic acid)

Although all approaches have proven to be successful, this was only for a short time period due to the ability of bacterial cells to rapidly adapt to novel drugs by the development of potent mechanisms of resistance. Intensive research on the underlying molecular mechanisms of antibiotic resistance have revealed several contributing factors: These include the following:

Bacterial factors contributing to antibiotic resistance

1. A haploid genome, so that a genetic alteration immediately results in a new phenotype
2. High numbers of pathogen cells either due to a high replication rate or to successful escape from the immune response, thereby increasing the probability for the development of resistant mutants which can be selected in the presence of antibiotics
3. The existence of efficient mechanisms of horizontal gene transfer allowing for simultaneous spread even of multiple resistance determinants encoded by extrachromosomal elements.

Human economic and ecologic factors contributing to antibiotic resistance

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

4. A continuing decrease of the number of novel antibiotics developed during the last two decades which restricts the therapeutic options and simultaneously favors the selection and spread of resistant mutants.
5. Inappropriate use of antibiotics in agriculture and livestock breeding as well as insufficient treatment of wastewater from hospitals or antibiotic manufactures resulting in a wide disposal of antibacterial compounds in the environment. Though the resulting antibiotic concentrations are in the sub-inhibitory range, this condition induces stress responses in bacteria resulting in the acquisition of genetic alterations associated with resistance in existing DNA or by horizontal transfer of DNA (Fig. 1).

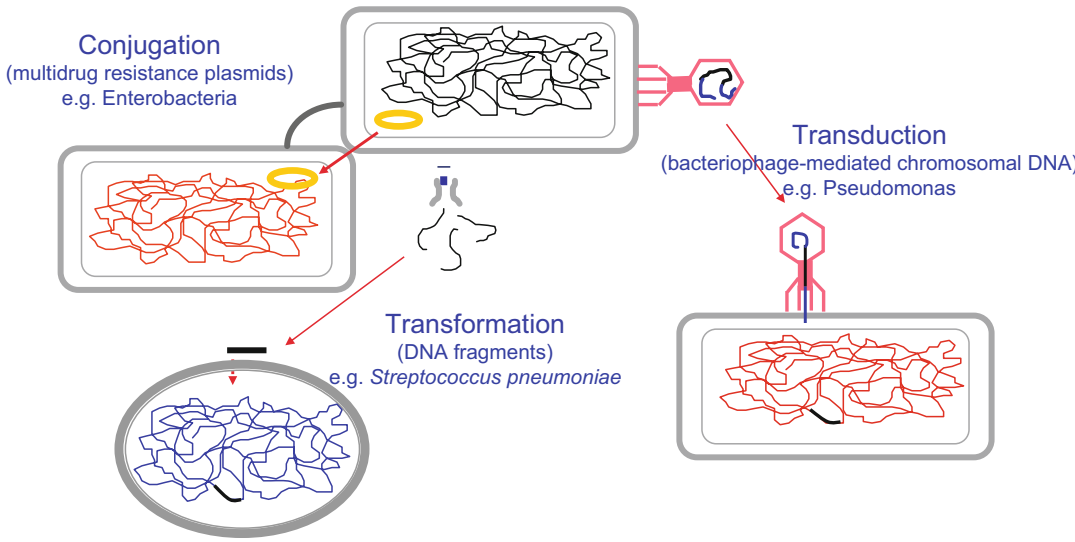
Antibiotic Resistance: Definitions

Biological Resistance

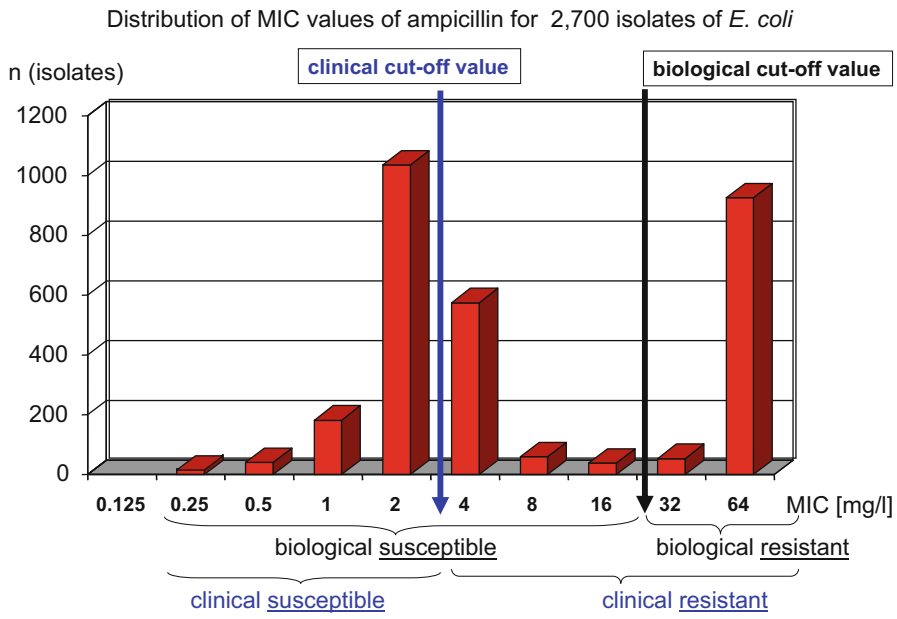
From the biological point of view, antibiotic resistance is the relative reduction of the susceptibility to a specific antibiotic either of all strains of a species compared to the strains of another species (primary or natural biological resistance) or of a bacterial strain compared to other strains of the same species (secondary or acquired biological resistance). For the identification of the respective type of biological resistance, the antibiotic susceptibilities of a set of different strains of a species are determined, and each strain is assigned to a category of antibiotic susceptibility (e.g., given as drug concentration in μg/ml capable of inhibiting the growth of these strains: minimal inhibitory concentration, MIC). The resulting diagram (Fig. 2) typically yields a bimodal distribution of the susceptibilities obtained for strains of a single species. The main peak at the lower drug concentration represents the majority of strains and defines the naturally susceptible population, while the minor peak at higher drug concentrations corresponds to strains expressing an acquired mechanism of resistance (secondary/acquired resistance).

Clinical Resistance

From the clinically point of view, the drug concentrations capable of inhibiting bacterial isolates from patients are compared to the drug concentrations typically achievable at the site of infection under conditions of a standard dose and normal metabolic activity of the patient. Depending upon



Bacterial Resistance to Antibiotics, Fig. 1 Mechanisms of horizontal transfer of antibiotic resistance genes



Bacterial Resistance to Antibiotics, Fig. 2 Definition of biological and clinical resistance

the type and location of infection, the type of pathogen, and its metabolic activity, the drug concentration obtained in vivo is required to exceed the inhibitory drug concentration for the given pathogen by a factor of 10 for a specific time period. This pathogen is said to be clinically susceptible, while pathogens showing lower susceptibilities are clinically resistant. Since this rule of thumb is not valid for any type of infection, several additional factors have to be considered for choosing the right antibiotic in the most effective dose for a specific patient. Nevertheless, one crucial factor is the degree of antibiotic susceptibility of the causative pathogen. Antibiotic susceptibility can easily be determined by one of two principle test procedures: agar diffusion and broth dilution.

Methods for the Determination of Antibiotic Resistance In Vitro

To determine the susceptibility of a pathogen for a specific antibiotic the first step is to isolate bacteria from the site of infection in pure culture and identify the species of the suspected causative pathogen. Typically a characteristic fingerprint of the molecular masses of different ribosomal proteins using matrix-assisted laser desorption ionization time-of flight (MALDI-TOF) mass spectrometric analysis is determined. Depending upon the species of the respective pathogen, the knowledge of its primary, i.e., natural resistance to some antibiotics, allows to exclude these drugs as therapeutic options.

The next step is the determination of the antibiotic susceptibility. The underlying principle is to expose a defined number of bacterial cells (inoculum) to various concentrations of antibiotics and incubate these mixtures under defined conditions (time, temperature, growth medium). For the *broth dilution test*, one volume of inoculated broth is added to one volume each of stepwise 1:2 dilutions of the antibiotic. After a defined incubation time, the minimal inhibitory concentration (MIC in μg/ml) of the respective antibiotic is determined as the lowest drug concentration showing no visible growth.

For the second method, the *agar diffusion test*, a defined number of cells (inoculum) is evenly

spread over an agar plate before paper discs containing defined amounts of different antibiotics are evenly distributed on the surface of the agar. During the incubation time, the antibiotics diffuse from the disc into the agar generating concentric gradients of decreasing antibiotic concentrations. According to the respective drug susceptibility, bacteria grow around the disc until they encounter the inhibitory concentration forming an inhibition zone (Fig. 4). The exact inhibitory concentration in μg/ml can be determined by using a linear regression obtained from a correlation of known reference concentrations with the corresponding zone diameter in mm. Based on these reference correlations, the zone diameter can be used directly for identifying susceptible and resistant pathogens (Tenover 2010).

Mechanisms of Antibiotic Resistance: Variations of a Theme

For an antibiotic to act, it has to interact with a bacterial cell and bind to an essential target structure, e.g., a protein, a nucleic acid, or a cell wall or membrane component. The immediate result of this interaction is the impairment of the target's activity or function. However, this primary effect usually triggers subsequent reactions which ultimately result either in the reversible inhibition of cell growth (bacteriostatic activity) or in an irreversible reaction leading to cell death (bactericidal activity). Many secondary bactericidal effects have been demonstrated to be associated with the induction of stress responses, e.g., formation of reactive oxygen species (ROS) which directly destroy essential cellular structures (DNA, RNA, proteins, membrane lipids) or induction of DNA damage response (SOS response) introducing mutations.

Genetic Basis of the Transfer of Antibiotic Resistance

The acquisition of antibiotic resistance results in a genetically stable phenotype. This is in contrast to the typically transient alteration of the phenotype of bacteria in biofilms which also show a reduced susceptibility to antibiotics. This phenotype, however, is due to the metabolic state of a subpopulation of cells in cell colonies, which do not carry a stable genetic alteration.

The genetic alterations associated with acquired resistance include either *mutations* which alter the existing genetic information or *uptake of additional genetic material (e.g., as transposable element or plasmid) by one of* three basic mechanisms (Fig. 1) (Courvalin 2008):

- *Transformation*, i.e., the uptake of naked DNA either as autonomously replicating extrachromosomal plasmid or as linear DNA fragment which is integrated into the existing chromosome via homologous recombination
- *Transduction*, i.e., the transfer of genetic material by bacteriophages which incorporate fragments of chromosomal DNA from a host cell to a newly infected cell followed by integration of the piece of foreign DNA into the chromosome of this cell via homologous recombination
- *Conjugation*, i.e., the direct transfer of DNA such as extrachromosomal plasmid DNA from a donor cell to a recipient cell mediated by a cell-to-cell contact via so-called sex or fertility (F) pili.

Molecular Basis of Antibiotic Resistance Mechanisms

These genetic alterations result in at least one out of three different principle types of antibiotic resistance mechanism:

1. Alteration of the target structure which subsequently reduce the affinity for the antibiotic
2. Reduction of the concentration of the antibiotic at the target
3. Inactivation of the antibiotic

The current problems with higher numbers of antibiotic resistant bacteria are exacerbated by:

- The *increasing variability of these three basic mechanisms* affecting even newest antibiotics
- The *combination of different genetic determinants* of resistance on extrachromosomal genetic elements (plasmids)

– The *wide distribution of such multi-drug resistant (MDR) plasmids* by transfer even between bacteria belonging to a different species

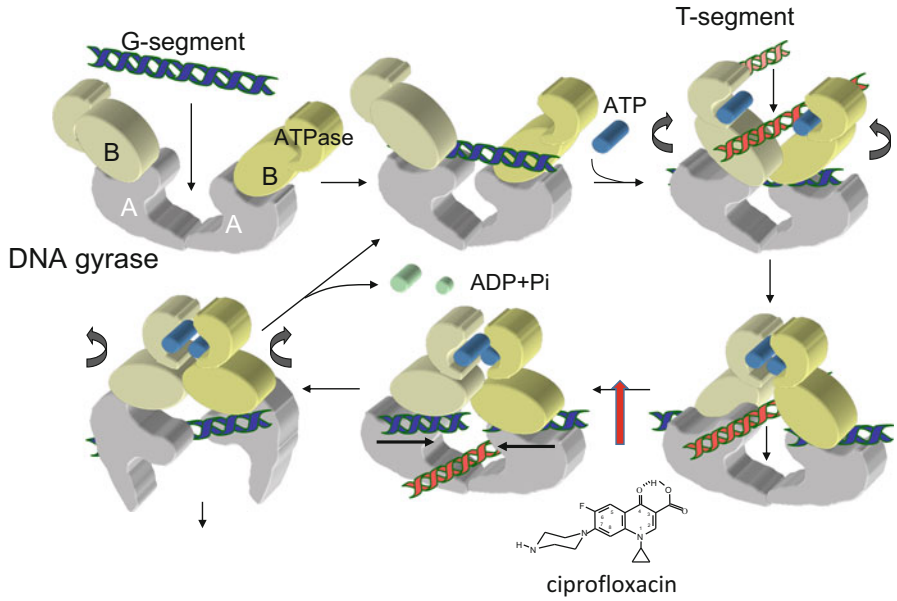
Alteration of the Target Structure

Bacterial targets of antibiotics typically are partial structural regions of a nucleic acid (e.g., ribosomal RNA), a protein (e.g., RpoB subunit of RNA polymerase holoenzyme), or a membrane component (e.g., anionic regions of phospholipids in the cytoplasmic membrane) which are essential for the cellular metabolism. Binding of an antibiotic to its target structure(s) affects the activity/function of the target resulting in reversible growth inhibition or even – irreversible – cell death. The binding site of a target typically is a three-dimensional pattern of functional chemical groups which covalently or non-covalently interact with complementary functional groups of the antibiotic molecule. Since the altered target is an essential compound of the cellular metabolism, only some specific alterations which retain the natural target function are tolerable for a cell. However, frequently, such alteration affects the fitness of the resulting mutant. Such mutant cells often acquire one or more additional mutations either in the respective target gene or in a different gene to compensate for this fitness deficit. Bacteria have evolved several mechanisms to alter the target susceptibility:

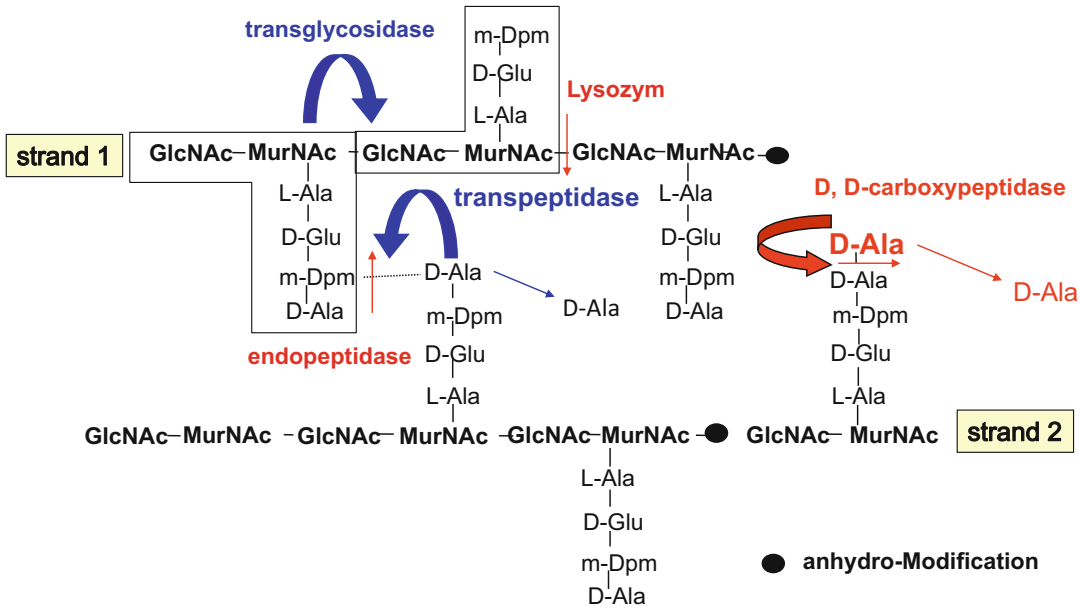
– Mutation resulting in amino acid substitution.
– Production of an alternate homologous target with adequate activity, but with reduced susceptibility for the antibiotic.
– Enzymatic modification of, e.g., the protein or RNA target. Thus, introduction of a single functional group (methyl, phosphate) interferes with the interaction between a functional group of the antibiotic and its corresponding binding partner (amino acid side chain, nucleotide) of the target.
– Overproduction of an pseudo-target which outcompetes the antibiotic for the target binding site.
– Overproduction of a protecting protein shielding the drug binding site of the target.

Target Alteration by a Mutation The easiest way to impair drug binding and thereby increase the inhibitory concentration of the antibiotic is to eliminate at least one of the functional groups at the binding site of a target. This can occur by mutational exchange of a respective binding partner, i.e., a nucleotide or an amino acid of the respective target structure. A prominent example is fluoroquinolone resistance which is primarily due to the acquisition of mutations in a conserved region of the *gyrA* gene encoding subunit A of the fluoroquinolone target DNA gyrase. Beside the homologous topoisomerase IV, DNA gyrase is an A_2B_2 tetrameric type II topoisomerase, which together with topoisomerase I (*topA* gene product) controls the global negative supercoiling degree of DNA in bacterial cells. This assures the continuous progress of replication and transcription. At the molecular level, gyrase acts by transiently introducing a DNA double-strand break with both GyrA subunits covalently bound to the free 5′-phosphate ends of the broken DNA (Fig. 3). The molecular mechanism of fluoroquinolone action is the stabilization of this reaction intermediate resulting in a blockage of DNA replication. A single point mutation in a highly conserved α-helical region (part of the so-called quinolone resistance-determining region, QRDR) affecting either a serine (aa 83 in *E.coli*) or a nearby aspartate (aa 87 in *E. coli*) residue reduces the binding affinity of the drug by a factor of about 20, a combination of both residues even by a factor of more than 2000 (Heisig et al. 1993).

Target Alteration by Producing an Alternate Homologous Target An alternative strategy to achieve antibiotic resistance by target alteration is to (over)express a functionally homologous but resistant target structure, as is seen in methicillin-resistant *Staphylococcus aureus* (MRSA) isolates. Methicillin belongs to the important group of β-lactam antibiotics, which act by imitating an intermediate of the natural reaction of transglycosidase/transpeptidase enzymes (an essential representative of the so-called penicillin binding proteins, PBPs) with the cell wall precursor disaccharide-pentapeptide. This essential PBP

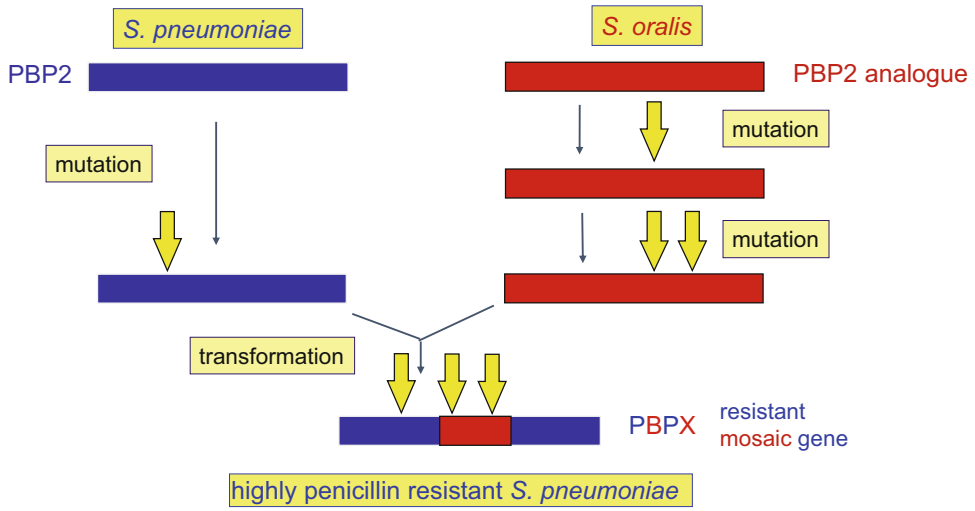


Bacterial Resistance to Antibiotics, Fig. 3 Steps of DNA gyrase-mediated DNA supercoiling and mechanism of quinolone action



Bacterial Resistance to Antibiotics, Fig. 4 Enzymes involved in regulation of peptidoglycan biosynthesis

catalyzes the cross-linking of growing glycan strands of the peptidoglycan layer in the bacterial cell wall by forming isopeptide bonds between two neighboring pentapeptide side chains. The different reaction steps involve (I) binding of the transpeptidase to its natural substrate, the terminal D-alanyl-D-alanine bond of the disaccharide-pentapeptide, (II) cleavage of this D-ala-D-ala peptide



Bacterial Resistance to Antibiotics, Fig. 5 Evolution of penicillin-resistant penicillin binding proteins in *Streptococcus pneumoniae*

bond by formation of a transient reaction intermediate between the transpeptidase covalently bound to the penultimate D-alanine, and (III) cross-linking of the carboxy-terminus of this D-alanine residue via an isopeptide bond to a basic amino acid (e.g., L-lysine) in an adjunct pentapeptide by transpeptidase (Fig. 4). The β-lactam core structure of a respective antibiotic mimics the structure of D-alanine covalently bound to the active site serine residue of the transpeptidase. However, the resulting β-lactam-enzyme-complex is extremely stable and permanently blocks cell wall synthesis. MRSA isolates have captured a gene complex presumably from another *Staphylococcus* species encoding a naturally β-lactam-resistant variant of a PBP, the *mecA* gene product, which can substitute for the activities of all *S. aureus* PBPs required for cell wall synthesis (Johnson et al. 2013).

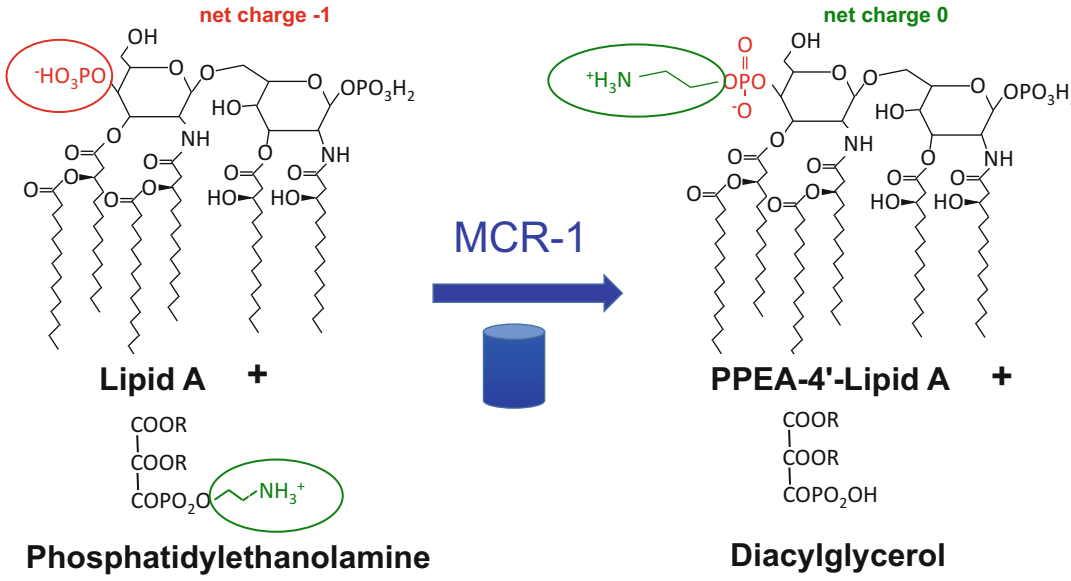
Isolates of *Streptococcus pneumoniae* share stretches of homology in genes encoding PBPs with many other streptococcal species of the oral microbiota. But these PBPs are naturally less susceptible to β-lactam inhibition due to genetic variations in the penicillin-binding regions of the PBP-encoding genes. Due to their natural competence, i.e., the intrinsic ability to take up linear DNA fragments from dead cells in the immediate environment, pathogenic *S. pneumoniae* strains in the upper respiratory tract can capture foreign gene fragments encoding less susceptible PBPs from oral streptococci. Following the uptake of such DNA fragments by *S. pneumoniae* regions of high homology in the PBP, gene sequences shared with naturally less susceptible oral streptococci can be exchanged by homologous recombination with the chromosome of *S. pneumoniae*. By this strategy, a set of resistance-associated mutations are transferred en bloc and give rise to novel PBP variants designated as PBPX (Fig. 5) (Sibold et al. 1994).

Target Alteration by Enzymatic Modification The enzymatic modification of structural elements of the target participating in drug binding often affects all antibiotics of one class. As a consequence, the number of functional groups available for drug binding is significantly reduced or even eliminated. Thus, a higher drug concentration is required for effective antibiotic activity.

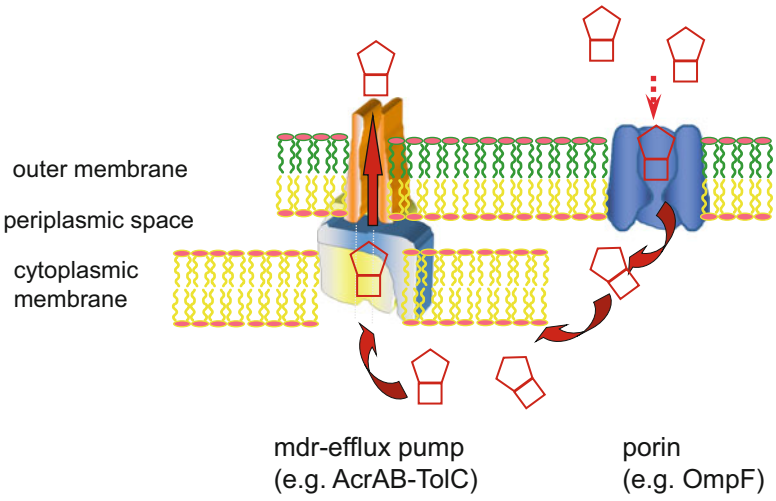
An example of a target modification reaction by a single enzyme is the resistance to all aminoglycoside antibiotics by the *armA* gene product. ArmA methylates a specific ribonucleotide in the aminoglycoside binding region. This

region is created by combining two three-dimensional folds of the 16 S RNA. After methylation the clustering of the two-folded regions is impaired resulting in a significant reduction of the aminoglycoside binding (Galimand et al. 2003). The *armA* gene and its homologues (*rmt*) are encoded on different plasmids, which can be transferred by conjugation or transformation between different bacterial cells even belonging to different species. In contrast, the most widely distributed mechanism of resistance to aminoglycoside antibiotics is due to the production of enzymes which very specifically modify a functional group of some, but not all aminoglycosides (see below).

Another type of enzymatic target modification is found for colistin, a derivative belonging to the cationic polymyxin group of antibiotics. The positively charged functional groups of colistin tightly bind to negatively charged functional groups of the lipopolysaccharide (LPS) in the outer membrane, e.g., phosphate moieties. Consequently, the LPS structure is disturbed allowing access of colistin to the cytoplasmic membrane which also carries anionic phosphate residues for colistin binding. Destruction of the cytoplasmic membrane is the final result leading to generation of reactive oxygen species and subsequently to cell death. To become resistant to colistin, Gram-negative bacteria can overproduce enzymes which are able to transfer building blocks containing positively charged functional groups (e.g., phosphoethanolamine or 4-amino-arabinose) to the phosphate residues of lipids. As a consequence, the negative charges of LPS, i.e., the binding sites of colistin, are eliminated either by conversion into positive charges or by neutralization. Many bacteria encode respective transferase enzymes, which are regulated to allow for a moderate transient LPS modification in response to changing environmental conditions. Exposing cells to colistin induces upregulation of genes encoding LPS-modifying enzymes by inducing two-component regulatory elements. The most widely distributed LPS-modifying enzymes are phosphoethanolamine transferases (e.g., plasmid-encoded MCR-1; see Fig. 6) and 4-amino-arabinosyl-transferases. Exposing cells for a longer period of time to higher colistin concentrations can select for genetically stable colistin-resistant mutants. Such mutants carry mutations in regulatory genes controlling the respective



Bacterial Resistance to Antibiotics, Fig. 6 Molecular mechanism of colistin resistance by enzymatic lipopolysaccharide modification



Bacterial Resistance to Antibiotics, Fig. 7 Antibiotic resistance by reduced influx combined with increased efflux of antibiotics

transferases on different levels (Wright et al. 2015).

Reduced Access of the Antibiotic to the Target Structure

For many classes of antibiotics, the respective target structure is located in the cytoplasm; however, for some others the target is associated with the peptidoglycan layer or even the outer membrane. Thus, for interacting with their target, most antibiotics have to pass the cytoplasmic membrane and the peptidoglycan layer. For Gram-negative bacteria additionally, the outer membrane is an effective barrier. Its unique structure with the inner layer resembling the phospholipid structure of the cytoplasmic membrane and the outer layer consisting mainly of lipopolysaccharides (LPS) makes the outer membrane nearly impermeable for hydrophilic antibiotics with a molecular weight above ca. 700 Da. Nevertheless, the controlled permeation of small hydrophilic molecules such as nutrients (influx) and some toxic compounds through the outer membrane (efflux) is essential for a living bacterial cell to adapt to changing environmental conditions. For these transport processes, different routes are accessible, and some participate in the uptake and export of antibiotics. For adapting to different environmental conditions, cells can alter the expression of transport-associated membrane proteins: (1) small hydrophilic molecules (e.g., many nutrients) passively diffuse through hydrophilic transmembrane pores in the outer membrane, called porins, and (2) energy-driven transmembrane efflux pump proteins incorporated in the cytoplasmic membrane to export hydrophilic toxic compounds, e.g., antibiotics (Fig. 7). Some efflux pumps act alone by shedding toxic molecules into the periplasm or as tripartite complexes with the pump docked to a specific outer-membrane protein (OMP) via a periplasmic membrane-fusion (MF) protein. Such a complex forms a hydrophilic channel through both membranes in Gram-negatives. Thus, to reduce the susceptibility for antibiotics, cells can use two complementary strategies which affect drug permeability of the cytoplasmic and/or outer membrane:

- Reduced influx
- Increased efflux

The underlying genetic mechanisms regulating these processes include inducible, i.e., reversible responses by transiently increased expression of efflux-associated and/or reduced expression of influx-mediating membrane components. This strategy enables the cell to transiently adapt to changing environmental conditions. Without genetic changes, bacteria can survive in the presence of high concentrations of toxic compounds (e.g., antibiotics). Mechanisms of induction often

include influx of a small amount of a key molecule (antibiotic) through one of the few porins produced at a low basal level. Inside the cell, these key molecules bind to a repressor controlling genes, e.g., for an efflux pump or for a negative regulator of porin gene expression. As a consequence, efflux pump expression is increased and/or porin protein expression is reduced resulting in a significant reduction of the intracellular antibiotic concentration (Fig. 7). Stable mutants inactivating global regulators showing this phenotype can easily be selected. The presence in most bacteria of more than one such efflux pump with partially overlapping substrate specificities reduces the impact of such alterations on antibiotic resistance. In contrast, in the absence of the respective antibiotic, the permanent inactivation of an efflux pump may reduce the adaptability of a mutant and cause a disadvantage for the cell in competition with wild-type cells.

Additionally, the broad substrate specificities of many efflux pumps mediate a multidrug resistance (MDR) phenotype. Consequently, the selection of efflux pump-associated mutants by one antibiotic frequently causes multiple resistance also to other structurally unrelated antibiotic substrates of the same MDR efflux pump.

Other strategies are:

- The overproduction of a target-protecting protein which shields the binding site sterically, thereby impairing the access of a drug to its target
- The production of a protein which can substitute for the activity of the original susceptible target protein due to its lower binding affinity for an antibiotic

Reduced Access to the Target due to Reduced Permeability of the Outer Membrane Two factors have an impact on the permeability of the outer membrane barrier function: (I) the number of outer membrane porins and (II) the specificity, number, and activity of efflux pumps. Mutations affecting either factor typically do not alter the structure but rather affect the amount of the respective membrane protein. In many Gram-negative pathogens, expression of major porins (e.g., OmpF, OmpC in *E. coli*) underlies several different regulatory circuits in response to varying environmental factors, such as temperature or osmolarity of the growth medium. Expression of major efflux pumps (e.g., the tripartite MDR efflux pump AcrAB-TolC in *E. coli*) often is regulated negatively by a local repressor (e.g., AcrR). In addition, at a higher level, the expression of efflux pump is controlled by the *marRAB* global regulatory system with MarR repressing the MarA gene activator. Any mutation inactivating the *marR* gene causes *marA* gene overexpression which in turn results in overexpression of both *acrAB* and tolC as well as the *micF* antisense RNA. *micF* functions as repressor of porin *ompF* gene expression by binding via complementary base pairing to its 5′ end. This block of the ribosomal binding site (rbs) prevents translation of the *ompF* mRNA. A *marR* mutation results in multiple drug resistance (MDR) to antibiotics of different classes (e.g., fluoroquinolones, chloramphenicol, and tetracyclines). The molecular basis for the broad substrate specificity is the existence of several only partially overlapping binding sites for the different substrates.

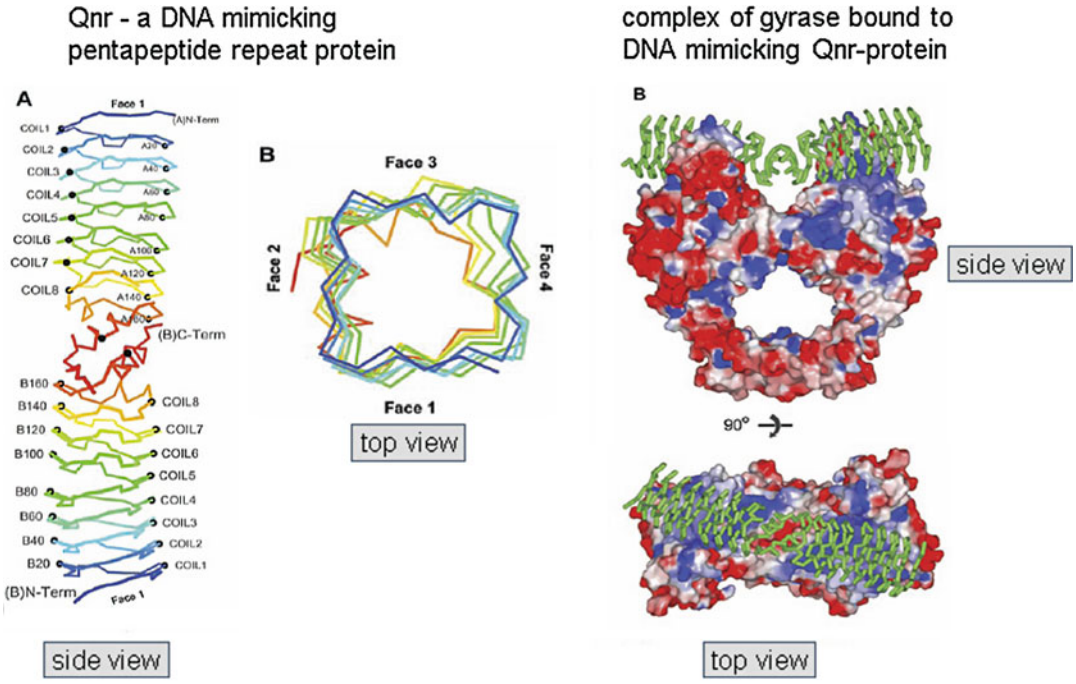
Expression of MDR efflux pumps is also a frequent cause for natural (i.e., primary) resistance of many Gram-negative pathogens (e.g., *P. aeruginosa*, *A. baumannii*) to different antibiotics. This has experimentally been demonstrated for mutants of *E. coli* lacking a functional AcrAB efflux pump: the MIC of vancomycin is reduced from 128 μg/ml to 1 μg/ml.

An important specific mechanism of resistance due to reduced intracellular concentration is tetracycline resistance by overexpression of a tetracycline-specific (Tet) efflux pump. Several different variants of Tet efflux pumps have been identified in both, Gram-positive and Gram-negative bacteria. The respective *tet* genes are typically encoded on plasmids and, therefore, are easily transferable between cells. The expression of some *tet* genes is inducible: after binding of a tetracycline molecule to a specific binding site of a TetR repressor, the conformational change results in a strong reduction of TetR binding affinity to DNA. In contrast to the moderate effect of overexpression of an MDR efflux pump, the induction of a Tet-specific

efflux pump significantly decreases tetracycline susceptibility. Tigecycline, a glycylcycline derived from tetracycline by introducing a glycyl-side chain to minocycyline, is refractory to Tet efflux pump-mediated resistance and also shows a strongly reduced binding affinity to TetR. As a consequence no relevant cross-resistance between tetracyclines and glycylcyclines is observed.

Reduced Access to the Target due to Production of a Target Protecting Protein Beside tetracycline-specific efflux pumps, another major mechanism of tetracycline resistance, which in contrast also affects glycylcycline susceptibility, is the expression of ribosomal protection proteins. These proteins show a high affinity to the ribosomal A-site. This site is the binding site of the aminoacyl-tRNA during the elongation reaction of protein biosynthesis and simultaneously the molecular target of tetracyclines. The sterical block by a ribosomal protection protein does not affect the vital ribosomal function. Ribosomal protection is found both in Gram-positive and Gram-negative bacteria.

Another mechanism of target protection has been identified as a very specific transferable mechanism of reduced susceptibility to fluoroquinolones. So-called quinolone resistance (Qnr) proteins contain a repetitive pentapeptide-repeat structure and fold into a DNA-like structure. These Qnr proteins imitate the natural reaction substrate DNA and compete with it for binding to the fluoroquinolone target topoisomerases, gyrase, and topoisomerase IV (Fig. 8) (Vetting et al. 2005). Unlike DNA, Qnr proteins cannot be cleaved by these enzyme. Instead, they bind to these enzymes in competition with DNA. This reduces the number of catalytically active topoisomerase-DNA complexes and thus



From Hegde, S.S. et al., (2005): A fluoroquinolone resistance protein from Mycobacterium tuberculosis that mimics DNA. Science 308:1480. Reprint with permission from AAAS

Bacterial Resistance to Antibiotics, Fig. 8 Quinolone resistance due to protection of DNA gyrase by a DNA mimicking Qnr protein

prevents the conversion of the complex to the true fluoroquinolone target, i.e., the topoisomerase covalently bound to DNA via two phosphodiester bonds (see above CCC). Since the Qnr-topoisomerase complex is non-covalent, the binding is reversible, and the number of complexes depends upon the amount of Qnr in the cell. Due to the essential function of DNA-topoisomerases for DNA metabolism (i.e., replication, transcription), it is obvious that not all enzymes can be protected by Qnr without killing the cell. Instead, few topoisomerase-DNA complexes are required to be active. Thus, fluoroquinolone resistance due to Qnr is only moderate, and the clinical importance of this mechanism alone is low.

Reduced Access to the Target due to Production of a Target-Substituting Protein with Reduced Binding Affinity for Antibiotics Sulfonamides are synthetic antibacterials and were the first antibiotics clinically used. Their target is the bacterial dihydropteroate synthetase (DHPS) required for the biosynthesis of the cofactor tetrahydrofolic (THF) acid. In essential biosynthetic pathways including biosynthesis of nucleotides and amino acids, THF is involved in the incorporation of C1-building blocks. Thus, inhibition of the THF biosynthesis finally causes cell death. The molecular structure of sulfonamides shares high homology to para-aminobenzoic acid (p-ABA) and, thus, can easily enter bacterial cells without being exported. Also single mutations altering the THF binding site of the susceptible DHPS target without affecting that of the natural substrate p-aminobenzoic acid are not found. However, in some bacterial species, variants of the DHPS target protein have evolved which show natural resistance to sulfonamides due to a set of variations in the sulfonamide/p-ABA binding region. Three such genes (*sul*-1, *sul*-2, and *sul*-3) encoding sulfonamide-resistant DHPS enzymes have been mobilized in ancient times by transposable genetic elements (integrons) from the chromosome to conjugative broad-host-range plasmids. These are easily transferable between different bacterial species and, thus, have spread from environmental bacteria to clinical isolates. During short-term evolution, the integron structures found in plasmids from clinical isolates have been expanded by acquisition of several additional antibiotic resistance genes to several different antibiotics, including e.g., different β-lactams, aminoglycosides, and tetracyclines) (Yun et al. 2012).

Enzymatic Inactivation of the Antibiotic

With the exception of sulfonamides and fluoroquinolones, which are purely synthetic drugs, antibiotics are of natural biosynthetic origin which are used unmodified or after partial chemical derivatization. The large group of β-lactam antibiotics originate from moulds (e.g., *Penicillium* spp., *Cephalosporium* spp.); most other biogenic antibiotics are produced by bacteria, presumably as a strategy to protect the producing cells in the microenvironment from other bacteria as competitors for nutrients. Consequently, for the antibiotic-producing bacterial cells, adequate mechanisms are required to self-protect them against the action of their own antibacterials. In bacteria production of secondary metabolites, such as antibiotics typically, is initiated in the late log phase. Simultaneously, expression not only of antibiotic biosynthesis genes but also of antibiotic resistance genes underlies a growth phase-dependent regulation in order to minimize potential impacts on the global fitness.

Among the three basic mechanisms of antibiotic resistance, mutational alteration of the target does not underlie a cell cycle-regulated expression, while upregulation of efflux pumps is (see above). A third basic mechanism of resistance – the expression of genes for antibiotic-modifying enzymes – is very efficient and can be regulated according to the cell cycle. Even a complete shutdown of the expression is not unusual in growth phases during which the enzyme is not required for the cell.

Enzymatic modification of antibiotics is a specific mechanism that has been found to affect several classes of antibiotics, especially of natural origin. Depending upon the antibiotic class, two types of enzymatic reaction mechanisms are known:

– Hydrolysis of a key chemical bond of an antibiotic (e.g., β-lactamase)
– Modification of a functional chemical group (e.g., O- or N-acetyltransferase)

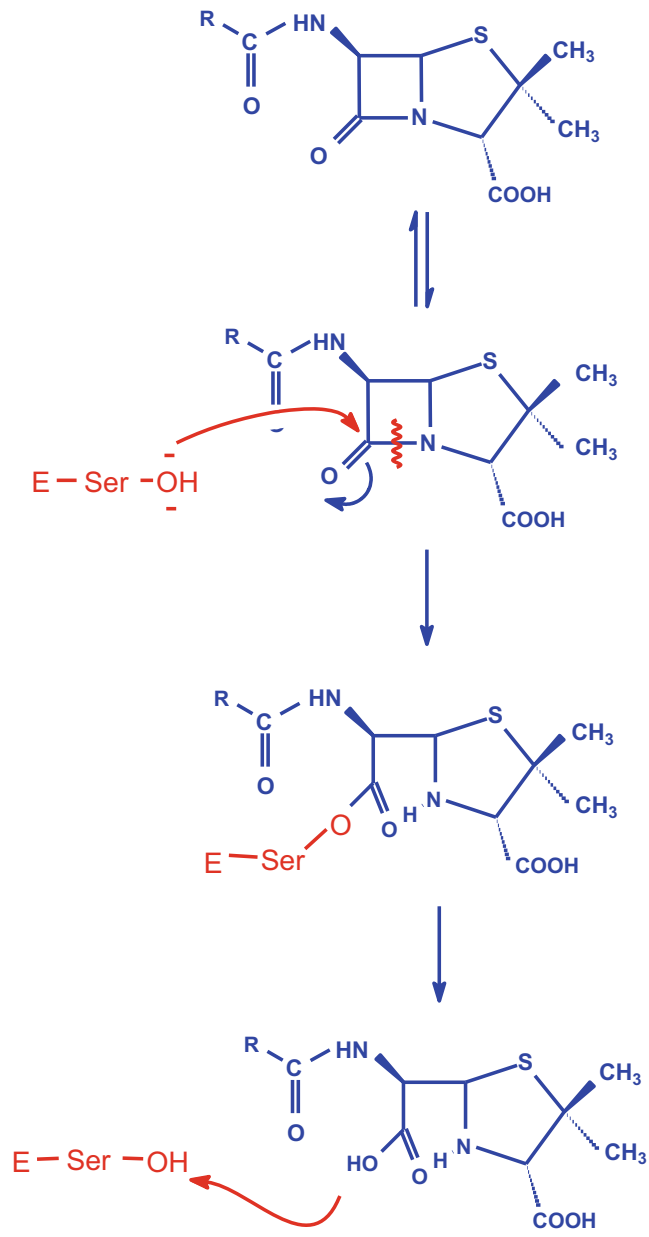
Resistance by Enzymatic Hydrolysis of β-Lactam Antibiotics The key element mediating antibiotic activity of β-lactam antibiotics is the four-membered β-lactam ring containing a peptide bond, which, however, is formed during non-ribosomal biosynthesis of a tripeptide (aminoadipyl-cysteinyl-D-valine, ACV). β-Lactam antibiotics imitate a reaction intermediate of the D-alanyl-D-alanine moiety of disaccharide-pentapeptide cell wall precursors as the natural substrate of cell wall-synthesizing transpeptidase/transglycosidase enzymes (see above). These so-called penicillin binding proteins (PBP) can react with either substrate, D-alanyl-D-alanine, and β-lactam and thereby introduce a covalent bond. However, while the natural reaction intermediate, i.e., a covalent complex of PBP and D-ala, is only transiently formed followed by a rapid release of a regenerated active PBP and a cross-linked disaccharide tetrapeptide in the growing cell wall once the peptide bond is cleaved, the PBP-β-lactam-complex is stable and blocks the essential PBP activity. Thus, a very effective strategy mediating β-lactam resistance in bacteria is to form and secrete β-lactamase enzymes. These very specific peptidases compete with the PBPs for cleaving the peptide bond in the β-lactam ring, thereby forming a covalent complex with the antibiotic molecule. However, a covalent complex of β-lactam with a PBP is highly stable, while that of the antibiotic with β-lactamase is rapidly resolved by deacylation releasing an inactive, i.e., hydrolyzed antibiotic (Fig. 9). Based upon their molecular mechanism of proteolytic cleavage, two different types of β-lactamases can be discriminated: (1) serine-type and (2) metallo-type β-lactamases. According to amino-acid sequence homology and substrate spectrum, serine-type β-lactamases are further subdivided (classes A, C, and D), while all metalloenzymes belong to class B (Fig. 10) (Bush and Jacoby 2010).

The serine-type enzymes share a common core structure of three sandwiched α/β/α domains which are linked by loops. The active site serine (Ser-70 in enzymes of the class A enzyme families TEM, SHV, and CTX-M) is part of one α helix and is located between this α-helical and the β-sheet domain. The important difference between both serine proteases – β-lactamases and PBP – is the presence in β-lactamases of a large flexible omega loop and the presence of a highly conserved glutamic acid residue (Glu-166). These two features reduce the affinity for peptidoglycan while favoring the binding to and hydrolysis of a β-lactam antibiotic by the active-site serine. Moreover, the Glu-166 supported by some other amino acid residues of the omega loop catalyzes the rapid deacylation of the β-lactamase enzyme. Due to the fact that only a small part of the enzyme molecule is involved in the formation of the active site and in β-lactam hydrolysis, the substrate binding pocket shows some flexibility which has favored the evolution of novel enzyme variants by acquisition of a few point mutations. The resulting so-called extended spectrum β-lactamases (ESBL) typically belong to class A and are able to hydrolyze also most novel β-lactams, with the exception of carbapenems. These antibiotics contain a β-lactam core structure as part of a penem moiety which is refractory to hydrolysis by many β-lactamases. Consequently, this results in a superior antibiotic activity. However, the metallo-β-lactamases belonging to class B contain a more flexible active site with a central Zn^{2+}-ion complexed by four histidine residues. These enzymes have the broadest spectrum of activity which also includes carbapenems and most other β-lactam antibiotics (Philippon et al. 2016).

Beside the production of novel, better adapted β-lactamase enzymes, two other relevant mechanisms can contribute to higher levels of β-lactam resistance against a broader spectrum of drugs in β-lactamase-producing bacteria: (1) overproduction of non-ESBL enzymes and (2) loss of outer membrane proteins (OMPs).

(1) ESBL-β-lactamases typically are encoded on small multicopy plasmids which are often

Bacterial Resistance to Antibiotics,
Fig. 9 Simplified scheme of the β-lactam hydrolysis reaction by a serine β-lactamase



transferable to other cells by conjugation. In contrast, non-ESBL-type β-lactamases (class C) have a less flexible structure of the binding pocket and often are encoded by a single gene copy on the chromosome. However, to increase β-lactam resistance, the production of non-ESBL enzymes can be induced by cell wall fragments which are increasingly released as a consequence of β-lactam action. In the absence of β-lactams, these fragments are imported into the cytoplasm for recycling. However, under β-lactam action, the recycling machinery is overloaded. As a consequence, the concentration of intermediates of the recycling reaction is increased resulting in the overexpression of a chromosomally encoded β-lactamase gene (*ampC*) as a stress response. In *Enterobacter* and *Citrobacter*

functional class	molecular class	enzymatic activity	genetic localisation distribution	examples β-lactamases

Bacterial Resistance to Antibiotics, Fig. 10 Classification and characteristics of serine-type and metalloenzyme-type β-lactamases

species, this is a class C β-lactamase which has a low affinity for modern cephalosporins but can mediate resistance due to its extremely high concentration. Mutations inactivating the AmpD repressor of *ampC* constitutively overexpress AmpC β-lactamase (Lister et al. 2009).

(2) In Gram-negative bacteria, the outer membrane is an effective barrier for hydrophilic molecules. However, to ensure sufficient uptake of small hydrophilic molecules, such as nutrients, pore proteins (porins, see above) can be inserted into the outer membrane allowing passive diffusion through small water channels. β-Lactams can also diffuse into the periplasmic space through porins. To protect itself from small toxic molecules, a bacterial cell can downregulate the expression of porins in order to exclude, e.g., antibiotics. In *Pseudomonas aeruginosa*, mutational loss of a specific porin, the OprD protein, which is an effective entry for β-lactams, results in significantly increased resistance (Fig. 7). Resistance is synergistically increased in strains overexpressing the chromosomally encoded β-lactamase.

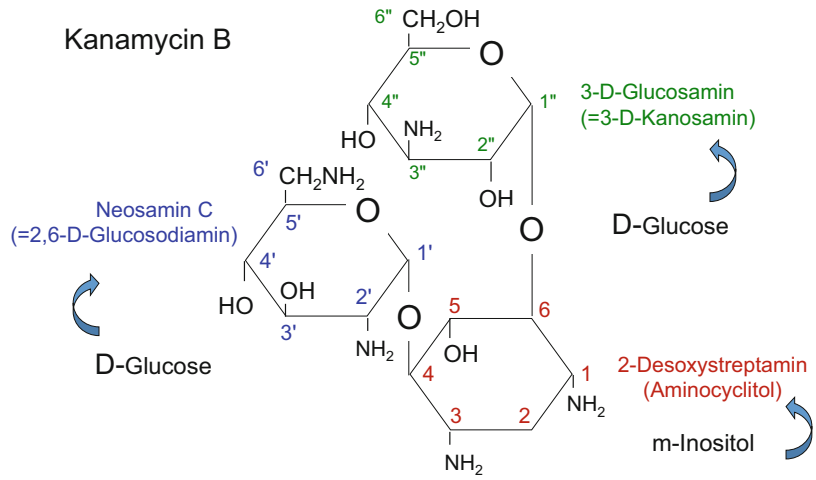
Resistance by Enzymatic Modification of Aminoglycoside-Aminocyclitol Antibiotics Streptomycin, the first aminoglycosid antibiotic which was isolated by Waksman et al. in 1943 from soil bacteria of the genus *Streptomyces*, was introduced into clinical use within 1 year due to its potent inhibitory activity against *Mycobacterium tuberculosis*. The isolation of several other aminoglycosides from species of the genera *Streptomyces* (e.g., kanamycin, neomycin, spectinomycin, tobramycin) and *Micromonospora* (e.g., gentamicin, isepamicin, sisomicin) followed. Except for streptomycin and apramycin, the core structural elements of clinically relevant antibiotics are the aminocyclitol 2-deoxystreptamine). It is linked by glycosidic bonds via the C4 and either the C5 or C6 position to two amino sugars. Consequently, they are named aminoglycoside-aminocyclitol antibiotics. Beside *M. tuberculosis*, their broad spectrum of activity includes many Gram-negative and several

Gram-positive pathogens. These highly hydrophilic compounds require an intravenous route of application.

Aminoglycosides act by specifically binding to the 30S subunit of the bacterial ribosome by interacting with the positively charged amino groups with negatively charged groups (e.g., phosphate) of ribosomal RNA regions in the aminoacyl-(A) site. The consequence is a deformation of the mRNA-tRNA binding site resulting in a less specific codon-anticodon interaction. This affects the discrimination between cognate and noncognate tRNA anticodons leading to an increase of misincorporated amino acids in growing peptide chains. Finally, such defect proteins are rapidly degraded or are inserted into membranes as misfolded membrane components which cause membrane disruption favoring an increased uptake of aminoglycosides and finally cell death.

Resistance to aminoglycoside-aminocyclitol antibiotics is a vital feature of bacterial producers of these antibiotics. The most effective strategy with a low impact of the producers' metabolism is the synthesis of an inactive precursor, which is activated after its export to the environment. This self-protecting strategy has been detected in the streptomycin producer *Streptomyces griseus*: it secretes the inactive phosphorylated streptomycin derivative together with a phosphatase, which activates the antibiotic outside the cell (Trieu-Cuot and Courvalin 1986).

Presumably, the gene for this streptomycin-modifying enzyme has been transferred to other bacteria which then have become resistant. Beside such aminoglycoside-O-phosphorylating (APH) enzymes which use ATP as cofactor, two other classes of aminoglycoside-modifying enzymes (AME) are known: aminoglycoside-O-nucleotidylating enzymes (ANT) and aminoglycoside-N-acetylating enzymes (AAC) using ATP and acetyl-CoA as cofactor, respectively. As a result, positively charged amino groups are masked, or hydroxy groups become negatively charged, both modifications interfering with the binding of the drug to its ribosomal target. Depending upon the pattern of substituents of the specific aminoglycoside, AMEs with different specificities are required to modify relevant functional groups. Thus, a broad variety of different AMEs have been identified in different pathogens. But, as a consequence, the presence of one specific AME does not necessarily mediate resistance to all aminoglycoside antibiotics (lack of cross-resistance). Thus, enzymes of one class are further subdivided according to their substrate specificity which is indicated as the position of the functional group modified. For example, among the AAC enzyme class, the AAC(6′) enzyme transfers an acetyl moiety to the 6′-amino group of, e.g., the amino sugar 2,6-D-glucosamine attached with the C4-OH via an O-glycosidic bond to the central aminocyclitol 2-deoxystreptamine (Fig. 11). The different AME subclasses are further divided into



Bacterial Resistance to Antibiotics, Fig. 11 Structural formula of kanamycin B and positions of enzymatic modification

molecular classes according to the degree of DNA homology of the respective gene, e.g., AAC(6′)-I and AAC(6′)-II, etc. Due to the restricted spectrum of activity of one subclass of AME, full resistance to all aminoglycosides is not found. However, since the genes encoding AMEs are located on transferable extrachromosomal elements, such as plasmids, combinations of AME genes may mediate a broad-spectrum resistance (Shaw et al. 1993; Vakulenko and Mobashery 2003).

Another mechanism of action to aminoglycosides is a mutational alteration of key residues associated with the ribosomal binding site. This mechanism is found for streptomycin in *M. tuberculosis* as a mutation altering the *rpsL* gene product which is part of the small ribosomal subunit.

Natural, i.e., primary resistance to all aminoglycoside antibiotics, is found in all anaerobic pathogens due to the fact that the uptake of the drugs into the cell requires a high membrane potential across the cytoplasmic membrane, only found under aerobic conditions.

Conclusion

During the period of antibiotic use, the introduction of a new antibiotic, either of natural origin or by pure chemical synthesis, was rapidly followed by the emergence of resistant bacteria.

The previous human counterstrategies, such as chemical modification of antibiotics, expanding the target preference (dual or multiple targeting strategy), combination of antibiotics showing different modes of action, and addition of inhibitors of enzymatic resistance mechanisms, have all proved to be ineffective after a short period of successful clinical use.

Thus, continuing to develop novel antibiotics combined with strategies, such as antibiotic stewardship programs, rapid diagnosis of present and developing resistance mechanisms as early as possible and antibiotic cycling will help to slower the development of resistance. However, considering the more than 2 billion-year-old presence of bacteria – and their resistance – on earth, these measures will not continuously abolish development of resistance and continue to provide a great challenge for successful anti-infective therapy.

Bacterial Toxins

Gudula Schmidt and Klaus Aktories
Institut für Experimentelle und Klinische Pharmakologie und Toxikologie, Albert-Ludwigs-Universität Freiburg, Freiburg, Germany

Uptake

Protein toxins acting intracellularly are often composed of two subunits (A/B model). One subunit is catalytic (A-subunit) and the other is responsible for binding and cell entry (B-subunit). Following binding to an extracellular membrane receptor, the toxins are endocytosed. From the endosomes, the A-subunit is directly (pH dependent) transferred into the cytosol (e.g., diphtheria toxin and anthrax toxin) or the toxin is transported in a retrograde manner via the Golgi to the ER (e.g., cholera toxin), where translocation into the cytosol occurs (Schiavo and van der Goot 2001).

Mechanism of Action

Toxins Modifying Target Proteins

Protein toxins of this type are generally very potent and efficient, because they act catalytically on specific substrates. The toxins usually activate or inactivate key eukaryotic proteins involved in essential cellular functions by covalent modification. One subfamily catalyzes the ADP-ribosylation of target proteins. For unknown reasons, many toxins of this subfamily modify eukaryotic GTPases. Examples are the diphtheria toxin from toxigenic *Corynebacterium diphtheriae* and the *Pseudomonas aeruginosa* exotoxin A, which ADP-ribosylate elongation factor 2 at diphthamide to cause inhibition of protein synthesis (Table 1). Pertussis toxin from *Bordetella pertussis* and cholera toxin from *Vibrio cholerae* act on heterotrimeric G proteins. Pertussis toxin consists of the catalytic subunit S1 and five binding subunits (S2, S3, 2 × S4, and S5) with masses of ~11–26 kDa. Cholera toxin consists of a ~28 kDa A-subunit and five B-subunits (~12 kDa). Although pertussis toxin ADP-ribosylates the α-subunits of the G_i subfamily of G proteins (exception G_z) at a cysteine residue, cholera toxin and the related *E. coli* heat labile toxins ADP-ribosylate α-subunits of the G_s subfamily at an arginine residue. Pertussis toxin–induced ADP-ribosylation blocks the interaction of the G protein with heptahelical receptors (GPCR). The ADP-ribosylation of G_s inhibits intrinsic GTPase activity and persistently activates the G protein. Increase in cellular cAMP, activation of protein kinase A, and subsequent disturbance of cellular electrolyte secretion is suggested to be the cause of cholera toxin–induced diarrhea. A recently characterized class of toxins (toxin complexes, TC) is produced by the entomopathogenic bacterium *Photorhabdusluminescens*. It resembles a megadalton protein machinery able to mechanically inject a toxic enzyme into target cells, which can be insect cells as well as mammalian cells. Some enzymes are identified as ADP-ribosyltransferases which modify actin (leads to actin clustering) and Rho GTPases (leads to constitutive activation), respectively (Schiavo and van der Goot 2001).

Small GTPases of the Rho family are ADP-ribosylated (e.g., at Asn41 of RhoA) and inactivated by C3-like toxins from *Clostridium botulinum*, *Clostridium limosum*, and *Staphylococcus aureus*. These proteins have a molecular mass of 23–30 kDa and consist of the enzyme domain exclusively. Specific inhibition of Rho functions (Rho but not Rac or Cdc42 are targets) is the reason why C3 is widely used as a pharmacological tool (Aktories 2011).

Another subfamily of ADP-ribosylating toxins modifies G-actin (at Arg177), thereby inhibiting actin polymerization. Members of this family are, for example, *Clostridium botulinum* C2 toxin, *Clostridium perfringens* iota toxin, and *Clostridium* (recently renamed *Clostridioides*) *difficile* transferase CDT. These toxins are binary in structure. They consist of an enzyme component and a separate binding component, which is structurally related to the binding component of anthrax toxin (Aktories et al. 2011).

Bacterial Toxins, Table 1 Intracellularly acting exotoxins

Toxin	Protein substrate	Activity	Functional consequences
Diphtheria toxin, *Pseudomonas* exotoxin A	Elongation factor 2	ADP-ribosylation	Inhibition of protein synthesis (diphtheria, *Pseudomonas* infection)
Cholera toxin, heat labile *E. coli* toxins	G_s proteins	ADP-ribosylation	Activation of adenylate cyclase (cholera, "traveler"-diarrhea)
Pertussis toxin	$G_{i,o}$ proteins	ADP-ribosylation	Inhibition of G protein signaling (whooping cough)
C. botulinum C2-toxin and related toxins	Actin	ADP-ribosylation	Inhibition of actin polymerization
C. botulinum C3-toxin and related toxins	Rho proteins	ADP-ribosylation	Inhibition of RhoA, B,C Destruction of the cytoskeleton
E. coli CNF1, 2 and 3, *Yersinia* CNFy	Rho proteins	Deamidation	Activation of RhoA, (Rac, Cdc42)
Bordetella DNT	Rho proteins	Transglutamination	Activation of RhoA, Rac, Cdc42
Pasteurella multocida toxin PMT	$G_{q/11}$, $G_{i,o}$ $G_{12/13}$ proteins	Deamidation	Activation of the G proteins
C. difficile toxin A and B	Rho proteins	Glucosylation	Inactivation of Rho proteins Destruction of the cytoskeleton
Photorhabdus luminescens Toxin complex *PTC3* *PTC5*	(3) Actin (5) Rho proteins	ADP-ribosylation	(3) Forced, unregulated actin clustering (5) Activation of RhoA, Rac, Cdc42
Botulinum neurotoxins (A–G), tetanus toxin	Synaptic peptides: (a) Synaptobrevin (b) Syntaxin (c) SNAP25	Zinc-dependent endoprotease	Cleavage of synaptic peptides Inhibition of transmitter release (tetanus, botulism)
Shiga toxins and related toxins from *E. coli*	No proteins (!) 28S rRNA	*N*-glycosidase	Cleavage of 28S rRNA Inhibition of protein synthesis
Anthrax toxin Lethal factor	MEKs	Endoprotease Increase in intracellular cAMP	Inhibition of MAP-kinase pathways Calmodulin-dependent adenylylcyclase

The above-mentioned Rho GTPases are glucosylated by the family of clostridial glucosylating cytotoxins. Important members of this toxin family are *Clostridium* (*Clostridioides*) *difficile* toxins A and B, which are implicated in antibiotics-associated diarrhea and pseudomembranous colitis. The large clostridial cytotoxins are single-chain toxins with molecular masses of 250–308 kDa. The enzyme domain is located at the N terminus. The toxins are taken up from an acidic endosomal compartment. They glucosylate RhoA at Thr37; also, Rac and Cdc42 are substrates. Other members of this toxin family such as *Clostridium sordellii* lethal toxin possess a different substrate specificity and modify Rac but not Rho. In addition, Ras subfamily proteins (e.g., Ras, Ral, and Rap) are modified. As for C3, they are widely used as tools to study Rho functions (Aktories 2011; Aktories et al. 2017).

Rho GTPases are activated by cytotoxic necrotizing factors 1, 2, and 3 (CNF1, 2, 3) from *Escherichia coli*, CNFy from *Yersinia pseudotuberculosis*, and by the dermonecrotic toxin (DNT) from *Bordetella*. CNF1 to 3 are more than 90% identical, whereas the more distantly related CNFy has ~60% sequence identity with CNF1. All four toxins are single-chain proteins with molecular masses of about 115 kDa. Their cell-binding domains are located at the N terminus and the catalytic domain at the C terminus of the

toxins. DNT is a protein of ~160 kDa that shares significant homology with CNFs in the catalytic domain. All these toxins activate the small GTP-binding proteins of the Rho family by deamidation (CNFs) and transglutamination (DNT) of a specific glutamine residue (Gln63 in case of RhoA), which is necessary for GTP hydrolysis. Moreover, the inactivation of Rho GTPases by GTPase-activating protein (GAP) is blocked by CNFs and DNT. According to the functions of Rho GTPases, the toxins cause formation of stress fibers, filopodia, and membrane ruffles, and induce cell flattening and multinucleation. The role of CNFs in the pathogenesis of *E. coli* infections is still unclear. CNFs and DNT induce dermonecrosis after intradermal application (Hoffmann and Schmidt 2004). The ~146 kDa *Pasteurella multocida* toxin (PMT) shares the deamidation reaction with CNFs. Similarly, it deamidates a crucial glutamine residue involved in GTP hydrolysis but targets are heterotrimeric G_q, G_i, and $G_{12/13}$ proteins, which are activated by deamidation. PMT activates osteoclasts and inhibits osteoblasts and thereby is responsible for bone loss in atrophic rhinitis of pigs (Aktories 2011).

The anthrax toxin is a tripartite toxin and consists of the binding component protective antigen (PA), the lethal factor (LF), which is a metalloprotease, and the edema factor (EF), which is a calmodulin-dependent adenylylcyclase. Both enzyme components are translocated via PA into target cells. PA is activated by furin-induced cleavage and forms heptamers, which are similar to the binding components of C2 toxin and iota toxin. In the low pH compartment of endosomes, the heptamers form pores to allow translocation of LF and EF. LF cleaves six of the seven MEKs (MAPK-kinases), thereby inhibiting these enzymes. The functional consequence is the blockade of the MAPK pathways that control cell proliferation, differentiation, inflammation, stress response, and survival. Whether this is the reason for the LT-induced cell death of macrophages is not clear (Schiavo and van der Goot 2001).

Shiga toxin is produced (i) by *Shigella dysenterica*, the cause of bacillary dysentery, (ii) by certain *E. coli* strains (EHEC, enterohaemorrhagic *E. coli*; cause of the hemolytic uremic syndrome, HUS), and (iii) by various enterobacteriaceae (e.g., *Enterobacter cloacae*). The toxin consists of an A-subunit (~32 kDa) and a pentameric B-subunit (7.7 kDa each). The toxin enters cells after retrograde transport to the Golgi. In the cytosol, the A-subunit acts as an *N*-glycosidase to remove one adenine residue in position 4324 of the 28S rRNA at the ribosome and blocks protein biosynthesis (Schiavo and van der Goot 2001).

Clostridial neurotoxins are mainly two-chain toxins having a ~50 kDa enzyme component and a ~100 kDa binding/translocation subunit. They are the cause of botulism, a generalized flaccid paralysis of skeletal muscles, mainly acquired by foodborne poisoning, and tetanus, which occurs subsequent to wound infection. Botulism is induced by *C. botulinum* neurotoxins types A, B, C1, D, E, F, and G. Tetanus is induced by tetanus toxin from *Clostridium tetani*. The toxins belong to the most potent agents known. About 1 ng of botulinum neurotoxin per kg body mass may be lethal for man or animal. The toxins are zinc metalloproteases and cleave synaptic peptides involved in transmitter release. Botulinum neurotoxins B, D, F, and G and tetanus toxin cleave synaptobrevin; neurotoxins A and E cleave SNAP25, and neurotoxin C cleaves syntaxin. The botulinum neurotoxins induce flaccid muscle paralysis (botulism) because they act presynaptically at the peripheral neuromuscular junction to block acetylcholine release. Tetanus toxin is taken up at the neuromuscular junction but is then transported in a retrograde manner to the spinal cord. Within the spinal cord, tetanus toxin migrates to interneurons and blocks the release of inhibitory transmitters to cause spastic paralysis (Schiavo and van der Goot 2001).

Bacterial Phospholipases

The α-toxin from *C. perfringens* is involved in the pathogenesis of gas gangrene and the sudden death syndrome of young animals. This toxin is a zinc metalloenzyme with phospholipase activity. Other phospholipase C-toxins are from *Listeria monocytogenes* and *Mycobacterium tuberculosis*. The phospholipase C-toxin from

Bacillus cereus is specific for phosphatidylinositol. It cleaves phosphatidylinositol and its glucosyl derivatives. In cell biology, this toxin can be used as a tool to study whether a protein is anchored to GPI. A second phospholipase C-toxin produced by *B. cereus* is specific for sphingomyelin. Cleavage of sphingomyelin generates ceramide, a second messenger involved in processes like apoptosis and differentiation.

Pore-Forming Toxins

Pore-forming toxins act by punching holes into mammalian cell membranes. Many different types are known. They can be divided into small and large pore-forming toxins. Pore-forming toxins oligomerize in the plasma membrane of the mammalian cell to build circular structures. These ring-like structures can be composed of a few molecules, generating small pores that allow the exchange of ions and nucleotides (*Aeromonas* aerolysin, *S. aureus* α-toxin). Large pores, which allow the passage of peptides or proteins are formed by toxins which insert up to 50 molecules into the plasma membrane generating a pore with up to 35 nm diameter. Examples for such toxins are *Streptococcus pyrogenes* streptolysin O or *C. tetani* tetanolysin.

Injected toxins (often called "effectors") are directly delivered into the cytosol of eukaryotic target cells mostly involving the bacterial type III or IV secretion systems. The pathogens (e.g., *P. aeruginosa*, *Yersinia*, and *Salmonella*) produce a set of proteins that are delivered into mammalian cells by complex secretion machines depending on the direct contact between bacterium and host cells. Some of these injected toxins (e.g., Yops in the case of *Yersinia*) do not covalently modify mammalian targets but act as modulators on important signal transduction pathways; they act as molecular mimics of cellular proteins. For example, they regulate the activity of small GTP-binding proteins as exchange factors to activate the small G proteins or as activators of GTP-hydrolysis to inhibit them. Notably, *Salmonella* produces two contrary acting molecular mimics. They inject an activator of Rho GTPases (SopE) to induce ruffling and the uptake of the bacteria into the mammalian cell, and they inject an inactivator of Rho GTPases (SptP) probably to switch off the induced cytoskeletal rearrangements.

Superantigens

Like physiological ligands, bacterial toxins can influence cells by binding to cell surface molecules. Best known are the superantigens produced by *Staphylococcus* strains. Superantigens are bivalent molecules that bind to the major histocompatibility complex (MHC) class II and to the variable regions of the T-cell receptor. This bridging leads to the activation of the T-cell receptor in the absence of an antigenic peptide. This unspecific activation of T-cells is followed by a massive release of cytokines, which is thought to play a role in diseases like toxic shock syndrome and some exanthemas.

Clinical Uses

Botulinum neurotoxins are widely used as therapeutic agents to cause reduction or paralysis of skeletal muscle contraction. They are used to treat cervical dystonia, which causes regional involuntary muscle spasms often associated with pain. Moreover, they are used in strabism, blepharospasm, hemifacial spasm, and achalasia. Meanwhile, a number of studies indicate efficacy for botulinum toxin for the treatment of tension headache, but further studies are necessary to demonstrate its short-term and long-term efficacy. Botulinum toxin is also used as a cosmetic agent and the effects occur a few days after injection into the muscle and last for several months. The treatment can be repeated several times without major development of antineurotoxin antibodies. In the case of antineurotoxin antibody production, the treatment is continued with a different botulinum neurotoxin.

Some toxins (e.g., the diphtheria toxin) fused to antibodies are used as immunotoxins against cell surface molecules, for example, to deplete T-cells as targeted therapy for cutaneous T-cell lymphoma. The use of bacteria with the type III secretion system (e.g., *Salmonella*) producing only an injected toxin-antigen fusion protein as

live vaccines is under current investigation. The aim is to directly deliver protein fragments into antigen-presenting cells in order to improve immunization.

Benzodiazepine

Uwe Rudolph
Department of Comparative Biosciences, College of Veterinary Medicine, University of Illinois at Urbana-Champaign, Urbana, IL, USA

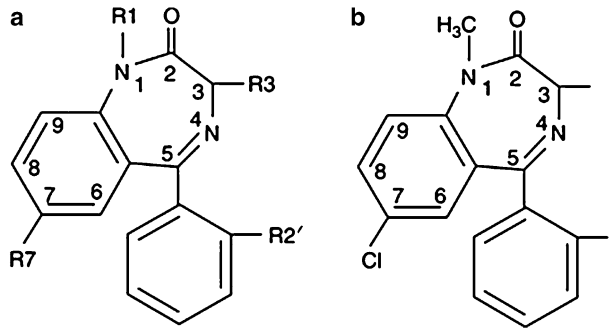
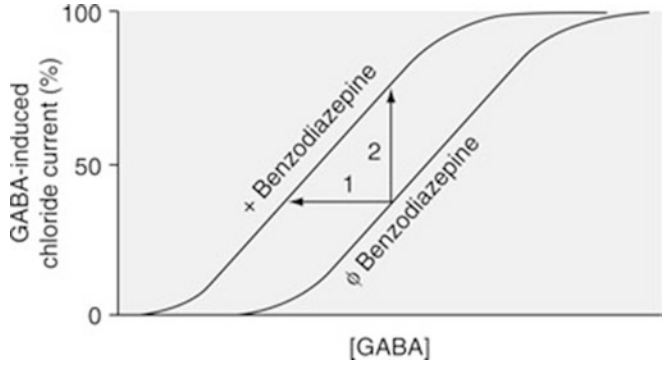
Definition

The term benzodiazepine refers to a chemical structure, consisting of a heterocyclic ring system in which the two N atoms are mostly located in positions 1 and 4 (1,4-benzodiazepines), e.g., in diazepam (Fig. 1b). Benzodiazepines have found wide therapeutic applications as anxiolytics, sedatives, hypnotics, anticonvulsants, and central muscle relaxants (Balon et al. 2018; Engin et al. 2018; Mohler et al. 2002; Rudolph and Knoflach 2011; Shader and Greenblatt 1993).

Mechanism of Action

GABA is the major inhibitory neurotransmitter in the mammalian central nervous system. Its fast synaptic actions are mediated by $GABA_A$ receptors, which are located on postsynaptic membranes. $GABA_A$ receptors have a central pore, with selectivity for chloride ions. Upon binding of GABA to $GABA_A$ receptors, negatively charged chloride ions flow into the postsynaptic





Benzodiazepine, Fig. 1 (**a**) Chemical structure of classical [1,4] benzodiazepines. R1, R2, R2', R3, and R7 denote variable substituents. (**b**) Chemical structure of the prototypical benzodiazepine diazepam

Benzodiazepine, Fig. 2 Schematic representation of the potentiation of the GABA-induced chloride current by benzodiazepines. The GABA dose–response curve is shifted to the left in the presence of benzodiazepines (arrow 1). The chloride current which is induced by a submaximal concentration of GABA is increased (arrow 2). Benzodiazepines are effective only in the presence of GABA (use-dependence) and cannot increase the inhibition by high concentrations of GABA (self-limiting action)

neuron, leading – in most cases – to hyperpolarization of the postsynaptic membrane and thus functional inhibition. In addition to a binding site for the physiological neurotransmitter GABA, most $GABA_A$ receptors contain binding sites for allosteric modulators, e.g., benzodiazepines, barbiturates, and neurosteroids. Benzodiazepines bind to a common modulatory site that is called benzodiazepine site. However, the ligands of the benzodiazepine site are not limited to ligands with a benzodiazepine structure. For example, the imidazopyridine zolpidem, a widely used hypnotic, also binds to the benzodiazepine site. The basic mechanism of action of benzodiazepines and nonbenzodiazepines acting via the benzodiazepine site appears to be the same. The binding of a benzodiazepine to the benzodiazepine site of the $GABA_A$ receptor enhances GABAergic inhibition by increasing the opening frequency of the GABA-gated ion channel. This leads to a shift of the GABA dose–response curve to the left, so that at any given concentration of GABA, the response is increased (Fig. 2). This can also be viewed as an increase in the affinity of GABA for the receptor. The action of benzodiazepines is use-dependent and self-limiting. Use-dependence indicates that benzodiazepines are only active in the presence of GABA. In the absence of GABA, benzodiazepines do not have an effect on their own, i.e., their action is dependent on the precondition that GABA is present and the respective synapse thus in use. Furthermore, benzodiazepines are not able to increase the response to GABA beyond its physiological maximum at high GABA concentrations, which is referred to as the self-limiting nature of their

action. The magnitude of the effect of benzodiazepines depends on the amount of GABA present in the synapse or in the extrasynaptic space and, hence, synaptic activity or activity mediated by extrasynaptic receptors. The self-limiting feature may help explain why the enhancement of GABA transmission by benzodiazepines is typically safe even at high doses, whereas overdoses with drugs that do not display this self-limiting feature, e.g., barbiturates, are life-threatening.

Subtype Specificity of BZ Actions

$GABA_A$ receptors that contain the α1, α2, α3, and α5 subunits in combination with β and γ subunits can bind classical benzodiazepines, e.g., diazepam, whereas $GABA_A$ receptors that contain the α4 and α6 subunits do not bind classical benzodiazepines. Essentially, all benzodiazepines that are currently in clinical use bind indiscriminately to $GABA_A$ receptors that contain the α1, α2, α3, and α5 subunits. The only clinically used drug that displays a significant subtype selectivity is the imidazopyridine hypnotic, zolpidem. Zolpidem has a high affinity at $GABA_A$ receptors containing the α1 subunit, an intermediate affinity at $GABA_A$ receptors containing the α2 or α3 subunits, and no affinity at $GABA_A$ receptors containing the α5 subunit. The $GABA_A$ receptor subtype specificity of benzodiazepine actions was assessed in genetically engineered mice. Whereas the diazepam-sensitive α1, α2, α3, and α5 subunits have a histidine residue in a conserved position in the N-terminal extracellular domain (H101 in α1, H101 in α2, H126 in α3, H105 in α5), the diazepam-insensitive α4 and α6 subunits have an arginine residue at the homologous position. By mutating the conserved histidine residue in the α1, α2, α3, and α5 subunits to arginine residues, the $GABA_A$ receptors containing the respective subunits were rendered diazepam-insensitive. Using this approach, it was discovered that the sedative and anterograde amnesic action of diazepam, and in part also the anticonvulsant action of diazepam, is mediated by $GABA_A$ receptors containing the α1 subunits, while the anxiolytic action of diazepam is mediated by $GABA_A$ receptors containing the α2 subunit. The central muscle relaxant action of diazepam is mediated by $GABA_A$ receptors containing the α2 or α3 subunits (Fig. 3) (Balon et al. 2018; Engin et al. 2018; Mohler et al. 2002; Rudolph and Knoflach 2011; Shader and Greenblatt 1993). The anxiolytic-like action of diazepam is observed at much lower doses than the muscle relaxant action. Interestingly, $GABA_A$ receptors containing the α3 subunit were not involved in mediating the anxiolytic-like action of diazepam in ethological tests of anxiety, indicating that this response is not dependent on neurons in the reticular activating system, where the α3 subunit is expressed. These findings demonstrate that subtype-selective drugs are likely to be

α1	α2	α3	α5
Sedation	Anxiolysis	Sensorimotor gating	Sensorimotor gating
Amnesia	Fear reduction	Myorelaxation	Cognitive impairment
Anticonvulsant	Myorelaxation	Antihyperalgesia	(low interference tasks)
Dependence liability	Antihyperalgesia	Itch suppression	Cognitive improvement
	Itch suppression		(high interference tasks)
			Anxiolysis
			Antidepressant

Benzodiazepine, Fig. 3 Benzodiazepine actions mediated by $GABA_A$ receptor subtypes. α1, α2, α3, or α5 indicates α1-, α2-, α3- or α5-containing $GABA_A$ receptors

of benefit, e.g., as anxiolytics without sedative side effects.

Interestingly, while the sedative action of diazepam is mediated by $GABA_A$ receptors containing the α1 subunit, its REM sleep inhibiting action, its enhancement of sleep continuity, and its effect on the EEG spectra in sleep and waking are mediated by $GABA_A$ receptors that do not contain the α1 subunit, indicating that the hypnotic effect of diazepam and its EEG fingerprint can be dissociated from its sedative action, defined as reduction of motor activity.

Several compounds have been developed which have activity at α2-containing (and also other) $GABA_A$ receptors but not at α1-containing $GABA_A$ receptors, e.g., L-838,417, which is a partial agonist at $GABA_A$ receptors containing the α2, α3, and α5 subunits, but has no activity at $GABA_A$ receptors containing the α1 subunit. This compound is active as an anxiolytic and anticonvulsant, but apparently does not impair motor performance (Rudolph and Knoflach 2011). The compound TPA023B has been tested in Phase 1 and Phase 2 studies, which were stopped prematurely as high doses of the related compound TPA023 were found to lead to cataracts and which were compatible with an anxioselective profile. These compounds have also been found to have antihyperalgesic actions in various rodent pain models, e.g., of inflammatory pain and of neuropathic pain, which are mediated by α2-, α3- and α5-containing $GABA_A$ receptors. TPA023B also reduces itching in mice and in dogs.

Positive and Negative Allosteric Modulators

Drugs that bind to the benzodiazepine site of the $GABA_A$ receptor and enhance GABA responses are termed positive allosteric modulators (or agonists). Essentially all ligands at the benzodiazepine site that are in clinical use are positive allosteric modulators. In contrast, negative allosteric modulators (or inverse agonists) diminish GABA responses. They are not in clinical use and have effects opposite to those of the positive allosteric modulators, e.g., they are convulsant and anxiogenic.

The Antagonist Flumazenil

Although flumazenil binds with high affinity to the benzodiazepine site of $GABA_A$ receptors, it has practically no action when given alone. However, flumazenil competitively blocks the action of benzodiazepine site positive allosteric modulators. Flumazenil can be used to (temporarily) terminate the action of benzodiazepines, e.g., after a benzodiazepine overdose. It may also serve as a diagnostic tool in this regard.

Pharmacokinetic Considerations

The benzodiazepines currently on the market differ in their pharmacokinetic properties, in particular, the duration of action, which guides the use of the drug to be used. The half-life is largely determined by the rate of metabolic degradation of the parent drug. In addition, long-acting metabolites (e.g., desmethyldiazepam) are generated that may contribute to the duration of action. Short-acting drugs might be used for patients with difficulties to fall asleep, with the expectation that there is no hangover effect on the next day. Long-acting drugs may be used if reawakening during the entire night is to be prevented. Short-acting benzodiazepines may have a half-life in the range of 2–6 h, e.g., midazolam, triazolam, and oxazepam; medium-acting benzodiazepines a half-life in the range of 10–12 h, e.g., lorazepam and lormetazepam; and long-acting benzodiazepines a half-life in the range of 20–50 h, e.g., diazepam and clobazam.

Clinical Use

Benzodiazepines are among the most frequently prescribed drugs; they have well-established uses in the treatment of anxiety disorders (anxiolytics) and insomnia, preanesthetic sedation, sedation and amnesia during medical procedures, suppression of seizures, and muscle relaxation.

Benzodiazepines such as alprazolam are used as tranquilizers to relieve anxiety states, e.g., in generalized anxiety disorder and panic attacks. The anxiolytic effects are observed at low doses, suggesting that only a small number of $GABA_A$

receptors need to be modulated to obtain the anxiolytic effect. As outlined previously, this action is, most likely, mediated by α2-containing $GABA_A$ receptors. In contrast, higher doses of benzodiazepines and thus a higher receptor occupancy are needed for the sedative action of diazepam, which is mediated by α1-containing $GABA_A$ receptors. When diazepam is used as an anxiolytic, sedative side effects are frequently troublesome. The reduction of the reactivity to external stimuli is the basis for the use of benzodiazepines as hypnotics in the treatment of sleep disorders. The anticonvulsant activity of diazepam can be explained by the GABAergic inhibition of neuronal responsiveness to excitatory inputs. Benzodiazepines (lorazepam and diazepam) are among the drugs of choice in the treatment of status epilepticus. Their use in the chronic treatment of epilepsy (e.g., clonazepam) is limited by the development of tolerance.

The definition of desired therapeutic and side effects in the case of the benzodiazepines very much depends on the clinical problem in question. The sedative and hypnotic actions are desired effects in the treatment of insomnia, but undesired effects in the treatment of anxiety disorders. Effects that are usually undesired include daytime drowsiness and potentiation of the sedative effects of ethanol. Anterograde amnesia is a desired when benzodiazepines are used during medical procedures. The known effects of benzodiazepines are mediated via the benzodiazepine site of $GABA_A$ receptors, since they can be antagonized with flumazenil. Repeated administration may lead to the development of tolerance to certain benzodiazepine effects; in particular, to the sedative, anticonvulsant, and muscle relaxant effects; and to the development of physical dependence, which can include withdrawal anxiety, insomnia, convulsions, and sensory hyperactivity and thus be similar to the symptoms that lead to the treatment. To avoid withdrawal symptoms, chronic treatment is discontinued by gradually tapering out the dose over a long period of time. The neurobiological nature of the adaptive changes, which occur after long-term treatment or withdrawal from long-term treatment, is poorly understood. Because of the adaptive changes that occur under chronic treatment, the long-term use of benzodiazepines is generally not recommended. For treatment of insomnia, benzodiazepines should not be given for more than, e.g., 4 weeks. For the treatment of anxiety disorders, benzodiazepines should not be used for more than, e.g., 6 months. Because of their potentiation of the sedative action of ethanol, benzodiazepines should not be used in patients with alcohol abuse. Likewise, the potential non-therapeutic use of benzodiazepines, for the purpose of euphoria, has to be kept in mind, and particular care should be taken while treating patients with a history of drug abuse. Benzodiazepines are frequently co-abused together with opioids, increasing the mortality of opioid abuse, potentially at least in part due to their respiratory depressant actions.

Blood Pressure Control

Reinhold Kreutz and Engi Abd el-Hady Algharably
Charité - Universitätsmedizin Berlin, corporate member of Freie Universität Berlin, Humboldt-Universität Berlin, and Berlin Institute of Health, Institute of Clinical Pharmacology and Toxicology, Berlin, Germany

Synonyms

Control of hypertension; Physiology of blood pressure

Definition

The blood pressure represents the tension or pressure of the blood within the arteries that is exerted against the arterial wall in vivo. Blood pressure is a quantitative trait that is highly variable. In population studies, blood pressure has a normal distribution that is slightly skewed to the right. The regulation of blood pressure within the intravascular system is a complex interaction of a number of systems and mechanisms. Raised blood pressure or hypertension is a substantial global health problem and continues to be the leading contributor to global burden of disease and mortality affecting over 1 billion adults worldwide (Global, regional, and national comparative risk assessment of 84 behavioural, environmental and occupational, and metabolic risks or clusters of risks for 195 countries and territories, 1990–2017: a systematic analysis for the Global Burden of Disease Study 2017 2018).

Despite important advances in our understanding of the pathophysiology of hypertension and the availability of effective treatment strategies, it still remains the leading modifiable risk factor for cardiovascular and renal disease. There is no specific level of blood pressure where clinical complications start to occur; thus the definition of hypertension is arbitrary but needed in clinical practice for patient assessment and treatment.

The relevance of clinical conditions with chronic low blood pressure or hypotension has been questioned, with the exception of a few rare clinical syndromes. Temporary increases or decreases of blood pressure are often seen in clinical medicine in the context of acute illnesses or interventions.

Basic Mechanisms

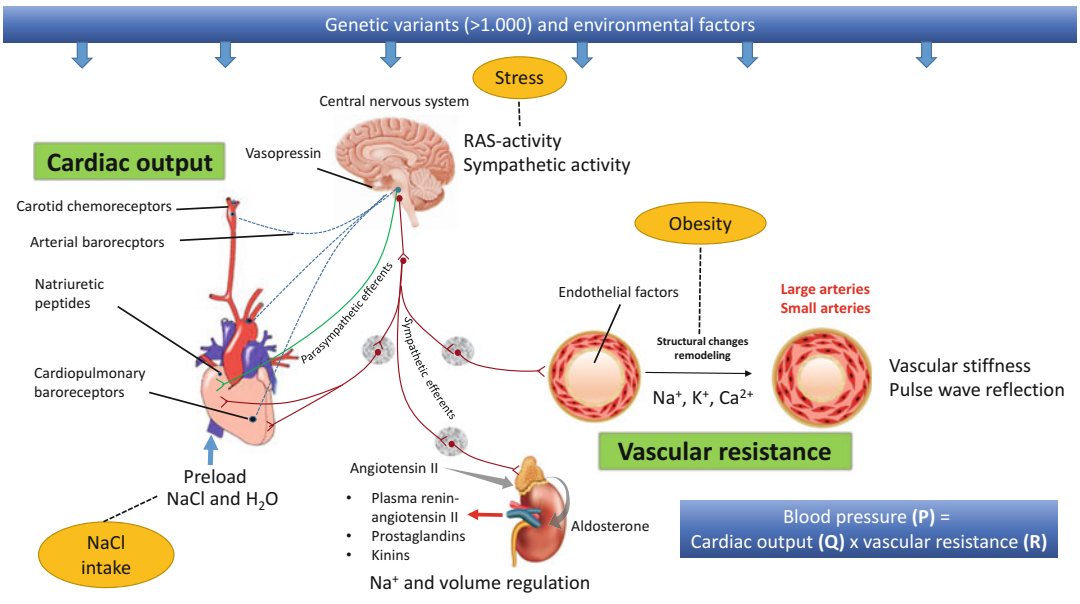
The circulation is divided into several compartments: the high-pressure arterial circuit, which contains 13% of the blood volume, the capillary bed containing 7% of the blood volume, and the low-pressure venous bed, which contains 64% of the blood volume. The pulmonary circulation contains 9% and the heart 7% of the blood volume. Although the venous system stores and propels large volumes of blood and regulates cardiac output by venous return to the heart, in considering blood pressure control, attention is focused on the high-pressure arteries. The basic function of the circulation is to provide nutrients to peripheral tissues. Blood vessels in local tissue beds regulate blood flow in relation to local needs. Blood flow (Q) is defined by Ohm's law and varies directly with the change in pressure (P) across a blood vessel and inversely with the resistance R ($Q = P/R$). It can be seen that pressure varies directly with blood flow and resistance ($P = QR$). Blood pressure is produced by the contraction of the left ventricle (producing blood flow) and by the resistance of the arteries and arterioles. Systolic pressure, or maximum blood pressure, occurs during left ventricular systole. Diastolic pressure, or minimum blood pressure, occurs during ventricular diastole. The difference between systolic and diastolic pressure is the pulse pressure (Systolic and Diastolic Blood Pressure and Pulse Pressure).

Although blood pressure control follows Ohm's law and seems to be simple, it underlies a complex circuit of interrelated systems. Hence, numerous physiologic systems that have pleiotropic effects and interact in complex fashion have been found to modulate blood pressure. Because of their number and complexity, it is beyond the scope of the current account to cover all mechanisms and feedback circuits involved in blood pressure control. Rather, an overview of the clinically most relevant ones is presented. These systems include the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, a variety of humoral factors, and molecular events at the cellular level. They are intertwined to maintain adequate tissue perfusion and nutrition. Normal blood pressure control can be related to cardiac output and the total peripheral resistance. The stroke volume and the heart rate determine cardiac output. Each cycle of cardiac contraction propels a bolus of about 70 ml blood into the systemic arterial system. As one example of the interaction of these multiple systems, the stroke volume is dependent in part on intravascular volume regulated by the kidneys as well as on myocardial contractility. The latter is, in turn, a complex function involving sympathetic and parasympathetic control of heart rate; intrinsic activity of the cardiac conduction system; complex membrane transport and cellular events requiring influx of calcium, which lead to myocardial fiber shortening and relaxation.

The ejection of blood into the aorta during systole acutely dilates the aortic wall and generates a pressure wave through the arterial tree, the velocity of which is a measure of arterial compliance. Aortic stiffening is associated with increased pulse wave velocity (PWV) as well as increased pulse wave reflection back to the heart at the end of the systole increasing the afterload and systolic blood pressure (Safar et al. 2018). On the other hand, a difference in PWV between distal and proximal arteries (impedance mismatch) protects small arteries and microcirculation from excessive pulsatility, a protective mechanism that is lost in hypertension. Aortic wall stiffening is a major contributor to the development of isolated systolic hypertension with age, an important risk factor for progression of hypertension and incident cardiovascular disease. Elevated PWV together with increased pulsatile diameter are standard features of hypertension

(Safar et al. 2018). The regulation of the total peripheral resistance also involves the complex interactions of several mechanisms. These include baroreflexes and sympathetic nervous system activity; response to neurohumoral substances and endothelial factors; myogenic adjustments at the cellular level, some mediated by ion channels and events at the cellular membrane; and intercellular events mediated by receptors and mechanisms for signal transduction. As examples of some of these mechanisms, there are two major neural reflex arcs (Fig. 1). Baroreflexes are derived from high-pressure baroreceptors in the aortic arch and carotid sinus and low-pressure cardiopulmonary baroreceptors in ventricles and atria. These receptors respond to stretch (high pressure) or filling pressures (low pressure) and send tonic inhibitory signals to the brainstem. If blood pressure increases and tonic inhibition increases, inhibition of sympathetic efferent outflow occurs and decreases vascular resistance and heart rate. If blood pressure decreases, however, less tonic inhibition ensues from the baroreflexes, and both heart rate and peripheral vascular resistance increase, thereby increasing blood pressure. In addition, the neural control of renal function produces alterations in renal blood flow; glomerular filtration rate (GFR); excretion of sodium, other ions, and water; and release of renin and other vasoactive substances. These, in turn, have effects on the regulation of intravascular volume, vascular resistance, and blood pressure. Activation of carotid chemoreceptors is also transmitted to the vasomotor center and responds not only to arterial pressure but also to oxygen tension and carbon dioxide tension (in opposite directions). A drop in blood pressure, a drop in oxygen tension, or a rise in dioxide tension results in increased sympathetic outflow to the adrenal medulla, heart, and resistance vessels.

In addition to the numerous changes, molecular changes at the tissue and cellular level that have been associated with blood pressure changes. Some important mechanisms that are linked to blood pressure regulation involve membrane sodium transport mechanisms, Na^+/K^+ ATPase, Na^+/Li^+ countertransport, Na^+-H^+ exchange, Na^+-Ca^{2+} exchange, Na^+-K^+ 2Cl



Blood Pressure Control, Fig. 1 Basic mechanisms involved in blood pressure control. The most important organs and mechanisms involved in blood pressure control are shown (for explanations see text). RAS, renin–angiotensin–aldosterone system

transport, passive Na^+ transport, calcium channels, and potassium channels.

Numerous vasoactive substances have major effects on blood vessels, the heart, the kidneys, and the central nervous system (CNS) and often serve to counterbalance one another. Nitric oxide is an important endothelium-derived vasoactive factor released in response to shear stress and activation of a variety of receptors (Hermann et al. 2006). Nitric oxide exerts a multitude of effects ranging from vasodilatation and antiproliferative effects on vascular smooth muscles to the inhibition of thrombocyte aggregation and leukocyte adhesion, hence contributing to blood pressure regulation but also additional important cardiovascular effect including hemostasis and inflammation (Hermann et al. 2006). Endothelial dysfunction that implies a risk for hypertension and cardiovascular diseases is characterized by impaired bioavailability of nitric oxide. The bioavailability of nitric oxide is reduced in hypertension due to increased generation of reactive oxygen species that scavenge nitric oxide (Brandes Ralf 2014). Another example of physiologic actions, norepinephrine (noradrenaline), via α-adrenergic mechanisms, is a potent vasoconstrictor, while epinephrine (adrenaline), via α- and β-adrenoceptors, increases primarily heart rate, stroke volume, systolic blood pressure, and pulse pressure. The ▶ Renin–Angiotensin–Aldosterone System generates angiotensin II (Ang II). Ang II, in turn, constricts vascular smooth muscle; stimulates aldosterone secretion; potentiates sympathetic nervous system activity; leads to salt and water reabsorption in the proximal tubule; stimulates prostaglandin, nitric oxide, and endothelin release; increases thirst; and is a growth factor. Aldosterone activates the epithelial sodium channel (ENaC) in the cortical collecting duct in the kidney, leading to sodium reabsorption and potassium excretion. Prostaglandin E_2 and prostacyclin (PGI_2) act to counterbalance vasoconstriction by Ang II and norepinephrine.

Vasopressin (antidiuretic hormone [ADH]) secretion increases in response to decreased blood volume and/or reductions in effective blood volume via a decrease in inhibitory tone from both low-pressure and high-pressure baroreceptors to the hypothalamus. The neuronal pathways that mediate hemodynamic regulation of vasopressin release are completely different from those involved in osmoregulation, and unlike the latter, small decreases in blood pressure or blood volume have little effect on vasopressin secretion. A rise in blood pressure causes a decrease in secretion of vasopressin related to increased baroreceptor activity, which inhibits hypothalamic vasopressin-releasing hormones. Vasopressin works by causing water conservation at the distal collecting duct of nephron. This alone, however, is a relatively inefficient mechanism of increasing intravascular volume because conserved water is distributed among total body water and only a small portion is intravascular. In addition, vasopressin is a potent vasoconstrictor, and the greater vasopressin secretion observed in response to more severe hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of large reductions of blood pressure or blood volume. Two important endothelial-derived factors have opposite effects on the blood vessels: nitric oxide is a vasodilator acting via activation of soluble guanylyl cyclase in vascular smooth muscle cells, whereas the endothelins, particularly endothelin-1, are vasoconstrictors coupled to G-protein signaling. The kallikrein–kinin system produces vasodilator kinins, which in turn may stimulate prostaglandins and nitric oxide. Natriuretic peptides induce vasodilation, induce natriuresis, and inhibit other vasoconstrictors (renin–angiotensin, sympathetic nervous system, and endothelin).

When the temporal sequence of adjustments of blood pressure is analyzed, it seems that CNS mechanisms (e.g., baroreflexes) will provide regulation of the circulation within seconds to minutes. Other mechanisms, such as the renin–angiotensin–aldosterone system and fluid shifts, occur over minutes to hours. Only the kidneys seem to have the ability for long-term adjustment in blood pressure, predominantly through regulation of extracellular volume. This theoretical concept has been – although indirectly – confirmed by genetic approaches applied to the analysis of rare

familial syndromes of high blood pressure, i.e., hypertension, or low blood pressure, i.e., hypotension. In those studies carried out in families with monogenetic forms of the disease, several molecular pathways have been successfully delineated. All defects identified so far raise or lower blood pressure through a common pathway by increasing or decreasing salt and water reabsorption by the nephron. Thus, these studies point to the kidney as a pivotal organ for chronic determination of blood pressure.

Pharmacological Intervention

The clinical consequences of high blood pressure have been documented by epidemiologic studies, which demonstrate a strong positive and continuous correlation between blood pressure and the risk of cardiovascular disease (stroke, myocardial infarction, and heart failure), renal disease, and mortality. This correlation is more robust with systolic than with diastolic blood pressure. While hypertension was once thought to be "essential" for perfusion of tissues through sclerotic and narrowed blood vessels and to maintain a normal sodium balance, the pathologic nature of elevated blood pressure has become clear. Primary (essential) or idiopathic hypertension is defined as high blood pressure in which causes such as renovascular disease, renal failure, aldosteronism, pheochromocytoma, or other causes of secondary hypertension or monogenic (mendelian) forms are not present. Primary hypertension accounts for the vast majority of all cases of hypertension. This condition is a heterogeneous disorder, with different patients having different causal factors that lead to high blood pressure. Primary hypertension is also influenced by a large number of genetic variants that interact with environmental factors such as salt intake, alcohol consumption, obesity, physical activity, and stress predisposing an individual to hypertension. Recently, more than 900 independent blood pressure-associated loci with more than 1000 genetic variants across the genome have been identified (Evangelou et al. 2018). There are no established clinical or laboratory tests to identify the factors that are responsible for the blood pressure elevation in an individual patient. Consequently, pharmacologic treatment of primary hypertension is largely empiric. Clinical treatment algorithms try to account for comorbidities and expected or observed side effects of drugs in individual patients. Pharmacologic treatment should always be implemented "on top" of non-pharmacologic interventions such as control of body weight, intake of salt and alcohol, regular physical activity, smoking cessation, and other modifications of lifestyle as necessary in the individual patient.

Randomized trials of pharmacologic treatment of hypertension have documented that blood pressure reduction lowers morbidity and mortality, with profound reduction in stroke and smaller reductions in cardiac and renal disease (for details see ▶ "Antihypertensive Drugs").

As a result of such studies, hypertension has been operationally defined as the blood pressure level above which therapeutic intervention has clinical benefit. As intensified treatment has continued to demonstrate benefits, this level has gradually reduced over time and is currently defined in Europe as systolic blood pressure $\geq$140 mmHg and/or diastolic blood pressure $\geq$90 mmHg (Table 1A). Isolated systolic hypertension is the predominant form of hypertension in older adults and defined as systolic blood pressure $\geq$140 mmHg and diastolic blood pressure $<$90 mmHg. In 2017 the definition of hypertension was changed in the USA by proposing even lower cutoff values of $\geq$130 mmHg for systolic and $\geq$90 mmHg for diastolic blood pressure (Table 1B) due to different interpretations of available research data, which is, however, a matter of ongoing controversy (Tsioufis et al. 2018). Despite some apparent differences between international guidelines, they share several important commonalities by shifting toward lower blood pressure thresholds for initiating antihypertensive drug therapy, and lower blood pressure targets during treatment, which collectively should lead to lower blood pressure-related complications and mortality (Whelton and Williams 2018).

Blood Pressure Control, Table 1 Definitions and classifications of blood pressure levels

Category	Systolic [mmHg]		Diastolic [mmHg]
A. **According to European guidelines** (Williams et al. 2018)			
Optimal	<120	and	<80
Normal	120–129	and/or	80–84
High normal	130–139	and/or	85–89
Grade 1 hypertension	140–159	and/or	90–99
Grade 2 hypertension	160–179	and/or	100–109
Grade 3 hypertension	≥180	and/or	≥110
Isolated systolic hypertension	≥140	and	<90
B. **According to US guidelines** (Whelton et al. 2018)			
Normal	<120	and	<80
Elevated	120–129	and	<80
Hypertension			
Grade 1 hypertension	130–139	or	100–109
Grade 2 hypertension	≥140	or	≥90

Synonyms

Blood-brain interface; Brain capillary endothelial cells; Cerebral microvessels

Definition

Homeostasis of the extracellular milieu in the brain and its protection against neurotoxic compounds, infections, and continuously changing composition of the blood are important for normal function of the neurons. It is warranted by a structure formed between blood and brain which is, therefore, called the blood-brain barrier (BBB). The blood-brain barrier is an anatomical formation, and on the other hand, it has also a molecular background associated with the endothelial cell membrane of cerebral microvessels.

Basic Mechanisms

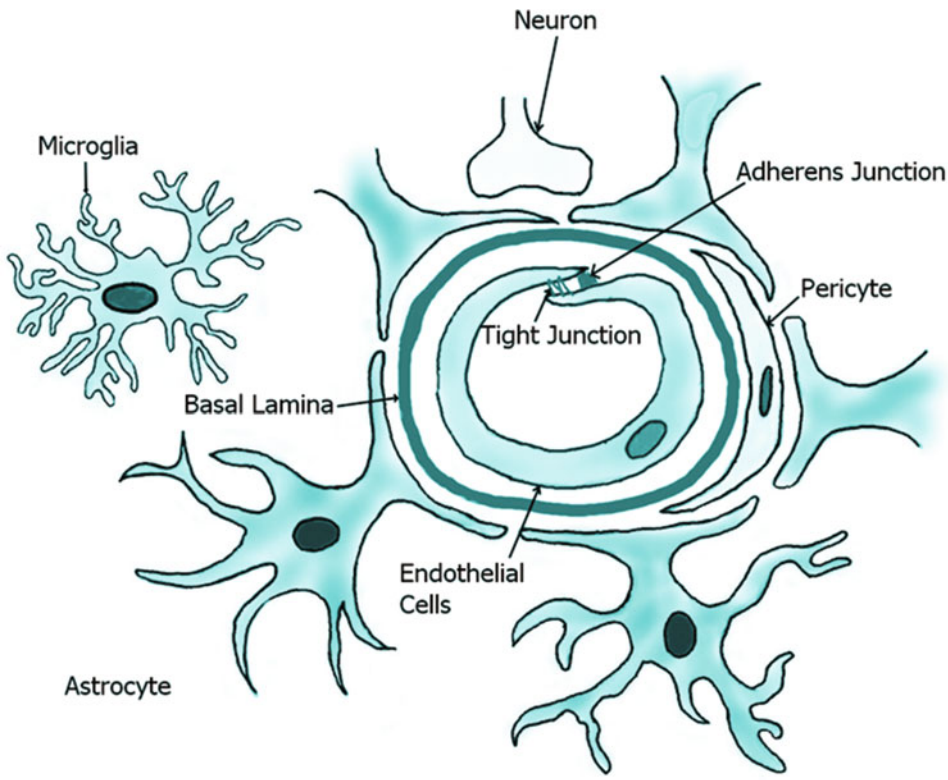
Cellular Background

The most important cell types forming the BBB are the capillary endothelial cells surrounded with pericytes and astrocyte end feet. There are some supporting cell types which are not directly connected to the BBB but also contributing the barrier function: these are microglia and neuronal cells. In the next points, these cell types and their roles in the BBB are presented (Fig. 1).

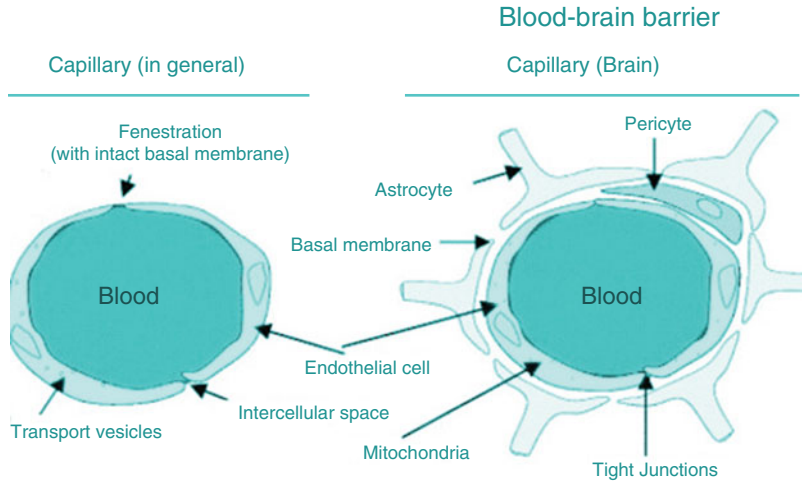
Endothelial Cells (ECs)

Compared to peripheral capillaries, BBB ECs are characterized by increased mitochondrial content, exhibit minimal pinocytotic activity, and lack of fenestrations (Fig. 2). Increased mitochondrial content is essential for these cells to maintain active transport mechanisms to transport ions, nutrients, and waste products into and out of brain parenchyma, thus contributing to precise regulation of the central nervous system (CNS) microenvironment and ensuring proper neuronal function (Oldendorf et al. 1977). The high concentration of mitochondria in cerebrovascular ECs might account for the sensitivity of the BBB to oxidant stressors. The physiology and pathophysiology of ECs are closely linked to their mitochondria, and mitochondrial dysfunction is an important mediator of disease pathology in the brain (Grammas et al. 2011).

The brain endothelium is highly reactive because it serves as both a source of, and a target for, inflammatory proteins and reactive oxygen species. Neuroinflammation and oxidative stress lead to BBB breakdown, which are implicated in the pathogenesis of CNS diseases. Cell polarity of ECs means different functional expression of transporter proteins and metabolic enzymes (Betz et al. 1980) on the luminal (or apical) and abluminal (or basolateral) membranes, which contribute to the high selectivity of the BBB. Of the many transporters expressed at the BBB endothelium membrane, several have been implicated in influx and/or efflux of drugs into/out of the CNS. Decreased expression and/or defective function of transporters leads to increased BBB permeability, toxic adverse effects of drugs, and can be an early event in the pathology of several disorders (Obermeier et al. 2013). Factors that can disrupt the BBB can be secreted elements, immune cells, and pathogens. Impaired BBB integrity manifests mainly as increased barrier permeability. In addition to direct effects on ECs, other members of the neurovascular unit can also be affected, like pericytes, astrocytes, and basement membrane, which in turn contribute impairment of BBB functions. Consequences can be dysregulated molecular and ionic flux across the BBB or the initiation of a central inflammatory response. Despite different causes, characteristics, and consequences, BBB breakdown generally culminates in neuronal dysfunction, neuroinflammation, and neurodegeneration. Pathological outcomes and potential for recovery are diverse (Erdő et al. 2017).



Blood-Brain Barrier, Fig. 1 The cellular structure of blood-brain barrier (BBB). The brain capillary endothelial cells connected to each other by tight junctions and adherens junctions. These cells are surrounded with pericytes and astrocyte end feet. Neurons and microglia cells are also contributing to the function of the BBB. (Modified from Erdő et al. 2017)



Blood-Brain Barrier, Fig. 2 Comparison of a peripheral (left) and a central (right) capillaries. While in the periphery the capillary endothelial cells are not connected tightly, there are fenestrations and intercellular space between them; in the brain there are no fenestrations but tight junction proteins between the endothelial cells. Endothelial layer and pericytes are embedded into basal membrane in the brain, and astrocytes are tightly connected to the parenchymal surface of blood microvessels (Modified from Neearti et al. 2012)

Astrocytes

Astrocytes are the most abundant cell type in the brain and display a fibroblast-like morphology within gray matter (Raff et al. 1983); however, this morphology can be influenced by their CNS location and associations with other cell types. Astrocyte end feet cover over 99% of cerebral capillaries (Abbott et al. 2006), leading to critical cell-cell interactions that directly modulate and regulate BBB characteristics. Several studies have demonstrated that astrocytes play a vital role in maintenance, and perhaps induction, of BBB characteristics (Ronaldson and Davis 2012).

Astrocytes are fundamental for homeostasis, defense, and regeneration of the CNS. Loss of astroglial function and astroglial reactivity contributes to the aging of the brain and to neurodegenerative diseases. Changes in astroglia in aging and neurodegeneration are highly heterogeneous and region-specific.

Several inducing factors secreted by astrocytes have been identified, including tumor growth factor-beta (TGF-β), glial cell-derived neurotrophic factor (GDNF), and basic fibroblast growth factor (BFGF), which are involved in induction and regulation of the BBB phenotype. Additionally, astrocytes can regulate brain microvascular permeability via Ca^{2+} signaling involving astrocyte-endothelial gap junctions and purinergic transmission. Astrocytes play a critical role in preventing excitotoxicity induced by acute elevations of glutamate in the brain. This is mediated via expression of astrocyte glutamate transporters excitatory amino acid transporters (EAAT1 and EAAT2) that are responsible for glutamate uptake into the astrocyte cell, thus reducing glutamate levels in the parenchyma.

Lipoproteins in plasma transport lipids between tissues; however, only high-density lipoproteins (HDL) appear to traverse the BBB; thus, lipoproteins found in the brain must be produced within the central nervous system. Apolipoprotein E (ApoE) and ApoJ are the most abundant apolipoproteins in the brain, which are mostly synthesized by astrocytes. ApoE has an important role in the pathology and BBB injury during the development of Alzheimer's disease.

There is also evidence that astrocytes accumulate in the normal aging brain, increasing in both number and size. These astrocyte changes in normal brain aging may contribute to the exacerbated injury response and poorer outcomes observed in older traumatic brain injury patients. Astrocyte morphology changes, and glial fibrillar acidic protein (GFAP) expression increases progressively during aging in humans and rodents.

Pericytes

Pericytes are multifunctional mural cells of the microcirculation that wrap around the endothelial cells that line the capillaries and venules throughout the body. Pericytes are embedded in basement membrane, where they communicate with endothelial cells of the body's smallest blood vessels by means of both direct physical contact and paracrine signaling. Pericytes are BBB associated cells. During aging, pericytes show ultrastructural changes such as vesicular and lipofuscin-like inclusions: an increased size of mitochondria and a foamy transformation. In the aging human brain degeneration and loss of pericytes were shown. Pericytes in aging brain begin to lose their contact to the EC and begin to migrate. This behavior seems to be a response of the pericytes to a yet unidentified age-related effect. Platelet-derived growth factor (PDGF) released by ECs is known to bind to the PDGF receptor expressed by pericytes and to attract pericytes to ECs (Erdő et al. 2017). If this ligand-receptor system is disturbed, the functional integrity of the vessel is impaired. With age, this system could deteriorate as well, but data are not available as yet.

Pericyte injury and possibly early degeneration correlate with increased BBB permeability within the hippocampus, a region known to be affected by pericyte loss and BBB breakdown on postmortem tissue analysis in Alzheimer's disease.

Microglia

Microglia, the primary immune cells of the brain, are ubiquitously distributed in the CNS and are activated in response to systemic inflammation, trauma, and several CNS pathophysiologies. This cell type is not the basic element of the BBB, but it has an impact on the BBB function and integrity. Microglia present with a ramified morphology that is characterized by a small soma and fine cellular processes during their "resting state."

Microglial activation in response to pathophysiological stressors can trigger changes in cell morphology, which include reduced complexity of cellular processes and transition from a ramified morphology to an amoeboid appearance. Activated microglia produce high levels of neurotoxic and proinflammatory mediators such as nitric oxide, peroxide, tumor necrosis factor alpha (TNF-α), and proteases, all of which result in cell injury and neuronal death. As immune cells microglia scavenge apoptotic cells, tissue debris after trauma, or microbes. They can also act as scavengers of extracellular molecules such as amyloid-β. Activation of microglia is associated with altered TJ protein expression and increased BBB permeability.

Briefly the major physiological protective effector functions of microglia: (1) proliferation, (2) morphological transformation, (3) motility and migration, (4) intercellular communication, (5) phagocytosis, and (6) proteostasis. With aging, microglia shift their morphology and may display diminished capacity for normal functions related to migration, clearance, and the ability to shift from a proinflammatory to an anti-inflammatory state to regulate injury and repair (Erdő et al. 2017).

Neurons

There is considerable evidence for direct innervation of both brain microvessel ECs and associated astrocyte processes via distinct connections with noradrenergic, serotonergic, cholinergic, and GABAergic neurons. Therefore, neurons are in connection with the BBB and have influence on the behavior of capillary endothelial barrier. For example, studies have shown that loss of direct noradrenergic input from the locus coeruleus results in increased BBB reactivity to effects of acute hypertension, resulting in significantly increased permeability to 125-I labeled albumin.

With aging, cell senescence can contribute to BBB disintegration. The damaged BBB allows an influx of inflammatory cytokines to enter the brain. These cytokines lead to neuronal and glial failure. Several factors contribute to the deterioration of synaptic plasticity with age, and one of these factors appears to be a heightened level of activation of microglia, which may reflect impairment in the homeostatic ability of these cells with age, or an increase in responsiveness to modulatory molecules. The age-related decrease in tissue perfusion, together with the increase in BBB permeability, may alter the microenvironment in the brain; this, combined with the age-related compromised homeostatic capability of microglia, may be a significant factor in the neuroinflammatory changes which were described in the aged brain and which had an impact on synaptic function. These combined changes may contribute to the deficit in long-term potentiation (LTP) in synapses of aged animals. Ultimately, the functional neuronal changes within the brain can cause age-related diseases.

Molecular Background

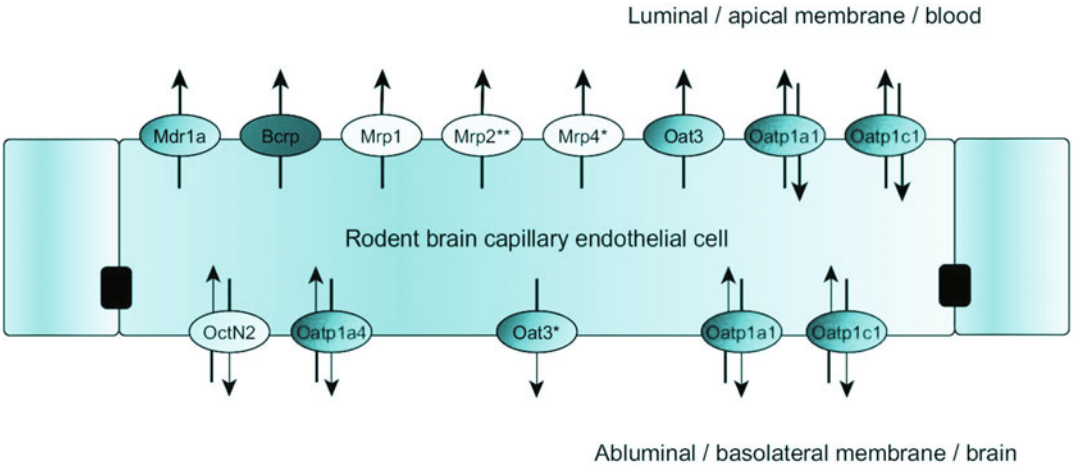
Membrane Transporters

Efflux transporters include P-glycoprotein (P-gp), breast cancer resistance protein (BCRP) and multidrug resistance proteins (MRPs) in the brain. Transporters that facilitate drug entry into the brain (uptake or influx transporters) include organic anion transporting polypeptides (OATPs), organic anion transporters (OATs), organic cation transporters (OCTs), nucleoside transporters, monocarboxylate transporters (MCTs), and putative transport systems for peptide transport (Sanchez-Covarrubias et al. 2014). The localization of the main membrane transporter proteins in the apical and basolateral surface of rodent ECs is presented in Fig. 3.

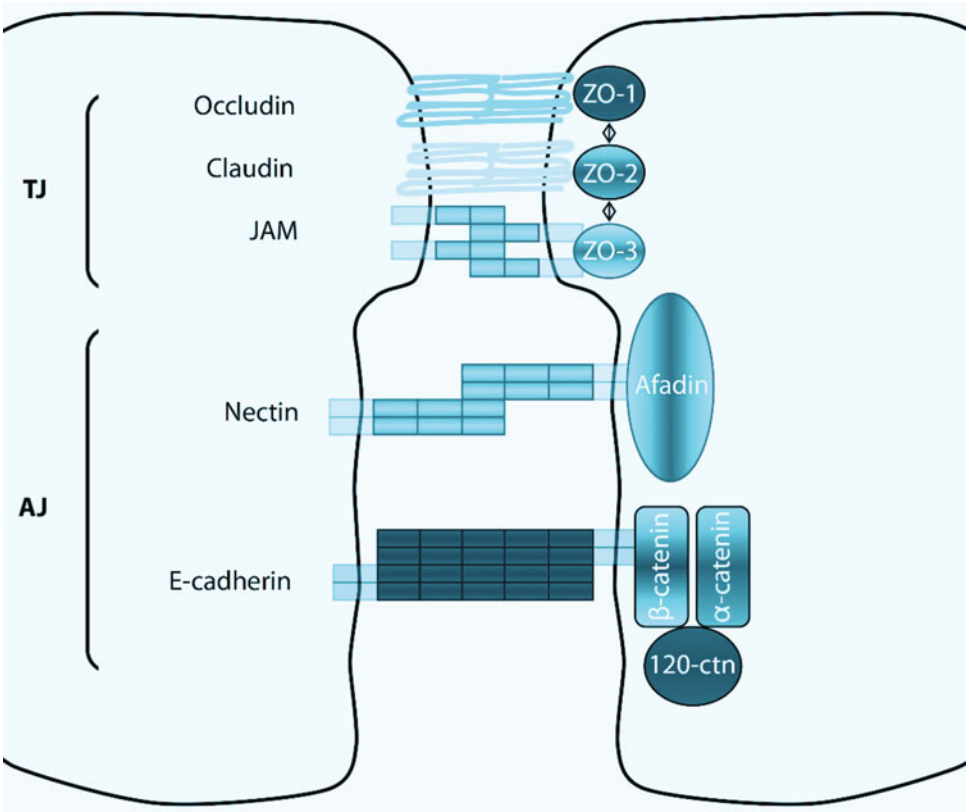
The restricted paracellular permeability of capillary EC layer is warranted by two intercellular molecular binding systems: the adherens junctions (AJ) and the tight junctions (TJ) (Fig. 4**)**.

Adherens Junctions

Adherens junctions (AJs) are found throughout the CNS microvasculature and are responsible for intercellular adherence between adjacent ECs (Vorbrodt and Dobrogowska 2003). AJs are composed of multiple protein components including vascular endothelium (VE) cadherin, actinin, and catenin. Cell-cell adhesion is mediated by homophilic interactions of VE-cadherin expressed on



Blood-Brain Barrier, Fig. 3 Schematic representation of the main efflux and uptake transporters on apical and basolateral surface of rodent brain capillary endothelial cells. (Modified from http://www.solvobiotech.com/)



Blood-Brain Barrier, Fig. 4 Schematic structure of tight junction (TJ) proteins and adherens junction (AJ) proteins making connection between the endothelial cells in the brain capillaries. (Modified from Erdő et al. 2017)

adjacent ECs. Such interactions mediate calcium-dependent cell adhesion by binding to the actin cytoskeleton. Cytoskeletal binding occurs via catenin accessory proteins. Specifically, β-catenin links VE-cadherin to α-catenin, an interaction that induces the direct binding to actin (Fig. 4).

Tight Junctions

Although disruption of AJs can result in increased BBB permeability, TJs are primarily responsible for restricting paracellular permeability at the BBB (Vorbrodt and Dobrogowska 2003). TJs form the primary physical barrier component of the BBB and function to greatly restrict paracellular entry of various endogenous and exogenous substances that can potentially be neurotoxic. Such TJs impart a high transendothelial electrical resistance (TEER) across the BBB (1500–2000 Ω cm2) that restricts free flow of ions and solutes. TJs are dynamic complexes of multiple protein constituents including junctional adhesion molecules (JAMs), occludin, claudins (i.e., claudin-1, −3, and − 5), and membrane-associated guanylate kinase (MAGUK)-like proteins (i.e., ZO-1, −2, and − 3) (Fig. 4).

Basement Membrane

Basement membranes (BMs) (it is also called as basal lamina) are considered to be uniform, thin extracellular matrix sheets that serve as a substrate for ECs. To find out whether BMs maintain their ultrastructure, protein composition and biophysical properties throughout life, the natural aging history of the human inner limiting membrane (ILM) was investigated by Candiello and coworkers (Candiello et al. 2010). Transmission electron microscopy showed that the ILM steadily increases in thickness from 70 nm at fetal stages to several microns at age 90. Furthermore, the relative concentrations of collagen IV and argin increase, and the concentration of laminin decreases with age. Force-indentation measurements by atomic force microscopy also showed that ILMs become increasingly stiffer with advancing age.

Extracellular Matrix

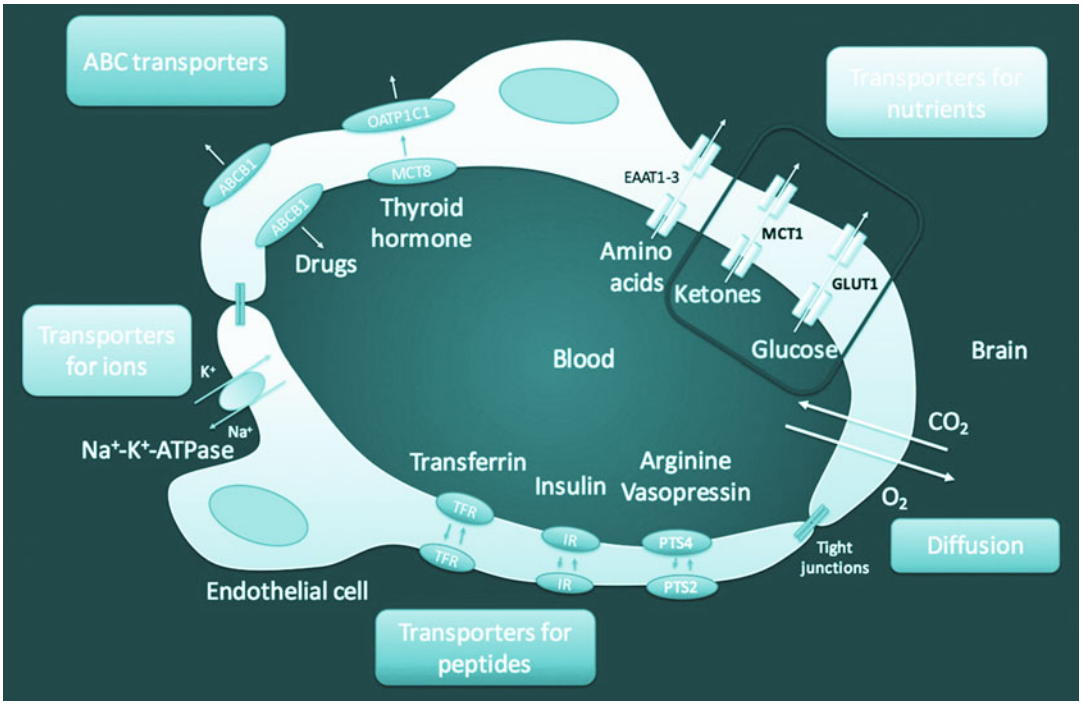
The extracellular matrix (ECM) of the basal lamina serves as an anchor for the cerebral microvascular endothelium. The anchoring function of the extracellular matrix is mediated via interactions between endothelial integrin receptors, laminin, and other matrix proteins. Disruption of extracellular matrix is associated with loss of barrier function, resulting in increased permeability. Additionally, matrix proteins have been shown to influence the expression of TJ proteins, such as occludin, suggesting that the extracellular matrix plays a role in maintaining TJ protein integrity.

Pharmacological Interventions

The number of molecules that can freely cross the BBB is very limited (O_2, CO_2, etc.). However, a huge amount of the oral or systemic drugs should reach the brain and their central target to develop their CNS effect. For this, they need to travel through the BBB (Takakura et al. 1991). To assist achieving the therapeutic goals, there are different technological, mechanistic, and physical approaches available to overcome the BBB and enhance the delivery of the compounds into the target brain regions (Bors and Erdő 2019) (Fig. 5).

How to Overcome the BBB?

Nanocarriers, nanoparticles (lipid, polymeric, magnetic, gold, and carbon-based nanoparticles, dendrimers, etc.), viral and peptide vectors and shuttles, sonoporation, and microbubbles all are able to improve the central drug delivery. The modulation of receptors and efflux transporters in the endothelial cell membrane can also be an effective approach to enhance brain exposure to therapeutic compounds. Intranasal administration is a noninvasive delivery route to bypass the blood-brain barrier because it has a direct connection to the brain through olfactory and trigeminal nerves (Erdő et al. 2018). Direct brain administration is an invasive mode to target the brain regions with therapeutic drug to reach proper concentrations locally. Nowadays, both technological and mechanistic tools are available to assist in overcoming the blood-brain barrier (Kacem et al. 2014). With these techniques more effective and even safer drugs can be developed for the treatment of devastating brain disorders.



Blood-Brain Barrier, Fig. 5 Schematic representation of different transport systems expressed on brain capillary endothelial cells. ABC transporters (ATP-binding cassette transporters) are responsible for drug transport through the BBB. MCT8 and OATP1C1 are uptake transporters of thyroid hormone. Nutrient transporters are involved in the transport of amino acids, ketones, and glucose. Transferrin receptor (TFR), insulin receptor (IR), and arginine-vasopressin receptor (PTS4) are transporters for peptides. Na^+-K^+-ATPase is responsible for ion transport. The gas molecules (O_2, CO_2) can freely diffuse across the BBB (Modified from Helbig 2015)

Synonyms

Blood-tissue barrier in testes; Seminiferous epithelial barrier; Sertoli cell barrier

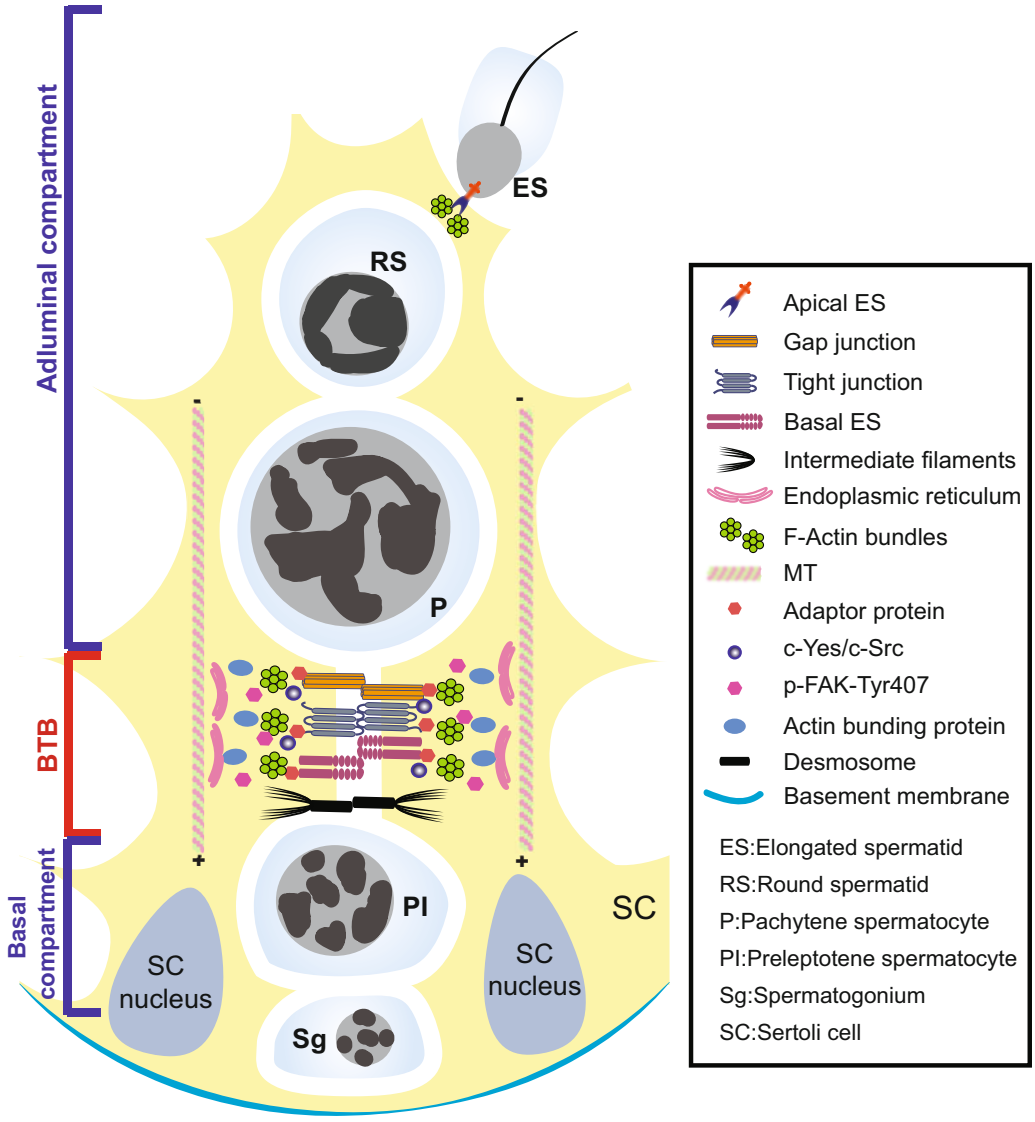
Definition

The blood-testis barrier (BTB) is a blood-tissue barrier found in the testis, located near the base of the seminiferous epithelium (Fig. 1) as noted in the cross section of seminiferous tubules which are the functional unit of the mammalian testis that produce millions of sperm daily in the male of any adult rodent or human. The BTB is created by specialized junctions between adjacent Sertoli cells near the base of the epithelium, which are composed of the actin-based tight junction (TJ), basal ectoplasmic specialization (basal ES), and gap junction, but also intermediate filament-based desmosome (Fig. 1). Thus, endothelial TJ-barrier in the microvessels located at the interstitial space between seminiferous tubules contributes virtually no barrier function to the BTB. The BTB limits paracellular (i.e., between cells) and transcellular (i.e., across cells) transport of water, electrolytes, biomolecules, and other substances across the barrier to protect postmeiotic spermatid development in the adluminal compartment of the seminiferous epithelium.

Basic Mechanisms

Background

The concept of the blood-testis barrier (BTB) in the testis originated from studies in the early 1900s when dyes injected into laboratory animals, they stained tissues in virtually all organs with the notable exceptions of the brain and the seminiferous tubules of the testis (Cheng and Mruk 2012). Since then, the concept and functions of the BTB have been considerably expanded and better understood (Cheng and Mruk 2012). In brief, the BTB restricts the paracellular and transcellular transport of biomolecules, ions, electrolytes, water, and other substances across the Sertoli cell barrier, providing the "gate" and the "fence" function. On the other hand, the BTB also divides the seminiferous epithelium into the basal and adluminal (apical) compartments (Fig. 1). To date, it is well established that the BTB is conferred almost exclusively by specialized junctions between adjacent Sertoli cells near the base of the seminiferous epithelium (Fig. 1). Interestingly, the TJs between adjacent Sertoli cells near the base of the seminiferous epithelium are supported by the testis-specific actin-rich ectoplasmic specialization (ES) designated basal ES, which together with the gap junction and the intermediate filament-based desmosome constitute the BTB (Fig. 1). The BTB is an important ultrastructure



Blood-Testis Barrier, Fig. 1 Schematic illustration of the cross section of a seminiferous tubule in the mammalian testis to show the relative location of the blood-testis barrier (BTB). The BTB divides the seminiferous epithelium into the basal and adluminal (apical) compartments. The BTB is comprised of actin-based basal ectoplasmic specialization (ES), tight junction (TJ), and gap junction (GJ), but also intermediate filament-based desmosome. Preleptotene spermatocytes transformed from type B spermatogonia at stages VII-VIII of the epithelial cycle are being transported across the BTB, while differentiating into leptotene spermatocytes, and then zygotene and pachytene spermatocytes. Following meiosis, haploid spermatids undergo spermiogenesis to produce elongated spermatids via 19 different steps in the rat testis. Once step 8 haploid spermatids arise in stage VIII tubule, they anchor onto the Sertoli cell via the apical ES which replaces gap junction and desmosome as the only anchoring device. The testis-specific apical ES adhesion protein complex α6ß1-integrin/laminin-α3/ß3/γ3 can be broken down by MMP-2 (matrix metalloprotease-2) to generate the F5-peptide, specifically released from laminin-γ3 chains. Seminiferous epithelium is in close contact with the basement membrane, wherein the structural proteins collagen α3 (IV) chains and laminin-α2 chains can also be proteolytically cleaved to generate the NC1- and LG3/4/5-peptides, respectively. These bioactive peptides, namely F5-, NC1- and LG3/4/5-peptides, in turn, regulate basal ES/BTB and apical ES remodeling to support spermatogenesis (see text for details)

in the testis to support spermatogenesis since the onset of meiosis that produces haploid spermatids in rodents and humans tightly correlates with the establishment of a functional immunological barrier.

Ultrastructural Features of the Blood-Testis Barrier (BTB)

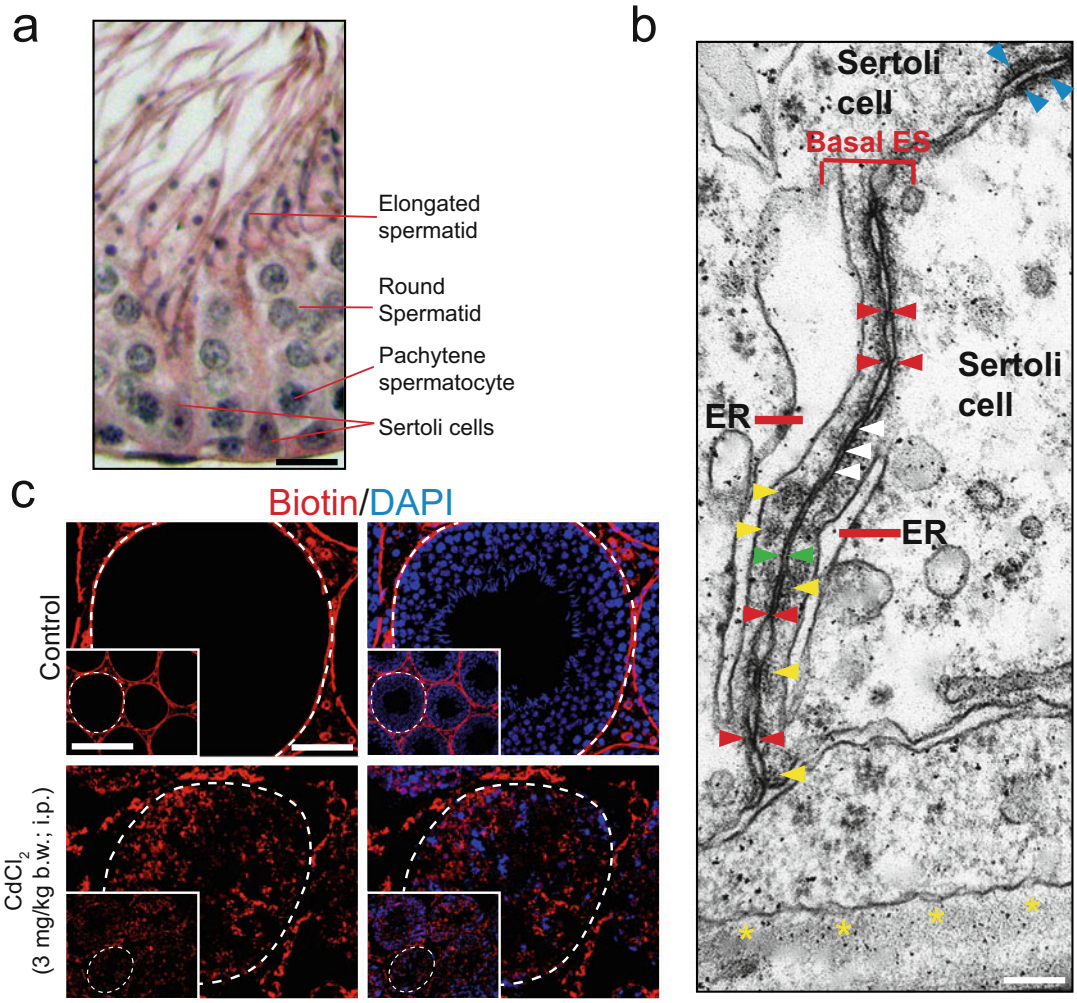
The most notable feature of the BTB under electron microscopy is the extensive network of actin filament bundles that lay across the Sertoli cell cytosol that close to the apposing plasma membranes, creating a unique ultrastructure in the testis designated the apical ES (Fig. 1). These bundled actin filament networks thus reinforce the TJs, making the BTB one of the tightest blood-tissue barriers. On the other hand, besides this network of F-actin at the basal ES/TJ to constitute the BTB, another network of microtubule (MT)-based cytoskeleton is located nearby. Interestingly, while the BTB provides the "gate" and the "fence" function to limit paracellular and transcellular transport across the barrier, it is not a static ultrastructure. The BTB undergoes rapid molecular remodeling in response to the stages of the seminiferous epithelial cycle, which is mediated by rapid internalization of BTB-associated proteins at the site, including TJ (e.g., claudins) and basal ES (e.g., N-cadherin) proteins, at stages VII–early IX of the epithelial cycle. These changes thus facilitate the transport of preleptotene spermatocytes across the immunological barrier once they transformed from type B spermatogonia. These observations also prompt investigators to examine if local regulating bioactive molecules are produced locally to modulate this specific cellular event.

Pharmacological Intervention

Regulatory Bioactive Peptides of the BTB

Studies in the past decade have shown that the testes generate several biologically active peptides at multiple sites across the seminiferous epithelium during the epithelial cycle, which exert their biological effects through several downstream signaling proteins. These biologically active peptides and their downstream signaling proteins have been shown to modulate the BTB function, either promoting BTB remodeling (i.e., to make the barrier "leaky") or BTB integrity (i.e., to make the barrier "tighter"), and other specific cellular events during spermatogenesis such as potentiating the degeneration of apical ES to facilitate the release of sperm at spermiation. At least three bioactive peptides and their unique downstream signaling proteins/pathways have been identified to date.

The F5-peptide. Studies have shown that the F5-peptide is a bioactive peptide capable of inducing Sertoli cell BTB remodeling and also apical ES degeneration, thereby promoting the transport of preleptotene spermatocytes across the BTB and the release of sperm at spermiation, respectively, based on studies in vitro and/or in vivo through the use of its recombinant protein or its overexpression following cloning of the F5-peptide cDNA into the mammalian expression vector pCI-neo (Yan et al. 2008; Su et al. 2012; Gao et al. 2016). These findings are important because they demonstrate that the F5-peptide is being used to coordinate two distinctive cellular events that take place concurrently but at the opposite ends of the epithelium. This includes the release of sperm at spermiation and BTB remodeling that take place at the luminal edge and the base of the epithelium, respectively (Fig. 2). Studies have shown that the F5-peptide is derived from domain IV of the laminin-γ3 chain (Yan et al. 2008; Su et al. 2012), an integrated component of the apical ES expressed specifically by elongated spermatids in stage VII–VIII tubules, via the action of MMP-2 (matrix metalloproteinase-2) through proteolytic cleavage (Siu and Cheng 2004). In brief, the testis is generating a bioactive peptide endogenously when the apical ES is undergoing degeneration to prepare for the sperm release at spermiation (Fig. 2), which in turn is used to potentiate further breakdown of the apical ES and to induce BTB remodeling (Su et al. 2012; Gao et al. 2016). More importantly, studies have shown that the F5-peptide exerts its regulating effects through integrin-based receptors (Su et al. 2012) via "inside-out" and "outside-in" signaling



Blood-Testis Barrier, Fig. 2 Ultrastructural features and function of the BTB. (**a**) Cross section of a stage VIII tubule, illustrating the two Sertoli cell nuclei near the basement membrane that create the BTB as ultrastructurally noted in (**b**). BTB is created by coexisting actin-based (i) tight junction (TJ) as noted by the "kisses" (annotated by the opposing red arrowheads), (ii) basal ES as shown herein is typified by the presence of actin filament bundles (yellow arrowheads) that are sandwiched in-between the endoplasmic reticulum (ER) and the adjacent Sertoli cell plasma membranes (see apposing green arrowheads), and (iii) gap junction (see white arrowheads); as well as intermediate filament-based desmosome (see blue arrowheads) typified by the presence of electron dense substances on both sides of the Sertoli cell plasma membranes. The seminiferous epithelium is in direct contact with the basement membrane (annotated by yellow asterisks). (**c**) The functional BTB is noted herein by its ability to block the diffusion of small biotin (visualized by red fluorescence) across the base of the seminiferous tubule at the site of the BTB (annotated by the dashed white line). However, in tubules from rats treated with a toxicant, cadmium chloride (at 3 mg/kg) via intraperitoneal administration which is known to damage the BTB function, biotin was able to permeate the BTB to enter the adluminal compartment. DAPI (4′,6-diamidino-2-phenylindole, blue fluorescence) stained cell nuclei in the seminiferous epithelium. Scale, 40 μm in (**a**), 0.2 μm in (**b**), and 200 μm (2 mm, inset) in (**c**)

cascade by inducing disruptive distribution and downregulating the expression of p-FAK-Y407 (Su et al. 2012; Gao et al. 2016). It is noted that p-FAK-Y407 is a signaling protein known to promote BTB integrity (Lie et al. 2012). Furthermore, the F5-peptide/p-FAK-Y407 cascade exerts its effects at the apical ES and the basal ES/BTB through disruptive cytoskeletal organization of

the actin and MT networks (Su et al. 2012; Gao et al. 2016).

The NC1-peptide. In the testis, the basement membrane is a modified form of extracellular matrix (ECM). It is universally found and located basolaterally to all epithelium and endothelium in the mammalian body, by providing structural and functional support to tissues by modulating epithelial and endothelial cell function. One of the major constituent proteins of the basement membrane in the testis is collagen α3 (IV) chains. Studies have shown that NC1 domain released from the C-terminal region of collagen α3 (IV) is a potent biologically active peptide designated NC1-peptide, capable of inducing reversible BTB disruption in vitro and/or in vivo through the use of its purified recombinant protein (Wong and Cheng 2013) or via its overexpressed following cloning of the NC1-peptide cDNA into the mammalian expression vector pCI-neo (Chen et al. 2017). Similar to the F5-peptide, besides promoting BTB remodeling, NC1-peptide is also able to induce apical ES degeneration, thereby affecting spermatid adhesion in the epithelium, which in turn leads to germ cell exfoliation (Chen et al. 2017). In the testis, NC1-peptide has been shown to exert its effects through an "outside-in" and "inside-out" signaling since the presence or absence of the signal peptide cloned into the NC1-peptide neither potentiates nor diminishes the biological effects of NC1-peptide that perturbs the Sertoli cell TJ-barrier function (Chen et al. 2017). A recent study has shown that NC1-peptide exerts its biological effects on Sertoli cell BTB function through an activation of Cdc42, but not Rho A, also involving an activation of the mTORC1/rpS6 downstream, which in turn modulates the cytoskeletal organization of F-actin and MTs in Sertoli cells (Su and Cheng 2019). On the other hand, NC1-peptide also induces an increase in endocytic vesicle-mediated protein trafficking by enhancing the endocytosis of BTB-associated protein CAR (Chen et al. 2017). These findings thus illustrate that while the F5- and NC1-peptides have similar effects on the Sertoli cell BTB function since their overexpression or the use of their recombinant proteins can both promote BTB remodeling by making the barrier "leaky," they exert their effects via distinctive signaling pathways downstream.

The LG3/4/5-peptide. Besides collagen α3 (IV) chains, the other major constituent protein of the basement membrane in the mammalian testis is the laminin-α2 chain. Using RNAi to knockdown laminin-α2 by using shRNA that targeted laminin-α2 in Sertoli cell epithelium, it was noted that this led to a transient disruption of the Sertoli cell TJ-barrier function, concomitant with disruptive organization of F-actin and MTs across the Sertoli cell cytosol (i.e., these cytoskeletons were extensively truncated across the Sertoli cell cytosol), thereby causing disruptive distribution of TJ (e.g., CAR, ZO-1) and basal ES (N-cadherin, ß-catenin) proteins at the Sertoli cell-cell interface since these proteins utilize actin for their attachments and supported by the MTs (Gao et al. 2017a). These findings also illustrate that the physiological function of laminin-α2 chain is to support BTB and spermatogenic function. More interestingly, laminin-α2 chain localized at the basement membrane could be cleaved (possibly via the action of MMP-9 at the site as earlier reported (Siu et al. 2003)) to generate an 80 kDa fragment containing LG3/4/5 domains as demonstrated by immunoblot analysis and immunofluorescence analysis, which was transported across the seminiferous epithelium via a microtubule (MT)-dependent mechanism since treatment of the testis with Taxol was shown to perturb the transport of this laminin-3/4/5 fragment from reaching the apical ES (Gao et al. 2017a). These observations thus support the notion that the testis is generating an 80 kDa LG3/4/5-peptide from the basement membrane to exert is regulatory effects at the apical ES. Subsequent study has shown that LG3/4/5-peptide exerts its effects to perturb Sertoli cell TJ-barrier function, via the use of shRNA to knockdown laminin-α2 in Sertoli cell epithelium by as much as 75%, through an activation of mTORC1/rpS6 signaling complex, including a surge in the expression of p-rpS6-S235/S236 and p-rpS6-S240/S244, and a concomitant downregulation of p-Akt1/2 (Gao et al. 2017b). Furthermore, the use of a specific p-Akt1/2 activator

SC79 is able to block the laminin-α2 knockdown-mediated cytoskeletal disorganization of F-actin and MTs (Gao et al. 2017b). This observation thus illustrates that the mTORC1/rpS6/Akt1/2 is the downstream signaling cascade used by LG3/4/5-peptide to support BTB and spermatogenic function in the testis. In brief, the NC- and LG3/4/5-peptides are utilizing the mTORC1/rpS6 signaling cascade downstream to mediate their corresponding effects to promote Sertoli cell TJ-barrier disruption (i.e., making the barrier "leaky" and integrity (i.e., making the barrier "tighter"), respectively, via an upregulation (activation) or downregulation (inactivation) of the mTORC1/rpS6 signaling complex. This thus provides a novel mechanism to induce BTB remodeling and also apical ES degeneration to support the transport of preleptotene spermatocytes across the BTB and the release of sperm at spermiation during the epithelial cycle of spermatogenesis.

Summary

The BTB is regulated by endogenous regulatory peptides produced locally in the testis during the epithelial cycle of spermatogenesis, which are being used to induce BTB remodeling to facilitate the transport of preleptotene spermatocytes across the barrier (such as the F5- and NC1-peptides), or to maintain its integrity (such as the LG3/4/5-peptide), to support spermatogenesis. These peptides are also used to modulate spermatid transport and adhesion. The bioactive peptides exert their effects through changes in the cytoskeletal organization of actin and microtubule cytoskeletons with distinctive downstream signaling pathways.

Bone Remodeling; Bone Turnover; Skeletal Metabolism; Skeletal Turnover

Definition

Bone metabolism involves the processes of ***bone formation*** and ***bone resorption***, the key actions by which skeletal mass, structure, and quality are accrued and maintained throughout life. In the mature skeleton, anabolic and catabolic actions are balanced through tight regulation of the activity of bone forming cells (***osteoblasts***) and bone resorbing cells (***osteoclasts***). This process is called ***coupling*** and mediated through the action of circulating ***osteotropic hormones,*** locally active factors such as cytokines, growth factors, and small glycoproteins, some of which are secreted by **osteocytes.**

Basic Mechanisms

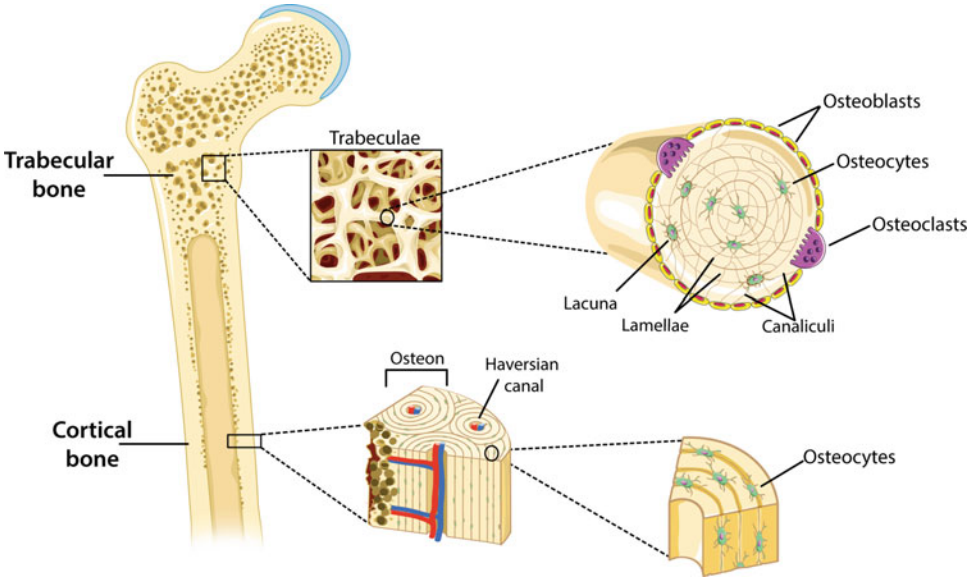
Biochemical Composition of Bone

Bone is composed of approximately 50% to 90% mineral (mainly calcium phosphate in the form of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] crystals), 5% to 40% organic matter (i.e., cells, collagen, and noncollagenous proteins) and water. The mineral component of bone provides mechanical strength and rigidity to the skeleton. The highest mineral content is found in the small bones of the middle ear, which need to be stiff and unyielding in order to transmit sound. Most other bones have a much lower mineral content, which gives them elasticity and the capacity to shock absorb. In these bones, the mineral is also sufficiently labile to be easily removed, enabling it to act as a store for supporting systemic calcium and phosphorus homeostasis.

The organic extracellular matrix of bone, termed "osteoid," is predominantly composed of 90% type I collagen, which assembles into fibrils that are covalently cross-linked to generate tensile strength. Of the noncollagenous proteins, osteocalcin, bone sialoprotein (BSP), and osteopontin are the most abundant. Most of the noncollagenous proteins play important roles in the organization of the extracellular matrix (cell-cell and cell-matrix attachment, cell migration, growth, development, fibril formation, and mineralization). Besides these components, several specific enzymes and small peptides are an integral part of the organic matrix and play an important role in skeletal metabolism (see below). The calcium-collagen-cell composite ensures the two main functions of bone: providing a structural framework and a reservoir for mineral ions.

Bone Structure

Most bones of the human skeleton are composed of two structurally distinct types of tissue: cortical (dense, compact) and trabecular (cancellous,



Bone Metabolism, Fig. 1 Structure of bone tissue

spongy) bone (Fig. 1). Both types contain the same elements: cells (osteocytes) embedded in a mineralized matrix and connected by small canals ("canaliculi"). In cortical bone, which makes up 85% of the skeleton, these components form elongated cylinders of concentric lamellae surrounding a central blood vessel (called osteon or Haversian system). Cortical bone constitutes the cortex of many bones, shows a high degree of mineralization, a comparatively low number of cells, and provides the framework for the interior cancellous parts of bone. In contrast, trabecular (or cancellous) bone is organized in a sponge-like network of thin, interconnected spicules (trabeculae) with a larger number of cells (**osteoblasts** and **osteoclasts**) distributed over a huge surface. Consequently, the metabolic rate of trabecular bone is much higher than that of cortical bone.

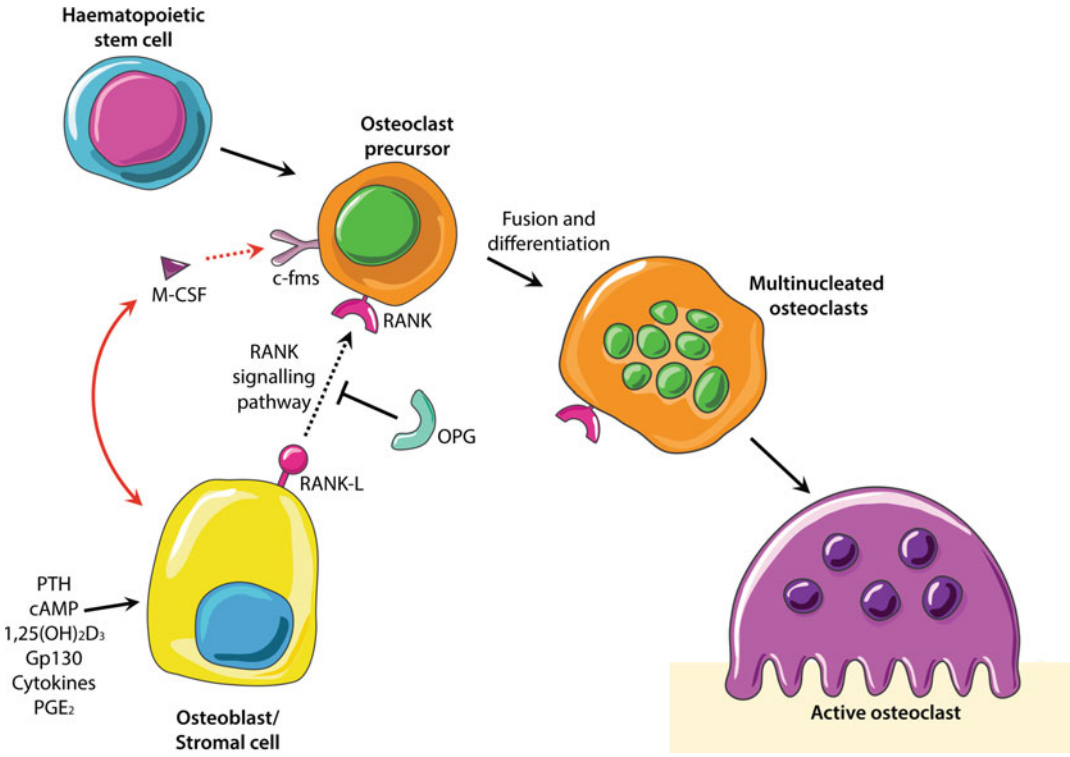
Mechanisms of Bone Remodeling

Bone is a metabolically active tissue that undergoes constant *remodeling*. The term "*modeling*" is restricted to the period of skeletal growth, when the size and shape of the bone is determined. *Bone remodeling*, on the other hand, continues throughout adult life and results in renewal of the entire skeleton every 7–10 years. Healthy remodeling requires that bone formation and resorption are in balance with each other, that is, osteoblasts replace the same amount of bone previously removed by the osteoclasts. Normal bone remodeling is necessary for repair and maintenance of normal bone structure in response to continuous stress and strain, as well as for mineral homeostasis (e.g., release of calcium in times of dietary calcium deficiency) and systemic fuel metabolism. While bone formation is achieved through cells of the osteoblast lineage (osteoblasts, bone lining cells, and osteocytes), osteoclasts are responsible for bone resorption. The coordinated actions of these cells together form the bone remodeling unit (BRU, also known as basic multicellular unit, BMU).

Osteoblast lineage cells – Osteoblasts are derived from mesenchymal stem cells (MSCs) that first differentiate into preosteoblasts and then into mature, bone matrix producing osteoblasts. The key molecular switch in the commitment of MSCs to the osteoblast lineage is "runt-related transcription factor 2" (*RUNX2*), which has multiple upstream regulators such as the Notch and Wnt signaling pathways. Canonical Wnt signaling regulates most aspects of osteoblast

physiology including cell commitment, differentiation, maturation, bone matrix formation, mineralization, and apoptosis. As preosteoblasts transition to mature osteoblasts, they increase the expression of osterix and secrete bone matrix proteins including osteocalcin, bone sialoprotein (BSP) I/II, and collagen type I. Resting or quiescent osteoblasts become "bone lining cells," covering the bone surfaces where neither bone resorption nor formation occurs. These cells serve as a reservoir for bone forming cells and reacquire their secretory activity during the next bone remodeling cycle. Osteoblasts trapped and embedded in the mineralized matrix are called osteocytes and are important for many properties of living bone (Fig. 1).

Osteoclasts – Osteoclasts are large, terminally differentiated multinucleated cells that originate from cells of the hematopoietic stem cell lineage (macrophages). Osteoclast formation is controlled by circulating hormones such as parathyroid hormone (PTH), 1,25-dihydroxyvitamin D_3, and estrogens, as well as by local growth factors (e.g., transforming growth factor (TGF) - β) and cytokines generated in the bone and bone marrow microenvironment. This control is mostly indirect as the receptors for majority of these factors are located on the osteoblast surface. Osteoblastic cells therefore control osteoclast formation through the expression of various stimulatory and inhibitory factors. For example, osteoblasts and stromal cells secrete macrophage colony-stimulating factor (M-CSF), which binds to the colony-stimulating factor-1 receptor (c-fms) on preosteoclasts, resulting in their differentiation to mature osteoclasts. Osteoblasts and osteocytes also secrete a cytokine known as receptor activator of nuclear factor kappa-B (RANK) ligand (RANKL), which acts by binding to its receptor, RANK, on osteoclast precursors to induce these cells to fuse and differentiate into mature osteoclasts. RANKL also stimulates existing osteoclasts to increase their bone resorbing activity (Fig. 2). The activity of RANKL is



Bone Metabolism, Fig. 2 Mechanisms of osteoclast activation

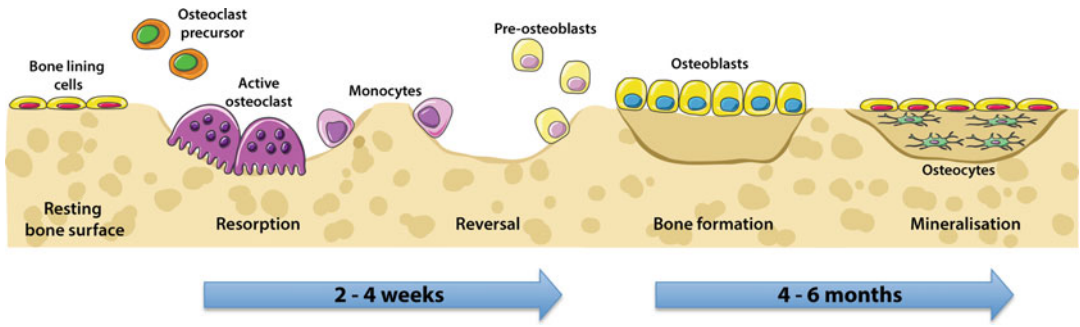
regulated by another osteoblast-derived protein, osteoprotegerin (OPG), which is a decoy receptor for RANKL, preventing its binding to RANK.

The bone remodeling cycle – Initiation of bone remodeling is the first important step that ensures remodeling only takes place when required. In *targeted remodeling*, the initiating signal comes from osteocytes that use their network of dendritic processes to receive and signal to other cells. For example, micro-damage to the matrix disrupts the osteocyte canaliculi, which in turn induces apoptosis of the osteocyte at that site. This leads to the release of paracrine factors that increase local angiogenesis and recruitment of osteoclast and osteoblast precursors. In contrast, *nontargeted remodeling* is not directed towards a specific site and refers to remodeling in response to systemic changes in hormones such as PTH, allowing access to bone calcium stores.

Once initiated, the remodeling cycle occurs in a highly regulated manner involving activation, resorption, reversal, formation, and termination, which occur over the course of 120–200 days (Fig. 3). Firstly, osteoclast precursor cells are recruited from the circulation and ***activated*** as described above. Next, bone lining cells separate from the underlying bone by forming a raised canopy over the site to be resorbed. Activated osteoclasts then attach to the exposed bone surface to form a sealed cavity, known as the resorption pit. This "construction site" is therefore well isolated from the surrounding bone.

The actual process of bone ***resorption*** involves rearrangement of the osteoclast cytoskeleton, resulting in the development of a specialized membranous structure referred to as the "ruffled border." It is through this structure that acids (H+) and proteases (cathepsin K and matrix metalloproteases) are secreted, dissolving both the mineral and matrix components of bone and ultimately creating a resorption pit, also known as Howship's lacuna. The minerals and protein fragments released during this process are absorbed into the osteoclast by endocytosis and are partly processed and later secreted from the distal side of the osteoclast, from where they eventually reach the circulation. The resorption phase is terminated by programmed cell death, ensuring that excess resorption does not occur.

The ***reversal*** phase couples bone resorption to bone formation at the remodeling site. Mononuclear cells, including monocytes and preosteoblasts, occupy the resorption lacuna. Identifying the coupling signals and mechanisms coordinating osteoclast and osteoblast activities has been the subject of ongoing research (see Sims and Martin (2020) for review). Several osteogenic molecules, likely released by osteoclasts, have been identified. These include factors released from the bone matrix during bone resorption (e.g., TGF-β, insulin-like growth factor 1 (IGF-1), platelet-derived growth factors) that stimulate the expansion and differentiation of osteoprogenitor cells, as well as coupling factors secreted by mature osteoclasts that are independent of its resorptive activity (e.g., cardiotrophin-1, BMP6, Wnt10b, sphingosine-1-phosphate). Factors expressed on the osteoclast cell membrane (e.g., EphrinB2 and Semaphorin



Bone Metabolism, Fig. 3 The bone remodeling cycle

D) that require cell-cell contact with osteoblast lineage cells have also been identified.

The ***formation*** stage lasts approximately 3–4 months. New bone formation can be divided into two parts. Once osteoblasts are fully matured, they first synthesize and secrete collagen (mainly type I collagen) and noncollagen proteins such as osteocalcin, osteonectin, BSP, osteopontin, and proteoglycans, which together form the organic bone matrix or "osteoid." Osteoblasts then co-regulate osteoid mineralization, which occurs in two steps: the relatively rapid primary mineralization, and the much slower process of secondary mineralization. The final phase of the formation process is cessation of osteoblast activity. It is not known how this level of spatiotemporal regulation is achieved. One possibility is that factors produced during osteoblast differentiation decrease osteoblast activity. One such factor could be TGF-β since active TGF-β decreases differentiated function in osteoblasts.

The remodeling cycle reaches the ***termination*** stage once mineralization is complete. At this stage, the mature osteoblasts can undergo apoptosis, change into bone lining cells, or become embedded within the bone matrix and terminally differentiate into the master of the bone universe, the osteocyte. Osteocytes play a key role in signaling the end of the remodeling process via secretion of antagonists of osteoblastogenesis, specifically antagonists of the Wnt signaling pathway such as sclerostin.

Hormonal Regulation of Mineral Homeostasis and Bone Remodeling

As bone remodeling is part of the body's mineral (calcium/phosphate) homeostasis as well as a mechanism for repair and adaptation, all cellular events are regulated by systemic and local factors. The latter include autocrine and paracrine signals produced by the bone cells (e.g., growth factors, prostaglandins, and cytokines) but also molecules released from the bone matrix during bone resorption (e.g., glycoproteins, collagen fragments, osteocalcin, and certain growth factors laid down in the osteoid during bone formation). Systemic (hormonal) modulators include parathyroid hormone, 1,25-dihydroxyvitamin D, calcitonin, glucocorticoids, androgens and estrogens, insulin-like growth factors, thyroid hormone, etc.

Parathyroid hormone (PTH) plays a central role in the regulation of bone remodeling and mineral homeostasis. PTH is an 84-amino acid polypeptide secreted by the parathyroid glands in response to reductions in blood levels of ionized calcium. The primary physiological effect of PTH is to increase serum calcium concentrations. It does so by increasing renal calcium reabsorption (while increasing phosphate excretion), and stimulating conversion of the inactive metabolite of vitamin D, 25-hydroxy-vitamin D, to its biologically active metabolite 1,25-dihydroxyvitamin D. PTH acts on bone to acutely increase bone resorption and thus release skeletal calcium from the skeleton into the circulation.

The steroid hormone **1,25-dihydroxyvitamin D** increases both intestinal calcium absorption and bone resorption, but has also been found to stimulate bone formation. In contrast, **calcitonin** rapidly inhibits osteoclast activity and thus decreases serum calcium levels. Calcitonin is synthesized in the parafollicular C-cells of the thyroid and acts on osteoclasts by increasing the intracellular cyclic AMP content of the cell. This then causes contraction of the ruffled border.

Estrogen binds directly to estrogen receptors (ER) α and β on bone cells. It plays a crucial role in bone homeostasis and is a central regulator of osteoclast activity and life span. The decline in estrogen levels postmenopause is considered the main cause of bone loss and osteoporosis in older women. At physiological (premenopausal) levels, estrogens reduce bone loss by inhibiting the generation of new osteoclasts, reducing the activation frequency and promoting apoptosis of mature osteoclasts. Some of the effects of estrogens seem to be mediated via the modulation of growth factors and cytokines, while others are associated with binding to at least two different estrogen receptors (ERα, ERβ).

Androgens, like estrogen, are essential for skeletal development and maintenance of bone mass and can act directly and indirectly through both the androgen receptor and ERα on bone cells. Testosterone's actions are mostly "anabolic," that is, supporting bone formation. However, as

testosterone is metabolized via the cytochrome P450 aromatase enzyme complex into 17-β-estradiol, it can also have antiresorptive effects.

The hypothalamic-pituitary-thyroid axis plays a major role in bone mineral homeostasis, skeletal development and peak bone mass achievement. **Thyroid hormones** increase the metabolic rates of both osteoclasts and osteoblasts and thus, increase the rates of both bone resorption and formation. With excessive amounts of thyroid hormone, there is increased bone surface engaged in bone remodeling, which in turn can result in low bone mineral density.

At physiological (endogenous) levels, **glucocorticoids** direct mesenchymal stem cells to differentiate towards osteoblasts, and thus increase bone formation via upregulation of the Wnt/β-catenin pathway in mature osteoblasts (Zhou et al. 2009). However, at supraphysiological concentrations (glucocorticoid therapy, endogenous hypersecretion), glucocorticoids inhibit bone formation. The main targets of glucocorticoids in bone are the cells of the osteoblast lineage: thus, high-dose glucocorticoids suppress osteoblast activity within hours of administration, and induce osteoblast and osteocyte apoptosis (Rauch et al. 2010; Weinstein et al. 1998). Excess glucocorticoids may also indirectly promote bone resorption via changing RANKL/OPG balance, sclerostin action, and decreasing renal calcium reabsorption and intestinal calcium absorption. From a pathophysiological point of view, glucocorticoid-induced osteoporosis (GIO) is a disease entity completely distinct from postmenopausal osteoporosis.

Pharmacological Intervention

Since the 1980s, numerous effective pharmacological strategies have been developed to modulate bone turnover, cell differentiation, or activity to prevent or treat bone loss/osteoporosis or metabolic bone diseases such as Paget's disease of bone (Table 1). Agents that inhibit osteoclast formation and/or activity are usually classified as antiresorptive or anticatabolic drugs, while stimulators of osteoblast formation and/or activity are

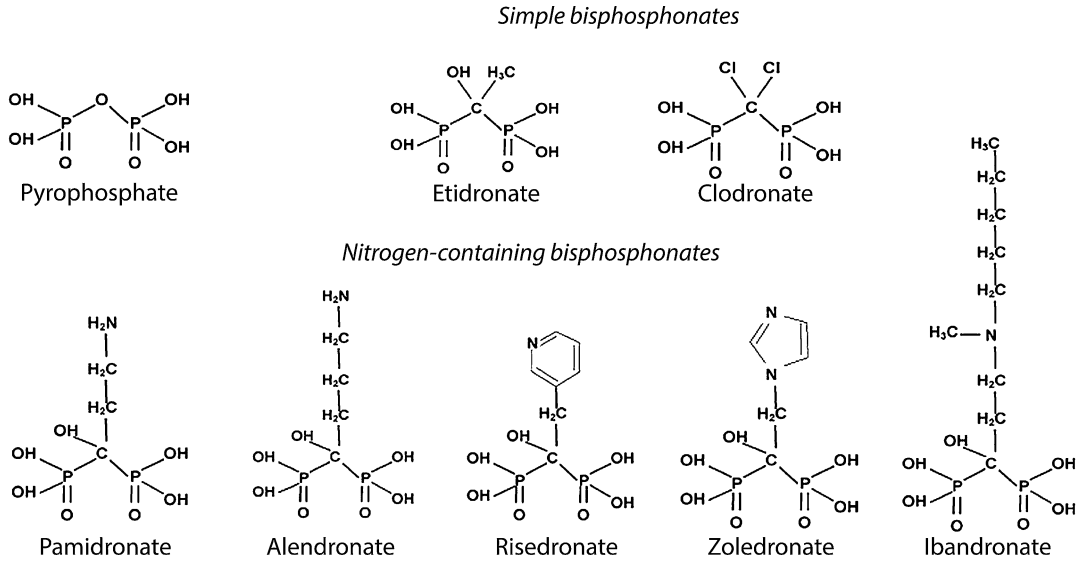
Bone Metabolism, Table 1 Current and future agents to modulate bone metabolism

Inhibitors of osteoclast activity	Stimulators of osteoblast activity
Agents currently approved in multiple countries for pharmacotherapy	
Bisphosphonates (e.g., alendronate, risedronate, zoledronic acid, ibandronate, etc.)	Parathyroid hormone and parathyroid hormone analogs (e.g., teriparatide)
RANKL antibody (denosumab)	Sclerostin antibody (romososumab)
Selective estrogen receptor modulators (SERMs) (e.g., raloxifene)	Calcitrol (1,25dihydroxy vitamin D) and analogs (e.g., 1-alpha-hydroxy vitamin D; very limited use; not for osteoporosis)
Strontium salts (e.g., Sr Ranelate; very limited use)	Androgens (limited use)
Estrogens	High dose estrogens (limited use)
Calcitonin and synthetic analogs (very limited use)	PTH-rP and PTHrP analogs (currently limited use)
	Fluorides (very limited use)
Agents currently under investigation	
Enzyme inhibitors (e.g., MMPs, cathepsin K)	Growth factors (e.g., GH, IGFs FGFs)
Calcium receptor modulators	Prostaglandins (PGs) and PG mimetics
Osteoprotegerin	Endothelins and analogs
Anticytokines (e.g., IL-1, TNFs, IL-1 Rc constructs)	Amylin and analogs
Protein pump inhibitors	Mechanoreceptor modulators (e.g., glutamate)
Nitric oxide modulators	Purinergic modulators
Adhesion molecule inhibitors	Proteosome inhibitors
	Intracellular signaling targets (e.g., SMADs)

called anabolic agents. Some compounds, such as bioactive vitamin D or estrogens, seem to affect both bone formation and bone resorption. Over the past 10 years, more and more specific agents have been developed that target a single molecule key to either of the two processes. However, due to the physiological coupling of bone formation and resorption, it has been difficult to reach the holy grail of osteoporosis therapy, that is, bone anabolic activity without an increase in bone resorption, or reduction in bone resorption without a synchronous decrease in bone formation activity.

Bisphosphonates are counted amongst first line treatments of benign and malignant bone diseases. Bisphosphonates are analogs of pyrophosphate (Fig. 4), an effective endogenous inhibitor of ectopic mineralization. All bisphosphonates have the phosphate-carbon-phosphate structure, with side chains bonded to the carbon. These side chains confer different properties, varying in their affinity to bind to hydroxyapatite and enzymes within the osteoclast, and thus their ability to resorb bone. Bisphosphonates can be classified into at least two groups with different mechanisms of action. The simpler nonaminobisphosphonates such as etidronate and clodronate can be metabolically incorporated into intracellular analogs of ATP and cause cell death. The newer and more potent nitrogen-containing bisphosphonates (e.g., alendronate, risedronate, ibandronate, and zoledronate) have a different mechanism of action. After entering the cell by fluid-phase endocytosis, they inhibit farnesyl pyrophosphate synthase, an enzyme in the mevalonate pathway that is necessary for osteoclast ruffled border formation. Bisphosphonates have been shown to be highly effective in the treatment of osteoporosis, cancer bone metastasis, multiple myeloma, and Paget's disease of bone. While generally very well tolerated, very rare adverse effects are osteonecrosis of the jaw (ONJ) and atypical femur fractures (AFF). ONJ is mostly seen in patients with multiple myeloma or bone metastases who receive high-dose intravenous bisphosphonate treatment in conjunction with other cell-toxic agents (chemotherapy, glucocorticoids) (Bamias et al. 2005). Atypical femur fractures are more often seen in osteoporotic patients on longer-term oral or intravenous bisphosphonate therapy.

The anti-RANKL antibody, denosumab, prevents RANKL from binding to its receptor RANK



Bone Metabolism, Fig. 4 Chemical structure of pyrophosphate, simple bisphosphonates, and nitrogen-containing bisphosphonates

on osteoclast precursors, thus inhibiting osteoclastogenesis, activation, and survival and thereby increasing bone mass and strength. Denosumab is monoclonal antibody administered by subcutaneous injection and has been demonstrated in numerous studies to reduce fracture risk in patients with osteoporosis, as well skeletal related events in patients with cancers metastasis to bone (Cummings et al. 2009; Gul et al. 2016).

Estrogens (usually in the form of hormone replacement therapy; HRT) have been shown to reduce the risk of osteoporotic fracture (and of colon cancer) but carry a small risk of breast cancer and cardiovascular events after prolonged use. While effective in controlling menopausal symptoms, the long-term use of estrogens to prevent bone loss or treat osteoporosis is not being recommended, particularly in older women. **Selective estrogen receptor modulators (SERMs)** have been designed to selectively activate estrogen receptors (ERs) in bone. Tamoxifen, a triphenylethylene compound used in the treatment of breast cancer, has long been known to moderately inhibit bone loss, while at the same time stimulating endometrial proliferation. In contrast, raloxifene reduces vertebral but not non-vertebral fracture risk in postmenopausal women without the unwanted endometrial effects (Ettinger et al. 1999). In fact, raloxifene has been shown to significantly reduce the risk of breast cancer recurrence. Estrogens and SERMs are not potent enough to inhibit the grossly exaggerated osteoclast activity in malignant or Paget's disease of bone. Combined SERM and estrogen drugs are also being developed (also known as **tissue-selective estrogen receptor complexes; TSECs**). The molecular mechanism is difficult to delineate as both components of the TSEC compete for the same ligand-binding pocket on the ER.

The antisclerostin antibody, romosozumab, is a potent anabolic agent targeting the Wnt signaling pathway. Romosozumab works by preventing the inhibitory actions of osteocyte-derived sclerostin on osteoblast activity. Unlike other Wnt antagonists such as dickkopf-related protein-1 (Dkk-1) or secreted frizzled-related protein-1 (sFRP-1) that are widely expressed, sclerostin is predominantly expressed in the bone. Twelve months of treatment with romosozumab, an injectable humanized monoclonal antibody, has been shown to increase bone formation without significant changes in bone resorption and results in rapid gains in bone mass (McClung et al. 2014; Chavassieux et al. 2019). It has been approved in several countries for the prevention and treatment of postmenopausal osteoporosis.

Cathepsin K inhibitors target osteoclasts to impair bone resorption by inhibiting the major protease response for type I collagen degradation. Several cathepsin K inhibitors have been developed and clinically evaluated; however, they have not been pursued due to safety concerns. For example, odanacatib was a promising agent to treat osteoporosis and bone metastasis as it substantially reduced risk of clinical vertebral fractures; however, its multibillion dollar development program was terminated in 2016 due to an increased risk of stroke found in clinical safety analyses (Mullard, 2016). MIV-711 is another cathepsin K inhibitor, which is currently still under development for the treatment of osteoarthritis.

Due to its strong and acute antiresorptive effect, **calcitonin** has been used in the past to treat a variety of metabolic bone diseases, including osteoporosis, hypercalcaemia of malignancy, and Paget's disease of bone, However, calcitonin has all but disappeared from clinical use as more potent and better tolerated drugs have become available.

PTH and PTH analogs have a dual effect on bone cells depending on the temporal mode of administration. Given intermittently, PTH and the PTH analog teriparatide stimulate osteoblast activity and lead to substantial increases in bone density. In contrast, when given (or secreted) continuously, PTH stimulates osteoclast mediated bone resorption and suppresses osteoblast activity. The anabolic effects of PTH on osteoblasts are probably both direct and indirect via growth factors such as IGF-1 and TGF-β. The multiple signal

transduction pathways mediating the effects of PTH on bone cells include activation of cyclic AMP, intracellular protein phosphorylation, activation of phospholipase C, protein kinase C, tyrosine kinase c-src, and the generation of inositol 1,4,5-triphosphate (IP3).

Teriparatide is a fragment of full length PTH (1-34 PTH) and has been shown to increase bone mass and reduce the risk of fractures in men and women with osteoporosis (Neer et al. 2001). The drug is administered via daily subcutaneous injection over 24 months; however, its anabolic effect diminishes with time, along with an increase in bone resorption. Abaloparatide is a highly selective and high affinity PTH-related protein (PTHrP) analog, which was approved by the US FDA in 2017 to treat postmenopausal osteoporosis.

Vitamin D and calcium supplements are often used as an adjuvant in the treatment of osteoporosis. In patients with clear calcium deficiency, oral calcium at doses of 1000–1200 mg per day corrects a negative calcium balance and suppresses PTH secretion. Sufficient calcium intake is important for the accrual of peak bone mass in the young. Its role in the prevention and treatment of osteoporosis (i.e., the effect of calcium supplements on actual fracture risk) is controversial.

Cholecalciferol (vitamin D_3) is synthesized in the skin through UV radiation (sun exposure) and is the main source of vitamin D in humans. Ergocalciferol (vitamin D_2) is derived from the diet and plays a minor role in human vitamin D supplies. Both forms are metabolized in the liver to 25-hydroxyvitamin D (calcidiol). The latter is the storage form of vitamin D and is believed to have little biologic activity. The active form of vitamin D is generated in the kidney through the hydroxylation of C1, leading to 1,25-dihydroxyvitamin D. This last step is tightly controlled by a number of regulators such as PTH. 1,25-dihydroxyvitamin D (calcitriol) is a potent steroid hormone with almost countless effects throughout the body. In bone, calcitriol has differentiation inducing as well as activating effects on both osteoblasts and osteoclasts. It also increases the absorption of calcium from the gut.

Data from clinical trials show that the daily supplementation with 500–1200 mg of calcium and 700–1000 IU of oral Vitamin D reduce the rate of bone loss in postmenopausal women (Tang et al. 2007; Boonen et al. 2007, DIPART (vitamin D Individual Patient Analysis of Randomized Trials) Group, 2010). Whether this treatment regimen also reduces the risk of fragility fractures in community-living younger men and women is rather controversial. If any, the effect in this population is minor. However, in the elderly, supplementation with oral calcium and vitamin D reduces the risk of hip and nonvertebral fracture by 30–40%. Warning: So-called "active" vitamin D-metabolites (i.e., calcitriol or 1-alpha calcidol) have no place in osteoporosis therapy and are outright dangerous drugs due to their very narrow therapeutic window (hypercalcaemia, renal calculi).

Strontium salts have long been under investigation as anabolic agents for bone. Strontium is naturally present in bone in trace amounts, with around 100 μg in every gram of bone. Given therapeutically, strontium substitutes for calcium in hydroxylapatite crystals, which is the major reason for the clinically observed, apparent increase in bone density. In humans, studies in high-risk patients have shown borderline reductions in vertebral fracture risk (Reginster et al. 2012). The mechanism of action is largely unknown and may involve modulation of the calcium receptor or calcium channels. Strontium ranelate has been discontinued in many countries due to associated life-threatening allergic reactions and increased risk of cardiac events.

Fluoride ions stimulate bone formation by a direct mitogenic effect on osteoblasts mediated via protein kinase activation and other pathways. Further to these cellular effects, fluorides alter hydroxyapatite crystals in the bone matrix. In low doses, fluorides induce lamellar bone, while at higher doses abnormal woven bone with inferior quality is formed. The effect of fluorides on normal and abnormal (e.g., osteoporotic) bone

therefore depends on the dose administered. Fluoride salts for the treatment of osteoporosis have been popular in some countries, but like calcitonin and strontium have virtually disappeared from clinical use.

The evolution of our understanding of bone metabolism has simultaneously driven considerable progress in the development of effective therapeutics to treat bone disease. Although several antiresorptive and anabolic drugs are now available, their use (or prolonged use) is hindered by side effects and long-term efficacy, thus the need for continuous drug discovery and development. Several new agents that target bone cell signaling/activity and local and systemic regulators of bone remodeling are currently under investigation (see Table 1).

Bone Morphogenetic Proteins

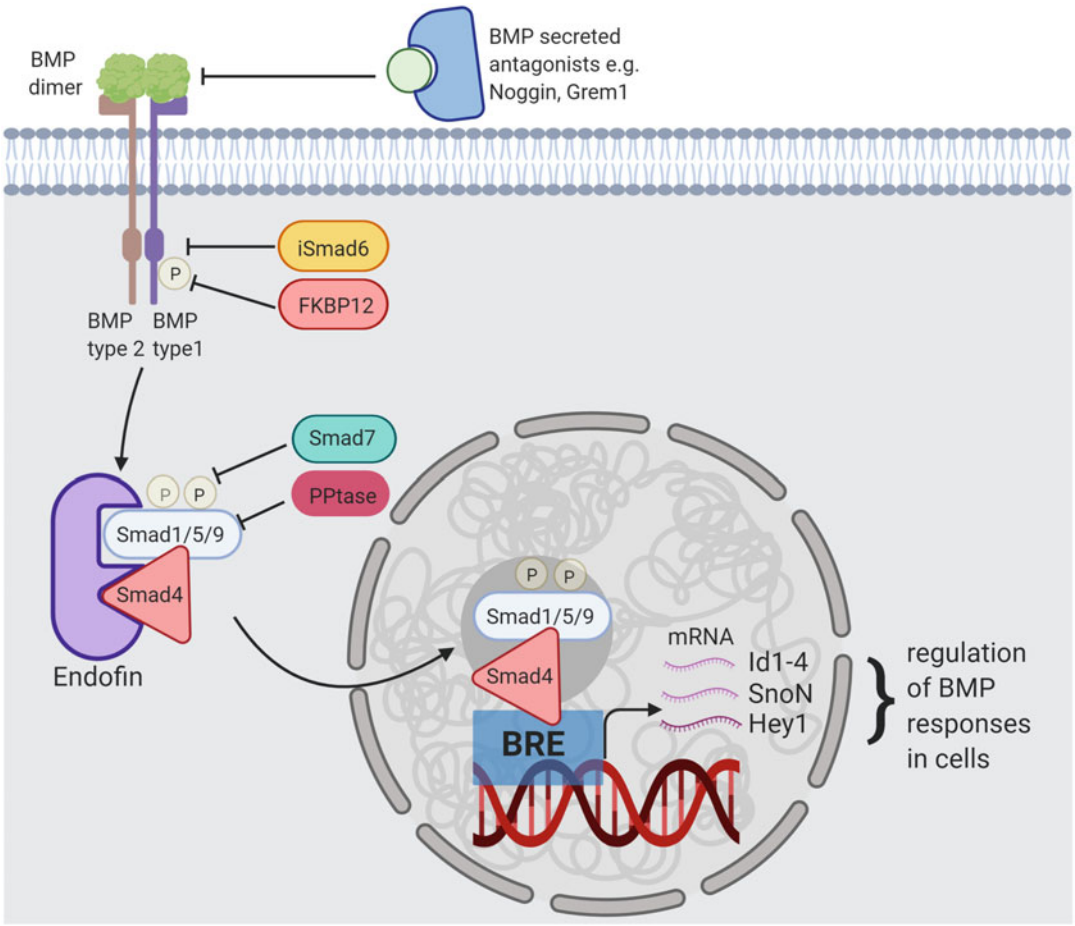
Derek P. Brazil
Wellcome-Wolfson Institute for Experimental Medicine, Queen's University Belfast, Belfast, Northern Ireland, UK

Introduction

Bone morphogenetic proteins (BMPs) are secreted glycoprotein members of the transforming growth factor-beta (TGFβ) superfamily. BMP signalling plays pivotal roles in developmental processes such as bone and cartilage, teeth, and kidney formation. There are about 22 members of the BMP family in mammalian cells, and all engage specific plasma membrane receptors to activate Smad signalling pathways that transmit BMP signals to the nucleus where a specific subset of genes are regulated. BMP signalling pathways are tightly controlled at multiple nodes inside and outside the cell. Significantly, a family of secreted BMP antagonists exist in the extracellular matrix that bind to and inhibit BMP signalling. This rigorous control of BMP signalling is critical for normal developmental processes, and disruption of this process leads to developmental disorders such as defective bone/cartilage formation, altered kidney development, and pulmonary artery hypertension (PAH). Aberrant BMP signalling is implicated in many human diseases including fibrosis of the kidney and lung, iron metabolism, and a range of cancers. Several pharmacological strategies based on increasing or decreasing BMP signalling have been developed as potential novel therapies for kidney and lung fibrosis, cancer, and vascular disease. This essay will provide an overview of BMP biology, summarize recent updates in BMP signalling, and provide sample vignettes of therapeutic targeting of BMPs and related proteins.

Basic Characteristics

Several excellent comprehensive reviews have been published in recent years that provide in-depth detail of BMP family biology and signalling (Miyazono et al. 2010; Gomez-Puerto et al. 2019; Walsh et al. 2010; Wang et al. 2014; Canalis et al. 2003; Massagué 2012; Brazil et al. 2015). The first BMP was discovered by Marshall Urist in 1965 as a factor that induced bone or cartilage formation when added to mesenchymal stem cells. At a very basic level, the basic model of BMP signalling is similar to many growth factors and cytokines. BMP dimers engage two distinct plasma membrane tyrosine kinase receptors (type 1 receptors, e.g., BMPR1A/1B or Alk1/2, and type 2 receptors, e.g., BMPRII or ActRIIA/B (Yadin et al. 2016)) that then dimerize and lead to receptor kinase activation and receptor autophosphorylation. This in turn leads to phosphorylation of intracellular mediators called receptor Smad proteins (R-Smad1/5/8) which then bind to Smad4 causing nuclear translocation of the Smad protein complex. The assembly of this complex of proteins is mediated by a scaffold protein called Endofin. Once in the nucleus, R-Smad1/5/8 localize to chromatin complexes centered around BMP response elements (BREs) in DNA to regulate the transcription of BMP target genes such as inhibitor of differentiation (Id1-4), SnoN, and Hey1 transcription factors in osteoblasts (Miyazono et al. 2005). Integrated within this somewhat simplified description of BMP signalling are multiple additional regulatory processes that add a high level of complexity to BMP signalling (summarized in Fig. 1). For example, proteins such as FKBP12 and Smad6 (an inhibitory Smad, iSmad) bind to BMPRI in the absence of BMP ligand and inhibit receptor activation. Binding of BMP proteins to their receptors leads to FKBP12 and iSmad6 dissociation from BMPRI, facilitating BMP receptor activation and signalling. The mechanism of iSmad6 dissociation involves methylation of Smad6 by PRMT1 on Arg74 and 81, allowing R-Smad1/5/8 phosphorylation and BMP signalling. The requirement for this methylation event to occur prior to transduction of BMP signalling may explain why the kinetics of BMP signalling is slower (~10 min) compared to other growth factors such as insulin or EGF (~1–2 min). A similar mechanism exists to control TGFβ1 signalling (see below).



Bone Morphogenetic Proteins, Fig. 1 Schematic summary of canonical BMP signalling pathway. BMP dimers bind to a heterotetrameric complex of two BMP type 1/type 2 receptors, which dimerize and lead to phosphorylation of the type 1 receptor by the type 2 receptor on serine/threonine residues. R-Smads 1/5/8 are then phosphorylated by the activated BMP receptor complex, which leads to their binding to Smad4, facilitated by the Endofin anchor protein. The R-Smad/Smad4 complex translocates to the nucleus where it binds to specific BMP response elements (BREs) on a subset of target genes such as Id1-4, SnoN, and Smad6. The protein products of these genes mediate the complex cellular responses to BMP proteins. Regulation of the pathway is achieved at multiple levels including secreted BMP antagonist binding to BMP dimers in the extracellular matrix, iSmad6 and FKBP12 preventing BMP receptor activation, and Smad7/protein phosphatase inhibition of R-Smad phosphorylation and nuclear translocation

A family of BMP antagonists that include Noggin, Gremlin (Grem1), Chordin, USAG-1, and crossveinless (CV2) control BMP action outside the cell. These secreted antagonists bind to BMPs in the extracellular milieu and prevent binding to their cognate receptors, attenuating signal transduction. Each of these BMP antagonists binds to specific target BMPs to regulate specific developmental processes. Perturbations in the balance of BMP v BMP antagonist levels can lead to defective mammalian development, as well as human disease (see below). Additional regulatory processes such as epigenetic modification of BMP response gene promoters/enhancers, miRNAs, ubiquitin ligases such as Smurf1 that target Smad proteins, and pseudo-receptors such as BAMBI create a hugely complex BMP signalling network in cells.

Despite the similarities in their signal transduction mechanisms, each BMP has distinct roles in mammalian development and physiology, linked to the tissue-specific temporospatial expression

and their interaction with secreted antagonists such as Noggin, Grem1, and USAG-1. Much of our knowledge of the biological roles of BMPs come from the phenotypes of BMP knockout mice. These data are beautifully summarized in a table from a review article from the Shi laboratory in Chicago (Wang et al. 2014). Perhaps not surprisingly, many BMP knockout mice display a broad range of defects in bone formation, increased fractures, defective fracture repair, and altered tooth formation. For example, mice lacking BMP2 are non-viable and die in utero due to defects in amnion/chorion and cardiac development. BMP4 knockout mice are also embryonic lethal due to a lack of mesoderm formation. Targeted disruption of BMP6 in mice causes a rapid and massive accumulation of iron in the liver, pancreas, heart, and kidney. BMP7 null mice survive gestation, but die shortly after birth, likely as a result of defective kidney formation and skeletal patterning. BMP9 knockout mice display defects in tooth development, lymphatic vessel formation, and retinal vascular remodelling. GDF5/6/7 (BMP14/13/12) have been shown to regulate tendon formation and fracture healing (Wang et al. 2014). BMP-Smad signalling plays a pivotal role in iron homeostasis via crosstalk with the hemojuvelin (HJV) receptor, which is a member of the repulsive guidance molecule (RGM) family. HJV acts as a co-receptor for BMP ligands and potentiates their signalling to Smad proteins. This leads to increased hepcidin transcription and iron uptake into liver cells and macrophages. Mutations in the BMP response element of the hepcidin gene are associated with iron overload in patients with hemochromatosis. Similarly, a range of mutations in HJV, the BMP ligand co-receptor, have been identified in patients with juvenile hemochromatosis.

Other genetic data from patients highlights the consequences of overactive BMP signalling in development and health. R206H mutations in ALK2 (the BMP type 1 receptor) lead to hyperactive BMP receptor signalling, likely due to a reduced receptor affinity for the inhibitory FKBP1A protein, leading to enhanced Smad phosphorylation. These patients develop a debilitating condition called fibrodysplasia ossificans progressive (FOP), which is characterized by heterotopic ossification, where bone forms in muscle and other soft tissue in the body (Song et al. 2010). Pulmonary artery hypertension (PAH) is another life-threatening disease where patients present with increased pulmonary artery resistance which can lead to right heart failure (Gomez-Puerto et al. 2019). Approximately 70% of familial PAH patients are heterozygous for inactivating mutations along the BMPR2 gene that lead to reduced BMP signalling and the PAH phenotype.

Myostatin/GDF8 signals via Alk4/5/ActRIIB receptors→Smad2/3 to inhibit myogenesis. Mutations in myostatin decrease myostatin signalling and lead to a "double-muscled" phenotype as seen in Belgian Blue cattle and very rare human patients. Mutations in Smad4 cause Myhre syndrome, characterized by muscle hypertrophy. The effect of these Smad4 mutations is linked to inhibition of myostatin signalling, leading to increased muscle mass similar to the examples above.

Overexpression of BMP2 has been identified in osteoarthritis and has been linked to cartilage degradation. Increased serum levels of BMP2 and BMP4 have been identified in osteoarthritis and have been suggested as markers of disease severity. Levels of the BMP antagonist Gremlin1 have also been identified in the synovial fluid of patients with rheumatoid arthritis. Amplified Gremlin1 expression may contribute to cartilage degeneration in arthritis by excessive mechanical loading and over-activation of the NFκB pathway. BMP7 has been explored as a potential treatment for osteoarthritis, given its anti-fibrotic potential. Downstream targets such as NFκB may be mediating the inflammatory effects of BMPs in these cells (see below).

BMP4 has been identified as a key regulator of both white and beige adipogenesis, and defective BMP signalling has been implicated in human hypertrophic obesity (Gustafson et al. 2015; Hammarstedt et al. 2018; Hedjazifar et al. 2019). Reduced BMP signalling in hypertrophic obesity

may occur due to increased Grem1 levels, which binds to BMP-4 and antagonises its receptor activation. A recent report identified that levels of Gremlin1 are upregulated in obesity and type 2 diabetes, leading to antagonism of insulin action in metabolic tissues. BMP9 regulates energy balance via inhibition of liver SREBP1 expression. BMP9 acts to reduce triglyceride accumulation and reduce fat accumulation in liver. Levels of BMP9 are reduced in insulin resistance and diabetes, suggesting a previously unappreciated role for BMP signalling in glucose metabolism, diabetes, and obesity.

Upregulated expression of the BMP antagonist Gremlin1 is also a feature of diabetic nephropathy (Walsh et al. 2008, 2010; Lappin 2002), pulmonary hypertension, and multiple human cancers, including colorectal, glioma, and breast cancer. A rare genetic form of colorectal cancer called hereditary mixed polyposis syndrome (HMPS) is caused by a 40-kb duplication event on chromosome 15 leading to ~2500-fold increase in Gremlin1 mRNA levels in colonic epithelial cells. This increase in Gremlin1 expression disrupts the finely tuned balance between BMP-4, Wnt Sonic Hedgehog (SHH), and Grem1 in the colonic villi, leading to increased epithelial cell proliferation at the tip of the villi and polyp/tumor formation. Other reports have corroborated these findings, showing that Grem1 levels are associated with metastasis and poor prognosis in ER-negative breast cancer. The source of Grem1 in these tumors is likely to be cancer-associated fibroblasts.

Apart from Grem1, other BMP antagonists have been implicated in human disease. USAG-1 is the most abundant BMP antagonist in the human kidney and acts to inhibit the renoprotective effects of BMP7 in this organ. Twsg1 is the main BMP antagonist secreted by glomerular podocytes. Expression of USAG1 and Twsg1 expression (as well as Grem1 discussed above) are increased in diabetic nephropathy, as well as other models of glomerular and tubular kidney injury. In liver disorders such as chronic hepatitis, cirrhosis, and hepatitis C, levels of BMP antagonists Grem1 and Follistatin have been shown to be amplified.

There are numerous papers describing roles for BMPs and their antagonists in cancer (Rider and Mulloy 2010). For example, Noggin has been implicated in melanoma, where it inhibits the anti-proliferative actions of BMP7, leading to tumor progression. Noggin has also been implicated in bone metastases of prostate cancer in men. The BMP antagonist Coco promotes the proliferation of breast cancer cells that have migrated to the lung, likely by overcoming the anti-proliferative drive mediated by locally produced BMPs. BMPs and their antagonists also play crucial roles in the regulation of cancer stem cell (CSC) phenotypes. For example, BMP2 produced by CSCs drives their differentiation and reduces CSC proliferative capacity. In extracts from glioblastomas from patients, expression of BMP2 was found to be high, and yet BMP2 activity was reduced in these cells. This anomaly was explained by high levels of Grem1 expressed by these tumors, leading to inhibition of BMP2 activity reducing CSC differentiation and attenuating the anti-proliferative effect of BMP2 (Seoane 2014). Crosstalk between BMP2 and TGFβ1 is critical in regulating the CSC phenotype, with TGFβ signalling implicated in maintaining CSC stemness and prevention of cell differentiation (see below).

BMP Signalling Crosstalk

There is a wealth of data in the literature describing crosstalk between BMP signalling and pathways critical in development and disease such as TGFβ, Wnt/β-catnenin, Notch, SHH, and NFκB. TGfβ1 ligand signalling (of which there are 32 members (Batlle and Massagué 2019)) occurs in a very similar manner to BMP signalling. TGFβ1 is produced in a pro-form that requires cleavage and activation by the extracellular endoprotease Furin. Active TGFβ then induces the dimerization of TGFβR1/TGFβR2 receptors triggering to the phosphorylation of R-Smad2/3, followed by Smad4 binding, nuclear

translocation, DNA binding, and gene regulation. In addition to canonical BMP→Smad1/5/8 and TGFβ→Smad2/3 pathways, crosstalk between these pathways has been described in a range of cellular contexts. In vascular endothelial cells, BMP and activin receptor membrane bound inhibitor (BAMBI) function as a competitive pseudo-receptor for the TGFβ family. Expression of BAMBI decreases TGFβ1-induced angiogenesis, by driving alternative TGFβ signalling via Smad1/5 and ERK1/2 phosphorylation. BAMBI expression and alternative TGFβ signalling have also been shown to play a role in the diabetic kidney disease, with evidence that targeting alternative TGFβ signalling may be a potential avenue for new treatments for diabetic nephropathy. TGFβ1 signalling via Smad1/5/8 pathways has been shown to regulate breast cancer epithelial cell migration and anchorage-independent epithelial cell growth.

Alternative BMP signalling to Smad2/3 has also been demonstrated during embryonic development and in invasive cancer of the breast and prostate. Both TGFβ and BMP alternative signalling pathways occur via the formation of non-canonical receptor complexes in specific cells that then facilitate the phosphorylation of specific Smad phosphorylation and alternative signalling. The balance between BMP and TGFβ1 signalling via canonical and alternative pathways is critical during development and disease. A protein called Kielin/Chordin-like protein-1 (KCP-1) acts as an inhibitor of TGFβ signalling by binding to TGFβ ligand, preventing receptor activation and reducing pro-fibrotic signalling (Vrijens et al. 2013). In contrast, KCP-1 binding to BMP7 enhances its receptor binding and increases anti-fibrotic BMP7 signalling. KCP-1 has been shown to attenuate high-fat diet-induced obesity and acute and chronic renal injury in mouse models. These reports demonstrate the potential of modulating the counterbalance between TGFβ and BMP signalling to improve outcomes in human disease.

BMPs and Wnt interact at several key signalling nodes during embryogenesis. Expression of BMP2 ligand is regulated by Wnt3a and β-catenin overexpression in osteoblasts during development. Smad4 has been identified in nuclear complexes with β-catenin, suggesting crosstalk at the DNA/transcriptional level. The interaction between BMP and Wnt signalling is exemplified in the intestine, where opposing gradients of BMP and Wnt expression exist. Levels of Wnt are highest at the villus base and lowest in the epithelial cells at the tip of the villus. In contrast, BMP expression is lowest at the villus base and increases as cells migrate up toward the tip of the villus. Dysregulation of this balance of BMP and Wnt has been identified in colon cancer. Loss of function of the APC tumor suppressor gene occurs in >90% of sporadic colon cancers. Loss of APC leads to enhanced Wnt signalling via stabilization of β-catenin, leading to increased β-catenin nuclear localization and amplified Wnt-mediated gene expression (Bertrand et al. 2012). This increased Wnt signalling leads to inappropriate epithelial cell proliferation, polyp formation, and increased cancer risk. A similar scenario exists when BMP signalling is perturbed in the intestine. Overexpression of Grem1, a BMP antagonist, leads to reduced anti-proliferative BMP signalling at the villus tip, leading to increased epithelial cell division, polyp formation, and cancer. BMP signalling also inhibits intestinal stem cell renewal via suppression of Wnt/β-catenin signalling. BMP-mediated suppression of Wnt/β-catenin-driven intestinal stem cell renewal has been shown to occur via PI3K/PTEN/Akt/14-3-3ζ signalling. Finally, Wnt/β-catenin signalling activates the transcription of the pseudo-receptor BAMBI, thus leading to suppression of TGFβ signalling as discussed in detail above.

The Notch pathway has been shown to act synergistically with BMP signalling in developing blood vessels and heart valves. Notch signalling is activated by Delta/Jagged ligand-mediated cleavage of the Notch transmembrane receptor, releasing the Notch intracellular domain (NICD) which translocates to the nucleus and forms a complex with the CBF-1 transcription factor to drive the expression of genes such as Hes1 and Hey1. BMP4 has also been shown to induce Hes1 and Hey1 in C2C12 mouse myoblasts, an event that is required for BMP-mediated myogenic differentiation. Physical complexes of Smad1 and NICD have been isolated and shown to

synergistically activate Hey1 expression to regulate fate determination in mouse neuroepithelial cells. In contrast, BMPs promote the migration of endothelial cells and the formation of stalk cells via induction of Id1 expression, a process that is inhibited by Notch-mediated Hey1 which represses Id1 expression. Others have shown that Notch signalling inhibits BMP9-induced osteogenic differentiation of mesenchymal stem cells (MSCs) by blocking JunB expression.

Sonic hedgehog (SHH) is a morphogen that regulates dorsoventral patterning during development (Zhu et al. 2019). SHH induces BMP4 expression in subepithelial fibroblasts in *Xenopus*, leaving to the development of cell-renewable epithelium. SHH is also a key morphogen in the colon and is primarily expressed at the tip of the villus in the differentiated zone. SHH has been shown to activate the expression of the BMP antagonist Grem1 in pancreatic cancer. Formation of limb buds in mice is regulated by a complex interplay of SHH, BMP/Grem1, and Jag1 acting on mesenchymal stem cells. A key element of this regulation is the repression of Grem1 expression via the action of Gli1, a transcriptional mediator of SHH signalling. Similar to Notch signalling, both SHH and Notch can both positively and negatively regulate BMP signalling, depending on the cellular context. Crosstalk between BMP signalling and the NFκB pathway has been identified by a number of groups. NFκB is the primary transcriptional mediator of pro-inflammatory cytokines such as TNF1 and IL-1β. NFκB activation has been shown to repress BMP2-mediated osteoblast activation and bone formation via interference with Smad proteins to BMP2 response genes in the nucleus. Signalling to NFkB may mediate many of the effects of BMPs and their antagonists on inflammatory diseases such as rheumatoid arthritis (see below).

The above examples highlight the complex nature of BMP signalling, with a range of regulatory loops, signalling nodes, and feedback circuits that can both amplify and dampen BMP signalling. These insights have given researchers useful leads on how best to intervene pharmacologically to manipulate BMP signalling in human disease. Some examples of these data are discussed below.

BMP Pharmacology

Pharmacological interventions aimed at both stimulating and inhibiting BMP action are in use and development in medicine. BMPs have been used as therapeutic agents for the treatment of bone fractures for a number of years. Recombinant human BMP2 (InFuse® from Medtronic) or rhBMP7 (OP-1 from Olympus) have been used as adjunct therapies for non-union fractures of long bones such as the femur (Gautschi et al. 2007). The osteoinductive properties of these BMPs are thought to accelerate bone healing in these patients, although reports questioning the efficacy and associated complications of BMP use exist in the literature. Given the proposed anti-fibrotic effects of BMP7 in kidney and other organs, its potential as a therapeutic anti-fibrotic agent has been investigated. Disappointingly, despite encouraging preliminary data, rhBMP7 did not display any clear benefit in treating fibrosis in the kidney, lung, and skin. Alternative approaches such as Thr123, a peptide mimetic of BMP7, and activators of BMP7 signalling such as tilerone and members of the flavonoid chalcone family have shown potential in mouse models of lung fibrosis. A novel peptide agonist of ALK2/BMPRI called P123 can block the growth of primary tumor cells and the progression of EMT in human breast cancer stem cells (CSCs). The BMP7 agonist THR-184 has been shown to have anti-inflammatory/anti-fibrotic actions in preclinical models of kidney injury. A recent study tested the ability of THR-184 to reduce acute kidney injury in patients post cardiac surgery in a placebo-controlled trial. No significant benefit was detected in THR-184 patients compared to placebo group. A recent report identified benzoxazole compounds as potent and efficacious agonists of BMP signalling in human renal cells. These compounds could be explored as potential anti-fibrotic agents based on their ability to activate BMP signalling.

Most of the focus in terms of BMP therapeutics centers on inhibiting overactive BMP signalling as the outcome of choice. Despite the low numbers of patients who develop FOP (97% of whom have the R206H mutation in the ALK2/BMPRI), significant efforts have focussed on developing

drugs to reduce excessive BMP signalling in these patients. The Bullock group in Oxford have identified a range of small molecule inhibitors of ALK2, and the crystal structure of ALK2 in complex with one of these (LDN-212854) has been solved and provides a useful template for developing new and improved treatments for FOP. Regeneron Pharmaceuticals has recently announced encouraging results from a Phase 2 trial to assess the efficacy of garetosmab (REGN2477), a drug designed to inhibit the R206H mutated form of ALK2/BMPRI in FOP patients (https://clinicaltrials.gov/ct2/show/study/NCT03188666). Other therapeutic strategies for FOP including saracatinib (a small molecule kinase inhibitor of ALK2/BMPR2) and rapamycin (an inhibitor of mTORC1 pathway) are also being explored for FOP. These and other strategies have been reviewed by Wentworth and colleagues (2019).

ALK2 inhibitors may also have potential as novel therapeutics for diffuse intrinsic pontine glioma (DIPG), where 25% of patients possess somatic mutations in ALK2. BMP9/10 have also been targeted in cancers, with Dalantercept, an ALK1-Fc fusion protein targeting the ALK1 receptor shown to reduce BMP9/10-mediated tumor angiogenesis. Dalantercept is now in Phase 2A clinical trials for advanced renal cell carcinoma. BMP9/10 are implicated in patients with hereditary hemorrhagic telangiectasia (HHT), a life-threatening vascular disorder with no current cure. Pulmonary artery hypertension (PAH) is characterized by vascular remodelling of the vasculature of the lung that can lead to death from heart failure within 3–5 years of diagnosis. The heritable form of PAH is caused by mutations in the BMPRII that reduce or inactivate receptor activity. Reversing BMPRII deficiency has therefore been explored as a novel treatment modality for PAH. One preclinical study has demonstrated that recombinant BMP9 enhanced BMPRII signalling and reversed lung damage in a genetic mouse model of PAH. A drug called sildenafil is used to treat PAH, as it enhances BMP4-mediated Smad1/5 phosphorylation and reduced smooth muscle cell proliferation in the lung. Sildenafil treatment has the potential to partially reverse the effects of reduced BMPR2 signalling in the lungs of PAH patients.

BMP9/10 have been shown to be crucial for postnatal retinal vascular remodelling in mice, with crosstalk to increased Notch signalling significant in this regard. Many patients present with mutations in the gene for the ALK1 receptor or Smad4. These mutations lead to defective BMP9/10 signalling and increased endothelial proliferation leading to inappropriate angiogenesis in these patients. Thus, BMP9/10 mimetic drugs have been sought to try to rectify the angiogenic imbalance in these patients. A drug-repurposing strategy screening the FDA-approved catalogue identified tacrolimus (FK506) as a potent activator of ALK1 in BMP9-challenged C2C12 cells. These authors also showed that tacrolimus could reduce the hypervascularization response in the retinas of BMP9/10-immunodepleted mice.

BMP2 and BMP4 have been identified as potential molecular targets in Barrett's esophagus, a chronic inflammatory condition associated with increased risk of esophageal adenocarcinoma. BMP4 has been identified as a driver of the altered columnar epithelial differentiation seen in Barrett's esophagus. Targeting the BMP4 pathway using the BMP antagonist Noggin has been explored as a novel therapy in a rat model of Barrett's esophagus. Targeting of the BMP antagonist Grem1 has also been suggested for a range of human diseases such as diabetic nephropathy, PAH, and colorectal cancer. Neutralizing antibodies against Grem1 have been developed by several pharma companies, and one report from Novartis demonstrated that inhibition of Grem1 action using a neutralizing antibody reduced the severity of lung damage in a mouse model of pulmonary artery hypertension. Small molecule inhibitors of Grem1 are also being explored as novel therapeutics for colorectal cancer. The predicted structures of Grem1 protein in complex with BMP2, as well as the crystal structure of Grem2 with GDF5, will be useful in pursuing a

rational drug design-based approach toward the development of novel Grem1 inhibitors.

Future Directions

As the above essay demonstrates, there are many exciting developments emerging in the field of BMP signalling. Insights into the molecular mechanisms of altered BMP signalling in diseases such as PAH and FOP have facilitated novel avenues of therapeutic exploration. Significant advances in our understanding of the role of BMPs and their antagonists such as Grem1 provide hope that targeting these pathways may enhance the effective treatment options for hard-to-treat diseases such as glioblastoma and colorectal cancer. Deeper dives into the cellular signalling pathways engaged by BMPs and their antagonists will shed new light on the pathogenic mechanisms of BMP and BMP antagonist signalling in human diseases. We look forward to new advances in our understanding of BMP signalling, which will likely extend our treatment options and improve patient outcomes for tissue fibrosis, iron metabolism, pulmonary hypertension, and cancer.

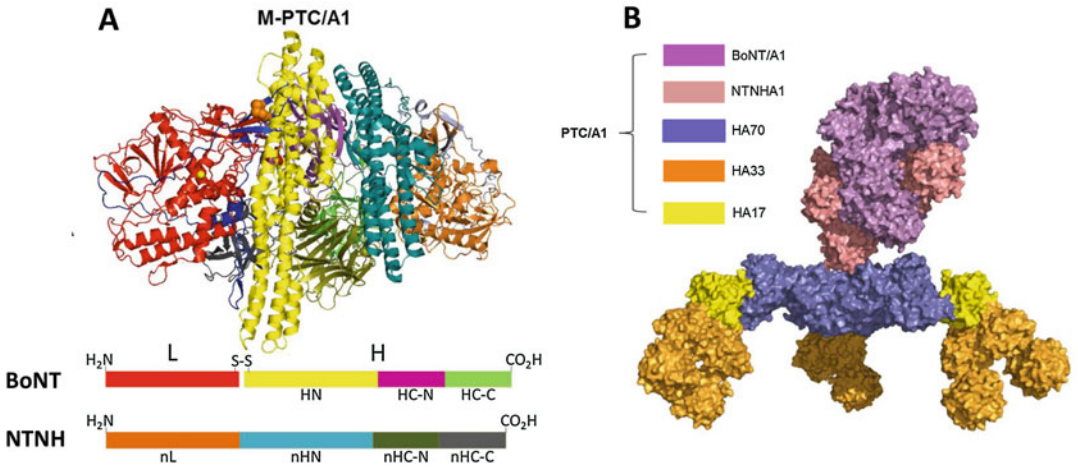
Botulinum Neurotoxins

Ornella Rossetto and Cesare Montecucco
Department of Biomedical Sciences and National Research Council Institute of Neuroscience, University of Padova, Padova, Italy

Definition, Serotypes, and Subtypes

The botulinum neurotoxins (BoNTs) form a family of protein neurotoxins endowed with a set of particular properties that have made them powerful therapeutics for a variety of human syndromes. Their development as medicines is still undergoing. They are synthesized by different *Clostridia* though bacteria of other phyla may harbor the gene encoding for BoNTs. They consist of two chains (L, 50 kDa and H, 100 kDa) linked by a single interchain disulfide bond (Fig. 1a). They are produced in eight different serotypes (indicated by letters BoNT/A, /B, /C, /D, /E, /F, /G, and /X) (Rossetto et al. 2014; Dong et al. 2019). In addition many subtypes of a serotype are known (dubbed with a suffix number: BoNT/A1, BoNT/A2, etc.) plus chimeric neurotoxins (BoNT/CD, BoNT/DC, BoNT/FA). Thus, the BoNT family comprises several dozens of proteins, and their number is growing as result of massive DNA sequencing. None the less all BoNTs share a four-domain structure, with a similar spatial folding of the polypeptide backbone, as depicted in Fig. 1a. The N-terminal domain is formed by the L chain, which is zinc endopeptidases (protease family M27) responsible for the intracellular biochemical lesion caused by the BoNTs. The L domain is followed by the HN domain (the first half of the H chain) which is responsible for the translocation of the L chain into the cytosol of nerve terminals. The third domain (HC-N, 25 kDa) likely contributes to neurospecific binding carried out by the C-terminus domain (HC-C, 25 kDa). HC-C has a conserved binding site for the oligosaccharide portion of polysialogangliosides, glycolipids highly enriched in the presynaptic membrane of neurons, and another site specific for the lumenal domain of the synaptic vesicle protein SV2 (BoNT/A and /E) or synaptotagmin (BoNT/B, /F, and /G). The neurospecific binding of BoNT/C and /D is not well characterized, but there is evidence that oligosaccharides of glycolipids or protein-linked N-glycans are involved together with an hydrophobic loop of the toxin that insert in the lipid bilayer (Rossetto et al. 2014; Dong et al. 2019).

The BoNT molecule is complexed with a BoNT-like molecule (NTNH: nontoxic non-hemagglutinin), devoid of protease activity, forming a hand-in-hand heterodimer creating a medium size protein complex (M-PTC) of 300 kDa that is more stable than BoNT to the acidic and proteolytic environment of the stomach (Fig. 1a). This heterodimer is then complexed with accessory nontoxic proteins (HA proteins), as shown in Fig. 1b, to form a so-called progenitor toxin complex (PTC ≈ 900 kDa in the case of BoNT/A) which is stable at acidic pH values, but dissociates in slightly alkaline physiologic solutions. The role of the HA proteins is believed to be that of assisting the translocation of the BoNT molecule from the intestinal lumen, across the mucus layer and the polarized epithelial monolayer, into the mucosa in the alimentary and infant forms of botulism. More detailed information are available in recent reviews (Rossetto et al. 2014; Dong et al. 2019).



Botulinum Neurotoxins, Fig. 1 (**a**) Crystal structure of BoNT/A1 in complex with the NTNH/A1 protein. NTNH/A1 exhibits the same domain organization as BoNT/A1, and the two proteins form a hand-in-hand complex, which suggests that NTNH/A1 protects BoNT/A1 from proteases and other damaging agents that the toxin meets in the stomach. The lower bar shows the schematic organization of the two proteins. (**b**) Structure of the precursor toxin complex of BoNT/A1 (PTC/A1) which consists of the NTNH/A1-BoNT/A1 heterodimer and the hemagglutinin proteins (HA). There are six HA33 proteins, three HA17 proteins, and one HA70 per one NTNHA1-BoNT/A1 complex. PTC/A1 forms three spiderlike legs that are suggested to have a role in binding to the intestinal epithelium to facilitate absorption of the toxin

Botulism and Botulinum Neurotoxins

Botulism was first described about 200 years ago following episodes of flaccid paralysis developed in people that had shared food. In 1897 van Ermengem demonstrated that the disease was due to a bacterium that produced a powerful poison of peripheral nerves causing the flaccid paralysis characteristic of botulism (Erbguth 2004). Botulism is rare but potentially fatal, and the death rate depends on the capability of identifying the symptoms at hospital admission (Fleck-Derderian et al. 2017). The first symptoms are a paralysis of cranial nerves with ocular and facial palsy, diplopia and ptosis, and dysphagia and dysarthria, followed by a descending flaccid paralysis that includes the respiratory muscles which is the most frequent cause of death. Additional symptoms are due to paralysis of the autonomic cholinergic nerves with abdominal pain, vomiting, nausea, dry mouth, and dizziness. The display of symptoms varies somewhat as well as the time intervening between intoxication and development of overt symptoms, and they mainly depend on the amount and type of BoNT and on the anatomical site of toxin assumption/injection (Rossetto et al. 2014; Fleck-Derderian et al. 2017).

The botulism patient remains conscious but cannot operate any muscle. If the disease is rapidly identified and the respiration is mechanically assisted, the patient survives and recovers almost completely after few to several months, depending on dose and type of BoNT: from the few weeks of BoNT/E to several months of BoNT/A. However, pathologies caused by prolonged permanence in the emergency room and by variable levels of permanent fatigue may follow.

All the manifestations of botulism are uniquely due to the actions of the BoNT, whose toxicity is due to their neurospecificity and to the neuroparalysis that results from the intraneural catalytic action of the metalloprotease L domain. BoNTs are, together with tetanus neurotoxin, the most poisonous substances known, and therefore they are included in the list A of substances with a possible bioterrorist use. At the same time, their neurospecific high affinity binding and the reversibility of the induced neuroparalysis are at the

basis of their therapeutic and cosmetic use. They are cell-specific biochemical scalpels of great therapeutical value in the treatment of a variety of human pathologies and conditions characterized by hyperfunction of peripheral cholinergic nerve terminals (Pirazzini et al. 2017).

Toxicity is generally measured as the mouse lethal dose 50% (MLD50), i.e., the dose that kills 50% of mice within 4 days, after a single intraperitoneal injection. The MLD50 values of the various BoNTs are comprised in the range 0.01–5 ng/Kg depending on the BoNT types and less on the mice strain. The human lethal dose can be extrapolated from data obtained with primates. For a 70 Kg man, the lethal doses are 90–150 ng when injected intravenously, 800–900 ng when inhaled, and 70 μg when introduced orally.

Basic Mechanism of Nerve Terminal Paralysis by the Botulinum Neurotoxins

Biological evolution of these neurotoxins has led to a structural organization designed to deliver the metalloprotease domain into the nerve terminal cytosol. This remarkable result has been attained by exploiting several physiological functions of nerve terminals. On the basis of the presently available experimental notions, the BoNT mechanism of nerve terminal paralysis consists of five major steps, as depicted in Fig. 2: (1) binding to cholinergic nerve terminals, (2) entry inside recycling synaptic vesicles (SV), (3) the L domain crossing of the vesicle membrane driven by low pH, (4) release of L in the cytosol by reduction of the interchain disulfide bond, and (5) cleavage with inactivation of one or more of the three proteins that form the core of the nanomachine that performs synaptic vesicle neurotransmitter release causing neuroparalysis (Pirazzini et al. 2017).

Neurospecific Binding

After entering the lymphatic and blood circulations, following intestinal absorption or inspiration or injection, the BoNTs rapidly gain access to the peri-neuronal fluid compartment, but do not cross the blood-brain barrier. The local intramuscular injection of very small doses (few MLD50s) of BoNT/A shows the remarkable and therapeutically very useful property of a very limited diffusion from the injection site (Pirazzini et al. 2017). The BoNTs bind with high affinity on the presynaptic plasma membrane of skeletal and autonomic cholinergic nerve terminals. The high affinity is due to a double receptor binding: (a) to the oligosaccharide portion of a polysiaganglioside and (b) to the intravesicular domain of synaptic vesicle proteins (SV2 for BoNT/A and /E or synaptotagmin for BoNT/B, /F, and /G); the binding of BoNT/C and /D is less defined (Rossetto et al. 2014; Pirazzini et al. 2017; Dong et al. 2019).

Internalization into Nerve Terminals

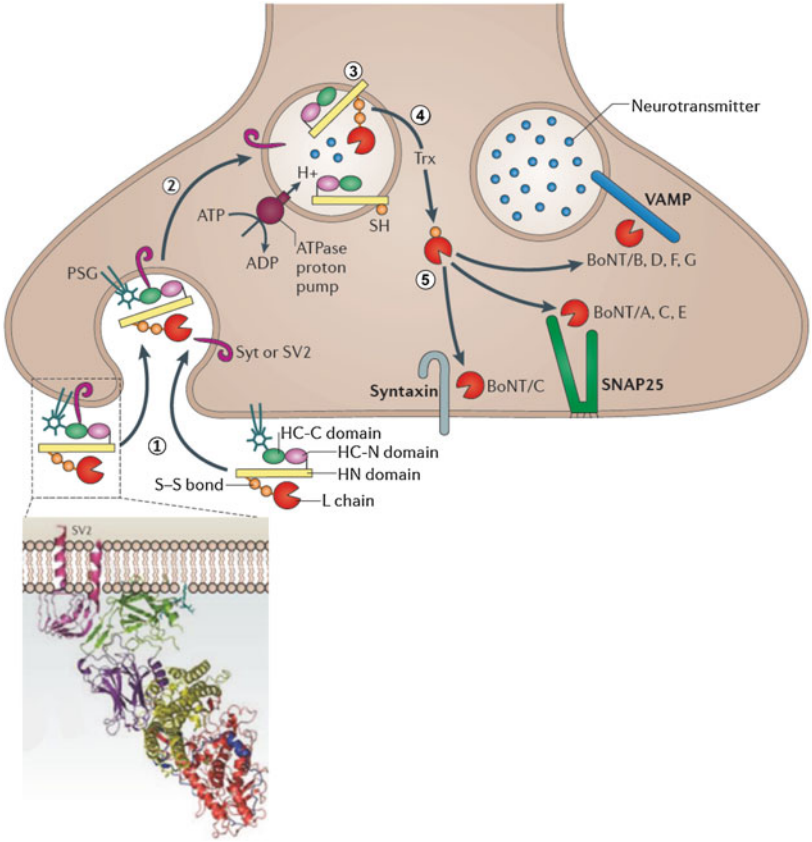
After intramuscular injection, one or two molecules of BoNT/A1 are rapidly taken up and found within the lumen of SV at the neuromuscular junction. The entry of other BoNTs is less defined. SV exocytosis is strictly coupled to their endocytosis, and this explains the fact that the time required for the development of paralysis after injection of BoNT/A decreases with increasing synaptic activity.

Membrane Translocation

After endocytosis, a proton pump present on the SV membrane drives protons inside generating a transmembrane pH gradient that drives the uptake of neurotransmitter from the cytosol to the lumen. The acidic pH induces a structural change of BoNT with translocation of the L domain across the SV membrane remaining attached via the SS bond to the HN domain.

Reduction of the Disulfide Interchain Bond

This bond is specifically reduced by the NADPH-thioredoxin reductase-thioredoxin redox system bound to the cytosolic surface of SV, thus releasing the metalloprotease L domain to display its catalytic activity on its very specific protein targets (Pirazzini et al. 2017). This notion has an important translational potential because inhibitors of this redox system do prevent the nerve terminal intoxication and paralysis and are strong candidates for the prevention of botulism in



Botulinum Neurotoxins, Fig. 2 The first step in intoxication involves the binding of the C-terminal part of the binding domain (HC-C in green) to a polysialoganglioside receptor present on the presynaptic membrane, followed by binding to a protein receptor (Syt or SV2) located inside the synaptic vesicle which becomes available upon vesicle exocytosis with neurotransmitter release (step 1). The crystallographic structures of BoNT/A1 bound to ganglioside and a luminal loop of SV2 are shown in the inset. The BoNT is then endocytosed inside synaptic vesicles (step 2), which are acidified by the vesicular ATPase proton pump to drive the reuptake of neurotransmitter. This physiological process is exploited by BoNTs, which become protonated, resulting in the translocation of the L chain of the toxin across the SV membrane (step 3) into the cytosol. The thioredoxin reductase-thioredoxin system (TrxR-Trx) breaks the interchain S-S bond (step 4) leading to the release of the L metalloprotease into the cytosol where it cleaves its specific SNARE target (step 5). (Adapted from Rossetto et al. 2014)

humans and for the treatment of those forms of botulism where there is a continuous production of novel toxin molecules.

SNARE Protein Cleavage

The vesicular neurotransmitter release is mediated by a nanomachine consisting of several proteins. Its core is composed by three proteins: the SV protein VAMP (vesicle-associated membrane protein) and the presynaptic membrane proteins SNAP-25 and syntaxin, which project into the cytosol. These three proteins are present in a number of isoforms and are collectively termed SNAREs. The SNARE proteins form a coiled coil heterotrimer termed SNARE complex, which contributes to bring the SV close to the presynaptic membrane, ready to fuse when the [Ca^{2+}] trigger is elicited by opening of the presynaptic membrane voltage-gated Ca^{2+} channels. BoNT/B, /D, /F, /G, and /X cleave VAMP at single sites within the coiling domain. BoNT/C cleaves both syntaxin and SNAP-25, while BoNT/A and /E cleave SNAP-25. These cleavages prevent the formation and/or function of the SNARE complex

and, consequently, of neurotransmitter release; for detailed information on the specificity of BoNTs for the various isoforms of the three SNARE proteins and the cleaved peptide bonds, see Rossetto et al. (2014) and Dong et al. (2019). Therefore, BoNT exploits three essential physiological functions of SV to paralyze the synapse: SV endocytosis, SV uptake of neurotransmitters, and SV surface redox activity.

Duration of the Peripheral Neuroparalysis Induced by Botulinum Neurotoxins

At variance from most bacterial and plant toxins, which kill cells, the BoNTs do not kill the intoxicated neurons; they merely paralyze it, and they are so toxic because respiration driven by the neuromuscular apparatus is essential for most vertebrates. All cytosolic proteins turn over, and the BoNT L chains are no exception. But they do so with different kinetics in such a way that the recovery of neurotransmission, which requires abolition of the L metalloprotease activity, takes place with different time courses for the different BoNTs: the L chain of BoNT/A (and paralysis) has the longest duration (3–4 months for human skeletal terminals, 9–12 months for autonomic cholinergic nerve terminals), while the L chain of BoNT/E is the shortest-acting one (paralysis of skeletal terminal lasting very few weeks). The duration of action of BoNT/A in humans is of major importance because it determines the therapeutic benefit length. Indeed long-lasting BoNTs require fewer injections and lower doses, limiting the possibility of immunization (see below).

Long-Distance Effects of Botulinum Neurotoxins

Peripheral neuroparalysis is the most evident symptom of botulism and is the one at the bases of the therapeutic use of BoNTs. However, indirect evidence that these neurotoxins could act at a distance from the injection site, i.e., within spinal cord and brain neuronal circuits, were reported long ago, and in some cases, it was shown to be due to retroaxonal transport of BoNTs similar to that occurring with TeNT (Mazzocchio and Caleo 2015). Compelling evidence of BoNT/A1 retrotransport to the central nervous system (CNS) was provided by tracing the cleavage of the SNARE within CNS neurons after peripheral injection of the toxin, using an antibody very specific for the novel epitope generated by the BoNT/A1 cleavage of SNAP-25. BoNT/A1 retrograde transport can occur also via sensory neurons, as the injection in the whisker pad induces the appearance of truncated SNAP-25 also in the trigeminal nucleus caudalis. These long-distance effects are mediated by an active retroaxonal transport of catalytically competent toxins inside motor axons or sensory neurons and not by passive spread of BoNT/A or to that of cleaved SNAP-25. Moreover, BoNT/A can undergo subsequent events of transcytosis and transport, remaining catalytically active (Mazzocchio and Caleo 2015).

Clinical Use

Many years before the discovery of *C. botulinum*, the clinical observation of the disease by Kerner inspired suggestions that the "sausage poison" causing botulism might have therapeutic potential. Based on observations and experiments described in his 1822 monograph, Kerner concluded that the toxin applied in minimal doses should reduce or block the hyperactivity and hyperexcitability of the motor and the autonomic nervous system (Erbguth 2004). After his farsighted vision, the therapeutic potential of botulinum toxin was tested and successfully illustrated 150 years later in the experiments of Dr Alan Scott, in monkeys first and then in human patients, showing that BoNT may be used as an alternative to strabismus surgery. Botulinum toxin was first approved by the US Food and Drug Administration (FDA) in 1989 for the treatment of strabismus, blepharospasm, and facial nerve disorders, including hemifacial spasm. Since that time the use of BoNT has continued to expand within and outside movement disorders and beyond

neurology, including aesthetic medicine and pain treatment (Jankovic 2018; Pirazzini et al. 2017). Today, BoNT is used in at least nine different medical specialties for more than 40 major indications (Pirazzini et al. 2017). Only a few of the indications are approved by regulatory agencies; most clinical uses are off label (Table 1).

BoNT Formulations

Despite the variety of botulinum toxin types, therapeutic preparations are currently only available for BoNT types A1 and B1. The commercially available neurotoxins that have been approved by US FDA and are sold in the Western Hemisphere include three main brands of BoNT/A1, OnabotulinumtoxinA (Botox®), AbobotulinumtoxinA (Dysport®), and IncobotulinumtoxinA (Xeomin®), and a brand of BoNT type B RimabotulinumtoxinB (Myobloc® in the USA or NeuroBloc® in Europe) (Table 2). The major Asiatic BoNT type A manufactures are sited in Korea (Medytox with Neuronox®, Hugel with Botulax®, and Daewoong with Nabota®/DWP-450) and in China (Lanzhou Institute of Biological Products with BTXA™, distributed by local/regional companies under different trade names). Overall, the BoNT/A containing drugs are a

[a]Vistabel, Azzalure, and Bocouture are the corresponding formulations for cosmetic treatment

multibillion US dollars business per year, with millions of patients injected over the world.

Botox®, Dysport®, and Myobloc® consist of the PTC including the neurotoxin and the nontoxic accessory proteins NTNHA and the HAs (Fig. 1b), whereas Xeomin® contains only the purified BoNT/A1 (Fig. 1a). They are sold in glass vials as a dry powder to be reconstituted in physiological medium/saline before injection into the patient (for BoNTa/A-based drugs) or an injectable sterile solution (BoNT/B drug). All formulations contain excipients (i.e., human serum albumin) to stabilize toxicity, to improve toxin shelf life, and to minimize nonspecific adsorption of the BoNT molecules onto the walls of vials and syringes.

Although the BoNT/A containing products have similar efficacies, they are differently formulated and demonstrate unique characteristics. BoNTs preparations potency is expressed in units (U), where 1 U corresponds to the amount of product needed to achieve 1 LD_{50} in the mouse bioassay. Since the bioassays used to assess the commercial toxins are performed under slightly different conditions, the units of biological activity are different and manufacturer-specific. Consequently, these products are not interchangeable, and doses are specific to each preparation. Comparison of data in the clinical literature assesses a dose conversion ratio Dysport®/Botox® between 2 and 3, while Botox® and Xeomin® are reported as equivalent in potency in most cases.

Notwithstanding the different formulations, these three toxin products display the same limited diffusion from the site of injection.

Therapeutic Applications

Depending on the target tissue, BoNT can block the cholinergic neuromuscular transmission, but also the cholinergic autonomic innervation controlling sweat, tear, and salivary glands and smooth muscles. In addition, in experimental animals, it induces blockade of transmitters involved in pain perception, transmission, and processing. Dosages for BoNT/A drugs vary widely in different therapeutic applications with minimum doses of few units for spasmodic dysphonia to maximum doses of hundreds of units for generalized spasticity. Whatever the dose, BoNT/A1 effects can be detected after 2–3 days from injection and reach its maximum value after 3–4 weeks. It maintains this level for a variable period of time depending on the anatomical site and then gradually declines to return to the original value within 3–4 months for skeletal nerve terminals and about 9–12 months for autonomic ones. Over the last decade, the high safety profile of BoNT/A-based drugs and the increasing understanding of the biology of the neurotoxin have resulted in significant growth of on-label indications but also favored the expansion of off-label use in a great variety of movement, urologic, gastrointestinal, secretory, dermatologic, and pain disorders (Table 1). Furthermore, in the coming years, the recent identification of diverse toxin types with different biological profiles and the availability of modified recombinant toxins are expected to expand even more in the future therapeutic use of BoNTs. Indeed, scientific challenges for BoNT drug development include modification of its duration of action, its needle-free delivery, and the design of BoNT hybrid drugs for specific target tissues.

Adverse Effects

Despite the remarkable safety profile of BoNT drugs due to their minimal migration from the site of injection, the possibility of local diffusion or potential leakage into the systemic circulation exists and depends on a number of factors including volume, dose, and injection technique. Most complications and unwanted effects of BoNT injections, such as weakness, are due to local diffusion and are generally limited to the adjacent muscles. Systemic adverse effects such as allergic reactions and generalized weakness are due to transport within the blood circulation and are very rare.

Contraindications to BoNT therapy are limited to a hypersensitivity to the toxin or an infection at

the site of injection, and there are no known drug interactions with botulinum toxin although caution is recommended when BoNT is used in patients treated simultaneously with aminoglycosides, anticholinergics, or other neuromuscular-blocking agents.

Acknowledgments The work in the authors' laboratory was supported by the grant NIB-2 and RIPANE of the Ministry of Defence and from grants provided by the University of Padova.

PT-141; VYLEESI

Definition

PT-141, or bremelanotide, is a melanocortin receptor (MCR) agonist that was approved by the FDA on June 21, 2019, for use in premenopausal women with generalized hypoactive sexual desire disorder (HSDD). HSDD is present in 1 out of 10 women. It is defined as low sexual desire that causes distress to an individual or relationship that is not due to interpersonal problems, the effects of drugs or medications, or the presence of a medical or psychiatric condition. In phase 3 clinical trials, bremelanotide was effective in treating HSDD but was accompanied by adverse events including nausea (40%), flushing (20.3%), and headache (11.3%). Currently, several studies of co-administering bremelanotide with anti-emetic (anti-nausea) drugs are ongoing in the hopes of seeing a reduction in the presence of adverse events (Dhillon and Keam 2019). Since its FDA approval, bremelanotide has been marketed by AMAG Pharmaceuticals under the brand name VYLEESI as a treatment for HSDD in premenopausal women. VYLEESI is a 1.75 mg subcutaneous injection that is taken at least 45 min before sexual activity (AMAG Pharmaceuticals Inc. 2019).

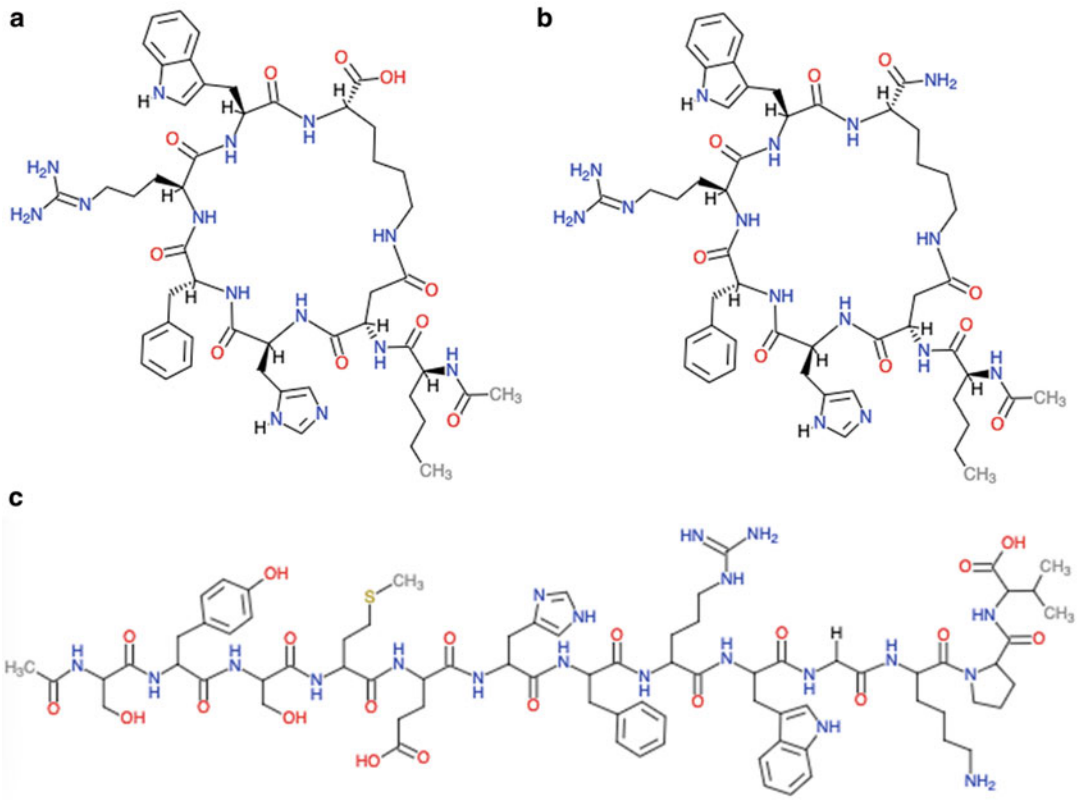
Although bremelanotide has been approved for use in women, it has also been studied as a treatment for men with erectile dysfunction (ED). ED is characterized as the inability to maintain an erection sufficient for sexual intercourse. The

primary treatment for men with ED is use of a phosphodiesterase 5 (PDE5) inhibitor such as Viagra. However, PDE5 inhibitors are not effective in all men. The prevalence of Viagra nonresponsive men has generated numerous phase 1 and phase 2 clinical trials investigating bremelanotide as an alternative or adjuvant treatment. Many phase 2 clinical trials have supported the efficacy of bremelanotide when used alone or when co-administered with PDE5 inhibitors (Hellstrom 2008). However, phase 1 clinical trials have demonstrated a host of adverse events including increased blood pressure (White et al. 2016). With the tight association between ED and cardiovascular disease, the increase in blood pressure elicited by bremelanotide has proven the biggest barrier preventing phase 3 clinical trials in men.

While bremelanotide has been investigated almost exclusively for its effects on reproductive behaviors, like other MC4R agonists, it also inhibits food intake. For example, bremelanotide has been used a positive control for food intake and body weight suppression in an investigation of other MCR-binding peptides in rats (Xin Chen et al. 2009). As mentioned, bremelanotide tends to induce nausea after acute administration in humans, which would be expected to produce food aversion.

Mechanism of Action

Bremelanotide is a cyclic heptapeptide lactam that is a functional analog of endogenous α-melanocyte-stimulating hormone (α-MSH) (Fig. 1a). α-MSH differs from bremelanotide as the former is a noncyclic tridecapeptide (Fig. 1c). Bremelanotide was originally derived from another synthetic α-MSH analog called melanotan



Bremelanotide, Fig. 1 **Melanocortin drugs:** (**a**) bremelanotide, (**b**) melanotan II, and (**c**) α-MSH

II which is primarily used as a sunless tanning agent. Although melanotan II has been shown to elicit erections, it is not ideal for treatment of sexual function due to a slow induction of erection (roughly 2 h). In contract, bremelanotide can induce erection as early as 45 min postinjection. Melanotan II's structure only differs from bremelanotide by the presence of a C-terminal amide (Fig. 1b) (King et al. 2007).

Bremelanotide is a melanocortin receptor (MCR) agonist. It non-selectively activates multiple MCR subtypes with the following order of affinity: MC1R, MC4R, MC3R, MC5R, and MC2R (AMAG Pharmaceuticals Inc. 2019). Not much is known about bremelanotide's mechanism of action, but some conclusions can be made based upon our current understanding of MCRs. MC1R is expressed by melanocytes found in skin and hair. Activation of MC1R by α-MSH leads to increased pigmentation, which reduces DNA damage from ultraviolet light exposure. MC1R activation is likely the cause of the focal hyperpigmentation prevalence seen after frequent dosing of bremelanotide. MC4R is prominently expressed in the central nervous system but is particularly concentrated in the PVN. In adult male Sprague-Dawley rats, immunostaining of c-fos (a protein expressed after neural activation) 2 h after bremelanotide treatment showed an increase in neural activation in the paraventricular nucleus (PVN) of the hypothalamus. In an in vitro study, bremelanotide treatment led to an increase in cAMP production in MC4R-expressing HEK-293 cells, which is associated with neural activation. These results indicate that bremelanotide primarily activates MC4R-expressing neurons in the PVN to mediate its effects on sexual function (King et al. 2007).

Various experiments have been done by Palatin Technologies to further understand the pharmacokinetic profile of bremelanotide. A 1.75 mg subcutaneous dose of bremelanotide has a mean plasma C_{max} of 72.8 ng/mL and a median T_{max} of about 1 h. When increased doses (0.3–10 mg) of bremelanotide are administered, C_{max} increases and plateaus at 7.5 mg in plasma. The bioavailability of bremelanotide was 100% with no difference between administration to the abdomen or thigh. The average volume of distribution is 25.0 L with 21% of bremelanotide binding to serum proteins. 1.75 mg of bremelanotide has a mean terminal half-life of roughly 2.7 h with a clearance of approximately 6.5 L/hr. A study utilizing a radiolabeled dose found that 22.8% of bremelanotide is excreted through feces and 64.8% is excreted in urine (AMAG Pharmaceuticals Inc. 2019).

Clinical Use (Including Side Effects)

Phase 1 Clinical Trials

Phase 1 clinical trials designed to test drug safety showed bremelanotide treatment leads to a transient increase in blood pressure (BP) in both men and women. For women, a randomized, double-blind, and placebo-controlled trial tested the effects of three doses of subcutaneous bremelanotide (0.75, 1.25, and 1.75 mg). The trial consisted of 397 premenopausal women with female sexual dysfunction. BP changes were not significant in women treated 0.75 mg of bremelanotide. Nevertheless, within 4 h, 1.25 mg of bremelanotide led to a significant increase in systolic BP by 2.4 mmHg while 1.75 mg led to a 3.1 mmHg increase. Additionally, in that same time period, diastolic BP significantly increased by 3.0 mmHg (1.25 mg) and 3.2 mmHg (1.75 mg). All three groups had a maximal heart rate decrease of roughly six beats per minute around 4–8 h after bremelanotide injection. Consistent with these results, a separate study on males receiving 4–6 mg of subcutaneous bremelanotide had a 4–5 mmHg increase in systolic BP. Bremelanotide was originally intended for intranasal delivery. However, intranasal bremelanotide is inconsistently absorbed into circulation leading to erratic systemic concentrations and unpredictable effects on BP (White et al. 2016). Intranasal administration was eventually replaced with subcutaneous injection. The above results are further supported by additional phase 1 clinical trials on women that were done by Palatin Technologies alongside the stage 3 clinical trials. These additional trials required by the FDA prior to approval of VYLEESI showed a maximal

increase of 6 mmHg in systolic BP, increase of 3 mmHg in diastolic BP, and decrease in heart rate of 5 beats per minute. The significant effects of bremelanotide occurred 2–4 h post dose and were completely gone within 12 h (AMAG Pharmaceuticals Inc. 2019).

Another phase 1 clinical trial tested the safety of bremelanotide when co-administered with alcohol. In this randomized, placebo-controlled, double-blind, three-period, three-way crossover study, 12 healthy female and 12 healthy male subjects drank a placebo beverage or 0.6 g/kg ethanol; 10 min later, a 20 mg dose of intranasal bremelanotide or a placebo was given. The quantity of ethanol consumed was three standard drinks (equivalent to three 1.5-ounce shots of 80-proof liquor). Incidence of flushing was similar between bremelanotide plus ethanol and bremelanotide alone. Additionally, incidence of headache was similar between bremelanotide plus ethanol and the ethanol alone. In all, alcohol consumption had no synergistic effects and did not impact the pharmacokinetic profile of bremelanotide (AMAG Pharmaceuticals Inc. 2019).

Phase 2 Clinical Trials

A critical phase 2 clinical trial provided evidence for the efficacy of bremelanotide treatment in women. This double-blind study used premenopausal women that were at least 21 years old who had been diagnosed with HSDD and/or female sexual arousal disorder for at least 6 months. The 327 participants were randomized to take bremelanotide 0.75, 1.25, or 1.75 mg or placebo. From baseline till the end of the 12-week study, an increase in 0.7 satisfying sexual events was reported in women taking 1.25 mg or 1.75 mg compared to a 0.2 increase in placebo ($p < 0.0180$). During further self-reported assessments, the study found that bremelanotide treatment lead to an increase in sexual desire and decrease in distress associated with sexual function (Dhillon and Keam 2019). The abundance of important phase 2 clinical trials provided enough support of bremelanotide's efficacy to begin phase 3 clinical trials in women.

In men with ED, two phase 2 studies analyzing the effects of bremelanotide provided evidence for its efficacy alone and when co-administered with the PDE5 inhibitor sildenafil. The first study was in sildenafil-resistant subjects, defined as having less than a 50% success rate of achieving an erection after taking 100 mg of sildenafil. Twenty-five men took a dose of 4 mg and 6 mg bremelanotide or a placebo before watching erotic videos. Erectile responses were measured using a RigiScan device during visual sexual stimuli. Subjects receiving 4 mg bremelanotide had an average duration of over 60% erectile rigidity for 28 min compared to 41 min in the 6 mg group and 6 min in placebo group. In the second study, 19 sildenafil-responders were assigned to take 25 mg of sildenafil with either 7.5 mg of intranasal bremelanotide or a placebo. Like the previous study, erectile responses were monitored using the RigiScan device during visual sexual stimuli. A statistically significant increase in the average duration of over 60% rigidity was seen in the bremelanotide/sildenafil group (≈67 min) compared to sildenafil alone (≈46 min). No additional side effects were reported from co-administration of bremelanotide and sildenafil. Thus, co-administration may lead to a synergistic effect on erectile function that improves quality of life in both sildenafil responsive and nonresponsive men. This synergy provides the potential for dose-reduction of both drugs while simultaneously reducing prevalence of adverse events (Hellstrom 2008).

A larger-scale phase 2 clinical trial of bremelanotide in men provided additional evidence of its efficacy for ED treatment. In this 12-week study, 728 nondiabetic men with ED were randomly assigned to take 5, 7.5, 10, 12.5, or 15 mg of intranasal bremelanotide or a placebo. At the beginning and end of the study, men took the International Index of Erectile Function (IIEF) questionnaire. Men treated with 7.5 mg of bremelanotide or higher showed a significant increase in their IIEF score. The Self-Esteem and Relationship (SEAR) questionnaire was also taken. From baseline to end of study, there was a significant increase in scores in the SEAR questionnaire for men taking bremelanotide. This indicates that

bremelanotide administration led to an improvement in self-esteem and in interpersonal relations (Hellstrom 2008). Overall, bremelanotide's efficacy in treatment of ED is well-supported; however, bremelanotide's effects on blood pressure has prevented continuation into phase 3 clinical trials.

Phase 3 Clinical Trials

Two identical, 24-week, randomized, double-blind, studies titled 301 and 302 occurred in premenopausal women with HSDD but are known collectively as the phase 3 RECONNECT studies. The phase 3 RECONNECT studies were completed by Palatin Technologies in 2017 and were included in a new drug application submitted in 2018. The results supported the FDA's approval of bremelanotide for premenopausal women with HSDD in 2019. For both studies, subjects were premenopausal women at least 18 years old, who were in a relationship for at least 6 months and had been diagnosed with HSDD for at least 6 months. The subjects received either 1.75 mg of bremelanotide ($n = 635$) or placebo ($n = 632$). Participants were instructed to self-administer the drug as needed 45 min before sexual activity. Roughly 40% of patients taking bremelanotide discontinued the study prior to its 24-week completion compared to 13–25% for placebo. The remaining participants, on average, took bremelanotide two to three times per month, no more than once a week. Two published efficacy assessments were made prior to the study as a baseline and after completion. The first assessment was the Female Sexual Function Index (FSFI) which composed of two questions. Participants were asked "Over the past 4 weeks, how often did you feel sexual desire or interest?" and "Over the past 4 weeks, how would you rate your level of sexual desire or interest?". The participants gave a rating for both questions from 1 (never or none) to 5 (always or very high). These questions are intended to document changes in sexual desire. The responses to these two questions were added together and the sum was multiplied by 0.6 to give scores ranging from 1.2 to 6. In Study 301, FSFI changed from baseline to end of study by 0.5 in bremelanotide versus 0.2 in placebo ($p < 0.0002$). Likewise, in Study 302, the bremelanotide-treated group changed by 0.6 versus 0.2 in placebo ($p < 0.0001$). The second assessment was the Female Sexual Distress Scale (FSDS) which asks, "How often did you feel: Bothered by low sexual desire?". Women responded on a scale of 0 (never) to 4 (always). This question was intended to assess the level of distress related to their low sexual desire. In Study 301, scores on the FSDS had decreased by 0.7 in the bremelanotide-treated group compared to placebo which decreased by 0.4 ($p < 0.00001$). Correspondingly, in Study 302, scores decreased in the bremelanotide-treated group by 0.7 compared to a 0.4 decrease in the placebo-treated group ($p < 0.0053$). Another test assessed the number of satisfying sexual events, but no differences were seen between bremelanotide or placebo treatment. Overall, these tests in the phase 3 RECONNECT studies provided evidence to the FDA of bremelanotide's efficacy (AMAG Pharmaceuticals Inc. 2019; Dhillon and Keam 2019).

The phase 3 RECONNECT studies also evaluated the safety of bremelanotide by analyzing the prevalence of adverse events (AEs). Of the common AEs, a majority were mild (31%) or moderate (41%) in intensity. The most common AEs of bremelanotide treatment (> 4% incidence) included nausea (40% vs. 1.3% in placebo), flushing (20.3% vs. 0.3% in placebo), injection site reactions (13.2% vs. 8.4% in placebo), headache (11.3% vs. 1.9% in placebo), and vomiting (4.8% vs. 0.2% in placebo). The most common bremelanotide-related AE was nausea (40%). This AE led to 13% of participants requiring an anti-emetic and 8% of participants leaving the study early. Notably, the incidence of nausea was 21% during the first dose of bremelanotide but declined to 3% after subsequent uses of the drug. The high number of women taking bremelanotide who prematurely discontinued the study and the lack of change in satisfying sexual events is likely attributable to the incidence rate of AEs, particularly nausea. For instance, 18% of participants left the study due directly to AEs (AMAG Pharmaceuticals Inc. 2019). Currently, a phase 1 study is planning to enroll 228 premenopausal women to understand the effects of co-administration of

bremelanotide with an antiemetic on the incidence of nausea (Dhillon and Keam 2019).

In men, bremelanotide's effects on blood pressure have been a major barrier preventing it from moving into phase 3 clinical trials for the treatment of ED. As mentioned (see *Phase Clinical Trials*), studies show that bremelanotide treatment leads to transient increases in both systolic and diastolic blood pressure (BP) in men and women (White et al. 2016). Although transient, this increase in BP is a health concern for people at high risk of cardiovascular disease, including people above the age of 50. ED correlates strongly with both age and cardiovascular disease risk, often developing in men over the age of 50; 94% of men with ED reported having their first problems with erection after 49 years of age (Bacon et al. 2003). Therefore, the number of men under the age of 50 with ED is a restricted demographic, making recruitment for phase 3 trials problematic and the potential drug market small. However, HSDD in women is not associated with the development of cardiovascular disease and is present in 8.9% of women between the ages 18 and 44 (Dhillon and Keam 2019). Therefore, bremelanotide can be marketed to a large demographic of premenopausal women for the treatment of HSDD with less risk.

Asthma bronchiale

Definition

According to the Global Initiative for Asthma (GINA, http://www.ginasthma.org), asthma affects about 340 million people worldwide. Men of all ages are affected by this chronic airway disorder that – without appropriate treatment – limits quality of life and may be fatal.

Asthma is a chronic inflammatory disorder of the airways associated with recurrent airway obstructions, airway hyperresponsiveness, and airway remodeling. Symptoms of asthma include **wheezing**, coughing, chest tightness, and shortness of breathing, particularly at night or in the early morning. Airway obstruction is often reversible either spontaneously or after treatment.

Missing or inadequate treatment will result in airway remodeling.

Basic Mechanisms

The majority of pediatric and adult patients with asthma have so-called extrinsic (allergic) asthma (Quirt et al. 2018) (Fig. 1). These asthmatics have increased serum IgE levels and suffer from Type I allergy characterized by high serum IgE levels and blood eosinophils. In susceptible individuals **allergens** are presented by dendritic cells (DCs), which then lead to an IL-25, IL-33, and thymic stromal lymphopoietin (TSLP)-driven induction of T_H2 CD4+ T-lymphocytes. Subsequently, T_H2 cells produce the T_H2 cytokines IL-4, IL-5, and IL-13 that induce the maturation of naïve T-helper cells (T_H0) into further T_H2 cells and induce B-cells to produce specific IgE antibodies. Among these, especially IL-4 triggers the IgE production of B lymphocytes. Allergic asthma depends on the presence of IgE bound to high-affinity Fcε-receptors ($Fc\varepsilon_\varepsilon R$) especially on mast cells and to low-affinity Fcε-receptors on other cells such as eosinophils. Without IgE allergic asthma cannot occur. These responses can be downregulated by IL-10 from regulatory T-cells (Treg) or macrophages that modulate T_H2 cell maturation and increase tolerance to allergens. In addition, IL-17 from T_H17 cells may downregulate eosinophil chemotaxis (Barnes 2018).

There is also non-allergic asthma (Fig. 1) that involves innate lymphoid cells (ILCs). Here, neither IgE nor mast cells are required to induce or perpetuate the inflammatory response. However, pro-inflammatory mediators comparable to those in allergic responses are released from epithelial cells upon exposure to xenobiotics, pathogens, or toxins. These mediators, including IL-25, IL-33, and TSLP, favor the polarization of ILC cells to the type 2 phenotype (ILC2) that produce IL-5 and IL-13, responses that may be enhanced by IL-9 and prostaglandin D_2 (PGD_2). Again, IL-5 recruits eosinophils from the bone marrow and increases their survival in the bronchial mucosa of the airways, while IL-13 induces bronchial hyperresponsiveness and goblet cell hyperplasia (Lambrecht and Hammad 2015).

Cardinal Symptoms

The activation of mast cells by allergen initiates the asthma symptoms: within minutes the early allergic response (EAR), within hours the late allergic response (LAR), and within years and after repeated asthma episodes chronic airway inflammation, airway remodeling, and airway hyperresponsiveness.

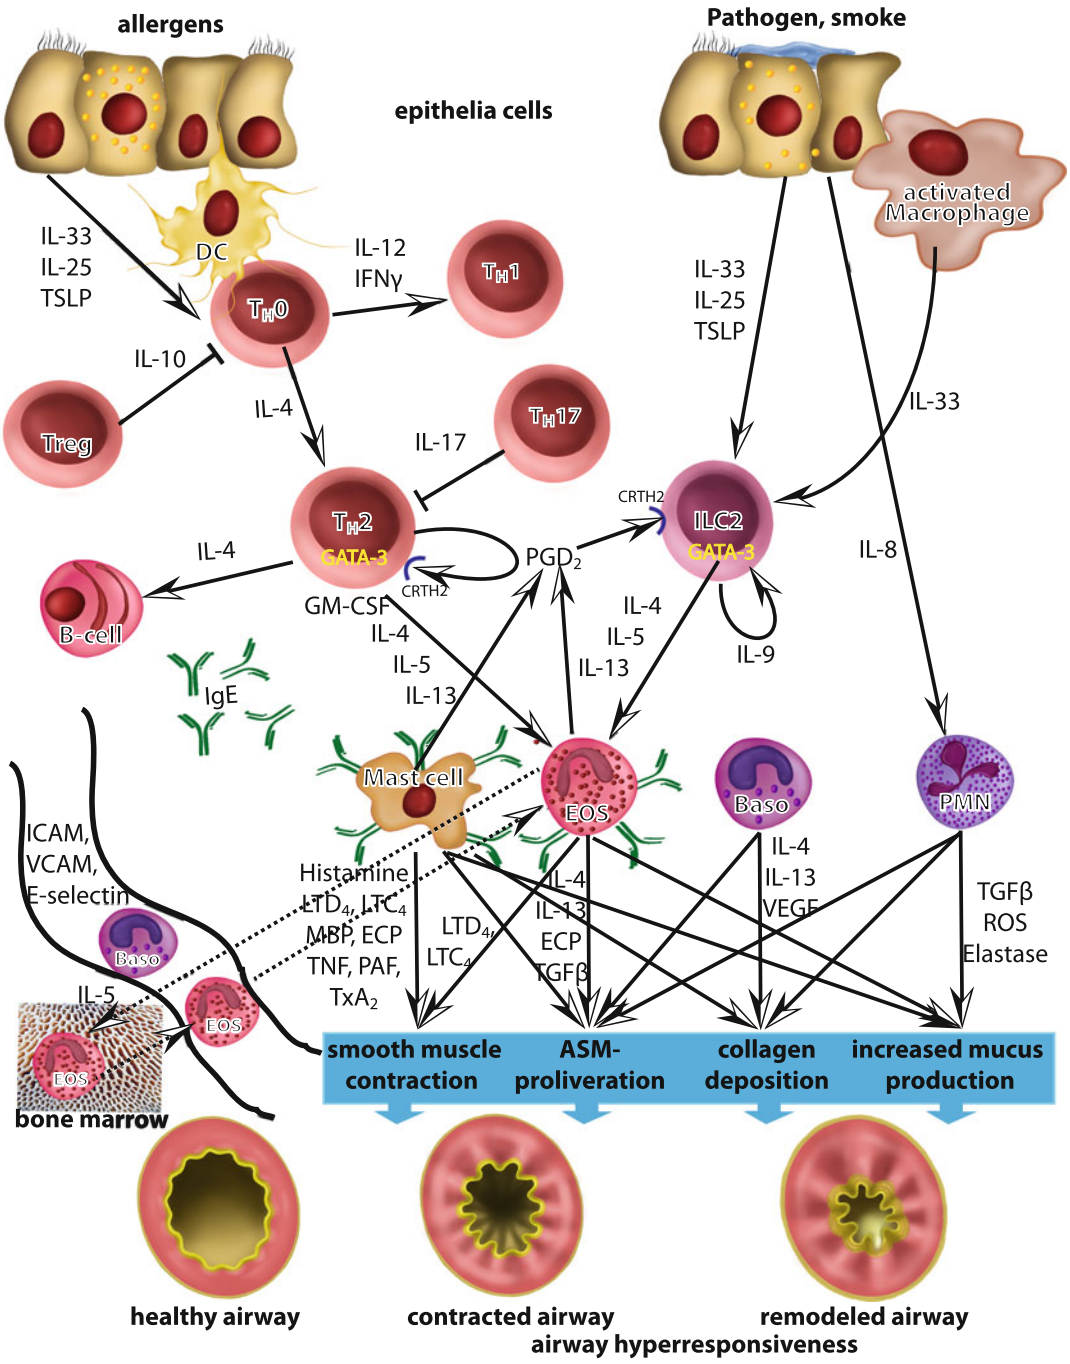
Early and Late Phase in Allergic Asthma

Immediate responses to allergen occur within minutes. Allergen-induced cross-linking of IgEs on mast cells causes degranulation of preformed (histamine, proteoglycans, serine proteases, TNFα) and secretion of newly formed mediators (prostaglandins, cysteinyl -leukotrienes, thromboxane, **platelet-activating factor**, cytokines). The mixture of histamine, prostaglandins, thromboxane, and cysteinyl leukotrienes causes airway smooth muscle contraction.

Frequently, the early allergic response is followed by a late-phase response (4–6 h later), caused by the pulmonary sequestration of immune cells, especially eosinophils, mast cells, and T-lymphocytes. This leukocyte recruitment depends on mast cell-derived mediators such as TNFα and various chemokines, as well as on the expression of adhesion molecules on leukocytes (e.g., VLA-4, CD11/18) and vascular endothelial cells (e.g., VCAM-1, ICAM-1, E-selectin). Products of these leukocytes have several functions and cause the second phase including bronchoconstriction, mucus secretion, and airway swelling. Finally, this leads to chronic inflammation and tissue destruction.

Inflammation

Airway inflammation is a characteristic clinical feature of asthma. The distinction between the LAR and chronic inflammation becomes more difficult as the disease progresses. Infiltrated leukocytes and macrophages release cytotoxic mediators such as **reactive oxygen species** and **cationic (basic) proteins** that cause epithelial damage and cytokines like IL-4, -5, -9, -13, -25, and -33 as well as alarmins like thymic stromal lymphopoietin (TSLP) that perpetuate the



Bronchial Asthma, Fig. 1 Pathophysiology of asthma. T-helper cells 2 (Th2) and innate lymphoid cells (ILC) take a central position in the pathophysiology of asthma. Various cytokines inactivate Th1 and Th17 cells, activate eosinophils, and trigger a class switch in B lymphocytes to make them produce IgE. These IgEs bind to mast cells activating mast cells, EOS, leukocytes, and macrophages. The mast cell mediators trigger the early allergic response, the late allergic response, the activation of Th2 cells, and other inflammation responses. The inflammatory response mobilizes eosinophils (EOS), neutrophils (PMN), macrophages, and lymphocytes that infiltrate the lung tissue and sustain the inflammation. Eosinophils release mediators that contribute to the EAR and cytotoxic agents that injure the epithelial layer. Repetitive and chronic inflammation leads to airway remodeling and airway hyperresponsiveness. Baso, basophils; DC, dendritic cell

inflammation. Sustained inflammation leads to airway hyperresponsiveness and airway remodeling.

Hyperresponsiveness

Airway hyperresponsiveness is an exaggerated airway narrowing in response to a variety of unspecific stimuli. It can be measured by bronchial provocation with histamine, methacholine, or adenosine. The reason for hyperresponsiveness may be stimulation of sensory nerves, located within the epithelium, that become easily accessible after denudation of the epithelium. This irritation of nerves leads to reflex smooth muscle contraction, mucus secretion, and edema formation. In addition, hyperresponsiveness can also be caused by IL-5, IL-13, major basic protein (MBP), eosin cationic protein (ECP), peptidoleukotrienes, and smooth muscle hypertrophy.

Bronchial Remodeling (BHR)

The term "airway remodeling" refers to structural changes in the airways and is the consequence of chronic airway inflammation. The structural changes involve a thickening of the airway wall that is induced by leukotriene C, VEGF, and tryptase from mast cells as well as TGFβ from eosinophils. IL-13 induces hyperplasia of goblet cells coupled with hypertrophy of submucosal glands. Increased vascularity of the airway wall amplifies mucus secretion and plasma protein leakage that are responsible for the formation of the characteristic mucus plugs that obstruct the airways. Other characteristic features are smooth muscle hypertrophy and hyperplasia and subepithelial fibrosis by growth factors. This explains the incomplete reversibility of airway narrowing in asthmatic patients.

Drug-Sensitive Asthma

Nonsteroidal anti-inflammatory drugs (NSAID) like aspirin affect about 10% of all asthmatics. This is a non-allergic response to aspirin and other agents that inhibit the cyclooxygenase. Mechanistically, the most likely explanation is a lack of bronchoprotective prostaglandin E_2 and shifting of arachidonic acid metabolism toward the leukotriene pathway, favoring the production of the bronchoconstrictive leukotrienes C_4 and D_4 and chemotactic leukotriene B_4.

General Principles of Managing Asthma

In asthma management the long-term goals are to reduce and control reoccurring. This involves a continuous approval of the status of asthma including symptoms and lung functions, as well as regular adjustment of the medication in a step-up/step-down manner (Fig. 2, GINA).

Pharmacological Interventions

In general, pharmacological agents are divided into **relievers** that lead to a rapid improvement of breathing during asthma attacks (β2-agonists, anticholinergics) and **controllers** (steroids, antileukotrienes, biologicals) that control the disease by suppressing the inflammation and the exacerbations (Fig. 2). The basic pharmacological therapy is inhaled corticosteroids (ICS). GINA recommends that every adult and adolescent with asthma should receive ICS-controller medication. There are five steps for the pharmacological therapy of asthma, depending on the asthmatic state (Quirt et al. 2018; Israel and Reddel 2017; Patel et al. 2018; Barnes 2018) (Fig. 2). The classification of asthma in patients should be initially higher to guarantee a sufficient anti-inflammatory therapy. The importance in asthma therapy is a continuous monitoring of asthma symptoms. The overall aim in asthma therapy is to achieve adequate asthma control and risk reduction. Once patients have no symptoms, asthma is considered under control, and therapy may be adjusted accordingly (step down). The basic principle is a step-up and step-down strategy to obtain the lowest possible therapeutic treatment for adequate control in order to control the inflammation-driven progression and chronification of the disease with the least possible side effects.

Some 5–10% of patients are resistant to corticoid therapy; these patients may benefit from new antibody-based therapies (biologicals). At present, healing of asthma by pharmacological

(Modified from https://ginasthma.org/, 2019)

therapy is not possible, except for hyposensibilization therapies in case of allergic asthma.

Allergen-Specific Immunotherapy (SIT)

In allergic asthma, with well-known allergens and high levels of specific IgE, allergen-specific immunotherapy is an excellent therapeutic option. This therapy depends on the availability of allergens to induce immunological tolerance and on the severity of the disease. A variety of immunogenic proteins from allergens, such as grass, ragweed, house dust mite, some animal hair, and dander, are available for either subcutaneous or sublingual hypersensitization. The problem of this therapy is a risk of occasional anaphylactic shocks. Although the hypersensitization does usually not lead to a complete remission of symptoms or airway inflammation, it can tremendously reduce the amount of medication needed to control the disease.

β_2-Receptor Agonists

Beta-2-receptor agonists relax the bronchial smooth muscle by increasing intracellular cAMP levels that in turn decrease calcium levels and interfere indirectly with myosin light chain phosphorylation (critical for smooth muscle contraction). Beta-2-receptor agonists are very effective bronchodilators and can rescue patients from asthma attacks. They are classified according to their duration of action: Short-acting beta-2 agonists (**SABA**) like terbutaline, albuterol, and fenoterol have a short biological half-life of 2–6 h and are used as the only therapy in nonpersisting asthma and as a standby medication in all other stages of asthma. However, the GINA guidelines do not prefer SABA use alone, as this may increase the risk of exacerbations. For other levels of asthma, long-acting beta-2 agonists (**LABA**) such as salmeterol, bambuterol, and formoterol with half-lives of 15–18 h are used. Ultra-long-acting beta-2 agonists (**ULABA**) like indacaterol or olodaterol, with half-lives up to 24 h, are mainly used for the treatment of **COPD**.

Typical side effects of this class of drugs are interactions with cardiac β_1-receptors, leading to tremor, arrhythmias, and tachycardia.

Anticholinergics

Cholinergic smooth muscle contraction occurs mainly via M_3 receptors. The clinically used anticholinergics (like ipratropium bromide, tiotropium bromide) bind competitively to M_3, M_2, and M_1 receptors on airway smooth muscle and mucosal glands, but only tiotropium dissociates quickly

from the postsynaptic inhibitory M_2 receptors, contributing to its enhanced inhibitory effect and its prolonged actions (16 h instead of 6 h). However, the lag phase of 30 min after intake limits their usefulness in acute asthma attacks. The inhaled anticholinergics are rarely used in asthma, but frequently as a long-term treatment of COPD. Despite inhalation, typical parasympathetic side effects such as increased heart rate, soporific effects, and dry mouth may occur.

Anti-leukotriene Therapy

Leukotrienes have multiple roles in asthma. They cause bronchoconstriction, swelling, and mucus secretion (LTC_4, LTD_4) as well as eosinophil recruitment (LTE_4). Anti-leukotriene therapy is based either on inhibition of 5-lipoxygenase (zileuton; only approved in the USA) or on cys-LT1 receptor antagonists (**LTRA**, like montelukast, zafirlukast, and pranlukast). The anti-inflammatory potential of leukotriene antagonists is smaller than that of steroids. Patients who cannot or will not take inhaled steroids are possible candidates for these drugs. Anti-leukotriene therapy is particularly effective in the treatment of NSAID-sensitive and exercise-induced asthma.

Corticosteroids (CS)

As asthma is a chronic, inflammatory disease, steroids represent the most important and most frequently used medication. Already after the first treatment, steroids reduce cellular infiltration, inflammation, and the LAR, whereas changes in the EAR require prolonged treatment to lower the existent IgE levels. The mechanisms of steroid actions are complex and only incompletely understood. Besides their general anti-inflammatory properties (see chapter ▶ "Glucocorticoids"), like the reduction of IL-4, IL-5, and IL-13 production, the induction of IL-10 production from T-lymphocytes is also of particular importance for asthma therapy. The introduction of inhaled steroids (**ICS**) has dramatically limited the side effects of steroids and is considered one of the most important advancements in asthma therapy. Inhaled steroids (beclomethasone, budesonide, fluticasone, triamcinolone, mometasone) are used in all stages of asthma. Oral steroids are used in severe uncontrolled asthma, during an acute exacerbation for a short period of time (3–5 days) and for the treatment of **status asthmaticus**. Minor side effects of most inhaled steroids are hoarseness and candidiasis, while oral corticosteroids are associated with systemic side effects (including adrenal suppression, osteoporosis, and cataracts), which is mostly avoided by the prodrug steroid ciclesonide. Nevertheless, it has been recently shown that the use of oral steroids in severe asthma is associated with corticosteroid comorbidities in nearly all patients (Sweeney et al. 2016). Therefore, long-term high-dose systemic steroids should be avoided or reduced by the use of **biologicals** such as specific antibodies.

Biologicals

To avoid severe side effects of orally given steroids, biologicals are new therapeutic options. Monoclonal antibody therapies have shown to reduce the frequency of severe asthma (Barnes 2018).

Anti-IgE

Allergic or extrinsic asthma affects the majority of all asthmatics. The production of IgE by B-cells and the FcεR-dependent activation of mast cells, eosinophils, basophils, and macrophages are critical for the development of asthma. A clear correlation exists between circulating IgE levels and disease severity. Reduction of circulating IgE antibodies by a humanized mouse anti-IgE antibody (omalizumab) mitigates asthma symptoms. Owing to their long half-life, (bi)monthly subcutaneous antibody injections are sufficient to suppress IgE levels and to reduce asthma symptoms in pediatric and adult asthmatics. This biological is approved as an add-on therapy to steroids in severe asthma.

Antibodies Against IL-4, IL-5, and IL-13

Interleukin-5 (IL-5) is the essential cytokine for recruitment and increased lifetime of eosinophils. Mepolizumab, reslizumab, and benralizumab are three IL-5-targeting agents approved for the treatment of severe eosinophilic asthma (>400 cells

per μL). Reslizumab and mepolizumab are IL-5-scavenging antibodies, whereas benralizumab blocks the IL-5 receptor. Mepolizumab and benralizumab are injected subcutaneously every 4 weeks, whereas reslizumab is administered every 4 weeks via intravenous infusion.

IL-13 is one of the main cytokines responsible for bronchial hyperresponsiveness. Tralokinumab is an anti-IL-13 human immunoglobulin G4 monoclonal antibody, neutralizing IL-13 levels and developed for the treatment of severe, uncontrolled asthma. The STRATOS trials showed the safety and efficacy of subcutaneous bi- or 4-weekly tralokinumab injections. Tralokinumab may be beneficial in patients with high fractional exhaled nitric oxide, even though it lacks an ICS-sparing effect (Busse et al. 2019).

T-helper 2 (Th2) lymphocytes are induced and persist in allergic asthma. IL-4 is the essential cytokine for the polarization of TH_0 toward TH_2 cells. In addition IL-4 and IL-13 together induce goblet cell hyperplasia, smooth muscle proliferation, and mucus production. Dupilumab is a fully human monoclonal antibody that blocks the heterodimeric receptor complex consisting of the IL-4 receptor α-subunit and the IL-13 receptor α1-subunit. Dupilumab is approved for subcutaneous injections on a weekly or bi-weekly basis in patients with moderate to severe allergic asthma (≥12 years).

Rarely Used Therapeutics

At the beginning of the twentieth century, methylxanthines like **theophylline**, bamifylline, and elixophyllin were among the first therapeutic options for asthma patients. Acting at least in part as adenosine (A1)-receptor and phosphodiesterase (PDE) antagonists, they increase intracellular cAMP levels. Accumulation of intracellular cAMP by inhibition of PDE3 relaxes airway smooth muscle, and inhibition of **PDE4** reduces inflammation. PDE4 inhibitors (roflumilast, cilomilast) have shown some effectiveness in advanced clinical trials but are mainly used for the treatment of **COPD**. Today methylxanthines are rarely used, and when then as an additional therapy for uncontrolled asthma (oral) and for status asthmaticus (i.v.).

Also, **cromones** may be used to prevent asthma attacks, if taken continuously. They act as mast cell-stabilizing agents that prevent the release of mast cell mediators. Cromones have virtually no side effects, but today they are only rarely used, mostly in children and sometimes in adults who do not tolerate or who are not willing to take steroids.

Future Therapeutic Options

In COPD patients with eosinophilia, the GATA3-specific DNAzyme SB010 attenuated inflammatory response. Therefore, this therapy is approved for **COPD** with eosinophilia. Eosinophilia is also a common phenotype of allergic patients with asthma. Therefore this therapy may be a promising therapeutic option in asthmatic patients.

The chemoattractant receptor-homologous molecule (CRTH2) is a G-protein-coupled receptor expressed on various cell types including T_H2 cells, ILCs, eosinophils, mast cells, and basophils. Prostaglandin D_2, a main mediator of mast cells, is the endogenous ligand. CRTH2 antagonists are in clinical development for the treatment of asthma.

Patients with severe non-eosinophilic asthma usually don't benefit from biologicals against IgE, IL4, IL5, and IL13. Thymic stromal lymphopoietin (TSLP) is released as an alarmin by epithelial cells (see above) and is central to the regulation of innate immune cells, dendritic cells, T-cells, and B-cells. Tezepelumab is a human monoclonal antibody that binds TSLP. In phase 2 clinical trial, subcutaneous Tezepelumab injections every 4 weeks reduced asthma exacerbations significantly. A phase 3 trial has started in October 2018 (Barnes 2017, 2018).

Asthma therapy is continuously developing toward personalized medicine. Increasingly, the therapy takes into account asthma subsets, IgE and eosinophil levels, and comorbidities.

Ca^{2+} antagonists; Ca^{2+} channel antagonists

Definition

Ca^{2+} is an important intracellular second messenger that controls several cellular functions including muscle contraction in smooth and cardiac muscle. Ca^{2+} channel blockers ("Ca^{2+} antagonists") inhibit depolarization-induced Ca^{2+} entry through one specific member of the voltage-gated Ca^{2+} channel family, so-called L-type channels. Inhibition of L-type channels in muscle cells of the cardiovascular system causes a decrease in blood pressure, a reduction of cardiac contractility, and has antiarrhythmic effects. Therefore, these drugs are used clinically to treat hypertension, myocardial ischemia, and cardiac arrhythmias.

Mechanism of Action

Voltage-gated Ca^{2+} channels are Ca^{2+}-selective pores in the plasma membrane of all electrically excitable cells, such as muscle cells, neurons, endocrine cells, and sensory cells. They open in response to membrane depolarization (e.g., an action potential) and permit the influx of Ca^{2+} ions along their electrochemical gradient into the cytoplasm. L-type Ca^{2+} channels, the pharmacological target of Ca^{2+} channel blockers, are one of the five different types of voltage-gated Ca^{2+} channels.

Ca^{2+} Channel Physiology

Ca^{2+} influx across the plasma membrane not only triggers Ca^{2+}-dependent intracellular signaling events but also supports membrane depolarization. In nerve terminals and sensory or endocrine

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

cells, Ca^{2+} channels initiate neurotransmitter or hormone release, respectively (stimulus-secretion coupling). Ca^{2+} entry into the soma and dendrites of nerve cells leads to the activation of intracellular pathways affecting gene transcription (excitation-transcription coupling) and neuronal plasticity. In smooth muscle and cardiac myocytes, Ca^{2+} influx through these channels induces muscle contraction (excitation-contraction coupling).

Ca^{2+} Channel Function

Like other voltage-gated cation channels, Ca^{2+} channels exist in at least three states: A resting state stabilized at negative potentials (such as the resting membrane potentials of most electrically excitable cells) is a closed state from which the channel can open. The open state is induced by depolarization. Channels do not stay open indefinitely because they are "turned off" during depolarization by transition into an inactivated state. Inactivation is driven both by depolarization (voltage-dependent inactivation) and by the permeating Ca^{2+} ions (Ca^{2+}-dependent inactivation). Inactivation helps to fine-tune Ca^{2+} signaling and to prevent toxicity induced by cellular Ca^{2+} overload during prolonged stimulation. Once the cell repolarizes, inactivated channels return to the resting state and are now again available for opening. These gating mechanisms are mainly driven by the voltage-dependent conformational changes of the four voltage-sensing domains of the pore-forming α1 subunit (Catterall et al. 2019).

Organic Ca^{2+} channel blockers can inhibit Ca^{2+} flux not only by obstructing the open pore but also by "allosterically" stabilizing inactivated closed states. By delaying its transition to the resting state after repolarization, drugs can also delay the recovery from inactivation, i.e., increase the "refractory period" of these channels (Zamponi et al. 2015).

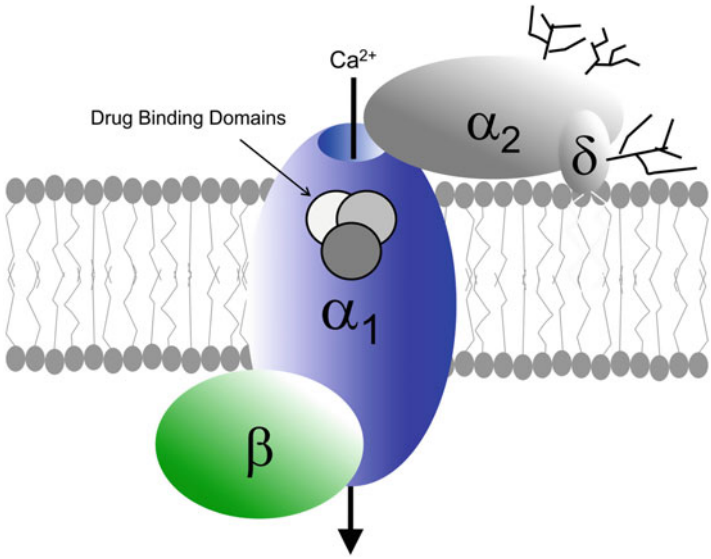
Ca^{2+} Channel Types

In order to accomplish these diverse physiological tasks described above, nature has created at least five different types of Ca^{2+} channels. These are termed L-, N-, P/Q-, R-, and T-type. Although they are all structurally similar (Fig. 1), they differ with respect to their biophysical properties and their tissue and subcellular distribution (Alexander et al. 2019). Some of them need only weak depolarizations to open and can conduct Ca^{2+} currents at membrane potentials below action potential threshold (e.g., low-voltage-activated T-type Ca^{2+} channels and Cav1.3 L-type channels). Others require stronger depolarizations and open during action potentials (e.g., high-voltage-activated N-, P/Q-, R-, and most L-type Ca^{2+} channels) (Alexander et al. 2019; Zamponi et al. 2015).

These channel types also differ with respect to their sensitivity to drugs. Only L-type Ca^{2+} channels are sensitive to the Ca^{2+} channel blockers widely known as "Ca^{2+} antagonists."

L-Type Ca^{2+} Channel Blockers

Organic blockers of L-type Ca^{2+} channels (also termed "Ca^{2+} antagonist") are widely used to treat hypertension and other cardiovascular disorders. They belong to the most frequently prescribed drugs worldwide. L-type Ca^{2+} channels are a major channel type mediating contraction in all types of muscle cells, including arterial vascular smooth muscle. Although they do not support fast neurotransmitter release from nerve terminals during short action potentials, L-type channels provide Ca^{2+} for neurotransmitter release in sensory (cochlear hair cells, retinal photoreceptors) and hormone release in endocrine cells (e.g., adrenalin and aldosterone release in adrenal chromaffin and adrenal cortical zona glomerulosa cells, respectively, insulin secretion in pancreatic β-cells). In neurons they drive Ca^{2+}-dependent signaling pathways (e.g., via the Ca^{2+}/calmodulin-dependent protein kinase CaMKII) important for coupling synaptic activity to gene transcription in neurons and contribute to synaptic plasticity, learning, and memory. Despite these multiple functions, in vivo therapeutic plasma concentrations of L-type Ca^{2+} channel blockers only cause relevant pharmacological effects in the cardiovascular system. Central nervous system side effects have not been reported, and inhibition of insulin secretion is only relevant during intoxications (Kumar et al. 2018). From the four L-type Ca^{2+} channel α1 subunit isoforms (Cav1.1–Cav1.4),

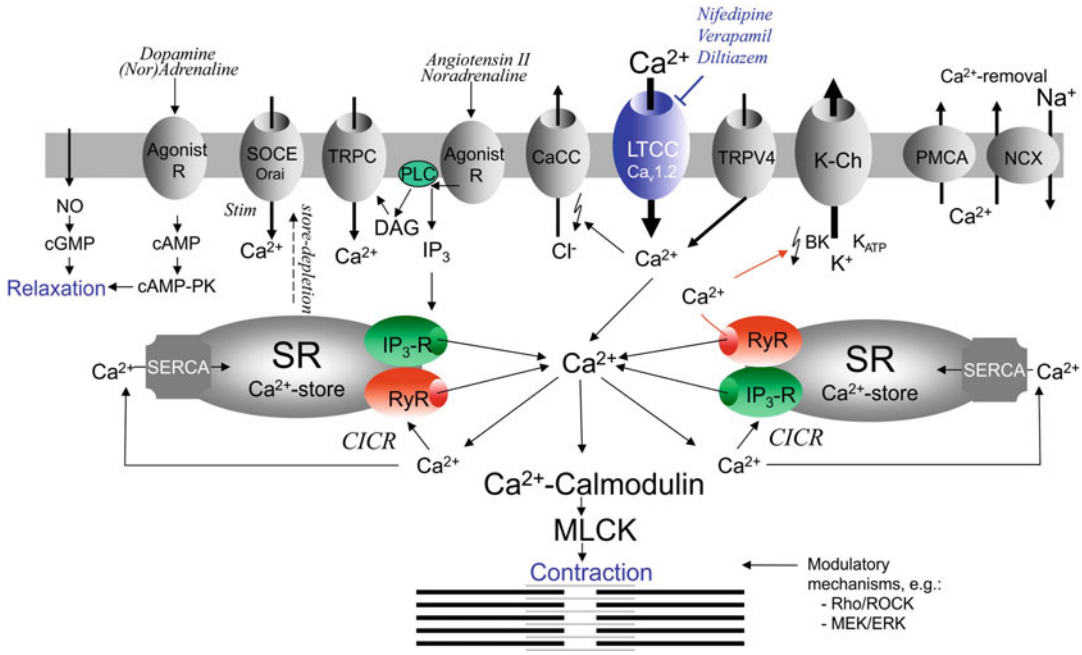


Ca^{2+} Channel Blockers, Fig. 1 Subunit structure of L-type Ca^{2+} channels: Most voltage-gated Ca^{2+} channels exist as hetero-oligomeric protein complexes. α1 subunits form the Ca^{2+}-selective ion pore and contain the voltage sensors of the channel. In the case of L-type Ca^{2+} channels, they also carry high-affinity binding sites for the different chemical classes of Ca^{2+} channel blockers (gray circles). The accessory α2-δ and β (and in some tissues also γ) subunits stabilize channel function and support their targeting to the plasma membrane. Notably, other proteins can associate with the channel allowing the formation of cell-specific signaling complexes important for channel targeting and modulation. The cryo-EM structure of the mammalian skeletal muscle (Cav1.1) L-type Ca^{2+} channel complex together with drugs bound to their binding domains within the α1 subunit has recently been reported (Zhao et al. 2019)

only Cav1.2 is expressed in arterial vascular smooth muscle and the ventricular myocardium. Cav1.3 is also expressed in the heart but serves mainly as a pacemaker channel in the sinoatrial node, a function enabled by its operating range at more negative potentials as compared to Cav1.2.

In the heart and in vascular smooth muscle, L-type channels are embedded in a network of other channels and transporters regulating intracellular Ca^{2+} signals and contractility. Simplified views of major signaling pathways are depicted in Figs. 2 and 3.

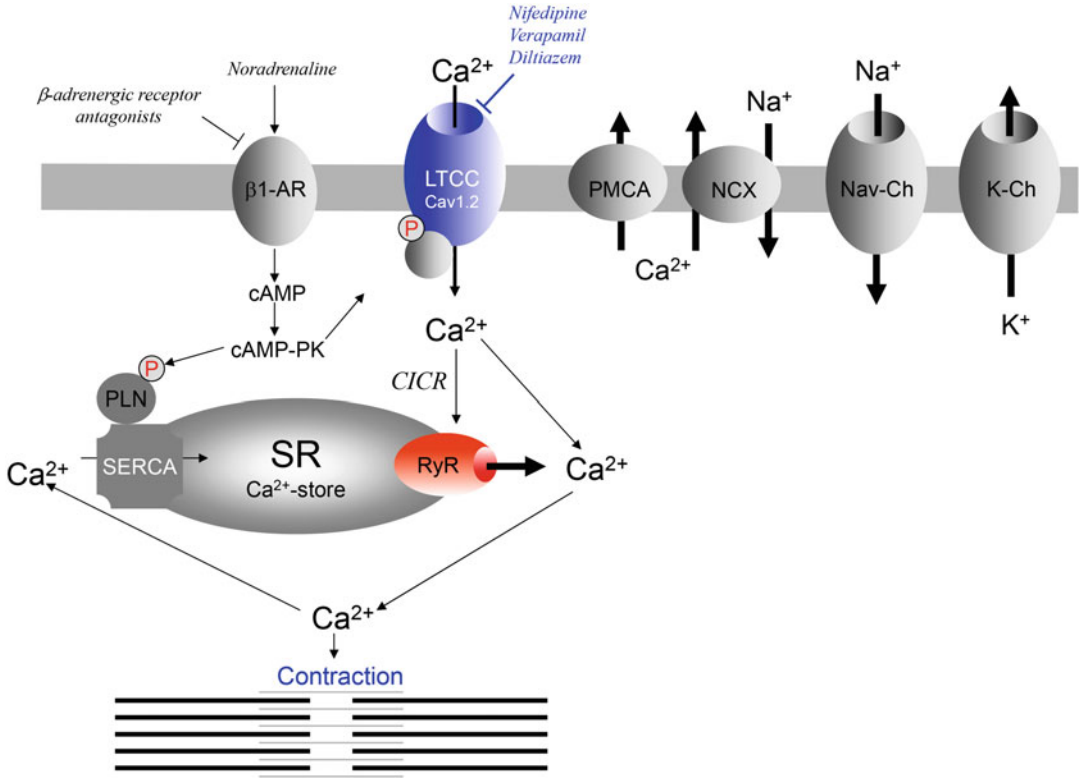
In arterial vascular smooth muscle, extracellular Ca^{2+} entry is mainly mediated by the opening of Cav1.2 L-type Ca^{2+} channels, which are a major determinant of myogenic tone, peripheral vascular resistance, and blood pressure. The inhibition of Ca^{2+} channels reduces depolarization-induced Ca^{2+} entry and therefore less Ca^{2+} is available for activation of calmodulin. Calmodulin activates myosin light chain kinase (MLCK) and thereby promotes actin-myosin interaction and contraction (Fig. 2). Vascular smooth muscle also contracts after stimulation of receptor-activated pathways, such as the pharmacologically relevant angiotensin II AT1 (by angiotensin II) and α1-adrenergic receptors (by, e.g., noradrenaline) and the IP_3-mediated release of Ca^{2+} through IP_3 receptors from sarcoplasmic reticulum (SR) stores (legend to Fig. 2 for details). Localized Ca^{2+} signals (such as sparklets, sparks, or Ca^{2+} waves) also play an essential role in orchestrating the interplay between Ca^{2+} entry and Ca^{2+} extrusion mechanisms (Brozovich et al. 2016). Agonist-induced contractions are much less sensitive to Ca^{2+} channel blockers. The differential contribution of depolarization-induced and receptor-activated contraction in different types of smooth muscle and under different pathophysiological conditions is one of the explanations why Ca^{2+} channel blockers are not effective smooth muscle relaxants in other disease states (such as bronchial asthma or urethral spasms).



Ca^{2+} Channel Blockers, Fig. 2 L-type Ca^{2+} channels in vascular smooth muscle: Simplified view of Cav1.2 L-type Ca^{2+} channel signaling as the pharmacological target of Ca^{2+} channel blockers in arterial smooth muscle. In contrast to cardiomyocytes, action potentials in smooth muscle are not carried by fast voltage-gated Na^{+}-channels, and membrane potential is more depolarized. Depolarizations are more long-lasting and induced by different mechanisms not further discussed here (including changes in intravascular pressure). Contraction requires the binding of Ca^{2+} ions to calmodulin, which then activates myosin light chain kinase (MLCK). MLCK phosphorylates the light chain of myosin, which initiates contraction. L-type Ca^{2+} channels opening in response to depolarization serve as a major global Ca^{2+} source for activation of this pathway. As a consequence, inhibition of these channels by specific blockers reduces contractility and can induce vasodilation. Alternatively, Ca^{2+} can be released from intracellular stores after activation of membrane receptors (e.g., of angiotensin II AT1 or α1-adrenergic receptors) coupled to inositol triphosphate (IP_3) production via phospholipase C (PLC). IP_3 opens Ca^{2+}-permeable IP_3 receptor (IP_3-R) channels present on the sarcoplasmic reticulum (SR) membrane. Ryanodine receptor Ca^{2+} channels (RyR) can also contribute to SR Ca^{2+} release. Receptor activation can also trigger Ca^{2+} entry, e.g., via diacylglycerol (DAG) through members of the TRPC channel family ("receptor-operated Ca^{2+} entry") or indirectly through intracellular store depletion. SR store depletion activates "store-operated Ca^{2+} entry" (SOCE) channels in the plasma membrane. These receptor-activated mechanisms are less sensitive to Ca^{2+} channel blockers. However, receptor activation and intracellular Ca^{2+} (e.g., through Ca^{2+}-activated chloride channels, CaCC) can depolarize the plasma membrane and may thus indirectly promote opening of Cav1.2 Ca^{2+} channels. Receptor-mediated activation of cAMP-dependent protein kinase (cAMP-PK) results in muscle relaxation through different mechanisms not depicted here. Activation of membrane potassium channels (K-Ch) can also oppose vasoconstriction by inducing membrane hyperpolarization. For example, Ca^{2+}-activated BK K^{+}-channels are activated by Ca^{2+} released from the SR by RyR. Note that both RyR and IP_3-R can be activated by Ca^{2+} itself ("Ca^{2+}-induced Ca^{2+} release," CICR), a positive feedback loop for Ca^{2+} release. TRPV4 channels appear to induce CICR through RyR and thus mediate membrane hyperpolarization. Major Ca^{2+} removal mechanisms involve the plasma membrane Ca^{2+} pump (PMCA) and the sodium-Ca^{2+} exchanger (NCX) in the plasma membrane and the SR Ca^{2+} pump in the SR (SERCA)

In the heart, Ca^{2+} entering through L-type channels during the action potential serves as a trigger ("trigger Ca^{2+}") for further Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum that initiates contraction (Fig. 3) (Eisner et al. 2017). β-Adrenergic receptor activation increases inotropy at least in part by cAMP-dependent phosphorylation of L-type channels or associated regulatory proteins, thereby increasing Ca^{2+} entry.

Three different chemical classes of organic Ca^{2+} channel blockers can be distinguished: Dihydropyridines (DHPs; prototype nifedipine),



Ca^{2+} Channel Blockers, Fig. 3 L-type Ca^{2+} channels in cardiac myocytes: Simplified view of the pharmacological action of L-type Ca^{2+} channel blockers in cardiac myocytes. In cardiac myocytes, L-type Ca^{2+} channels (Cav1.2) open when the plasma membrane is depolarized by an action potential carried along the muscle cells by the opening of voltage-gated Na^{+}-channels (Nav-Ch). The action potential duration is both dependent on the depolarizing effect of Ca^{2+} influx through L-type channels and the repolarizing action of multiple potassium channels (K-Ch). Ca^{2+} influx triggers massive release of Ca^{2+} (Ca^{2+}-induced Ca^{2+} release, CICR) by opening ryanodine-sensitive Ca^{2+} channels (RyR) in the sarcoplasmic reticulum (SR), resulting in an intracellular Ca^{2+} transient triggering contraction. Contraction is terminated by the rapid uptake of Ca^{2+} into the SR by SR Ca^{2+} ATPases (SERCA). β-Adrenergic receptor stimulation increases inotropy by phosphorylation (P) of phospholamban (PLN) and L-type channels (or associated proteins, Liu et al. 2020) through cAMP-dependent protein kinase (cAMP-PK). The resulting stimulation of Ca^{2+} influx and Ca^{2+} pump activity increases the load of Ca^{2+} in the SR stores. This leads to enhanced Ca^{2+} transients upon depolarization. Inhibition of Ca^{2+} influx through L-type Ca^{2+} channels by Ca^{2+} channel blockers decreases Ca^{2+} entry and SR load. Less Ca^{2+} influx and reduced release from the SR results in smaller Ca^{2+} transients and reduces inotropy. *PMCA* plasma membrane Ca^{2+} pump, *NCX* sodium-Ca^{2+} exchanger

phenylalkylamines (prototype verapamil), and benzothiazepines (prototype diltiazem). The drugs reversibly interact with their binding domains in a stereoselective manner and with dissociation constants in the (sub)nanomolar range (0.1–50 nM) (Striessnig et al. 1998). Radioligand binding, photoaffinity labeling, and site-directed mutagenesis studies (Hockerman et al. 1997; Striessnig et al. 1998) predicted that they all bind to adjacent, allosterically coupled, and partially overlapping sites close to or within the pore of the channel. These predictions have recently been confirmed in high-resolution structures of the drugs bound to the skeletal muscle Cav1.1 L-type channel (Zhao et al. 2019) and a Ca^{2+}-selective bacterial voltage-gated Na^{+}-channel (Tang et al. 2016).

Dihydropyridines (DHPs)

Widely used DHPs are amlodipine, lercanidipine, nisoldipine, nicardipine, nifedipine, and isradipine.

They do not act as pore blockers by binding directly within the ion-conducting pathway. Instead they act "allosterically" by stabilizing the inactivated state of the channel and do not require the channel to open in order to access their binding domain (Tang et al. 2016; Zhao et al. 2019). Inactivated channels are more likely to exist in arterial vascular smooth muscle because of its more depolarized membrane potential and longer-lasting depolarizations than in cardiac muscle. Moreover, the arterial smooth muscle channel differs slightly from the cardiac isoform due to alternative splicing of Cav1.2 α1 subunits, which also facilitates channel block by DHPs. As a consequence, DHPs inhibit the channels in arterial smooth muscle at lower concentrations than in cardiac muscle or in neurons (Ortner et al. 2017). Their clinically relevant actions therefore primarily result from their vasodilating properties in arterial smooth muscle (including the coronary arteries) and not from direct actions on the myocardium and the conduction system (i.e., antiarrhythmic and cardiodepressant effects), which are observed at higher concentrations in vitro or at toxic plasma levels.

Phenylalkylamines

Verapamil is the most widely used phenylalkylamine. At therapeutic plasma concentrations, verapamil inhibits not only Cav1.2 L-type channels in vascular smooth muscle but also in the heart. In addition to vasodilation, this results in negative chronotropic, dromotropic, and inotropic effects. Access to its binding domain is greatly enhanced by opening of the intracellular channel mouth (the so-called activation gate; Tang et al. 2016; Zhao et al. 2019). Once bound to the open state, it can also promote inactivated channel conformations. Verapamil also slows the recovery of channels from inactivation. This increases the "refractory period" of the drug-bound channel. As a consequence, the number of channels available for opening and Ca^{2+} influx decreases when the time between depolarizations shortens (i.e., when stimulation frequency increases). The open channel block and slowing of recovery explain why inhibition by a given verapamil concentration increases at higher heart rates (frequency-dependent block). Like the lidocaine block of voltage-gated Na^{+}-channels, the verapamil block of Ca^{2+} channels in the heart becomes more pronounced during tachyarrhythmias. Together these pharmacological effects allow its use not only for the treatment of hypertension but also of angina (limitation of oxygen consumption through its cardiodepressant action) and supraventricular tachyarrhythmias.

Benzothiazepines

Diltiazem is the only benzothiazepine in clinical use. Its binding domain in the channel overlaps with the one of verapamil (Tang et al. 2016; Zhao et al. 2019). Its molecular mechanism of action as well as its pharmacological effects also closely resembles those of phenylalkylamines.

All three classes of Ca^{2+} channel blockers also inhibit depolarization-induced contraction of venous smooth muscle in vitro. However, venous relaxation does not substantially contribute to the hemodynamic actions of Ca^{2+} channel blockers.

Clinical Use (Including Side Effects)

DHPs are potent arterial vasodilators and are therefore classified as "selective Ca^{2+} channel blockers with mainly vascular effects" (WHO ATC classification). At therapeutic plasma levels, they act on resistance vessels and therefore reduce peripheral vascular resistance, lower arterial blood pressure, and antagonize vasospasms in coronary or peripheral arteries. By reducing afterload, DHPs also reduce cardiac oxygen demand. Together with their vascular spasmolytic effect, this explains most of the beneficial actions of DHPs in angina pectoris. Most DHPs are only licensed for the therapy of hypertension, some of them also for the treatment of angina pectoris and vasospastic (Prinzmetal) angina. Long-acting DHPs are recommended as first-line drugs for the treatment of primary hypertension, either as monotherapy or as part of antihypertensive combination therapy (Whelton et al. 2018; Williams et al. 2018). There is solid clinical evidence demonstrating that their use reduces the risk of subsequent cardiovascular events.

Fast DHP-induced lowering of blood pressure results in compensatory sympathetic activation and a subsequent increase in heart rate and cardiac oxygen demand. This unfavorable effect has been mainly associated with the use of short-acting DHPs, such as immediate-release formulations of nifedipine, nitrendipine, or isradipine. The use of such formulations that cause fluctuations in plasma levels upon multiple dosing is discouraged. Instead, DHPs with slower onset and longer duration of action (amlodipine or extended-release formulations of, e.g., nifedipine, felodipine, isradipine) are recommended. Due to their vasodilating properties in the absence of negative inotropic actions, DHPs have also been evaluated as vasodilators in the treatment of heart failure with reduced ejection fraction in addition to standard therapy. Although long-acting DHPs (like amlodipine and extended-release felodipine) seem to be safe in these patients, they are not recommended for this indication.

Nimodipine, but not other DHPs, is also a potent inhibitor of nucleoside transport with actions similar to known nucleoside transport inhibitors such as dipyridamole. It is likely that this mechanism also contributes to the potent vasodilating properties of this DHP. Nimodipine is licensed for the prevention of vasospasms after subarachnoid hemorrhage.

DHPs are also used to treat vasospasms of peripheral arteries (e.g., Raynaud's phenomenon) and pulmonary hypertension.

Therapeutic doses of verapamil and diltiazem also exert negative inotropic, dromotropic, and chronotropic actions, in addition to their vasodilatory and spasmolytic properties. They are classified as "selective Ca^{2+} channel blockers with direct cardiac effects" (WHO ATC classification). As a consequence, compensatory tachycardia does not occur and heart rate may even decrease. Similar to β-adrenergic antagonists, verapamil and diltiazem inhibit exercise-induced increases in heart rate and myocardial oxygen consumption. Therefore both drugs are licensed for the treatment of angina, vasospastic angina, and hypertension. Due to their negative dromotropic and antiarrhythmic properties (see above), they are indicated for slowing AV conduction and to treat supraventricular arrhythmias. In patients with normal contractile function, the negative inotropic action of verapamil is partially compensated by the decreased afterload and improved myocardial perfusion. However, verapamil may decrease left ventricular function in patients with heart failure and reduced ejection fraction. Unlike β-adrenergic blockers, verapamil and diltiazem are not recommended in patients with heart failure and for the early treatment or secondary prevention of myocardial infarction.

C

Side Effects

Many unwanted effects are related to the vasodilatory effects of Ca^{2+} channel blockers, such as flushing, headache, dizziness, and hypotension. DHPs cause leg edema and ankle swelling upon chronic use, which is therapy-limiting in some patients. Constipation is a frequent side effect of verapamil likely due to its inhibitory action on intestinal smooth muscle. Bradycardia, atrioventricular block, or a decrease in left ventricular function are observed with verapamil (and to a lesser degree diltiazem), especially in patients taking β-adrenergic blockers or who have preexisting cardiac disease (impaired left ventricular function, atrioventricular block). Worsening of angina has also been observed with DHPs. This is most likely due to their effect on coronary resistance vessels resulting in "coronary steal" directing blood flow away from already hypoperfused regions. It may also be caused by the reactive sympathetic activation with an increase of heart rate and of cardiac oxygen consumption.

Epidemiological and case-control studies suggested that Ca^{2+} channel blockers cause increased risk for myocardial infarction, cancer, and gastrointestinal bleeding. The increased cardiovascular morbidity was associated with short-acting DHPs and with fast-release formulations of verapamil and diltiazem. It was explained by the unfavorable hemodynamic effects of short-acting drugs. Enhanced cardiovascular morbidity has not been consistently shown for long-acting formulations. An increased risk of cancer or of gastrointestinal bleeding was not confirmed in other large trials.

Ca^{2+} channel blockers cause no side effects expected from channel block in other tissues (e.g., cochlear inner hair cells, retinal photoreceptors, neurons, or pancreatic β-cells). Despite the dependence of insulin secretion on L-type Ca^{2+} channel function, impaired glucose tolerance is not a frequent side effect of Ca^{2+} channel blockers in clinical practice. The reason for the absence of such side effects may be explained by the lower bioavailability in these tissues, by different cellular activity patterns (affecting channel state- and frequency-dependent block), by alternatively spliced channel subunits conferring different drug sensitivity (see above), and by the existence of various L-type channel isoforms, which differ in drug sensitivity. Cav1.2 channels, the major L-type channel isoform in vascular smooth muscle and cardiac ventricular muscle, are more sensitive to Ca^{2+} channel blockers than Cav1.3 and Cav1.4 (see references in Ortner et al. 2017), the major isoforms expressed in cochlear inner hair cells and retinal photoreceptors, respectively.

Other Pharmacological Actions of Ca^{2+} Antagonists

Although the clinical benefit of Ca^{2+} channel blockers is due to inhibition of Cav1.2 channels as outlined above, inhibition of Cav1.2 or Cav1.3 L-type channels in other tissues may also be of therapeutic interest. In the brain both L-type channel isoforms are involved in neuronal signaling events underlying drug-taking behaviors. In preclinical models systemic isradipine treatment decreases cocaine relapse, a finding that will be pursued in clinical trials (Addy et al. 2018). Ca^{2+} influx through Cav1.3 channels appears to contribute to oxidative stress and neurodegeneration of substantia nigra dopaminergic neurons in Parkinson's disease (Guzman et al. 2018). This prompted the phase 2 and 3 STEADY-PD clinical trial program (Biglan et al. 2017). However, treatment with 5 mg immediate-release isradipine b.i.d. over 36 months was not neuroprotective, likely because brain drug concentration is too low to fully inhibit Cav1.3 channels in these neurons (Ortner et al. 2017).

Somatic de novo mutations in the pore-forming α1 subunit of Cav1.3 Ca^{2+} channels are frequently found in aldosterone-producing adenomas or adrenocortical aldosterone-producing cell clusters. These mutations activate Cav1.3 channels and drive autonomous Ca^{2+}-dependent aldosterone secretion resulting in primary aldosteronism (Azizan et al. 2013). The development of Cav1.3-selective inhibitors may therefore represent a nonsurgical treatment option for these patients.

Notably Cav1.3 channels also control cardiac pacemaking in the sinoatrial node but do not contribute to cardiac inotropy and arterial myogenic tone. Cav1.3-selective Ca^{2+} channel blockers may therefore also act as bradycardic agents lacking negative inotropic actions.

Definition

After entering the cell, Ca^{2+} is reversibly complexed to specific Ca^{2+}-binding proteins which decipher the information carried by Ca^{2+} and pass it on to various targets regulating a myriad of biological functions. These proteins contain highly specific Ca^{2+}-binding sites, a characteristic helix-loop-helix structure called the EF-hand, with one Ca^{2+}-binding in the loop (Grabarek 2006; Schaub and Heizmann 2008). This highly conserved motif is found to date in a great number of Ca^{2+}-binding proteins grouped into distinct subfamilies (Haynes et al. 2012; Kawasaki and Kretsinger 2017). Figure 1 shows the structure of sorcin as an example of a penta-EF-hand calcium-binding protein expressed at high levels in several human cancers.

S100 proteins constitute the largest subgroup within the EF-hand protein family involved in many cellular activities (*see separate entry in this volume*). Protocols for studying the many facets of Ca^{2+}-binding proteins in cellular functions, their clinical relevance, and their use as diagnostic and prognostic biomarkers in laboratory medicine and as novel therapeutic drug targets, have been published (Heizmann 2019).

Basic Characteristics and Clinical Relevance

Cardiology

The *cardiac troponin complex* is composed of troponin I (cTnI), troponin T (cTnT), and the Ca $^{2+}$-sensing troponin C (cTnC). The heart-specific isoforms of TnT and TnI were found to be organ-specific biomarkers of cardiac necrosis when released into the blood. More than a hundred mutations have been reported in all three subunits of cardiac troponin associated with inherited hypertrophic (HCM), dilated (DCM), and restrictive cardiomyopathies. Most mutations have been found in cTnT and cTnI, with only a few in cTnC in HCM and DCM. Some of these mutations directly affect the Ca^{2+}-sensitivity and Ca^{2+}-affinity of cTnC and normal heart functioning (Li and Hwang 2015).

Calmodulin regulates more than 100 different proteins in a Ca^{2+}-dependent manner (Ikura and Ames 2006). Mutations in calmodulin have been identified, linked to dominantly inherited ventricular tachycardia (CPVT) and severe cardiac arrhythmias (Nyegaard et al. 2012). These results indicate that calmodulin could be a therapeutic target for some cardiac disorders.

Parvalbumin was the first Ca^{2+}-binding protein to have its amino acid sequence and atomic 3D structure resolved (Kawasaki and Kretsinger 2017). Parvalbumin functions as a Ca^{2+}-buffer, enhancing relaxation of fast-contracting skeletal muscles in small mammals, but is absent from the human heart (Heizmann et al. 1982). Based on these results, parvalbumin was therapeutically introduced into the human heart to speed up relaxation after each heartbeat in diastolic heart failure (HF) to improve Ca^{2+}-handling and cardiac performance (Coutu et al. 2004).

Myosin light chain-2 (MYL2, also named MLC-2) exists as three isoforms in mammalian muscles, encoded by three distinct MLC-2 genes: MCL-2f, fast-twitch skeletal muscle isoform; MLC-2v, cardiac ventricular and slow-twitch skeletal muscle form; and MLC-2a, cardiac atrial form. Genetic loss-of-function studies of the cardiac forms in mice have demonstrated their key roles in cardiac function during early embryogenesis. In adults, MLC-2v phosphorylation regulates cardiac myosin cycling kinetics and normal cardiac function. Dephosphorylation of MLC-2v has been implicated in dilated cardiomyopathy and heart failure (Sheikh et al. 2015).

Calcineurin (Cn), a serine-threonine protein phosphatase, is a heterodimer consisting of two subunits: CnA and CnB (containing 4 EF-hands each). On activation, calmodulin binds as a third subunit. The immunosuppressive Cn inhibitors cyclosporine and FK506 can prevent cardiac hypertrophy and dilated myopathy. Constitutive overexpression of activated Cn leads to cardiac hypertrophy in mice, and genetic deletion of the

stress-responsive isoform of Cn (CnB beta) inhibits the development of myocardial hypertrophy. Cn levels, when measured in left ventricular samples of heart failure individuals, indicate that Cn may play a critical role in the progression of human heart failure (Wolska 2009).

CIB1 is a 22-kDa protein with 4 EF-hand domains, but only the third and fourth C-terminal domains bind calcium at physiological concentrations. CIB1 interacts with many signaling proteins including CnB. Ablation of CIB1 was found to protect the mouse heart from hypertrophy and the development of heart failure, suggesting that CIB1 could be a potential target for future therapeutic strategies (Heineke 2013).

Penta-EF-hand (PEF) protein family: calpains, sorcin, grancalcin, ALG-2, and peflins (Maki et al. 2002).

Calpains are a family of cysteine proteinases activated by Ca^{2+}. The human m-calpain is composed of a large 78–80 kDa catalytic subunit and a small 29 kDa regulatory subunit; each subunit contains five EF-hand motifs. Calpain activity is tightly controlled by its endogenous inhibitor calpastatin. Overactivation of calpain and mutations of calpain have been associated with cardiac and cerebral ischemia (Zatz and Starling 2005).

Sorcin undergoes Ca^{2+}-induced conformational changes which enable them to translocate from the cytoplasm to membranes and to interact with a variety of target proteins (Fig. 1). In the heart, sorcin modulates key regulatory processes such as the calcium-induced Ca^{2+}-release and excitation-contraction coupling. A natural F112L sorcin mutant was found to be associated with hypertrophic cardiomyopathy and hypertension. This F112L variant was unable to translocate to the membrane and showed a decrease in both Ca^{2+}-affinity and interaction with target proteins, resulting in an alteration of E-C coupling in the heart (Ilari et al. 2015; Collins et al. 2007) (Table 1).

Ca^{2+}-Binding Proteins, Table 1 Calcium-binding proteins in heart failure

Proteins	Disease association
Cardiac troponin

Oncology

Sorcin is overexpressed in many cancer cells as a result of the increased drug resistance to several chemotherapeutic agents (Shabnam et al. 2018). Multidrug resistance (MDR) is one of the major causes of treatment failure in pediatric acute leukemia (ALL), one of the most common types of cancer in children. Overexpression of sorcin is a prognostic marker for multidrug-resistant pediatric ALL, correlating with upregulated MDR1/P-glycoprotein (P-gp) expression in these patients. Sorcin may be a biomarker of MDR and

therapeutic target for reversing multidrug resistance in ALL and other types of cancers (Dabaghi et al. 2016).

CIB1 was also identified in cancer, considered to be a novel drug target in human tumors (Wang et al. 2017).

Swiprosin-1, an actin-binding protein also known as EF-hand domain-containing 2 *(EFHD2),* is overexpressed in various human cancer tissues, especially at highly invasive stages of malignant melanoma. Swiprosin-1 stimulates cancer invasion and metastasis through activating the Rho family of small GTPases suggesting that these proteins could be considered as a potential therapeutic target to prevent cancer invasion and metastasis (Hu et al. 2015). *EFHD2* expression was found to correlate with postsurgical recurrence of cancer in patients with stage I adenocarcinoma, and the multivariate Cox regression analysis revealed that EFHD2 expression was an independent clinical predictor for this cancer type (Fan et al. 2017).

Tescalcin is a Ca^{2+}- and Mg^{2+}-binding protein with one consensus EF-hand and three additional domains with EF-hand homology. Tescalcin shares sequence homology with the calcineurin-B homologous protein 3 (CHP3), can inhibit the phosphatase activity of calcineurin A, and has emerged as a regulator of cell differentiation and growth. Tescalcin is overexpressed in colorectal cancer (CRC) contributing to the invasive and metastatic activity. Patients with CRC showed increasing serum levels of CRC. The protein is therefore considered to be a potential diagnostic marker and oncotarget in CRC (Kang et al. 2016).

LETM1, a leucine zipper/EF-hand containing transmembrane protein, is located in the inner membrane of mitochondria. Elevated levels of expression have been correlated with carcinogenesis and tumor progression of breast cancer and were found to be an independent marker for a poor prognosis for patients with this type of cancer (Wang et al. 2015) (Table 2).

Ca^{2+}-Binding Proteins, Table 2 Calcium-binding proteins in cancer

Proteins	Disease association
Calmodulin	Autophagy in cancer, glioblastoma invasion, HRAS- and NRAS-driven cancers
Sorcin	Multidrug resistance, gastric, colorectal, breast cancers, childhood ALL [a]
CIB1 [b]	Tumor progression
Swiprosin-1/ EFHD2 [c]	Malignant melanoma, stage I lung adenocarcinoma

Inflammation and Allergies

Calpains, a family of cysteine proteases (Zatz and Starling 2005), are involved in the process of several inflammation-associated diseases and are considered as therapeutic targets for these diseases (Ji et al. 2016).

Calcineurin is a serine-threonine protein phosphatase (Wolska 2009). Calcineurin-NFAT signaling is essential for infection control, and calcineurin inhibitors, used in translation medicine (e.g., cyclosporine A and tacrolimus), are now being tested in various inflammatory conditions and autoimmune pathologies (Bendickova et al. 2017).

Parvalbumin isoforms are major fish allergens in humans. Approximately 70% of fish allergies, mediated by parvalbumin IgE antibodies, lead to respiratory and gastrointestinal symptoms. A FAST (food allergy-specific immunotherapy) project was

initiated to develop a safe and effective subcutaneous immunotherapy for fish allergy, using recombinant hypoallergenic carp parvalbumin, Cyp C 1. These results have now warranted first-in-man immunotherapy studies to further develop this new vaccine for a safe and effective therapy for fish allergy (Freidl et al. 2019) (Table 3).

Brain Injury and Neuropathology

The structures, functions, and their use as markers of different neuronal subpopulations of these neuronal calcium-binding proteins have been published (Heizmann 2019; Burgoyne et al. 2019; Schwaller 2019; Mundhenk et al. 2019). Proteins are involved in learning and memory (e.g., parvalbumin (Tripodi et al. 2019)) and are associated with various brain disorders (some listed in Table 4). Recently a novel mutation in CAPN1 (encodes calpain-1) was reported to cause a pure hereditary spastic paraplegia in an Italian family (Cotti Piccinelli et al. 2019).

[c]Downstream Regulatory Element Antagonist Modulator

Drugs

Studies are in progress to develop drugs against calcium-binding proteins and their target proteins. For example, the binding of sorcin to doxorubicine, vincristine, paclitaxel, and cisplatin was investigated, and it was shown that binding of doxorubicin impairs cell death and increases drug resistance in cancer cells. Troponin-modulating drugs are being developed for future treatment of cardiomyopathy and heart failure. Blockade of DREAM activity by repaglinide or even better by IQM-PC300 is neuroprotective in Huntington's disease (Lopez-Hurtado et al. 2019).

Outlook

So far, only a small number of this largest family of Ca^{2+}-binding proteins (with over 200 human genes coding for proteins containing the EF-hand Ca^{2+}-binding motif) have been explored for their clinical relevance, and this does not include their intra- and extracellular targets/surface receptors or posttranslational modification (e.g., phosphorylation, myristoylation, or sumoylation). Some of

those proteins also bind Mg^{2+}, Zn^{2+}, and Cu^{2+} at position distinct from the Ca^{2+}-binding sites resulting in the modulation of their activities. Mutations have been reported in cardiac troponin, calmodulin, and other EF-hand proteins making them novel therapeutic targets for more selected interventions to improve the diagnosis and treatment of human diseases.

Ca^{2+}-Induced Ca^{2+} Release (CICR) Channel

▶ Ryanodine Receptor

Ca^{2+}-Sensing Receptor (CaSR)

Giovanna Valenti
Department of Biosciences, Biotechnologies and Biopharmaceutics, University of Bari Aldo Moro, Bari, Italy

Synonyms

Calcium-sensing receptor

Definition

CaSR is a G protein-coupled receptor highly expressed in the parathyroid glands, where it regulates the production and secretion of parathyroid hormone (PTH) in negative feedback way. CaSR can detect minor changes in serum calcium levels, and calcium is the primary ligand for the CaSR. Serum calcium $<1.1–1.2$ mmol/l promotes PTH release, which results in reabsorption of calcium by the kidney, intestine, and bone. Conversely, serum Ca^{2+} levels >1.2 mmol/l have the opposite effect (Fig. 1). CaSR is also expressed in numerous other tissues, where it has different functions. Defective calcium sensing by the parathyroid glands, associated to altered CaSR expression or function, results in altered divalent cation homeostasis, which can lead to long-lasting morbidity in patients.

Basic Characteristics

CaSR expressed in the parathyroid and its genetic variants. CaSR was first cloned from bovine parathyroid and characterized in 1993 by Brown and coworkers (Brown et al. 1993) who demonstrated a key role of CaSR in maintaining extracellular calcium levels by its ability to regulate PTH biosynthesis and release.

Calcium binding at the CaSR stimulates a Gq G-protein signaling leading to activation of phospholipase C pathway and prevents exocytosis of PTH. This event is accompanied by release of calcium from intracellular stores resulting in an increase in cytosolic calcium (Brown and MacLeod 2001).

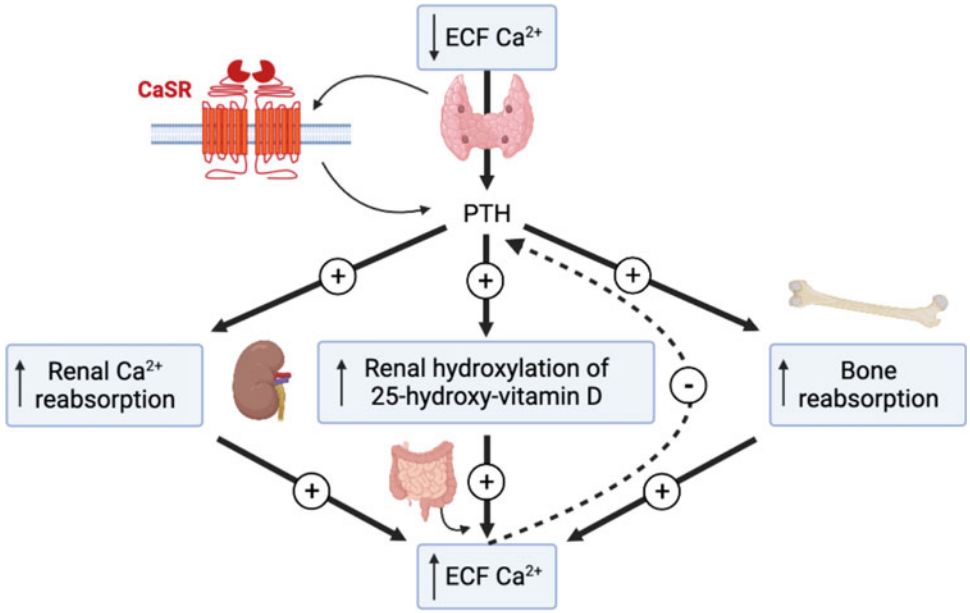
CaSR is however a pleiotropic receptor since different endogenous ligands can activate the receptor initiating multiple intracellular cascade in the same cell type or the same signaling in the different organs. Besides parathyroid, CaSR is expressed in many tissues involved in the regulation of extracellular calcium levels, such as the thyroidal calcitonin-secreting C-cells, kidney, bone, and intestine (Alfadda et al. 2014).

Nevertheless, several studies demonstrated the expression of CaSR in tissues not apparently involved in calcium homeostasis such as the brain, airways, blood vessels, breast, and liver.

Naturally occurring mutations of the CaSR gene in humans, as well as selective CaSR deletion in mice or some polymorphisms, are associated with severe alterations in calcium homeostasis.

Loss of function mutations of *CaSR* such as the two inherited conditions familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT) are characterized by altered calcium homeostasis (Pollak et al. 1993).

Conversely, the gain-of-function mutations of the CaSR such as autosomal dominant hypocalcemia (ADH) or type 5 Bartter syndrome are associated to hypocalcemia due to inhibition of



Ca^{2+}-Sensing Receptor (CaSR), Fig. 1 Role of the CaSR in calcium homeostasis
The CaSR is highly expressed in the parathyroid glands. The parathyroid CaSR detects reductions in extracellular calcium causing release of PTH. PTH increases resorption of calcium from bone, promotes urinary calcium reabsorption, and enhances expression of the biologically active 1,25-dihydroxyvitamin D that increases absorption of dietary calcium. CaSR expressed in the kidney acts independently of PTH to regulate urinary calcium reabsorption. Increases in calcium concentrations lead to negative feedback on the parathyroid glands, thereby inhibiting further PTH release. *CaSR* calcium-sensing receptor, *PTH* parathyroid hormone, *ECF* extracellular fluid

PTH secretion. Two examples of gain-of-function mutations of CaSR are N124K and R990G (Ranieri et al. 2013). N124K CaSR mutation causing ADH in humans is located in the extracellular domain, whereas the non-conservative polymorphism R990G is located in the intracellular tail of the receptor and in humans and is associated with primary hypercalciuria in patients. These two gain-of-function CaSR mutation sites are at opposite locations within the CaSR protein sequence; however functional analysis revealed comparable biological regulatory effects within cells. Specifically, functional expression of these mutations resulted in significantly higher calcium accumulation in the ER associated with higher SERCA expression and activity and reduced expression of the PMCA and basal cytosolic calcium (Ranieri et al. 2013).

Role of CaSR in the Cardiovascular System An interesting role for CaSR has been proposed as regulator of blood pressure and in vascular calcification. Both in vitro and in vivo evidences support this role. More precisely, a complex interplay between CaSR expressed in VSMC and in the endothelium has been suggested to play a critical role in the regulation of blood pressure (Loot et al. 2013). In vitro treatment with calcimimetics reduced calcification of vascular smooth muscle cells (VSMC). A mouse model of targeted CaSR deletion from VSMC displayed reduced endothelium contractility in aorta and mesenteric artery compared to wild-type animals in response to different stimuli (Schepelmann et al. 2016). More recently CaSR has been proposed as a new therapeutic target to pulmonary hypertension (Zhou et al. 2021).

Role of CaSR in the Bone The CaSR has a pivotal role in the bone and mineral metabolism (Hannan et al. 2018). In vivo and in vitro evidence demonstrated that CaSR regulates bone

remodeling by directly acting on bone cells. Osteoblasts and osteoclasts express functional CaSR and are able to sense changes in the extracellular calcium. During remodeling, local calcium released in the microenvironment can be sensed by CaSR of skeletal cells and in turn modulate bone turnover. Although calcilytics have failed thus far as anabolic therapies for osteoporosis, calcimimetic and calcilytic are under investigation for treating bone and mineral-related disorders.

Role of CaSR in Gut CaSR transcripts and proteins are abundantly expressed in the crypt and villous enterocytes of the small intestine as well as the surface epithelial cells of the large intestine.

CaSR is expressed in the gut and can be considered a nutrient-sensing receptor which activates multiple signaling pathways within the gut. Several evidences demonstrated that CaSR coordinates food digestion and nutrient absorption, regulates immune response, and promotes cell proliferation. Moreover CaSR promotes hormone secretion and reduces diarrhea and enhances intestinal barrier function (reviewed in Liu et al. 2018). CaSR has an emerging role in the maintenance of gut homoeostasis and protection of intestinal health.

Interestingly, recent evidence indicates that enterocytes use CaSR also to monitor luminal and extracellular calcium levels inducing paracrine and endocrine feedback responses to restrict calcium absorption (Chanpaisaeng et al. 2020).

Role of CaSR in the Kidney Several evidence demonstrated that the kidney is a calcium-sensing organ and senses changes in both luminal (urine) and serum calcium levels though the CaSR expressed in several nephron segments from the glomerulus to the inner medullary collecting ducts (Riccardi and Valenti 2016).

CaSR is expressed across the entire length of the nephron, with the highest expression within the TAL, and might directly contribute to the regulation of many aspects of renal function in a PTH-independent manner (Riccardi and Valenti 2016).

In the TAL, the CaSR is a major player for regulating urinary calcium excretion. CaSR activation by serum calcium in the TAL promotes urinary calcium excretion. Conversely, activation of the CaSR in the proximal tubule antagonizes the phosphaturic action of PTH and promotes proton secretion. In the collecting duct, CaSR activation decreases water reabsorption by inhibiting the tubular response to vasopressin and aquaporin-2 expression and trafficking (Ranieri et al. 2018) and increases proton excretion by stimulating proton pump activity. Therefore, CaSR activity in the proximal tubule and collecting duct can reduce the risk of calcium phosphate precipitation that is associated with the ability of the CaSR to enhance calcium excretion in the TAL.

CaSR as Pharmacological Target in Polycystic Kidney Disease CaSR activation has also been proven to correct some alterations found in cell models of autosomal polycystic kidney disease (ADPKD). Specifically, in human conditionally immortalized proximal tubular epithelial cells silenced for polycystin 1 (PKD1) or generated from a patient with ADPKD selective activation of the CaSR with calcimimetics increased cytosolic calcium, reduced intracellular cAMP and mTOR activity (Di Mise et al. 2018b), and rescue defective ATP mitochondrial production (Di Mise et al. 2018a), reversing the principal (ADPKD) dysregulations found in ADPKD.

CaSR as Pharmacological Target in Asthma CaSR has emerged as a potential therapeutic target for asthma (Yarova et al. 2015). Allergic asthma is associated to increases in certain polycations that activate CaSR in bronchi leading to activation of a signaling cascade characterized by increased intracellular calcium mobilization and p38 mitogen-activated protein kinase phosphorylation in airway smooth muscle (ASM) cells. In vivo treatment with calcilytics (CaSR antagonists) prevented these effects and reduced airway hyperresponsiveness and inflammation in allergen-sensitized mice in vivo indicating that calcilytics may represent effective asthma therapeutics.

Drugs

The development of pharmacological CaSR modulators calcilytics and calcimimetics has markedly

enhanced our understanding of the pathophysiology of the CaSR and has opened new possibilities in the clinical setting.

Calcimimetics Calcimimetic (such as cinacalcet) are able to rectify abnormal CaSR expression or function and have been successfully administered to adult patients to treat hyperparathyroidism secondary to kidney failure (Bushinsky et al. 2015). Calcimimetics correct CaSR function since they enhance CaSR sensitivity to extracellular calcium and reduce serum PTH levels by activating the CaSR expressed in the parathyroid gland and the kidney. There are two types of calcimimetics: type I are inorganic or organic polycationic agonists, and type II functions as positive allosteric modulators of CaSR activity. Cinacalcet belongs to the type II calcimimetic and, as mentioned, has been approved for the treatment of secondary hyperparathyroidism, a complication of end-stage renal disease. Conversely, the calcimimetic peptide AMG416 is being evaluated in case of secondary hyperparathyroidism in hemodialyzed patients with chronic kidney disease. AMG416 functions as a CaSR agonist and is administered intravenously. After a phase II clinical trial (Bushinsky et al. 2015), a phase III trial is now complete, but the data are not yet published.

Calcilytics Calcilytics function as CaSR antagonists and are being investigated for the treatment of autosomal dominant hypocalcemia with hypercalciuria caused by activating mutations of the *CaSR* gene conferring gain of function to the receptor (Letz et al. 2014). Basically, calcilytics are allosteric antagonists of the CaSR, and their action results in a rightward shift in the calcium concentration-response curve so that higher than normal calcium levels are required to suppress PTH release. Due to their ability to promote fluctuations in serum PTH which is known to have an anabolic effect on bone, calcilytics such as ronacaleret and JTT-305 were tested to treat age-related osteoporosis (Fitzpatrick et al. 2011). Unfortunately, those drugs were found to have no efficacy to improve osteoporosis. Nevertheless, calcilytics might be appropriate to treat hypercalciuric disorders caused by a gain of function variants of *CaSR*.

In clinical setting, the systemic treatment with allosterical modulators of the CaSR should take into account that CaSR is expressed in numerous tissues, and therefore there is the potential of adverse effects. As an example, in kidney transplant recipients, cinacalcet normalizes serum PTH and calcium concentrations, but long-term treatment might cause increase in urinary calcium excretion and the risk of renal calcium deposits that could compromise graft function. Conversely, calcilytics might be used to treat gain-of-function variants of the CaSR associated with hypercalciuria and stone diseases. However, an undesired effect would be the stimulation of PTH release, which might worsen hypercalciuria.

Undoubtedly the CaSR can be the target for therapeutic intervention for several inherited and acquired conditions, whereby the level of expression or function of the CaSR is altered. The next challenge will be to identify molecules and targeting strategies for tissue-specific CaSR expression.

Cadherins/Catenins

Jürgen Behrens
Nikolaus-Fiebiger-Center for Molecular Medicine, Erlangen, Germany

Synonyms

Calcium-dependent adhesion protein/plakoglobin

Definition

Cadherins (calcium-dependent adhesion proteins) are transmembrane proteins, which consist of an extracellular domain composed of cadherin repeats, a transmembrane domain, and a cytoplasmic domain that interacts with catenins and/or other cytoplasmic proteins.

Catenins are defined as cytoplasmic interaction partners of cadherins that form a chain of proteins ("catena," Latin for chain), which connects cadherins to the actin cytoskeleton.

Basic Characteristics

Structural Characteristics of Cadherins

Cadherins are a superfamily of Ca^{2+}-sensitive cell-cell adhesion molecules, which cause homophilic cell interactions. Cadherins can be divided into different subfamilies, namely, classical cadherins, desmosomal cadherins, protocadherins, and nonconventional cadherins (7TM cadherins, T-cadherin, FAT). Classical cadherins are often denoted by a prefix reflecting their principal expression domains; e.g., E is epithelial, N is neuronal, and P is placental. However, this classification is not stringent, as, for instance, E-cadherin can also be found in certain neuronal tissues and N-cadherin is also found in epithelial cells. Among the desmosomal cadherins, two subfamilies can be distinguished: the desmocollins 1–3 and the desmogleins 1–4.

The extracellular domain of cadherins consists of a variable number of a repeated sequence of about 110 amino acids. This sequence is termed the "cadherin repeat" and resembles in overall structure, but not in sequence, the Ig-like domains. The cadherin repeat is the characteristic motive common to all members of the cadherin superfamily. Classical and desmosomal cadherins contain five cadherin repeats, but as many as 34 repeats have been found in the FAT cadherin (see below). Cadherins are calcium-dependent cell adhesion molecules, which means that removal of Ca^{2+}, e.g., by chelating agents such as EDTA, leads to loss of cadherin function. The Ca^{2+}-binding pockets are made up of amino acids from two consecutive cadherin repeats, which form a characteristic tertiary structure to coordinate a single Ca^{2+} ion (Gumbiner 2005).

The classical cadherins are translated as precursor because they are N-terminally cleaved to reveal the mature proteins. This processing is required to activate the cell adhesion function of cadherins. Cadherins interact in trans (i.e., from opposite cells) via the most N-terminal cadherin repeats. A short amino acid sequence within this repeat, histidine-alanine-valine (HAV), has been implicated in mediating cell-cell contacts as HAV peptides can disrupt cadherin-dependent cell adhesion. Besides the trans-interactions of cadherins, the extracellular domains are also capable of forming cis-dimers through lateral amino acid contacts between cadherin molecules on one cell. This dimerization again mainly involves the first cadherin repeat. A zipper model based on the pattern of alternating cis- and trans-dimers for the adhesive interactions has been proposed (Gumbiner 2005).

Several nonconventional cadherins that contain cadherin repeats have been described, but they have specific features not found in the classical cadherins. Protocadherins constitute a big family of proteins with cadherin repeats at the extracellular domain, a transmembrane domain, and a cytoplasmic domain that differs from classical cadherins (Gumbiner 2005). The cadherin Flamingo, originally detected in *Drosophila*, contains seven transmembrane segments and in this respect resembles G protein-coupled receptors. The extracellular domain of Flamingo and its mammalian homologs is composed of cadherin repeats as well as EGF-like and laminin motifs. The seven transmembrane span cadherins have a role in homotypic cell interactions and in the establishment of cell polarity. The FAT-related cadherins are characterized by a large number of cadherin repeats (34 in FAT and 27 in dachsous). Their cytoplasmic domains can bind to catenins. T- (=truncated-) cadherin differs from other cadherins in that it has no transmembrane domain but is attached to the cell membrane via a glycosylphosphatidylinositol anchor (Gumbiner 2005).

Cytoplasmic Interactions of Cadherins

The cytoplasmic domains of cadherins bind to various proteins. The most C-terminal portion of classical cadherins directly associates with either β-catenin or the structurally related γ-catenin (more commonly called plakoglobin). β-Catenin/plakoglobin in turn binds to α-catenin, which is related to the cytoskeletal protein vinculin and associates with actin-binding proteins. Thus, β- and α-catenin provide a link of cadherins to the actin cytoskeleton (Gumbiner 2005). Another catenin, $p120^{ctn}$, binds to the cytoplasmic juxtamembrane domain of cadherins and appears to be involved in the cis-dimerization and clustering of cadherins. Based on their structure, β-catenin, plakoglobin,

and $p120^{ctn}$ belong to a protein superfamily, called the armadillo repeat family (Peifer et al. 1994). These proteins contain repeats of about 40 amino acids that were initially identified in armadillo, the Drosophila homolog of β-catenin. The armadillo repeats are built up of three α-helices that form a superhelix. The number of repeats varies between different members of the family; for instance, β-catenin contains 12 consecutive armadillo repeats. More distantly related members of the armadillo family include nonjunctional proteins, such as the importins, which are involved in nuclear protein import, and the tumor-suppressor APC. $p120^{ctn}$ is the founding member of a subfamily of armadillo proteins that include the plakophilins 1–3, p0071, ARVCF, and the nervous system-specific δ-catenin; the latter two are binding to the same region of cadherins as $p120^{ctn}$. Interestingly, the $p120^{ctn}$-related proteins are also found in the cell nucleus. $p120^{ctn}$ binds to the transcription factor Kaiso relieving its repressor activity, and plakophilin 2 is associated with RNA polymerase III complexes. Loss of $p120^{ctn}$ function in mice leads to activation of NF-κB signaling and inflammation. The desmosomal cadherins also associate with plakoglobin but not with β-catenin, and in addition they bind to plakophilins. Plakoglobin and plakophilins connect desmosomal cadherins to the desmosome-specific component desmoplakin, which links the complexes to the intermediate filament network (mainly cytokeratins in epithelial cells).

The cytoplasmic domains of protocadherins are unrelated to those of classical cadherins. They do not bind catenins, and it is not clear whether they are associated with the cytoskeleton (Gumbiner 2005). Some protocadherins contain a common cytoplasmic domain combined with different extracellular domains by differential pre-mRNA splicing.

Gene Organization

Several classical cadherin genes (e.g., E-, P-, VE-cadherins, and others) are found in a cluster on human chromosome 16 or on the syntenic mouse chromosome 8. The gene clustering is even more pronounced in the case of the desmosomal cadherins, which are all located on human chromosome 18q12 in relatively close vicinity to each other. Interestingly, the desmocollin and desmoglein genes (termed *DSC* and *DSG*) form two subclusters that have opposite transcriptional orientation. Protocadherins show a particularly striking genome organization. Subfamilies of protocadherins can be defined as those that share a common intracellular domain but differ in their extracellular domains (Gumbiner 2005).

Functional Characteristics

Classical and desmosomal cadherins are constituents of different types of intercellular junctions. E-cadherin, the classical cadherin of epithelial cells, is part of the adherens junction (zonula adherens), which is attached to a belt of actin via the catenins. As the name says, desmosomal cadherins are part of the desmosomes, which are rivet-like structures that make focal connections between cells. Desmosomes are characterized by a prominent intracellular plaque structure, which serves as an attachment point for intermediate filaments.

Functional studies show the adhesive role of cadherins (Gumbiner 2005). For example, cell-cell adhesion in vitro can be blocked by treatment of cultured cells with anti-cadherin antibodies, resulting in dissociation of the cell monolayer. Conversely, forced expression of cadherins by cDNA transfection in cells lacking these molecules leads to establishment of intercellular contacts. Thus, cadherins act as an adhesive glue that efficiently holds cells together. However, they may also have signaling function, as several in vitro studies show that cadherins influence differentiation and growth of cells. In vitro, cadherins can mediate the sorting out of cells, i.e., cells transfected with different cadherins separate from each other and forming homotypic aggregates. Accordingly, one of the main functions of cadherins might be in the delineation of tissue boundaries. Gene knockout experiments have revealed essential and cell-type-specific functions of cadherins in vivo. The knockout of the E-cadherin gene results in dissociation of cells of blastocyst-stage mouse embryos. The α-catenin knockout has a similar phenotype, while loss of plakoglobin leads to defects in cell adhesion of

heart muscle cells. The knockout of β-catenin does not affect cell junctions but rather has a Wnt signaling phenotype (see below), which is manifested at early stages of embryonic development. Apparently, plakoglobin, which is also present in the affected cells, can overtake the adhesive function of β-catenin under these circumstances. The mutation of desmosomal cadherins frequently leads to the disruption of skin layers. These phenotypes resemble those of the pemphigus blistering diseases in humans, which are caused by autoantibodies against desmocollins and desmoplakins (Spindler and Waschke 2014).

E-cadherin appears to play a major role in cancer as its expression is frequently downregulated in dedifferentiated, metastasizing tumors as well as during epithelial-mesenchymal transitions in embryonic development. E-cadherin gene expression is repressed by transcription factors of the Snail/Slug and ZEB1/ZEB2 families, as well as by Twist and E12/47 transcriptional repressors, which all bind to specific DNA elements in the E-cadherin promoter. E-cadherin inhibits invasion of tumor cells in in vitro systems and prevents tumor progression in vivo animal models. Moreover, E-cadherin has a role in contact-mediated inhibition of cell proliferation by its interaction with the Hippo signaling pathway (Mendonsa et al. 2018). Loss-of-function mutations of the E-cadherin gene occur in gastric carcinomas and certain types of breast tumors. The function of cadherins can be modulated by signaling pathways involving tyrosine kinases, which disrupt cell contacts, as well as by RhoA family GTPases. Conversely, E-cadherin can modulate the activity of these GTPases, although these signaling events have not been clearly defined in molecular terms so far (Gumbiner 2005).

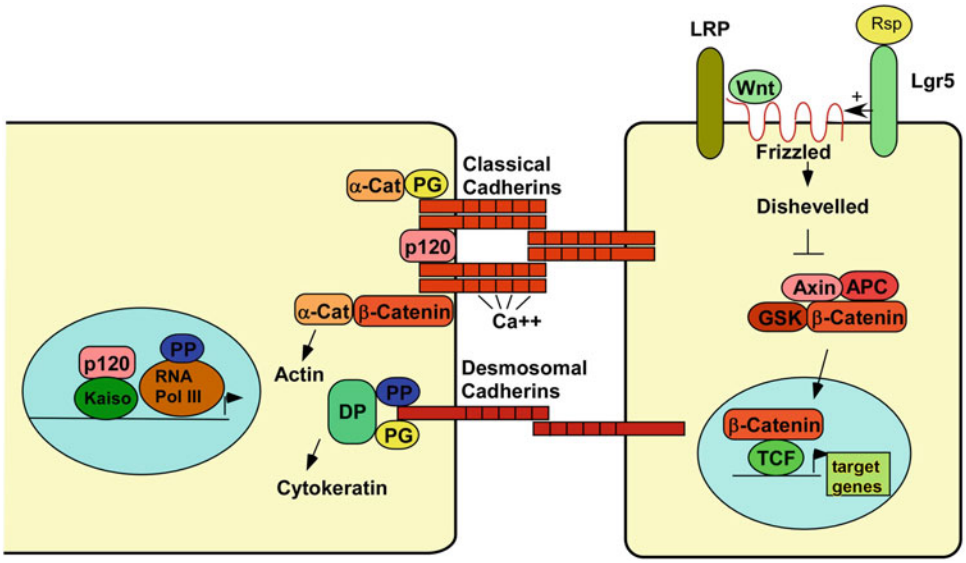
Protocadherins were shown to promote homophilic cell interaction via formation of cis- and trans-dimers in cell aggregation assays like classical cadherins (Gumbiner 2005). However, whether they reach a similar strength in cell-cell adhesion is not clear. Since there are so many members of the protocadherin family, which are mostly expressed in the nervous system, it has been speculated that protocadherins play discrete roles in setting up neuronal networks. Loss of protocadherins leads to various neuronal phenotypes including axonal patterning (Mountoufaris et al. 2018).

In *Drosophila*, *Fat* functions as a tumor-suppressor gene through interaction with Hippo signaling, and *dachsous* is involved in thorax, leg, and wing development. Several human and mouse *FAT* homologs have been identified, regulating various developmental steps involving cell proliferation (Blair and McNeill 2018).

β-Catenin in the Wnt Pathway

Besides its role in cell adhesion, β-catenin has an important function as a central signal transduction component in the Wnt pathway (Nusse and Clevers 2017). Wnts are a family of secreted glycoproteins that regulate a variety of developmental processes. Binding of Wnts to Frizzled receptors, which are seven transmembrane span proteins, induces stabilization of β-catenin. This pool of β-catenin is not associated with cadherins but accumulates in the cytoplasm and eventually enters the nucleus, where it teams up with transcription factors of the TCF family. TCFs bind to specific DNA sequences in Wnt-target promoters via an HMG box but lack transactivation domains. In the absence of β-catenin, TCFs behave as transcriptional silencers, in part, because they bind to diverse transcriptional repressors. β-Catenin lacks DNA-binding activity but contains strong transactivating sequences in its N- and C-terminal domains. Thus, when β-catenin binds to TCFs, a bipartite transcription factor is formed in which DNA-binding and transactivation domains reside on separate molecules. The TCF/β-catenin complexes can activate specific Wnt-target genes involved in determining cell fate and differentiation and inducing cancer (see below). For a list of Wnt-target genes, see www.stanford.edu/rnusse/wntwindow.html.

In the absence of Wnts, cytoplasmic "free" β-catenin is targeted for degradation by a multiprotein complex containing the scaffold component axin or the related protein conductin, the tumor-suppressor APC (adenomatous polyposis coli), and the serine/threonine kinases CK1 and GSK3β. When β-catenin binds to axin, it becomes phosphorylated by CK1 and GSK3β.



Cadherins/Catenins, Fig. 1 Overview of cadherin-mediated cell adhesion and the Wnt signaling pathway. Schematic representation of classical and desmosomal cadherins showing extracellular cadherin repeats and Ca^{2+}-binding sites and cytoplasmic interaction partners (the latter being depicted in the left cell only, which also shows association of $p120^{ctn}$ and plakophilin 2 with transcriptional regulators in the nucleus). The hypothetical cadherin zipper, which is made up of consecutive cis- and trans-dimers, is indicated (Gumbiner 2005). The basic outline of the Wnt pathway is shown in the right cell. LRP (lipoprotein receptor-related protein) is a coreceptor for Wnts. LGR5 (leucine-rich repeat containing G protein-coupled receptor5) is a receptor for Rsp (R-spondins), PG, plakoglobin, PP, plakophilin

Hyperphosphorylated β-catenin is recognized by the E3 ligase βTrCP/slimb, a component of the ubiquitination machinery, ubiquitinated, and finally degraded in proteasomes (Nusse and Clevers 2017). APC has several β-catenin and axin-binding sites and may function by sequestering free β-catenin and delivering it to the axin complex (Nusse and Clevers 2017). Thus, APC acts as a safeguard to prevent aberrant accumulation of β-catenin. Mutations of APC occur in up to 80% of colorectal carcinomas and lead to the formation of truncated proteins that are no longer able to interact with axin/conductin and to induce degradation of β-catenin. Therefore, these mutations result in the stabilization of β-catenin and in the formation of constitutive TCF/β-catenin complexes, which activate transcription of oncogenic target genes in a Wnt-independent fashion. In some colorectal tumors, and more frequently in other tumor types (e.g., hepatoblastomas), stabilization of β-catenin occurs through mutations of the critical serine or threonine residues normally phosphorylated by GSK3β. Thus, both genetically and functionally, β-catenin behaves as an oncogene, and the Wnt pathway has a major role in tumorigenesis. The pathway has also a prominent role in stem cell development in particular in the gut. In intestinal crypts, Wnts produced by surrounding mesenchymal cells called telocytes stimulate division of epithelial stem cells. In addition, secreted R-spondin proteins (Rsp) derived from myofibroblasts bind to receptors of the LGR (leucine-rich repeat containing G protein-coupled receptor) family such as LGR5 leading to the stabilization of Wnt receptors at the cell surface thereby enhancing Wnt signaling (Nusse and Clevers 2017) (Fig. 1).

Drugs

There are several potential approaches for pharmacological interference with the cadherin/

catenin system. Drugs that upregulate E-cadherin in tumors could be of potential benefit as part of a differentiation strategy to "normalize" epithelial cancers and to prevent metastasis formation. There are a number of substances reported to upregulate E-cadherin expression albeit in a rather indirect manner (Song et al. 2019). In contrast, more specific drugs targeting components of the Wnt pathway, e.g., by blocking the interaction of TCFs with β-catenin or raising the levels of negative regulator axin, have been identified and are candidates for interference with tumor growth. Moreover, certain diseases are associated with reduced Wnt signaling leading to efforts to increase activity of the pathway, e.g., by blocking GSK3 (Nusse and Clevers 2017).

Calcitonin Family Receptors

Michael L. Garelja and Debbie L. Hay
School of Biological Sciences and Maurice Wilkins Centre for Molecular Biodiscovery, The University of Auckland, Auckland, New Zealand

Synonyms

Adrenomedullin receptor; Amylin receptor; CGRP receptor

Definitions

The calcitonin (CT) receptor (CTR) and the CT-like receptor (CLR) are class B G protein-coupled receptors (GPCRs). These two GPCRs are able to interact with receptor activity-modifying proteins (RAMPs), and these interactions can influence all stages of the receptor lifespan. These receptors can be activated by several peptides, notably CT, CT gene-related peptide (CGRP), amylin, adrenomedullin (AM), and adrenomedullin 2/intermedin (AM2). Collectively this family regulates a diverse range of processes including appetite and satiety, neuromodulation, reproduction, development and maintenance of the cardiovascular and lymphatic systems, and maintenance of the skeletal system.

Basic Characteristics

Peptides

The CT peptide family comprises five structurally similar peptides: CT, CGRP, amylin, AM, and AM2. Since its discovery, AM2 has been referred to by two names – AM2 and intermedin (IMD). IMD has also been used as an alternative name for

melanocyte-stimulating hormone; to avoid confusion we recommend referring to this peptide as either AM2 or AM2/IMD but not IMD on its own. In humans and a number of other mammalian species (e.g., mice and rats), CGRP is found in two forms – αCGRP and βCGRP. In other species (such as pigs), βCGRP is not found, instead an alternative peptide known as the CT-receptor stimulating peptide is expressed (Hay et al. 2018).

These peptides have low amino acid sequence identity (Fig. 1a). However, they are united as a family by two structural features. These are: (1) a disulfide loop structure of 6–7 amino acids in the N-terminus formed by a disulfide bond between two cysteine resides, and (2) an amidated C-terminus. Removal of the disulfide loop creates antagonists with binding profiles that mimic the full length peptides; however, these antagonists often have lower affinities than the full length peptide (Hay et al. 2018). Removing the C-terminal amide also reduces the affinity of peptides for their receptors (Pioszak and Hay 2020). AM and AM2 are longer than the other peptides in the family due to the presence of an 14–15 amino acid extension prior to the disulfide loop structure (Fig. 1b). Synthetically created AM fragments which lack this extension have comparable pharmacologic and physiologic properties to the full-length AM, indicating that this region is not required for full AM function (Schönauer et al. 2017).

Receptors – Overview

This peptide family exerts its effects through two cell-surface class B GPCRs, CTR, and CLR. As class B GPCRs, CLR and CTR are made up of an extracellular N-terminus (~150 amino acids in length), seven membrane-spanning helices, and an intracellular C-terminus (~80 amino acids in length). Peptide activation of class B GPCRs occurs via the two domain model, in which the peptide C-terminus interacts with the receptor N-terminus to drive high affinity binding, which then allows the peptide N-terminus to interact with a binding pocket formed by the receptor transmembrane helices. This interaction between the transmembrane binding pocket and the peptide N-terminus stabilizes the receptor in a conformation that promotes signaling (Wootten and Miller 2020). CTR and CLR primarily couple to Gs proteins. This means that peptide activation results in the production of cyclic adenosine monophosphate (cAMP) within the cell; however, these receptors also activate other intracellular signaling pathways (Hay et al. 2018).

CTR can exist as one of many splice variants, displaying both species and tissue dependent expression. In humans the most well-characterized forms of CTR are $CTR_{(a)}$ and $CTR_{(b)}$, which are differentiated by the absence or presence of a 16 amino acid insert in intracellular loop 1, respectively. The presence of this insert affects signaling (Hay et al. 2018). CLR does not appear to display the level of variation associated with CTR.

Both CLR and CTR can interact with RAMPs. There are three RAMPs in humans. RAMPs are proteins of ~120–150 amino acids in length, with a large extracellular N-terminus (~100 amino acids), one membrane spanning helix, and a short intracellular C-terminal tail (~10 amino acids). CTR is able to traffic to the cell surface and act as a receptor

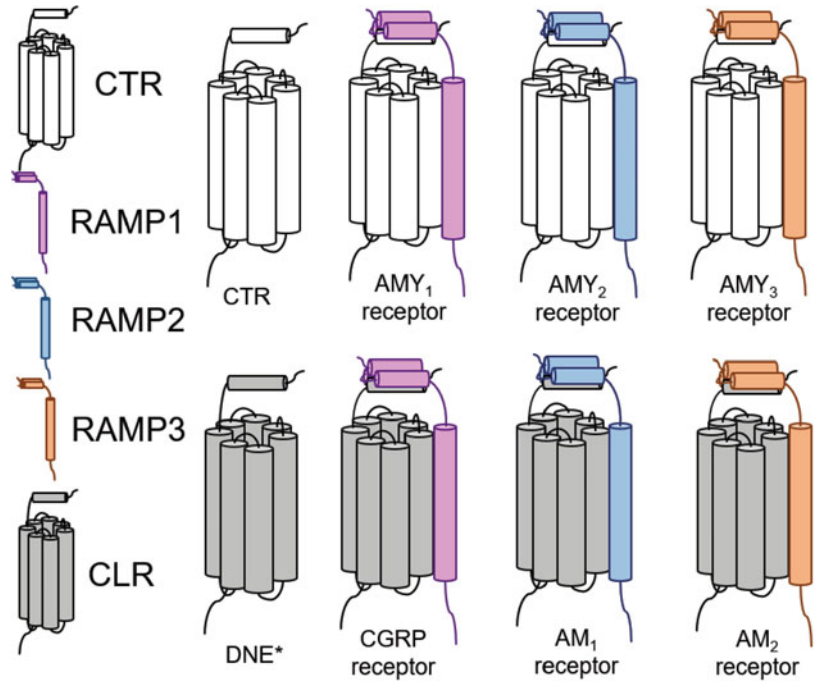
Calcitonin Family Receptors, Fig. 1 (**a**) Amino acid sequence alignment of human CT family peptides. In (**a**), AM and AM2 are shown as N-terminally truncated sequences. (**b**) shows a sequence alignment of the full-length AM and AM2 (53 amino acid form). Alignments performed in Geneious. Dark blue background with white text indicates an exact residue match, medium blue background indicates >80% similarity, and pale blue background indicates >60% similarity. All similarities were scored by Geneious. The C-terminal residue is amidated in all cases. The golden line above the sequences indicates the disulfide loop structure

without RAMP co-expression. In contrast, CLR is retained intracellularly when expressed alone, it is only when co-expressed with a RAMP that CLR can traffic to the cell surface and act as a receptor (Hay et al. 2018). Receptors formed through the interaction of CLR/CTR and RAMPs appear to exist as stable complexes for their entire lifespan (Poyner et al. 2002).

Receptor Composition and Pharmacology

The interactions between CLR/CTR and RAMPs create at least 7 distinct receptors. By interacting with RAMPs, CTR creates the AMY_1 (CTR:RAMP1), AMY_2 (CTR:RAMP2), and AMY_3 (CTR:RAMP3) receptors; the interaction of CLR with RAMPs creates the CGRP (CLR:RAMP1), AM_1 (CLR:RAMP2), and AM_2 (CLR:RAMP3) receptors (Fig. 2). CTR has (a) and (b) splice variants, meaning that the AMY receptors can also exist in (a) or (b) forms, that is, $AMY_{1(a)}$ and $AMY_{1(b)}$ receptors (Poyner et al. 2002).

Each receptor created through the interaction of CLR/CTR and RAMPs has a unique pharmacological profile. This paragraph, and Table 1, briefly summarizes the pharmacological profiles of the human receptors as defined by the ability of peptides to stimulate the production of cAMP. Alone, CTR is most potently activated by CT and more weakly activated by amylin. CGRP and amylin are the most potent peptides at the AMY_1 receptor at which they act with similar potencies. The AMY_2 receptor currently has a poorly defined pharmacological profile; however, it is likely that amylin is the most potent activator of this receptor. The AMY_3 receptor is most potently activated by amylin and more weakly activated by CGRP. The CGRP receptor is most potently activated by CGRP and is more weakly activated by AM and AM2. The AM_1 receptor is most potently activated by AM, followed by AM2 and then CGRP. At the AM_2 receptor, AM and AM2 are approximately equivalent, and both of these peptides are more potent than CGRP. It is worth highlighting that while the pharmacological profiles of these receptors are well defined, there is considerable overlap in peptide activity at these receptors, and the pharmacology can vary between species (Hay et al. 2018; Bower and Hay 2016).



Calcitonin Family Receptors, Fig. 2 Different receptors created through the interaction of CLR or CTR with RAMPs. DNE* – Does Not Express; this indicates that alone, CLR does not traffic to the cell surface and cannot act as a functional receptor

Calcitonin Family Receptors, Table 1 Relative rank order of peptide potency at defined human CTR- and CLR-based receptors

	CTR	CLR
Expressed alone	CT > amylin	Does not express on cell surface
+RAMP1	Amylin = CGRP	CGRP > AM = AM2
+RAMP2	Poorly defined (Amylin)	AM > AM2 > CGRP
+RAMP3	Amylin > CGRP	AM = AM2 >> CGRP

Rank orders are for cAMP production (Hay et al. 2019); ">" indicates an ~10-fold difference, while ">>" indicates an ~100-fold difference.

Molecular Understanding of Receptor Pharmacology

There are multiple interaction sites between CLR and RAMPs. The extracellular domain of the RAMP interacts with the extracellular domain of CLR. Additionally, the transmembrane domain of the RAMP interacts with CLR transmembrane helices 3, 4, and 5. It is presumed that a similar interaction mechanism exists between RAMPs and CTR (Pioszak and Hay 2020).

RAMPs influence the pharmacology of CLR and CTR by multiple complementary mechanisms. Residues within the RAMP extracellular domain augment the extracellular binding pocket of the receptor, providing a few key interaction points for residues in the peptide C-terminus. RAMPs also exert allosteric effects on CLR and CTR, causing the receptors to adopt subtly different conformations when complexed with different RAMPs. These conformational differences contribute to the binding specificity of the receptor. Conformational differences have been well defined for the extracellular N-terminus of these receptors and it is thought that RAMPs exert conformational effects across the entirety of CLR/CTR. It is likely that RAMPs also influence the conformational dynamics of CLR/CTR to influence specificity (Pioszak and Hay 2020).

Physiological Relevance of These Receptors

While there is much work on the physiological significance of this receptor family, the strong overlap in peptide activity at the different receptors means that it is difficult to conclusively link specific receptors to given physiological effects of individual peptides. Some headway has been made using animal models. However, because receptor components are involved in multiple receptor systems, and there is the possibility of functional redundancy in this receptor family, it is important to interpret these studies with care (Hay and Pioszak 2016).

CLR, RAMP1, RAMP2, and RAMP3 have been implicated in the lymphatic and cardiovascular systems, albeit to varying degrees. CLR and RAMP2 are critical and their deletion results in embryonic lethality, while mice lacking RAMP1 or RAMP3 survive to adulthood with less pronounced effects. RAMP1 and RAMP3 are also implicated in weight and metabolism, as mice lacking RAMP3 have a modest reduction in body weight in adulthood, and neuronal overexpression of RAMP1 is associated with decreased body weight and increased energy expenditure (Hay and Pioszak 2016). CLR is implicated in reproduction, as heterozygosity is associated with female subfertility (Serafin et al. 2020).

The effects of the peptides themselves are better defined. CT acts to reduce blood calcium levels and inhibit bone resorption. In many animals, CT is involved in physiological calcium homeostasis; however, in humans this effect is less established. Amylin is a neuroendocrine hormone which regulates energy homeostasis, nutrient influx, and satiety. CGRP causes powerful vasodilation, while also having roles in metabolism and pain sensation. AM is primarily known for its potent vasodilatory effects; however, this peptide also has regulatory roles in the lymphatic and reproductive systems and plays an important role in maintaining organ integrity. Like AM, AM2 is primarily known for its cardiovascular effects; this peptide also plays a role in renal function and has markedly high expression in the thyroid (Hay et al. 2018).

Drugs

In the past, drugs which targeted this family were typically analogues of the endogenous

Calcitonin Family Receptors, Table 2 FDA approved drugs that target the CTR/CLR receptor family

Name	Drug type	Mechanism	Disease(s)
Salmon CT	Peptide	Agonist of CTR	Hypercalcaemia and Osteoporosis
Pramlintide	Peptide	Agonist of CTR:RAMP complexes	Type 1 and 2 Diabetes
Erenumab	Antibody	Targets the CGRP receptor to inhibit function	Migraine (Preventative)
Eptinezumab	Antibody	Targets CGRP to inhibit function	Migraine (Preventative)
Fremanezumab	Antibody	Targets CGRP to inhibit function	Migraine (Preventative)
Galcanezumab	Antibody	Targets CGRP to inhibit function	Migraine (Preventative) and Cluster Headache (Preventative)
Ubrogepant	Small molecule	Antagonist of the CGRP receptor	Migraine (Acute)
Rimegepant	Small molecule	Antagonist of the CGRP receptor	Migraine (Acute)

peptides. Recently however, we have seen the successful development of nonpeptide small molecules and antibodies which target this family (Table 2).

CT-Based Drugs and Diagnostics

Analogues of human CT have been used clinically to treat hypercalcemia and osteoporosis. Salmon CT (which has ~50% amino acid sequence identity with human CT) has been approved as a therapeutic for the treatment of hypercalcemia since the 1970s; however, in practice its use is rare due to the rapid development of tolerance. A nasal spray formulation of salmon CT has been used for the treatment of osteoporosis in postmenopausal women for whom other treatments are not suitable; however, the efficacy of this treatment has been called into question. Additionally, circulating CT levels are used as a diagnostic marker for medullary thyroid cancer, with high CT levels being linked to the presence of tumors (Wells et al. 2016).

Amylin-Based Drugs

The combination of effects attributed to amylin has made it a target for the treatment of diabetes and other metabolic diseases. Pramlintide is an FDA-approved injectable peptide analogue of amylin that is used as an adjunct to insulin for the management of type 1 diabetes and insulin-requiring type 2 diabetes. Patients inject pramlintide before each meal as well as injecting insulin. At present these two treatments cannot be delivered in one injection due to differences in formulation requirements (Bower and Hay 2016). Pramlintide is also linked to decreases in body weight; this is currently being explored through the development of a new amylin mimetic, AM-833, which is in clinical trials for obesity management.

CGRP-Based Drugs

CGRP has long been targeted for the treatment of migraine. Initial progress was made with the development of nonpeptide small molecule antagonists of the CGRP receptor (the –gepant family of drugs); however, developments were delayed due to concerns of hepatotoxicity. Recent progress in this field has led to the development of ubrogepant and rimegepant. These drugs are now approved by the FDA for the treatment of migraine and are taken orally at migraine onset for acute migraine treatment.

Alongside these small molecules, antibodies targeting the CGRP peptide (eptinezumab, fremanezumab, and galcanezumab) or the CLR:RAMP1 complex (erenumab) have been approved by the FDA for the preventative treatment of migraine. These antibodies are delivered by injection either monthly (erenumab, fremanezumab, galcanezumab), or every 3 months (eptinezumab, fremanezumab). Galcanezumab has also been approved for the preventative treatment of cluster headache (Dubowchik et al. 2020).

AM-Based Drugs and Diagnostics

Recently, an antibody which targets the AM peptide (adrecizumab) completed phase II clinical trials for the treatment of sepsis with promising results. This same antibody may also be useful for the treatment of congestive heart failure; a phase II clinical trial is being developed to investigate its utility in this disease (Voors et al. 2019). In addition, mid-regional pro-AM (a stable by-product of AM production in the body) is gaining popularity as a diagnostic tool for cardiovascular disease and as a prognostic marker for septic shock (Nishikimi and Nakagawa 2018; Onal et al. 2018).

Immune treatment; Immuno-oncology; Immunotherapy

Definition

Cancer immunotherapy identifies a type of cancer treatment that acts by exploiting the immune system. The term cancer immunotherapy can identify whether a treatment capable of activating the host immune system or be used to describe components of the immune system (synthetic, autologous, or allogeneic) that are administered to the host. Immunotherapy can be distinguished as follows: (1) active, i.e., exerts its effect only by engaging with the host immune system, or (2) passive, i.e., is designed to have a direct antineoplastic activity (Galluzzi et al. 2014).

Examples of active immunotherapy are monoclonal antibodies (MoAb) that can modulate immune effector cells activation or vaccines. Passive immunotherapy includes MoAb directed against protein expressed on the surface of cancer cells or the infusion of genetically modified immune cells (mainly T cells).

Basic Mechanism

Monoclonal Antibodies

Monoclonal antibodies (MoAbs) are laboratory-produced molecules designed to bind to antigens that are generally more numerous on the surface of tumor cells than on healthy tissues. MoAbs can exert their effect in different ways and can be divided into five main classes according to their preeminent mechanism of action: (1) MoAbs inhibiting signaling pathways required for the survival of cancer cells; (2) MoAbs capable of activating lethal receptors expressed on the surface of cancer cells; (3) MoAbs targeting tumor-associated antigens (TAA), thus opsonizing the cancer cell and activating antibody-dependent cell-mediated cytotoxicity (ADCC), antibody-dependent cellular phagocytosis (ADCP), and complement-dependent cytotoxicity (CDC); (4) bispecific T cell engagers (BiTe), formed by single-chain variable fragments (scFv) of two distinct MoAb one targeting an antigen expressed on the tumor cell and the other a T cell surface antigen, hence engaging the T cell in the recognition and subsequent killing of cancer cells; and (5) MoAbs coupled with toxins or radionuclides, the so-called immune conjugates (Galluzzi et al. 2014). MoAbs of the last class are clearly a form of passive immunotherapy, in which the molecule coupled with the MoAb exerts a direct antitumor effect. The monoclonal antibody enables the delivery of the coupled drug directly to the target cell, minimizing off-target effects. Examples of this class of MoAbs are brentuximab vedotin, an anti-CD30 monomethylauristatin E conjugate used in the treatment of Hodgkin lymphomas and CD30 anaplastic lymphomas and belantamab mafodotin, an anti-BCMA (B cell maturation antigen) auristatin F conjugate currently under investigation for

multiple myeloma. TAA targeting MoAbs (class three) and BiTes (class four) directly engage the host immune system, thus classifying themselves as active immunotherapy. Example of class three is the anti-CD20 MoAb rituximab, the first antibody to be approved for the treatment of B cells non-Hodgkin Lymphomas. The effect of BiTes resides on their ability to bring the T cells in contact with the cancer cell, bypassing the need for antigen presentation through the major histocompatibility complex (MHC-I). The prerogative of BiTe of engaging a T cell response without the need of MHC enables the activation of all T cells not restricted to a specific T cell receptor. At present blinatumumab is the only BiTe construct approved for the treatment of acute lymphoblastic leukemia (ALL), but other BiTes against other malignancies are being developed. Regarding MoAbs of the first two classes, the precise mechanism of action is less clear. Although these MoAbs have traditionally been classified as passive immunotherapy, a growing body of evidence suggest that they might also promote ADCC and stimulate the host immune system by enhancing the activity of B- and T-lymphocytes, while inhibiting regulatory T cells, working as an active immunotherapy. A list of monoclonal antibodies and their main mechanism of action is reported in Table 1.

Immune Checkpoint Inhibitors

See ▶ "Immune Checkpoint Blockade".

Cellular Immunotherapy

Adoptive cell transfer or adoptive cell therapy (ACT) is the term used to indicate a type of immunotherapy characterized by the infusion in the host of lymphocytes. ACT involves the collection of circulating lymphocytes, their selection or modification in vitro, and the reinfusion in the host usually after a lymphodepleting therapy. Different types of ACT have been studied over the years: reinfusion of tumor infiltrating lymphocytes after ex vivo expansion and activation, reinfusion of NK cells or infusion of T cells genetically engineered with T cell receptor to be tumor specific. Currently the main approach of this kind of therapy relies on the use of chimeric antigen receptor (CAR) T cells. A CAR is a synthetic construct where a scFv recognition domain is linked to the cluster of differentiation 3 zeta (CD3ζ) portion of the T cell receptor (TCR), through a transmembrane domain (usually CD28). The scFv domain recognizes specific antigen on the cell surface without the need of MHC presentation, and activates the T cell through the CD3ζ domain. Examples of scFv domains currently approved for use in the clinic or undergoing clinical studies are anti-CD19, anti-B cell maturation antigen (BCMA), and anti-SLAMF7. The CD3ζ portion of the CAR contains immune tyrosine activation motifs (ITAMs), which, upon phosphorylation, activate the signaling cascade of the TCR. In second- and third-generation CAR-Ts the ITAMs are modified to contain signaling endodomains, such as CD28, 4-1IBB, and inducible T cell co-stimulator (ICOS). These signaling endodomains mimic the co-stimulation that is provided by the antigen-presenting cell in physiological condition, making the CAR-T cell more efficient in cell killing. More recently fourth- and fifth-generation CAR-Ts have been developed, including inducible expression of inflammatory cytokines or signaling domains from cytokines receptors (Benmebarek et al. 2019). Upon engagement of the CAR, an immunological synapse (IS) between the CAR-T cell and the cancer cell is formed. Once the IS has been formed CAR-T cells induce cell death by exocytosis of cytotoxic granules containing perforine and granzyme. Perforine enables granzyme to enter the cytoplasm of the tumor cell by forming pores on the cell membrane. Once in the cytoplasm, granzyme induces both caspase-dependent and independent apoptosis by activating caspases such as caspase 3 and BH3-only members of the BCL-2 family such as Bid (BH3-interacting domain). The IS formed during CAR-T cell engagement differs from "normal" IS, as they are smaller and show a more disorder pattern of activating clusters. As a result CAR-T cells have an earlier release of granzyme and perforine, shorter receptor–initiated signal duration, and a faster detachment from the target cell. Despite the signal being shorter, it has a higher strength compared with physiological TCR signaling. Interestingly, the amount of lytic granules

Oportuzumab monatox	Bladder cancer	EpCAM, Class V	Under review
Belantamab mafodotin	Multiple myeloma	BCMA, Class V	2020 conditional approval (EU), 2020 (USA)
Naxitamab	Neuroblastoma	GD2, Class III	Under review
Margetuximab	HER2+ breast cancer	HER2, Class I	Under review

delivered is comparable with those of cytotoxic T cells (Davenport et al. 2018). In addition to this fast acting killing mechanism, CAR-T cells can induce the apoptosis of the target cell by activating tumor necrosis factor (TNF) family receptors such as Fas via the expression on their membrane of ligand of the TNF family. The Fas/FasLigand (FasL) axis engagement leads to the activation of caspase 8 and pro-caspase 8. Active caspase 8 is able to induce apoptosis through the activation of caspase 3. Following receptor engagement FasL expression is upregulated in CAR-T cells, effectively enabling the killing also of antigen-negative tumor cells (Hong et al. 2018).

CAR-T cells currently used in the clinic are generated in autologous fashion, upon viral transduction and subsequent expansion of patient's derived peripheral leukocytes. Studies are currently ongoing to produce allogeneic CAR-T cells, to overcome production limitations due to ineffective transfection or ineffective in vitro expansion of patient-derived T cells.

Vaccines

Vaccines are the prototype of active immunotherapy. Differently from vaccines developed to prevent infective disease, cancer vaccines are not though to prevent the development of cancer, but are administered to patients with overt tumors to activate the host's immune system against the malignant cells. Different type of vaccines have been developed over the years, including autologous patient-derived immune cell vaccines, tumor antigen–expressing recombinant virus vaccines, peptide vaccines, DNA vaccines, and heterologous vaccines derived from tumor cell lines (Guo et al. 2013). Autologous tumor cell vaccines are prepared using patients-derived tumor cells that are reinjected in the patient usually after irradiation and combination with an immunostimulatory agent such as the Bacillus Calmette-Guérin (BCG). To overcome the availability of specimen that limits the applicability of autologous vaccines, allogeneic vaccines made of three or more established tumor cell lines have been developed. In addition to this approach peptide and DNA-based vaccines have also been developed. Peptide vaccines comprise peptide from a defined TAA; in contrast with autologous or allogeneic vaccines, which can activate the immune system against the tumor as a whole, peptide-based vaccines recognize only one or few epitopes of the chosen TAA. An additional limitation is the poor immunogenicity of TAA. To improve immunogenicity an approach consists in generating peptide vaccines by autologous tumor lysates that are then merged with immunostimulatory adjuvants or chaperons. DNA-based vaccines utilize bacterial plasmid to deliver tumor antigens. The vectors transfect somatic or dendritic cells (DC), resulting in indirect antigen presentation or cross-priming of DC, which in turn activates the immune response against the tumor. Viral vectors can also be used to deliver TAA, usually combined with immunomodulatory molecules. Messanger RNA can also be administered to induce an immunogenic response (Guo et al. 2013). A well-studied type of cancer vaccination is vaccine developed directly from patient's DC. Patient's derived monocytes or hematopoietic stem cells (HSCs) are induced to differentiate and maturate through treatment with various cytokines. DCs are then loaded with different types of TAA and reinfused in the patient, in order to induce immune responses that are tumor specific (Perez and De Palma 2019).

Others

Other forms of cancer immunotherapy include immunomodulatory drugs such as thalidomide and its derivate, immunostimulatory cytokines such as interferons (IFN) and interleukine 2 (IL-2), and even some conventional chemotherapy. All these treatment have shown to be able to modulate the host immune system, acting as an active cancer immunotherapy. Thalidomide was the first immunomodulatory drug to show effectiveness in hematologic malignancies. Its effect was mainly thought to occur via modulation of TNF-α. To reduce thalidomide side effect and increase antineoplastic activity lenalidomide and pomalidomide were later developed. These drugs not only have a direct antitumor effect, but are also active on the host immune system. Immunomodulatory drugs enhance antigen-specific T cell cytolysis and stimulate the production of IL-2 that can expand antigen-specific memory effector T cells. Furthermore immunomodulatory drugs can increase NK activity and can increase the production of granzyme B and FasL expression. The immunomodulatory drug lenalidomide also increased the secretion of IFN-γ by NKT cells (Davies and Baz 2010). Recently the effect of immunomodulatory drugs was shown to be dependent on their binding to the E3 ubiquitin ligase cerebron (CRBN) and consequent down regulation of IKAROS family zinc finger 1 (IKZF1), IKZF3, and interferon regulatory factor-4 (IRF-4) (Lopez-Girona et al. 2012). IKZF1 and IKZF3 regulate lymphocytes development

and differentiation and IKZF3 can control the apoptosis of T cells. IRF-4 is important in the activation of both innate and adaptive immune system by negatively regulating toll-like-receptor (TLR) signaling. Downregulation of IKZF1, IKZF3, and IRF-4 might account at least in part for the immunomodulatory properties of these drugs. Conventional chemotherapeutic also can have immunomodulatory effects. Chemotherapy can induce immunogenic cell death, and some drugs such as 5-fluoruracil and gemcitabine, when used in low doses and with a metronomic fashion, are able to stimulate the host immune system as an off-target effect (Galluzzi et al. 2014).

Pharmacological Relevance (Including Side Effects)

The discovery of immunotherapy has dramatically changed cancer treatment. The implementation of MoAb into treatment of hematologic and solid tumors was able to increase progression-free survival as well as overall survival. The first MoAb, the anti-CD20 rituximab, revolutionized the treatment of non-Hodgkin's lymphoma and forms now the backbone of almost all lymphoma treatment. More recently, MoAb anti-CD30, anti-CD38, and anti-SLAMF7 have been developed to treat Hodgkin lymphoma and anaplastic T cell lymphomas (anti-CD30) or multiple myeloma (anti-CD38, anti-SLAMF7). Like the anti-CD20, these drugs as well revolutionized treatment of hematologic malignancies and are rapidly moving forward in the first-line treatment of these diseases both as single agent as well as being part of combination therapy. MoAb are also exploited in the treatment of solid cancer, such as the MoAb anti-VEGF (used in gastrointestinal malignancies) or the MoAb anti-EGFR (used in head and neck cancer and gastrointestinal tumors). Similarly to what is seen in hematologic malignancies monoclonal antibodies are being associated in a wide variety of anticancer treatment as part of polychemotherapeutic schemas.

BiTe therapy has proven to be extremely effective in relapsed/refractory acute lymphoblastic leukemia, and is now under investigation in other hematologic malignancies as well as in solid tumors. The main hurdle of BiTe treatment is the short half-life of the compounds, which requires repeated or continuous infusion of the drugs. Research is ongoing to produce BiTe with a longer half-life (e.g., by coupling them with heavy-chain fragments) and more manageable administration schedule (Liu et al. 2017).

The first two CAR-T cell products were approved in 2017 and 2018 in the USA and in 2018 in Europe for the treatment of relapsed/refractory diffuse large B cell lymphoma (DLBCL) in adults and relapsed/refractory ALL in children. Approval was based on the impressive results of phase II clinical trials showing an overall response rate of 82% (ALL) and 52% (DBLCL) with 45% of ALL patients still in complete remission after 2 years and a median progression free survival that in the case of DBLC has not yet been reached. Interestingly the survival curves showed a plateau, suggesting that a proportion of patients with relapsed/refractory disease might be cured with this treatment approach. The success obtained by CAR-T cells in the treatment of DLCBL and ALL prompt their use also in other hematologic malignancies and in solid tumors. Trials are ongoing investigating the role of CAR-T cells in multiple myeloma, chronic lymphocytic leukemia, and gastrointestinal cancers (Kruger et al. 2019).

Despite being extremely interesting, the development of vaccines to treat cancer has so far not fulfilled the promised expectation. DC vaccines are safe and immunogenic, however clinical responses so far have been disappointing. This is likely due to the immunosuppressive tumor microenvironment that limits DC's function (Perez and De Palma 2019). The high production costs, especially of personalized vaccines, further limits their applicability. The possibility to combine vaccine strategy with ▶ "Immune Checkpoint Blockade" might help to overcome the immunosuppressive tumor microenvironment and increase vaccines efficacy (Mougel et al. 2019).

Immunomodulatory drugs have changed treatment paradigm of the hematologic malignancy multiple myeloma (the second most frequent hematologic malignancy after non-Hodgkin lymphomas), and form now the backbone of almost all anti-myeloma treatment.

The development of immunotherapy, especially of CAR-T cells and of BiTes, has seen the rise of new toxicity profiles different from what expected with conventional chemotherapy. Due to the activation of the immune system a wide range of reaction can develop, according to the type of immunotherapy used. Cytokine release syndrome (CRS) and neurological toxicities are the main nonhematological adverse events seen with the use of BiTes and CAR-T treatment. They have been reported in 5 to up to 50% of patients according to study and treatment indication. CRS is typically an early event, which develops within the first 7–14 days after CAR-T infusion. It is characterized by fever, gastrointestinal symptoms, headache, hypotension, dyspnea, and arthralgia. According to the degree of severity can be treated with steroids, inhibitors of interleukin-6 (IL-6) or even lymph depleting chemotherapy such as cyclophosphamide. Neurological toxicity can develop as an early event, usually in association with CRS, or as a later event occurring when the symptoms of CRS start to improve. Neurological toxicity is characterized by encephalopathy, aphasia, cognitive defects, seizures, EEG alteration, and edema seen in MRI. CAR-T cells are usually found in the liquor of these patients. Neurological toxicity is generally managed with high-dose steroids, as the use of IL-6 inhibitors has shown disappointing results in this indication. IL-6 could be administered in case of neurological toxicity with concomitant CRS. IL-1 inhibitors could also have a role in the management of toxicities (Brudno and Kochenderfer 2019). The tyrosine kinase inhibitor dasatinib can interfere with the lymphocyte-specific protein tyrosin kinase (LCK), thus inhibiting the phosphorylation of CD3ζ. Due to this inhibition, dasatinib can act as an "off switch" abrogating CAR-T cell function and proliferation (Mestermann et al. 2019). Further CAR-T products with build-in "off switch" that can induce programmed apoptosis in case of uncontrolled side effects are currently under development. In addition of these side effects, patients receiving CAR-T can develop prolonged leukocytopenia and thrombocytopenia that might require transfusion and antibiotic prophylaxis.

Cardiac Glycosides

Benito Soto-Blanco
Veterinary School, Federal University of Minas Gerais, Belo Horizonte, MG, Brazil

Synonyms

Cardiac steroids; Cardiotonic steroids; Digitalis

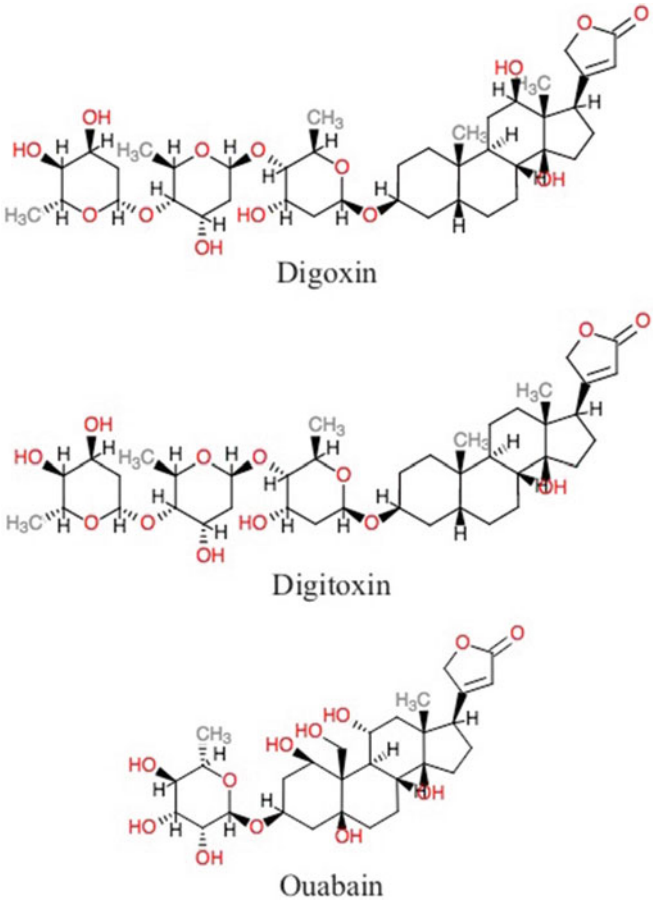
Cardiac glycosides are pharmacologically active compounds derived from different plants and the toad venom. Furthermore, these endogenous compounds evidently control blood pressure, and disturbances in their physiological levels have been observed in several diseases, including myocardial ischemia and infarction, diabetes, and cancer. Cardiac glycosides act on the membrane-bound sodium-potassium-adenosine triphosphatase (Na^+/K^+-ATPase) pump. The most important cardiac glycosides are digoxin, digitoxin, and ouabain (Fig. 1).

Cardiac glycosides are chemically characterized by a steroid nucleus comprised of four fused rings of 17 carbons (cyclopentanoperhydrophenanthrene nucleus in a *cis-trans-cis* configuration), with an unsaturated lactone ring at C17, and a sugar moiety (glycone portion) coupled through a hydroxyl group at C3. Usually, the glycone portion is composed of one to three units of digitoxose, glucose, thevetose, rhamnose, cymarose, gentiobiose, and oleandrose. There are two classes of cardiac glycosides, cardenolides, and bufadienolides, chemically distinguishable by the lactone ring. Cardenolides, derived from plants, contain the butyrolactone ring, a five-membered ring with a double bond. On the other hand, bufadienolides, found in some toad venoms and plants, have an α-pyrone ring, a six-membered ring with two double bonds.

Notably, some chemical features affect the inhibitory activities of Na^+/K^+-ATPase. The presence of a hydroxyl group at C14 of the steroid nucleus is essential for Na^+/K^+-ATPase activity. Furthermore, the type and number of sugar units in the aglycone portion affect the relative binding affinity of cardiac glycosides. Digoxin, digitoxin, and ouabain have a higher binding affinity than their aglycone counterparts. A rhamnose residue provides nearly an 18-fold higher affinity in comparison to compounds without the sugar moiety. The presence of digitoxose provides a lower binding affinity than cymarose. Moreover, binding affinity is not always related to the inhibitory activity. Modifying the lactone ring from five to six atoms could reduce the binding affinity but increase the inhibitory activity.

Digitoxin is almost completely absorbed following oral administration, whereas the intestinal absorption of digoxin is 60–80%, and that of ouabain is 3%. Protein binding of digitoxin is more than 90%, with digoxin about 30% protein bound. Serum protein binding is about 20% for digoxin, 97% for digitoxin, and 3% for ouabain. Peak concentration is achieved in 1–3 h for digoxin and 0.5–4 h for digitoxin. The biotransformation of cardiac glycosides is predominantly mediated by hepatic microsomal enzymes, with the elimination half-life of digoxin ranging from 36 to 48 h. Ouabain demonstrates an elimination half-life 11 h, which is 7–9 days for digitoxin. The principal elimination route for digoxin is through urinary excretion, with 50–70% eliminated as the parental compound in urine after intravenous administration. The major route of digitoxin elimination occurs through biliary excretion. Hence, impaired kidney function affects the elimination of digoxin but not digitoxin.

The gut bacteria *Eggerthella lenta* may reduce the lactone ring of digoxin, generating dihydrodigoxin, an inactive metabolite, decreasing drug bioavailability (Haiser et al. 2014).



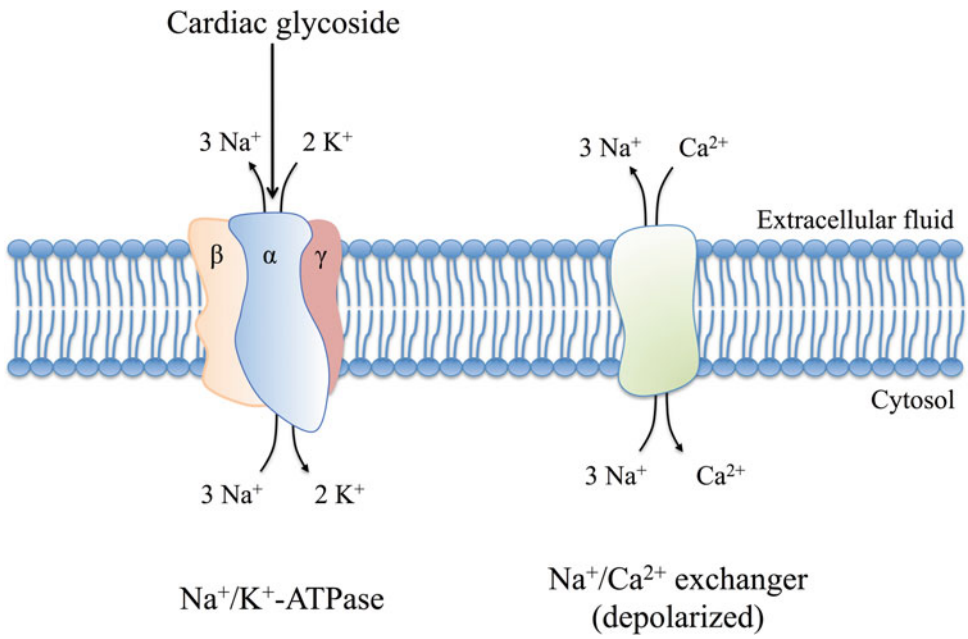
Cardiac Glycosides, Fig. 1 Cardiac glycosides – molecular structure of digoxin, digitoxin, and ouabain

Mechanism of Action

Cardiac glycosides act in the cardiac muscle cells to inhibit the activity of Na^+/K^+-ATPase, which is an entropy-driven reversible reaction (Fig. 2). This enzyme is a P-type pump that physiologically maintains low levels of intracellular Na^+, by actively transporting Na^+ outside and K^+ into cells in a 2:3 stoichiometry. Na^+/K^+-ATPase is composed of an αβ heterodimer and an accessory FXYD regulatory (γ) subunit. The α subunit demonstrates a molecular weight of approximately 112 kDa and 10 transmembrane segments. Particularly, the binding sites of Na^+, K^+, ATP, and cardiac glycosides are present within this subunit. The β subunit, with a molecular weight ranging from 40 to 60 kDa, contains one transmembrane domain and several extracellular glycosylation sites. There are four isoforms of the α subunit (α_1, α_2, α_3, and α_4) and three isoforms of the β subunit (β_1, β_2, and β_3). These isoforms demonstrate a differential distribution within the body as follows:

- α_1: throughout the organism
- α_2: heart, muscles, placenta, cartilage, adipocytes, and some areas of the brain
- α_3: muscles, heart, placenta, ovaries, erythrocytes, and neurons
- α_4: testis
- β_1: throughout the organism
- β_2: heart, muscles, cartilage, nervous system, and erythrocytes
- β_3: brain, cartilage, erythrocytes, liver, lungs, retina, and testis

The α_1 isoform is markedly abundant in cardiomyocytes compared to the α_2 isoform, but



Cardiac Glycosides, Fig. 2 Cardiac glycosides – schematic representation of the Na^+/K^+-ATPase

α_2 has a greater significance in cardiac muscle contractility by regulating the cytosolic Ca^{2+} levels. Digoxin and digitoxin present a higher binding selectivity for α_2 and α_3 than α_1, whereas ouabain has higher binding selectivity for α_1 than α_2.

In the most accepted model for the pump reaction cycle, Na^+/K^+-ATPase can be presented in two states, E_1 and E_2P. In the E_1 state, the enzyme associated with ATP and Mg^{2+} at the cytoplasmic side has three Na^+ ions. Next, it undergoes a conformational change hydrolyzing ATP into ADP, preserving the released inorganic phosphate attached to the enzyme. As Na^+ ions are transported outside the cell, the enzyme alters its conformation from the E_1 to the E_2P state. Na^+/K^+-ATPase in the E_2P state has a low affinity for Na^+, with a high affinity for K^+ present in the extracellular fluid. Two K^+ ions bind to the enzyme, which is dephosphorylated and has another bound ATP. Na^+/K^+-ATPase undergoes another conformational change, releasing K^+ into the cytosol and returning to the E_1 state (Crambert et al. 2000; Wasserstrom and Aistrup 2005; Katz et al. 2010).

Cardiac glycosides inhibit Na^+/K^+-ATPase, stabilizing it in the E_2P transition state. Intracellular Na^+ is maintained at physiological levels by action of the Na^+/Ca^{2+} exchanger, which in depolarized stage transporting Na^+ outside and Ca^{2+} into cells. Finally, the intracellular Ca^{2+} levels are enhanced, which increases its uptake by the sarcoplasmic reticulum via the $SERCA_2$ transporter. Thus, large amounts of Ca^{2+} are released after the depolarizing impulse reaches the myocyte, causing a more vigorous contraction. Beyond the positive inotropic effect, cardiac glycosides decrease the heart rate by increasing the refractory period of the atrioventricular node.

Clinical Use

Digoxin, as well as digitoxin in some countries, is used in the treatment of mild to moderate heart failure (NYHA III-IV) and cardiac arrhythmia owing to its positive inotropic and antiarrhythmic effects. Experimental studies have demonstrated the potential therapeutic uses of cardiac glycosides, including the treatment of some tumors (Botelho et al. 2019), viral infections (Amarelle and Lecuona 2018), and autoimmune diseases (Huh et al. 2011).

Furthermore, digoxin and digitoxin are used in association with other drugs in the management of mild to moderate heart failure related to left ventricular systolic dysfunction. These drugs increase the left ventricular ejection fraction, consequently increasing cardiac output and lowering the pulmonary capillary wedge pressure. At low doses, digoxin is responsible for neurohormonal modulation, improving the parasympathetic tone and suppressing sympathetic tone and the renin-angiotensin-aldosterone system. Parasympathetic activity is evidenced by the augmented heart rate variability, whereas the sympathetic effects are characterized by reduced serum norepinephrine levels and enhanced carotid sinus baroreflex sensitivity. In case of the renin-angiotensin-aldosterone system, digoxin reduces the plasma renin activity without affecting the aldosterone levels. The clinical signs and symptoms of heart failure are improved, mainly in patients who remain symptomatic regardless of being treated with other drugs (Ambrosy et al. 2014; Konstantinou et al. 2016).

In patients with atrial fibrillation, controlling the heart rate indicates beneficial effects on the quality of life, decreasing morbidity and the risk of developing tachycardia-induced cardiomyopathy. Even though β-blockers and nondihydropyridine calcium channel blockers are the most frequently used drugs, digoxin effectively reduces the ventricular heart rate. However, digoxin is not indicated in patients with pre-excitation and atrial fibrillation as it can induce ventricular fibrillation. Heart rate control is initiated at least 1 h after intravenous administration, peaking about 6 h later. Following prolonged oral maintenance dosing, the ventricular rate is reduced at rest, but not during exercising. The association of digoxin with β-blockers or nondihydropyridine calcium channel blockers raises the rate of control during exercise; this association may be useful in patients with concomitant heart failure. Notably, increased mortality has been mainly reported with long-term use. For heart rate control, digoxin is initially administered intravenously over 24 h, with an oral formulation prescribed for maintenance therapy (January et al. 2014).

Additionally, digoxin can be used for the management of paroxysmal supraventricular tachycardia (PSVT), especially in patients who do not undergo catheter ablation and who fail or cannot be prescribed preferred therapies, such as β-blockers, diltiazem, verapamil, or a class Ic antiarrhythmic agents (Page et al. 2016).

The digoxin dose must be adjusted in patients with renal dysfunction, in the elderly, and in case of concomitantly used drugs that reduce its elimination. Amiodarone, dronedarone, propafenone, quinidine, spironolactone, and verapamil increase blood digoxin concentrations as these drugs inhibit P-glycoprotein, which is responsible for the renal elimination of digoxin. Erythromycin, omeprazole, and tetracycline increase digoxin absorption, also increasing blood digoxin concentrations. In such patients, determining serum digoxin has been recommended to ensure adequate dosing (January et al. 2014).

Cardiac glycosides must be cautiously used owing to their narrow therapeutic window. The mechanism of toxicity is associated with excessive Na^+/K^+-ATPase inhibition. Excessive intracellular Ca^{2+} overloads the storing capacity of the sarcoplasmic reticulum. Transient increases in Ca^{2+} give rise to transient inward depolarizing currents, consequently delaying afterdepolarizations that can generate extrasystoles and ventricular arrhythmias. Notably, the symptoms observed in cases of poisoning include anorexia, nausea, vomiting, diarrhea, headache, fatigue, drowsiness, and visual disturbances. Several cardiac dysrhythmias can be observed, including sinus bradycardia, premature ventricular complexes, first-degree atrioventricular block, bigeminy, atrial tachycardia with atrioventricular block, and ventricular fibrillation. Death may occur following cardiac arrest (Konstantinou et al. 2016; Botelho et al. 2019).

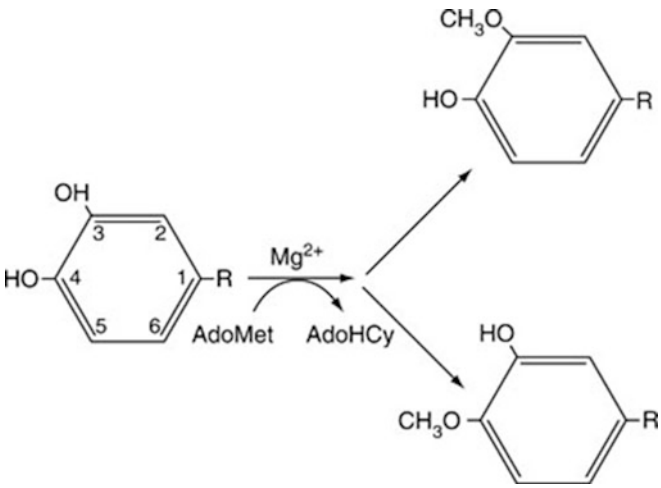
COMT; COMTase; EC 2.1.1.6

Definition

Catechol-*O*-methyltransferase (COMT) is a widespread enzyme that catalyzes the transfer of the methyl group of *S*-adenosyl-L-methionine (AdoMet) to one of the phenolic group of the catechol substrate (Fig. 1). High COMT activity is found in the liver, kidney, and gut wall (Guldberg and



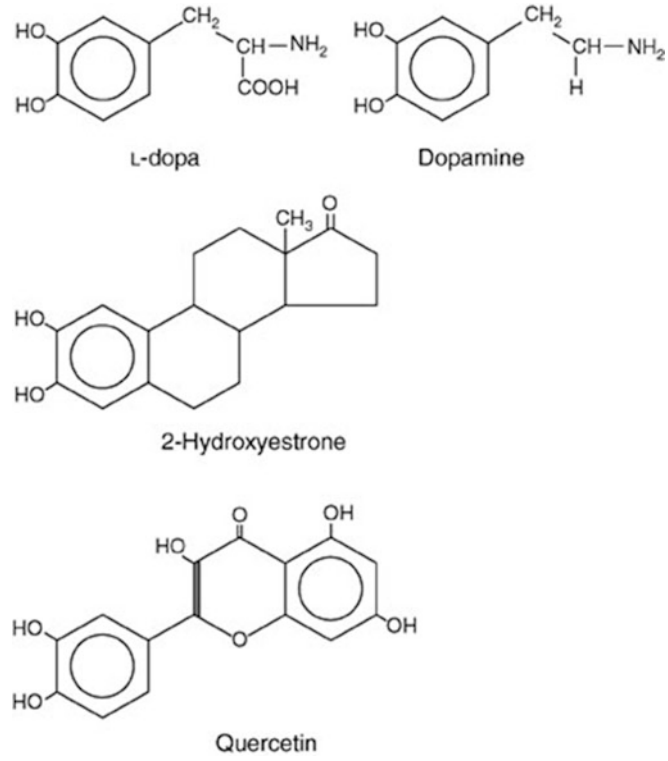
Catechol-*O*-Methyltransferase, Fig. 1 The basic function of COMT. Enzymatic *O*-methylation of the catechol substrate to 3-methoxy (major route) or 4-methoxy (minor route) products in the presence of Mg^{2+} and *S*-adenosyl-methionine (AdoMet)

Marsden 1975; Männistö and Kaakkola 1989). A single *COMT* gene codes for two separate enzymes, soluble (S-COMT) and membrane-bound (MB-COMT) forms. S-COMT contains 221 amino acids. MB-COMT has an additional amino-terminal extension of 43 (rat) or 50 (man) amino acids. The hydrophobic 17 and 24 amino acid residues in rat and man, respectively, form an α-helical transmembrane domain that serves as a membrane anchor; otherwise the two proteins are similar. MB-COMT is associated with intracellular membranes, not with cell membranes. Also S-COMT is strictly intracellular locating either in cytoplasm or nucleus. Synthesis of recombinant S-COMT in *Escherichia coli* and MB-COMT in insect cells, using baculovirus vectors, has helped to clarify the biochemistry, physiology, and pharmacology of COMT (Männistö and Kaakkola 1999). The active site of COMT consists of the AdoMet-binding domain and the catalytic site. S-COMT is abundant in peripheral tissues, while MB-COMT prevails in the brain. The catalytic site is formed by a few amino acids that are important for the binding of the substrate, water, and Mg^{2+} and for the catalysis of *O*-methylation. The Mg^{2+}, which is bound to COMT only after AdoMet binding, improves the ionization of the hydroxyl groups. The lysine residue (Lys144), which accepts the proton of one of the hydroxyls, acts as a general catalytic base in the nucleophilic methyl transfer reaction. Mice lacking totally COMT (knockout mice) or only S-COMT or MB-COMT have been developed. These animals breed quite normally suggesting that COMT is not a vital enzyme. Interestingly, MB-COMT-deficient male mice exhibit schizophrenia-associated behavioral abnormalities such as aggressive behavior and reduced prepulse inhibition. Both male and female mice move normally, but they are sensitized to acute pain and have impaired short-term memory. It appears that of the two COMT isoforms, MB-COMT is critical for normal behavior, and its function in COMT-dependent brain areas cannot be entirely substituted by S-COMT (Männistö and Kaakkola 1999; Tammimäki et al. 2016).

Mechanism of Action

COMT *O*-methylates catecholamines and other compounds having a catechol structure including catecholoestrogens (Fig. 2). The two isoforms of COMT may have distinct roles: MB-COMT, a high-affinity isoform of COMT, is supposed to be partially responsible for the termination of dopaminergic and noradrenergic synaptic neurotransmission. S-COMT, on the other hand, is a high capacity enzyme isoform being mainly responsible for the elimination of biologically active or toxic, particularly exogenous, catechols and some hydroxylated metabolites. During the first trimester of pregnancy, COMT present in the placenta protects the developing embryo from hydroxylated compounds. COMT also acts as an enzymatic detoxicating barrier between the blood

Catechol-*O*-Methyltransferase, Fig. 2 Some substrates of COMT



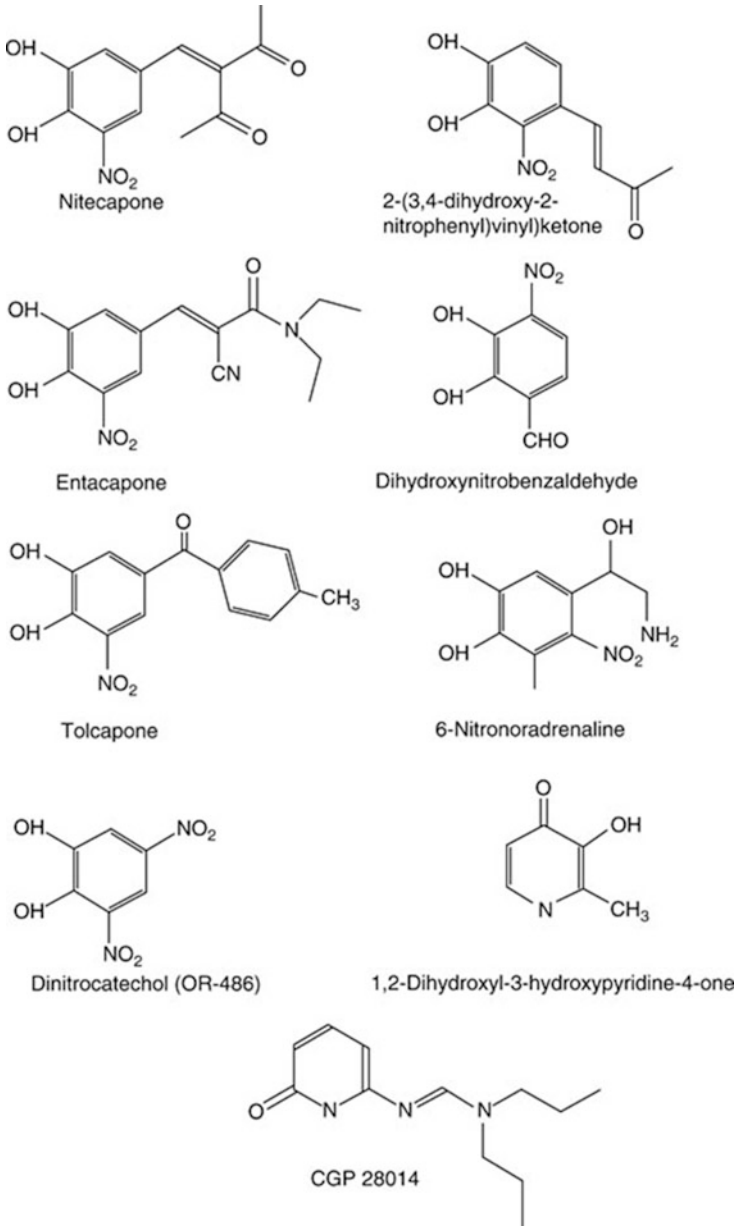
and other tissues, shielding against the detrimental effects of hydroxylated xenobiotics. COMT may serve some unique or indirect functions in the kidney and intestine tract by modulating the dopaminergic tone. The same may be true in the brain: COMT activity may regulate the amounts of active dopamine particularly in frontal cortical areas of the brain and therefore be associated with mood and other mental processes. COMT has several genetic one-nucleotide polymorphisms of which the most important one is caused by a change of valine amino acid to methionine leading to thermolability even at +37 °C and a significant decrease of COMT activity. Low COMT activity is connected to improved cognitive functions, probably due to increased dopaminergic activity. However, from population studies there is some evidence that certain psychiatric illnesses (e.g., schizophrenia, rapidly fluctuating depression) and even breast cancer in postmenopausal women may be slightly increased in people having low COMT activity (Männistö and Kaakkola 1999).

COMT Inhibitors

Early COMT inhibitors, like gallates, tropolone, and U-0521 (3′,4′-dihydroxy-2-methyl-propiophenone), have IC_{50} and K_i values in the micromolar range or higher but may still be practical in vitro tools. However, owing to unfavorable pharmacokinetics and toxicity, their clinical use is not possible (Guldberg and Marsden 1975).

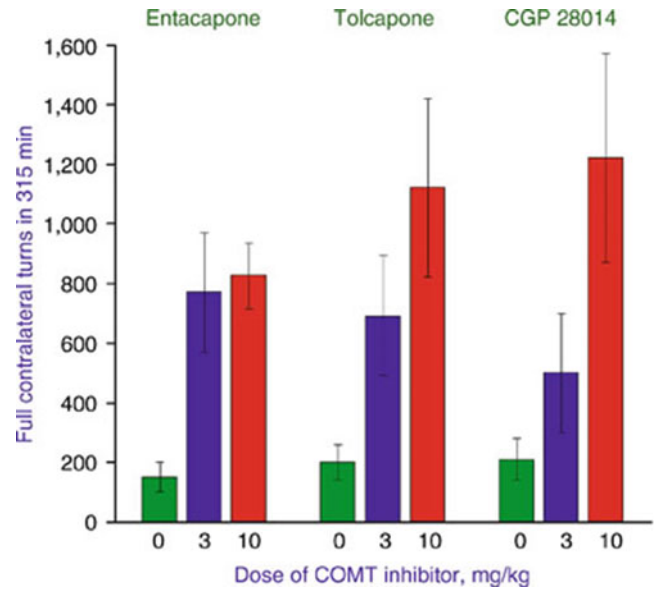
First second-generation COMT inhibitors were developed by three laboratories in the late 1980s. Apart from CGP 28014, nitrocatechol is the key structure of the majority of these molecules (Fig. 3). The current COMT inhibitors can be classified as follows: (i) mainly peripherally acting nitrocatechol-type compounds (entacapone, nitecapone, BIA 3–202, opicapone) (ii) broad-spectrum nitrocatechols having activity both in peripheral tissues and the brain (tolcapone, Ro 41–0960, dinitrocatechol, vinylphenylketone), and (iii) atypical compounds, pyridine derivatives (CGP 28014, 3-hydroxy-4-pyridone and its derivatives), some of which are not COMT inhibitors in

Catechol-*O*-Methyltransferase, Fig. 3 Chemical structures of some inhibitors of catechol-*O*-methylation



vitro but inhibit catechol *O*-methylation by some other mechanism. The common features of the new compounds are excellent potency, low general toxicity, and activity through oral administration. Their biochemical properties have been fairly well characterized. All nitrocatechols are fast acting, reversible, but tight-binding enzyme inhibitors. The extra long-lasting COMT inhibition of opicapone can be explained by its particularly tight binding. Most of these compounds have an excellent selectivity in that they do not affect any other enzymes studied (Männistö and Kaakkola 1989, 1999; Katsaiti and Nixon 2018).

Tolcapone, Ro 41–0960, and opicapone are longer acting than entacapone and nitecapone in in vivo studies in rats and man. All types of COMT inhibitors prolong the L-dopa-induced turning



Catechol-*O*-Methyltransferase, Fig. 4 Rat model of Parkinson's disease. Comparison of entacapone, tolcapone, and CGP 28014 in the rat turning model of Parkinson's disease (Tammimäki et al. 2016)

behavior of rats having unilateral nigral lesions (Fig. 4). This has generally been used as a reliable rat model of Parkinson's disease. It is noteworthy that the peripherally acting compounds entacapone and opicapone are practically as effective as the broad-spectrum compound tolcapone. This suggests that the majority of the beneficial action is peripheral in origin, evidently through enhanced bioavailability of L-dopa.

Clinical Use (Including Adverse Effects)

The main clinical use of COMT inhibitors is as adjunct (or additional adjunct) in the therapy of Parkinson's disease. The standard therapy of Parkinson's disease is oral L-dopa (as a drug levodopa) given with a dopa decarboxylase (DDC) inhibitor (e.g., carbidopa and benserazide), which does not reach the brain. When the peripheral DDC is inhibited, the concentration of 3-*O*-methyldopa (3-OMD), a product of COMT, in plasma is many times that of L-dopa. Since the half-life of 3-OMD is about 15 h, compared to about 1 h for L-dopa, the concentration of 3-OMD remains particularly high during chronic therapy, especially if new slow release levodopa preparations are used. A triple therapy (L-dopa plus DDC inhibitor plus COMT inhibitor) will evidently substitute the present double therapy in the coming years. A fixed combination preparation containing all three active drugs is indeed getting very popular worldwide.

COMT inhibitors rescue L-dopa and improve the brain entry of L-dopa by decreasing 3-OMD formation in peripheral tissues. The dose of L-dopa could be decreased, compared with the present combination therapy. Dose interval of L-dopa could also be prolonged. Further, COMT inhibitors should decrease fluctuations of dopamine formation in the brain.

Clinical studies, available only for entacapone, tolcapone, and opicapone, support preclinical findings. A dose-dependent (100–800 mg) inhibition of the COMT activity of the erythrocytes can be seen after entacapone and tolcapone. However, effective and sufficient dose levels of both entacapone and tolcapone, given concomitantly with L-dopa and DDC inhibitors to patients with Parkinson's disease, appear to be 100–200 mg. However, the treatment strategies of entacapone and tolcapone differ: entacapone is a short-acting compound that is given with each dose of L-dopa, and COMT activity may even recover between the doses. Tolcapone, as a longer-acting compound, is given three times a day, and the aim is to keep

COMT inhibited most of the time. Opicapone is so long-acting that it is given only once a day (Männistö and Kaakkola 1989, 1999; Katsaiti and Nixon 2018).

Since several adrenergic drugs, having a catechol structure, are also COMT substrates, it is possible to prolong or even potentiate in some cases their actions by COMT inhibitors. Such drugs include bronchodilating compounds (adrenaline, isoprenaline, rimiterol), dopamine agonists (dobutamine, fenoldopam, apomorphine), and antihypertensive drugs (α-methyldopa). It is possible to potentiate interactions with endogenous catecholamines during stress and exercise and adverse drug interactions with, e.g., exogenous noradrenaline and the drugs mentioned above. Fortunately, interaction studies in animals and man have not been able to substantiate this threat. Evidently, the capacity of S-COMT in the peripheral tissues is so high that only a minor general COMT inhibition can ever been achieved. Estrogens are easily hydroxylated to catecholoestrogens, which serve as COMT substrates. The consequence of preventing the major metabolic pathway of catecholoestrogens by COMT inhibitors requires further studies; it is possible that quinone-forming pathways are activated (Männistö and Kaakkola 1989, 1999).

In patients having Parkinson's disease, both entacapone and tolcapone potentiate the therapeutic effect of L-dopa and prolong the daily ON time by about 1 h. In the clinic, COMT inhibitors have been well tolerated, and the number of premature terminations has been low. In general, the incidence of adverse events has been higher in tolcapone-treated patients than in entacapone-treated patients. The main events have comprised of dopaminergic and gastrointestinal problems (Männistö and Kaakkola 1989, 1999; Katsaiti and Nixon 2018).

Dopaminergic overactivity causes an initial worsening of levodopa-induced dyskinesia, nausea, vomiting, orthostatic hypotension, sleep disorders, and hallucinations. Tolcapone has been associated with diarrhea in about 16–18% of cases and entacapone in less than 10% of cases. Diarrhea has led to discontinuation in 5–6% of patients on tolcapone and in 2.5% of those on entacapone. Urine discoloration to dark yellow or orange is related to the color of COMT inhibitors and their metabolites. Elevated liver transaminase levels are reported in 1–3% of patients treated with tolcapone but very rarely, if at all, in patients treated with entacapone or opicapone. Three cases of acute, fatal fulminant hepatitis have been described in association of tolcapone where more than 100,000 patients have been treated. In addition, a few potentially fatal neurological adverse reactions, including neuroleptic-like malignant syndrome, have been described. Because of these serious adverse drug reactions, tolcapone marketing was temporarily suspended in Europe and Canada in 1999. Now tolcapone is again available in most markets, but certain precautions and a regular follow-up of liver function need to be obeyed. So far, no restrictions of the use of entacapone and opicapone have been proposed (Männistö and Kaakkola 1989, 1999; Katsaiti and Nixon 2018).

Cell Cycle Regulation

Simranjeet Kaur and Holger Bastians
Institut für Molekulare Onkologie, Sektion Zelluläre Onkologie, Universitätsmedizin der Georg-August Universität Göttingen, Göttingen, Germany

Definition

The eukaryotic somatic cell cycle is defined by an order of two major tasks a dividing cell has to complete: replication of its DNA during the DNA synthesis phase (S phase) and segregation of the duplicated DNA onto two newly formed daughter cells during mitosis (M phase). These two events are timely separated by two so-called gap phases (G1 and G2 phases) during which cell growth and preparation for the main tasks takes place. S, G1, and G2 phases are typically termed interphase, while mitosis can be further subdivided into subphases, prophase, metaphase, anaphase, and telophase, which are followed by cytokinesis, the actual division of the cytoplasm.

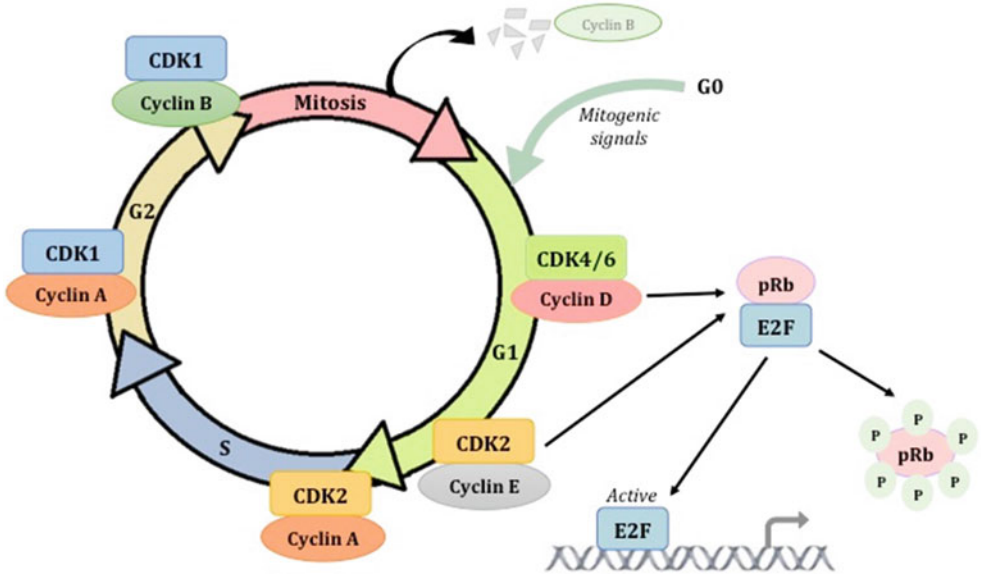
Basic Mechanisms

Upon encountering a mitogenic signal, a cell can enter the cell cycle, triggering a combination of events. The cell cycle progresses in an ordered fashion and typically lasts about 24 h in a human somatic cell. The fidelity of cell cycle events highly depends on various regulatory mechanisms that enable coordinated progression through the cycle. How a cell monitors the cell cycle and how cancer cells surpass these regulatory mechanisms is still incompletely understood and remains a subject of intense research. It has become clear in recent years that the mechanisms involving the trigger forces and control mechanisms of the cell cycle have been conserved throughout evolution. These mechanisms involve complex regulatory networks of proteins and are termed the cell cycle control system and cell cycle checkpoints, which ensure the correct order and timing of a faithful execution of the cell cycle. These systems constitute of a series of biochemical mechanisms and can broadly be categorized as:

1. Reversible protein phosphorylation
2. Regulated ubiquitin-dependent protein degradation
3. Transcriptional control mechanisms
4. Regulation by CDK inhibitors
5. Cell cycle checkpoint mechanisms

Cell Cycle Regulation by Protein Phosphorylation

Periodic activation and inactivation of protein activity play a dominant role in driving the different phases of the cell cycle. Central to this process are a class of protein kinases known as cyclin-dependent kinases (CDKs). CDKs generally consist of a catalytic subunit (the CDK) and a regulatory subunit, called cyclin, and catalyze the transitions from one cell cycle phase into another. The concentrations of CDKs remain constant throughout the cell cycle, but the levels of cyclins oscillate, thereby enabling the formation of active CDK-cyclin complexes at different time points during the cell cycle. In fact, various CDK-cyclin complexes are formed at different cell cycle stages and serve as a driving forces for cell cycle progression (Fig. 1). The first evidence for the key role of CDKs in cell cycle regulation goes back to the discovery of mitosis (maturation) promoting factor (MPF), which drives interphase cells into mitosis, subsequently leading to the idea that certain oscillating activities are responsible for the initiation of mitosis. MPF was first discovered in frogs and later in starfish oocytes and other animals such as mouse and surf clam. A large number of genetic experiments in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* using various cell division cycle (cdc) mutants then revealed that MPF is a heterodimeric protein kinase complex. The complex was shown to be

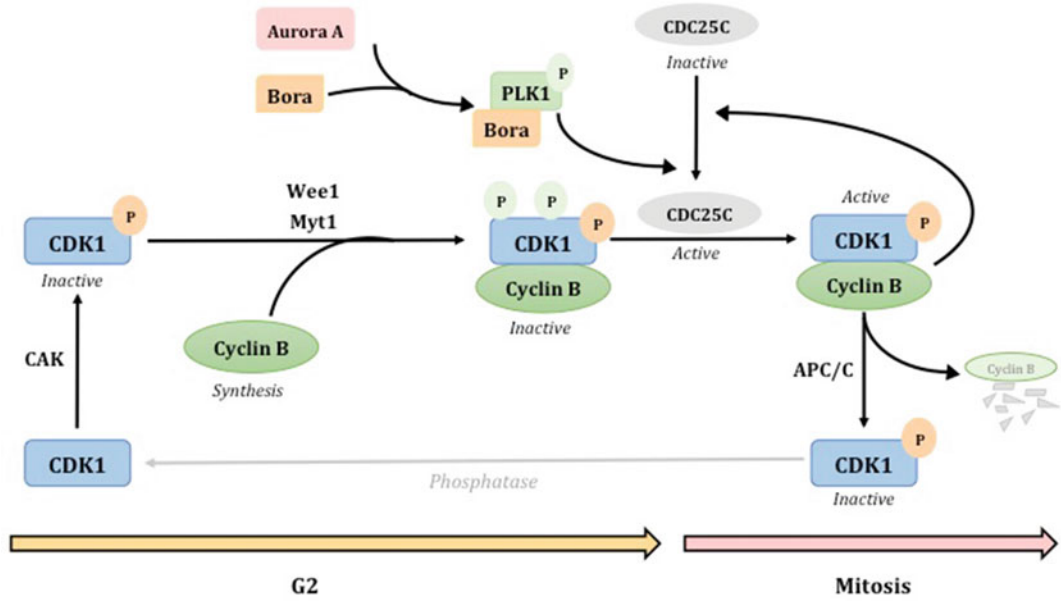


Cell Cycle Regulation, Fig. 1 Cell cycle regulation by cyclin-dependent kinases (CDKs). Different cyclins bound to different CDKs promote the transition from one cell cycle phase to another. CDK-dependent phosphorylation of Rb is required to release active E2F transcription factors, which promotes entry into S phase

constituted by CDK1 (CDC28 and cdc2 in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, respectively) and cyclin A or cyclin B. However, it later became clear that this complex can contain also additional components. The discovery of CDK1 was the first step to the identification of multiple CDKs such as CDK1, 2, 4, and 6 and different cyclins, including cyclin A, B, E, and D and their roles in different cell cycle stages. To date, more than 20 different CDKs and 30 cyclins are known in human cells. Not all of them are involved in cell cycle regulation (Li et al. 2015).

The CDK comprising CDK1 and cyclin B serves as a key trigger for mitosis (Fig. 2). In late S and G2 phase of the cell cycle, cyclin B accumulates in the cell and binds to CDK1, leading to formation of a in principle functional kinase complex. However, full activation of CDK1-cyclin B requires phosphorylation at threonine 161 on the CDK1 subunit, which is catalyzed by a CDK-activating kinase (CAK). Since CDK1-cyclin B complexes are only fully activated when cells enter mitosis, preformed CDK1-cyclin B complexes need to be kept inactive until the actual G2 to M transition is reached. For this, two phosphorylations at residues threonine 14 and tyrosine 15 (in mammals) are induced by the kinases Wee1 and Myt1, respectively, in G2 phase, and these phosphorylations block CDK1 activity. This inactive CDK1-cyclin B complex was also termed as pre-MPF and can be activated just prior to mitosis by removing both the inhibitory phosphorylation sites. This action is performed by CDC25C, a member of the CDC25 family of dual-specificity phosphatases, and leads to rapid CDK1 activation at the start of mitosis (Fig. 2). Consequently, at the G2/M transition, CDC25 activity increases while, Wee1 and Myt1 kinase activities decrease; this is at least partly caused by a positive feedback loop involving CDK1 itself (Li et al. 2015). Thus, initial activation of CDK1 (which occurs at centrosomes) supports its maximal activation at the beginning of mitosis.

More recently, it became clear that CDK1 may promote its own activation by stimulating another important serine/threonine kinase, called as polo-like kinase (PLK1, in mammals). Activation of PLK1 in turn relies on the phosphorylation of its activation loop at Thr-210 within its catalytic domain. This is performed by another serine/



Cell Cycle Regulation, Fig. 2 Regulation of CDK1 activity at the G2/M transition. Preformed kinase complexes consisting of CDK1 and cyclin B are kept inactive by two inhibitory phosphorylations mediated by Wee1 and Myt1 kinases. Activation of CDK1-cyclin B is triggered by CDC25C-mediated dephosphorylation at the G2/M transition. Active CDK is required for entry into mitosis, which is further promoted by Aurora A-mediated activation of PLK1 that also promotes CDK1 activation. CDK is inactivated at the end of mitosis by ubiquitin-dependent protein degradation of cyclin B

threonine kinase Aurora A along with its co-factor Bora. In late G2, CDK1 phosphorylate Bora, and this promotes an interaction between PLK1 and Bora, a step important for the Aurora A-mediated PLK1 activation (Joukov and De Nicolo 2018). The Aurora A/PLK1/Bora axis functions in a spatio-temporal manner, serving not only as a mitotic switch but also operating throughout mitosis by phosphorylating many different proteins involved in the execution of mitosis (Fig. 2).

Cell Cycle Regulation by Ubiquitin-Mediated Protein Degradation

To ensure proper progression of the cell cycle, a cell cycle control system is present in eukaryotic cells, which centers around the periodic formation of CDK-cyclin complexes. The protein levels of cyclins oscillate in a cell cycle-dependent manner, which are the result of transcriptional regulation, stability of their mRNA, and their protein stability. Decline in different cyclin proteins present at certain cell cycle stages is achieved by proteasome-mediated protein degradation. Timely degradation of cyclins results consequently in inactivation of the respective CDK1, which cannot be reactivated, thereby ensuring irreversibility of the cell cycle progression.

Protein proteolysis plays a critical role throughout the cell cycle and in particular in mitosis at transition from metaphase to anaphase. While high levels of cyclin B are required for full activation of CDK1 and for the entry into mitosis, cyclin B levels start to drop at the metaphase to anaphase transition, leading to an irreversible inactivation of CDK1, which contributes to the segregation of sister chromatids during anaphase and is required for the exit from mitosis. The decrease in cyclin B levels is due to regulated ubiquitin-mediated protein degradation by the 26S proteasome. Cyclin B is "tagged" by multiple copies of ubiquitin, a process termed as polyubiquitination, which serves as a prerequisite for its recognition and subsequent degradation by proteasome. Ubiquitination requires three

enzymatic activities including a ubiquitin-activating enzyme (E1), a ubiquitin-conjugating enzyme (E2), and a ubiquitin ligase (E3). UbcH10 is the relevant ubiquitin-conjugating enzyme involved in cyclin B ubiquitination, and a multi-subunit protein complex known as anaphase-promoting complex or cyclosome (APC/C) serves as a ubiquitin ligase for cyclin B ubiquitination (Borg and Dixit 2017). During mitosis, the APC/C activity requires the co-activator protein Cdc20 or (later in mitosis) Cdh1. These subunits contribute to substrate recruitment via their WD40 repeat domains. The WD40 repeats help in recognizing a destruction motif (defrost) within their substrates, typically a destruction (D-) box or KEN box or both. In addition to mitotic cyclins, the APC/C is involved in the destabilization of various other mitotic target proteins including "securin." The degradation of securin at the metaphase to anaphase transition is required for sister chromatid separation by activating the protease "separase" that causes the release of cohesins from the two sister chromatids in order to allow sister chromatid separation to happen. At the end of mitosis, the APC/C dissociates from its activator Cdc20 and binds to its other activator Cdh1, thereby maintaining its activity as the cell enters G1 phase. APC/C^{Cdh1} maintains G1 and blocks premature entry into S phase by catalyzing S and M phase-specific cyclin destruction. Moreover, the APC/C controls the degradation of regulators of the S phase until the assembly of pre-replication complexes has taken place. APC/C is also active in non-dividing and differentiated cells, suggesting its role beyond the cell cycle (Peters 2006).

In addition to protein proteolysis during mitosis, ubiquitin-mediated protein degradation is also required at the G1 to S transition and during the S phase. At this stage, an E3 ubiquitin ligase complex termed SCF (consisting of *S*kp1, *C*ullin, *F*-box protein, and Rbx1 subunits) is functional. The F-box subunit of SCF acts as a substrate recognition subunit that specifically binds to proteins exposing phosphorylated degron sequence motifs. It then binds to Skp1 using its F-box motif and brings substrate in close proximity of a functional E2 ubiquitin-conjugating enzyme. The SCF is involved in the ubiquitination of several proteins including the CDK inhibitor $p27^{KIP1}$, cyclin E, and the transcription factor E2F1. Thus, SCF-mediated ubiquitination contributes to proper G1 to S transition of the cell cycle (Li et al. 2015; Borg and Dixit 2017).

Together, it is now well recognized that ubiquitin-mediated protein degradation is an important regulatory mechanism throughout the cell cycle for an irreversible inactivation of various cell cycle regulators, including cyclins, mitotic regulators, CDK inhibitors, and transcription factors.

G1/S Transition and Transcriptional Control

The transition from G1 phase into S phase is one of the most studied cell cycle transitions. There is a transcriptional wave and tight regulation at G1/S, also known as "restriction point," which represents a point of commitment to cell division. This transition requires mitogenic signals and extensive transcriptional changes. The mechanism of G1 to S transcriptional program is well-established and depends on the E2F family of transcription factors, which is regulated by CDK-cyclin activity. E2Fs are the key transcription factors involved in gene expression required for the entry and execution of S phase as well as for later cell cycle progression. When cells enter the cell cycle from quiescence (G0), cyclin D (different types of cyclin D1, D2, and D3), cyclin E, and cyclin A are synthesized sequentially in a mitogen-dependent manner. Cyclin A and cyclin E preferentially activate CDK2, whereas D type cyclins activate either CDK4 or CDK6. The regulatory principles described for CDK1-cyclin B at G2/M apply similarly to the cyclin A/E-CDK2 and CDK4/6-cyclin D complexes. They also acquire an activating and two inhibitory phosphorylations, which are removed at or near G1/S transition by CDC25A, belonging to CDC25 family of dual-specificity protein phosphatases (Bertoli et al. 2013).

During the early G1 phase (and also during G0) of the cell cycle, activating E2F transcription factors (e.g., E2F1 and E2F2) are bound and thereby inhibited by hypophosphorylated retinoblastoma protein (Rb) – a so-called pocket protein. Rb

functions as a transcriptional inhibitor of the activating E2F transcription factors, thereby preventing expression of genes required for S phase and, thus, inhibiting entry into the S phase. In addition, repressive E2F transcription factors (e.g., E2F4 and E2F5) bind to p130 and p107 – another set of pocket proteins, which are transported into the nucleus, where they bind together with repressive E2Fs in order to prevent gene expression. During progression of G1, cyclin D-dependent CDK activity increases, followed by an increase in cyclin E- and cyclin A-dependent kinase activities, leading to hyperphosphorylation of pocket proteins. As a result, Rb can no longer bind to activating E2Fs resulting in the activation of E2F transcriptional activity. On the other hand, phosphorylation of p130 and p107 releases E2F4 and E2F5, and their repressive function at S phase gene promotors is abrogated (Bertoli et al. 2013; Giacinti and Giordano 2006). Hence, CDK-mediated phosphorylation of pocket proteins causes activation of a complex transcriptional program required for progression into S phase of the cell cycle (Fig. 1).

During the S phase, the genome has to be replicated completely and only once per cell cycle to maintain genomic integrity and prevent tumorigenesis. Replication is initiated at specialized sites on DNA called "replication origin." The first step of replication involves assembly of a pre-replication complex at replication origins, a process referred to as "origin licensing." This takes place already in late mitosis and in early G1 phase when CDK activity is low. The pre-replicative complex consists of CDC6, ORC/CDT1, and MCM2-7 proteins. The chromatin "licensed" for replication is then guided to the S phase by the phosphorylation of CDKs that are active at the G1/S phase transition. Upon entry into the S phase, pre-replicative complexes are transformed into active complexes, leading to the establishment of replication forks by unwinding origins and recruiting the DNA synthesis machinery including DNA polymerases. Upon accomplishment of DNA replication within a replicon, MCM proteins dissociate from the chromatin, and CDK2 activity during S phase prevents its reloading onto chromatin. This restricts the initiation of replication to only once per cell cycle (Pack et al. 2019).

Cell Cycle Control by CDK Inhibitors

CDK activities can be regulated by CDK inhibitor proteins (CKIs). CKIs are small proteins, which can be subdivided into two distinct groups: the INK4 proteins (inhibitors of CDK4) and CIP/KIP family of inhibitors (CDK-interacting protein/kinase inhibitory protein).

Proteins of the INK4 protein family including $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$ specifically inhibit CDK4/6-cyclin D complexes and, thereby, can block the transition from G1 to S phase of the cell cycle by preventing phosphorylation of pocket proteins. This leads to a cell cycle stop, preventing further proliferation of cells. The loss of $p16^{INK4a}$ is a well-established tumor suppressor protein, whose loss results in the deregulation of CDK4/6-Rb- $p16^{INK4a}$ axis (Giacinti and Giordano 2006; Pack et al. 2019).

Despite similarities in their structure and biochemical activities, regulation of each of the INK4 proteins differs significantly. $p16^{INK4a}$ is often induced in response to expression of oncogenic proteins to counteract transformation and hyperproliferation. Elevated levels of $p16^{INK4a}$ are also detected during cellular senescence, which results in delayed or abrogated cell cycle progression. $p15^{INK4b}$, however, is induced by growth inhibitory factors such as TGFβ signaling, where it plays an essential role in mediating the TGFβ triggered G1 arrest. $p18^{INK4c}$ and $p19^{INK4d}$ have roles for permanent exit from the cell cycle associated with terminal differentiation.

The KIP/CIP family represents the second group of CDK inhibitor proteins. These proteins are typically induced upon cellular stress signals (e.g., after genotoxic damage) and function as biological brakes of the cell cycle. They bind to preformed cyclin-CDK complexes (preferentially to CDK1 and CDK2) and render them inactive by blocking their substrate access. The best characterized of these inhibitors is $p21^{CIP1}$ that acts as part of the DNA damage checkpoint. It is transcriptionally activated by p53 in response to DNA

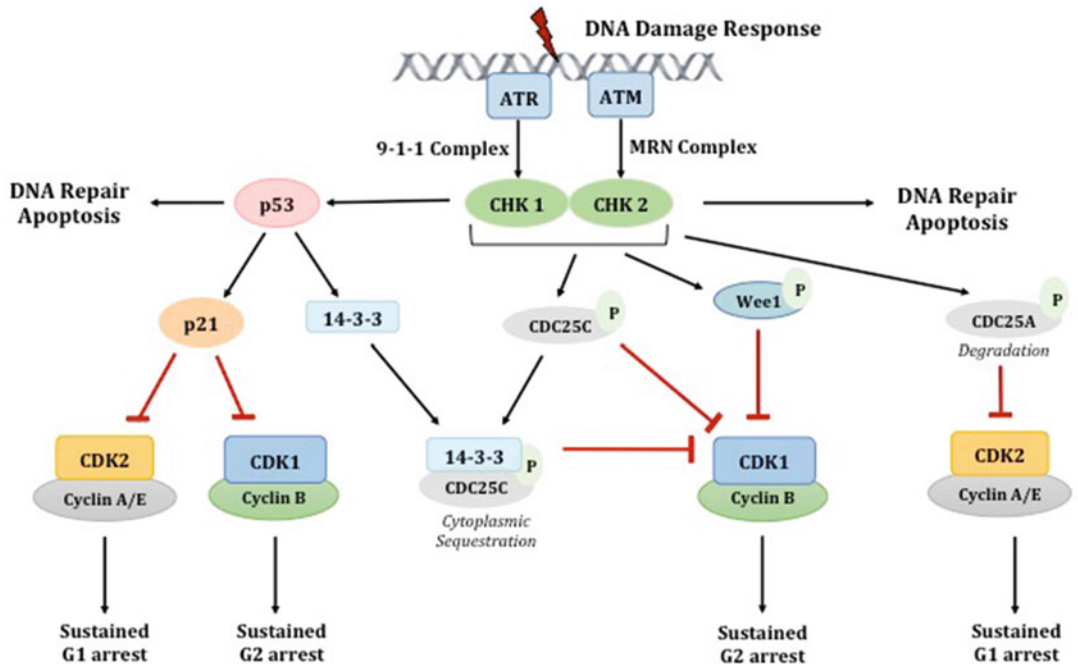
damage. Accumulated $p21^{CIP1}$ binds directly with CDK2-cyclin A/E and CDK1-cyclin A/B and inhibits their kinase activities, resulting in a cell cycle block at G1/S (where CDK2 is essential) and at the G2 to M transition (where CDK1 is essential). Upon cellular stress or genotoxic damage, the $p21^{CIP1}$-mediated cell cycle block provides a time window for, e.g., DNA repair, whereupon $p21^{CIP1}$ levels decline and cell cycle progression can resume. Another member of the KIP/CIP family of CDK inhibitors is $p27^{KIP1}$, which controls deregulated proliferation by inhibiting cyclin E-CDK2. More recently, it became clear that $p27^{KIP1}$ has also multiple non-canonical functions unrelated to its role in inhibiting CDKs during the cell cycle. Low levels of $p27^{KIP1}$ are caused by enhanced protein degradation and appear to be associated with tumorigenesis and poor prognosis. This is also underlined by studies in $p27^{KIP1}$ heterozygous mice showing a haplosufficiency for tumor suppression (Pack et al. 2019).

Cell Cycle Checkpoints

The healthy survival of cells depends on proper cell cycle progression and the ability to transmit the genetic information properly onto two daughter cells. Any errors in these processes are strongly associated with diseases, most notably with cancer. The faithful transmission of genetic information depends on proper DNA replication during the S phase, the absence of DNA damage throughout the cell cycle, and the equal distribution of sister chromatids during mitosis. The error-free progression of the cell cycle and faithful chromosome segregation are monitored at various transition phases by so-called cell cycle checkpoints.

DNA Damage and Replication Checkpoint

The DNA damage checkpoint pathway is among the best-understood checkpoint pathways (Fig. 3). The first step upon detection of DNA damage is the activation of either ATR or ATM kinases, depending on the nature of the damage. Generally, these kinases bind directly at the site of DNA



Cell Cycle Regulation, Fig. 3 The DNA damage checkpoint. In response to DNA damage cells activate p53-dependent and independent checkpoint pathways leading to cell cycle arrest at G1/S and G2/M allowing DNA repair. If the cellular damage cannot be repaired, cells induce apoptosis

damage and activate the effector kinases CHK1 and CHK2, which are responsible for halting the cell cycle in order to allow repair to occur. Typically, ATR is recruited to single-stranded DNA (ssDNA), which can be the result of single DNA strand breaks or of stalled replication forks during S phase. With this, ATR also acts as part of the so-called replication checkpoint. Upon occurrence of ssDNA, replication protein A (RPA) coats and stabilizes the single-strand site. This allows the recruitment of the ATR-interacting protein (ATRIP) to RPA, which is a prerequisite for the subsequent binding of ATR to the single-strands DNA site. The establishment of the ATRIP-ATR complex at the site of ssDNA causes the recruitment of RAD9-HUS1-RAD1 complex, also called the 9-1-1 complex, which stimulates ATR's kinase activity. One of the most important substrates of ATR is CHK1, whose phosphorylation also involves a protein called Claspin. Upon its activation, CHK1 becomes mobile and phosphorylates numerous substrates. One of the key substrates is the CDC25A phosphatase, which is inactivated (and in some cases degraded) upon CHK1-mediated phosphorylation, thereby preventing the activation of CDKs. This results in cell cycle block before or in S phase but also prevents entry into mitosis. In this way, the ATR-CHK1 axis also ensures that cells only enter mitosis when DNA replication is completed (Awasthi et al. 2015).

Upon detection of double-strand breaks (DSBs) of the DNA, the ATM kinase fulfills an important function as part of the DNA damage checkpoint. Activation of ATM at the site of damage requires the MRE11-RAD50-NBS1 (MRN-) complex localized at DSBs. ATM kinase activity is stimulated by the MRN complex, initiating a DNA damage response by phosphorylating the effector kinase CHK2. Similar to CHK1, activated CHK2 halts the cell cycle by phosphorylating and inactivating CDC25 phosphatases. Phosphorylation of CDC25C was shown to cause not only its catalytic inactivation but also its cytoplasmic sequestration mediated by binding to 14-3-3 sigma proteins. Overall, this prevents the activation of CDK2 and CDK1 at G1/S and G2/M transitions, respectively, leading to a stop of the cell cycle at these cell cycle transitions. In addition to targeting CDC25 phosphatases, both, ATM-CHK2 and ATR-CHK1, are able to phosphorylate and to activate the transcription factor p53. Activation of p53 induces the expression of a large number of target genes including *CDKN1A*, which encodes $p21^{CIP1}$, a CDK inhibitor protein. Accumulation of $p21^{CIP1}$ protein in response to DNA damage results in a sustained cell cycle arrest at both the G1/S and G2/M transition by directly inactivating CDK2 and CDK1 kinases, respectively. p53 also induces the transcription of DNA repair genes and genes responsible for the induction of apoptosis. The latter ensures that a damaged cell will rather die than transmitting damaged DNA onto newly formed daughter cells (Pack et al. 2019; Awasthi et al. 2015). Thus, p53 is a central regulator of the DNA damage response (DDR). Tumor cells frequently lack functional p53, which can directly contribute to tumorigenesis by promoting the accumulation of DNA damage and genomic instability.

Additionally, other upstream regulators of CDK1-cyclin B such as PLK1 or Aurora A seem to be also part of a DNA damage response. They also contribute to the cell cycle arrest at G2/M transition, independent of p53. Upon DNA damage, recruitment of Aurora A to the PLK1/Bora complex is inhibited to prevent PLK1 activation. This additional layer of regulation assures repression of pro-mitotic machinery in response to DNA damage (Joukov and De Nicolo 2018; Bruinsma et al. 2017). However, the detailed regulation of the PLK1-Aurora A axis in the DNA damage response is not completely understood.

Spindle Assembly Checkpoint

An important cell cycle checkpoint pathway that monitors the proper execution of mitosis is the spindle assembly checkpoint (SAC). The SAC is activated in the early phases of a normal unperturbed mitosis and monitors the proper alignment of chromosome. During a normal mitosis, progression into anaphase is inhibited until all chromosomes are bi-orientated and properly attached to the mitotic spindle. The SAC involves several proteins that are conserved from yeast to mammals; the core components include MAD1,

MAD2, BUB1, BUB3, BUBR1, and MPS1, which are specifically recruited to kinetochores only when kinetochores lack proper attachment to microtubules of the mitotic spindle. The latter is the case in the early phases of an unperturbed mitosis but also upon damage in mitosis (e.g., upon interference with microtubule function) that affects chromosome alignment. Binding of the SAC proteins at kinetochores is required to generate a diffusible mitotic checkpoint complex (MCC), which consists of MAD2, BUB3, and BUBR1. The MCC binds and inhibits a large ubiquitin ligase complex known as the anaphase-promoting complex or cyclosome (APC/C) in complex with its activator protein CDC20. The APC/C complex is involved in the degradation of various mitotic proteins, most notably securin and cyclin B. Securin is an inhibitor of separase, a protease that cleaves the cohesion ring complex in order to trigger sister chromatid separation at the metaphase to anaphase transition of mitosis (Peters 2006; Musacchio 2015). Thus, the APC/C is required for the onset of anaphase to allow the further progression of mitosis. Consequently, the blockage of APC/C activity by the SAC ensures that anaphase is initiated only upon complete chromosome alignment and, hence, prevents premature chromosome segregation, which is essential to maintain chromosomal stability. Since the APC/C also mediates the degradation of cyclin B leading to the inactivation of CDK1 at the end of mitosis, the SAC prevents premature exit from mitosis (Musacchio 2015).

Pharmacological Intervention to the Cell Cycle

Regulators of the cell cycle are frequently altered in human cancer often resulting in uncontrolled high CDK activities. A promising anti-cancer therapy is therefore the inhibition of CDKs using pharmacological CDK inhibitors that lead to a proliferative arrest of cells. Since prolonged cell cycle arrest results in the induction of apoptosis, the use of CDK inhibitors is a plausible strategy to eliminate tumor cells. In addition, other kinases or regulators of the cell cycle might be suitable targets as potential cancer therapeutics. Cell cycle checkpoints also represent potential targets for anti-cancer drugs. Cells damaged by genotoxic agents or by spindle poisons activate the appropriate checkpoint and halt the cell cycle until the damage is repaired. When these checkpoints are abrogated, cells progress through mitosis or the S phase prior to repair of the genotoxic damage, which promotes cell death. Hence, drugs abrogating cell cycle checkpoints were shown to sensitize cells to chemotherapy.

Pharmacological CDK Inhibitors

The rationale behind CDK inhibition during anti-cancer treatment is to stop hyperactive cell cycles and to inhibit the activity of cyclins that are frequently overexpressed in human cancer. Currently, various CDK inhibitors are evaluated in clinical trials. The first generation of CDK inhibitors included the broad inhibitor flavopiridol, which inhibits CDK1, CDK2, CDK4, CDK6, CDK8, and CDK9, leading to cell cycle arrest in G1 and G2 phases. Other investigated drugs are roscovitine, a purine-based CDK inhibitor, and paullone and indirubin, which are both selective and potent inhibitors of CDKs and GSK-3. With the aim to increase selectivity, specificity, and overall potency, a second generation of CDK inhibitors has been developed. Of these inhibitors, dinaciclib (MK-7965) has been extensively studied in the clinic. It was developed as a highly potent and specific inhibitor of CDK1, CDK2, CDK5, and CDK9. Other inhibitors include, olomoucine, a purine-based drug with high specificity for CDK1, CDK2, CDK5, and CDK7. Purvalanol B is more potent than olomoucine and selectively inhibits CDK1 and CDK2 inducing G2/M arrest. Palbociclib, a CDK4/6 inhibitor, is one of the first drugs to receive approval for first-line treatment of estrogen receptor-positive (ER+) breast cancer (Asghar et al. 2015). All these drugs arrest (tumor) cells in G1, S, or G2, and a prolonged cell cycle arrest is followed by the induction of apoptosis. While most of these CDK inhibitors have reasonable

toxicity profiles, specificity and selectivity remain an issue.

Pharmacological Cell Cycle Inhibitors

Many cell cycle regulatory kinases are overexpressed in human cancers and are therefore prime targets for chemotherapy to be targeted selectively in tumor cells. Several kinases that regulate mitotic progression are tested as anticancer drug targets. These include the Aurora and polo-like kinases (PLKs). First-generation Aurora kinase inhibitors showed off-target effects against other kinases, which led to high toxicity in cells. Second-generation Aurora kinase inhibitors were, however, highly specific and highly potent against rapidly dividing cancer cells. Hesperadin AT9283 and MLN8287 are examples targeting both Aurora kinase A and B. Another way to target mitotic progression of cancer cells is the inhibition of PLK1, which was shown to be frequently overexpressed in cancer cells and has been considered as a "druggable target." PLK1 inhibitors include rigosertib, volasertib, GSK461364, and B12536, all of which mainly targeting ATP-binding domain of PLK1. In addition to kinases, some non-kinase molecules acting in mitosis have been considered as suitable cancer therapeutic targets. For instance, the activity of mitotic kinesin Eg5 (KSP,kinesin 5) can be inhibited by small molecules (e.g., monastrol, KSP-IA) leading to the formation of monopolar mitotic spindles that prevent further progression of mitosis. The first small molecule inhibitor of KSP to be in clinical trials is ispinesib. These inhibitors usually result in mitotic defects associated with the induction of apoptosis (Otto and Sicinski 2017). However, it is currently unclear whether the efficacy of these new anti-mitotic drugs is superior over classical microtubule-targeting drugs like taxanes or *vinca* alkaloids.

Pharmacological Abrogation of Cell Cycle Checkpoints

The introduction of DNA damage leads to the activation of the DNA damage checkpoint resulting in G1 and G2 cell cycle arrest. Overriding this cell cycle block and inappropriate induction of S phase or mitosis, respectively, results in cell death in most cases. Thus, drugs that facilitate these transitions might sensitize cells to chemotherapy. Prime targets for checkpoint abrogating drugs are the ATM-CHK2 and ATR-CHK1 kinases. ATM can be inhibited by several methylxanthine derivatives (e.g., caffeine and pentoxifylline). The ATR inhibitor, NU6027, abrogates checkpoint signaling in both S and G2/M phase of the cell cycle. However, the cytotoxicity of these drugs limits their use in patients. In contrast, UCN-01, a staurosporine-derived drug, acts as a potent inhibitor of the CHK1 kinase and efficiently abrogates the G2 checkpoint upon DNA damage. The forced entry into mitosis in the presence of DNA damage results in apoptosis, which is also often referred to as mitotic catastrophe. Several clinical trials are now focusing on second-generation CHK1 inhibitors (e.g., SCH900776), which have shown promising results in the clinic. Recently, inhibitors targeting Wee1 kinase have also been considered as checkpoint abrogator. Wee1 kinase regulates G2/M transition by inhibiting CDK1 and halts cell cycle progression upon DNA damage. In order to exploit this property, the Wee1 inhibitor AZD1775 is being used in preclinical and clinical studies. AZD1775 is a pyrazolopyrimidine derivative that sensitizes (cancer) cells to chemotherapy and radiation therapy by disrupting the checkpoint at the G2/M transition (Otto and Sicinski 2017).

In contrast to the DNA damage checkpoint, the mitotic spindle assembly checkpoint is essential for cell viability. Therefore, targeting kinases of the spindle checkpoint might be a valid strategy for anti-cancer treatment. It is assumed that upon inhibition of the SAC, massive chromosome missegregation during mitosis is induced, which results in a lethal level of aneuploidy. On the other hand, drugs that target microtubules and the mitotic spindle directly are intensively used for many years in the clinic and are among the most effective drugs with a broad spectrum of activity in many cancer types. These drugs include microtubule stabilizers like taxanes (e.g., paclitaxel, docetaxel) and microtubule destabilizers like *vinca* alkaloids (e.g., vinblastine, vincristine), which affect the dynamic

properties of microtubules and the mitotic spindle leading to cell cycle arrest in mitosis and subsequent cell death (Otto and Sicinski 2017). Interestingly, a combination of anti-microtubule drugs and inhibitors of the spindle assembly checkpoint (e.g., MPS1/TTK inhibitors) were shown to show higher efficacy than either drug alone (Janssen et al. 2009) indicating that also combinations of different anti-cell cycle drugs might be beneficial for anti-cancer treatment.

Cephalosporins

Margherita De Rosa and Anna Marabotti
Department of Chemistry and Biology "A. Zambelli", University of Salerno, Fisciano, Italy

Synonyms

7-ACA derivatives; Beta-lactam antibiotics; Derivatives of the 7-aminocephalosporanic acid

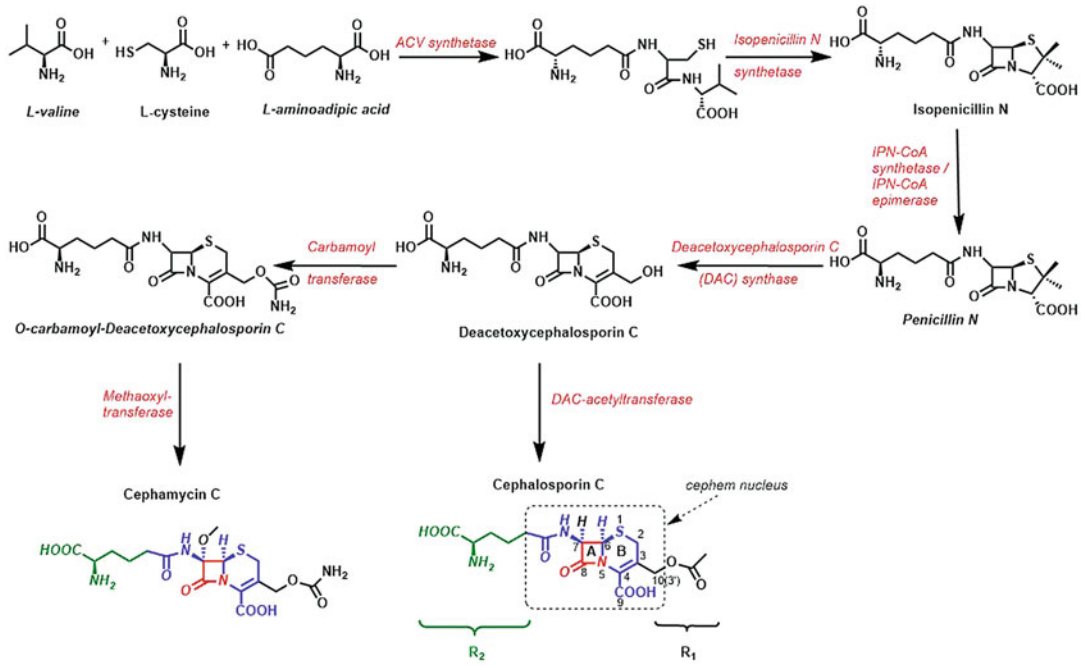
Definition

Cephalosporins are a group of β-lactam antibiotics similar to penicillin in their chemical structure and mechanism of action. Natural cephalosporins are produced as secondary metabolites by fungi of the genus *Acremonium* (formerly known as *Cephalosporium*) (Fig. 1).

The first evidence of their existence was obtained in 1945 by Giuseppe Brotzu, an Italian pharmacologist (Bo 2000), about 50 years after the first discovery of another "principle with bactericidal action" contained in molds, made by another Italian physician, Vincenzo Tiberio (Bucci and Galli 2011), and about 15 years after that such "principle" was serendipitously rediscovered and identified as the penicillin by the British Nobel laureate Alexander Fleming (1929).

Brotzu observed that crude filtrates of *Cephalosporium* cultures were able to inhibit the growth in vitro of several pathogens. It was only in 1953, however, that the founder of this new group of antibiotics, cephalosporin C (Fig. 1), was isolated from these crude extracts and its active nucleus, the 7-aminocephalosporanic acid (7-ACA), was chemically characterized (Abraham 1987).

Starting from this compound, many semisynthetic derivatives were obtained to modulate the



Cephalosporins, Fig. 1 Biosynthesis of cephalosporin C

spectrum of action, the bioavailability, the safety, and the pharmacological properties of this class of antibiotics.

Nowadays, hundreds of cephalosporins are known, and they are usually classified into different "generations" according mainly to their spectrum of coverage against Gram-positive and Gram-negative bacteria, and against bacteria that have developed resistance. First-generation cephalosporins have a fairly good activity against Gram-positive bacteria (in particular *Staphylococci* spp. and *Streptococci* spp.) and are moderately active against few Gram-negative bacteria. Second- and third-generation cephalosporins increase progressively the antimicrobial coverage against Gram-negative bacteria; fourth- and fifth-generation cephalosporins show enhanced coverage against bacteria that have developed resistance towards the previous generations of cephalosporins (Table 1).

Chemistry

The basic chemical structure of cephalosporins contains a four-membered beta-lactam ring (A) fused to a six-membered dihydrothiazine ring (B). Other common structural characteristics include a carboxyl group on the six-membered ring on the carbon next to ring nitrogen and an amino group on the carbon of the four-membered ring opposite to nitrogen (Fig. 1).

Regarding the chemical nomenclature, two different systems are generally reported in literature: (1) a systematic nomenclature (IUPAC) adopted by *Chemical Abstracts* where the fused system is named as 5-thia-1-azabicyclo[4.2.0]oct-2-ene; (2) a more simplified and common nomenclature with the fused ring system called cephem or Δ^3-cephem to indicate the position of the double bond, and the carbon atom bound to C-3 position numbered as C-10 or C-3′ (Fig. 1). The two nomenclature systems show a different structure numbering of the basic nucleus, even if the key C-7, C-6, and C-3 positions remain unchanged. The stereochemistry around the β-lactam ring of naturally occurring cephalosporins shows an absolute configuration *R* at C-7 and C-6 positions. For the substituents attached to the bicyclic system, the notation α/β is generally used depending on the orientation of the substituent below (α) or above (β) the imaginary plane of the

Cephalosporins, Table 1 Representative cephalosporins of different generations and variation of their spectrum of action (Bui and Preuss 2020). The general nucleus is shown at the top of the table

bicyclic system. Naturally occurring compounds containing a cephem nucleus are all characterized by the presence of a D-α-aminoadipic acid 7-acyl side chain on the cephem nucleus (Table 2) and, on the basis of further structural characteristics, they can be grouped in: (1) Cephalosporins with the aminoadipic side chain in C-7β, (2) cephamycins with an additional methoxy substituent at C-7α position, and (3) cephabacins or chitinovorins with a 7α-formamido group and different amino acids or oligopeptides at the C-3 position (Aharonowitz et al. 1992) (Table 2).

Most of compounds belonging to this class of β-lactam antibiotics are semisynthetic cephalosporins synthesized starting from 7-ACA or from 7-aminodeacetoxycephalosporanic acid (7-ADCA) (García-Estrada and Martín 2019). 7-ACA is derived from naturally occurring cephalosporin C by chemical or enzymatic removal of the amino adipoyl side chain at C-7 position. The chemical route is generally based on three steps: (1) protection of the amino and carboxylic groups, (2) treatment with phosphorous pentachloride, and (3) a hydrolysis reaction. The enzymatic approach has become an effective alternative to chemical one. There are two principal routes: (1) direct conversion of cephalosporin C to 7-ACA via an enzymolysis reaction by Cephalosporin C acylase, or (2) a no fully enzymatic procedure consisting in an oxidation reaction to keto acid by an amino acid oxidase (DAO), a nonenzymatic oxidative decarboxylation by H_2O_2 and a hydrolysis reaction by glutaryl acylase (GAC).

The other intermediate 7-ADCA is traditionally produced on an industrial scale from natural penicillin G by chemical expansion of the five-membered thiazolidine ring into the six-membered dihydrothiazine ring followed by enzymatic deacylation. However, over the years alternative processes have been developed in order to improve the cost-efficiency and environmental impact (García-Estrada and Martín 2019).

The cephem core offers many opportunities for chemical modifications at the two side chains in

C-7 and C-3 position, and it is possible to identify few structural features common to different cephalosporine generations. The first generation cephalosporins shows fairly simple structural modifications (Table 1). All compounds belonging to this generation have an α-amide group at C-7 position which makes them vulnerable to hydrolysis by β-lactamases. In some of them, there is a methyl at C-3 position, responsible for low affinity for common penicillin-binding proteins (PBPs) and consequently for their low level of antibacterial activity, or an aminobenzyl group at C-7 position, which is important for oral absorption (Neu 1986). The second generation cephalosporins are a heterogeneous group including also cephamycins, compounds characterized by the presence of a 7-alpha-methoxyl group on the cephem nucleus which confers more resistance to β-lactamases (Table 1). Their chemical structure is similar to the previous generation; an interesting modification is the introduction of a α-iminomethoxy group in the side chain at C-7 position, which enhances the stability of the β-lactam ring to β-lactamases.

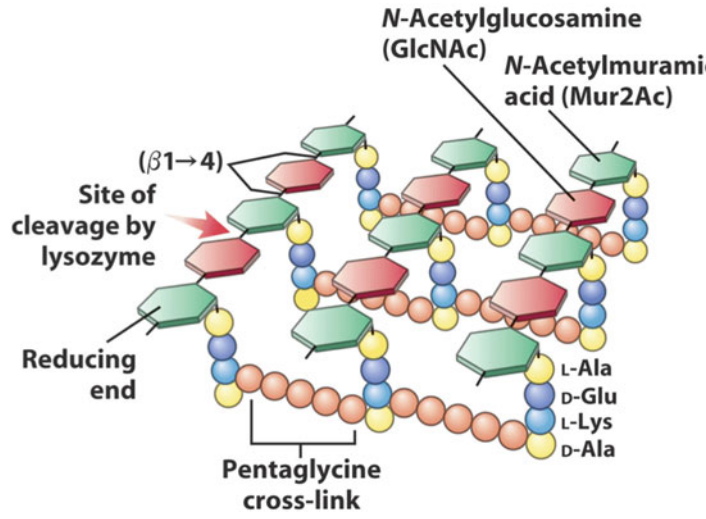
The third generation cephalosporins are generally characterized by the presence of an aminothiazoyl group and iminomethoxy group as substituents (Neu 1986) that improve the antibacterial activity against Gram-negative bacilli and the stability to β-lactamases (Table 1). Furthermore, the substitution at the C-3 position affects the half-life and the toxicity. For example, in ceftriaxone the heterocyclic moiety at the C-3 increases the plasma half-life, in ceftazidime the presence of a charged side chain in C-3 enhances penetration through the porins embedded in the outer membrane of Gram-negative bacteria. The fourth generation cephalosporins are structurally related to third ones but, in addition, they possess a quaternary ammonium group at the C-3 position, useful in facilitating the crossing of the Gram-negative bacterial membrane.

The fifth generation cephalosporins are not characterized by a general structure (Table 1); the molecules belonging to this class have been developed to specifically target against resistant strains of bacteria. For example, ceftobiprole and ceftaroline are the only β-lactam antibiotics that are effective against methicillin-resistant *Staphylococcus aureus* (MRSA) (Nisha et al. 2017). In ceftobiprole, the C-3 side chain is specifically planned to possess a strong binding affinity to PBP2a and PBP2x, and the aminothiazoylhydroxyimino side chain in C-7 to enable good resistance to β-lactamases from *S. aureus*. In ceftaroline, the alkoxyimino group at C-7 and a 2-thioazolythio spacer linkage in C-3 improve its stability to many β-lactamases and anti-MRSA activity, respectively. Furthermore, the introduction of a N-phosphonoamino group in ceftaroline fosamil acetate derivative allows to overcome its poor water solubility.

Mechanism of Action

Like penicillin, the target of cephalosporins are PBPs, a group of enzymes involved in the synthesis of peptidoglycan, an essential component of the bacterial cell wall (Fig. 2).

This structure allows bacteria to assume a well-defined shape and is of outmost importance for their survival, since it confers resistance towards the very high intracellular pressure. Peptidoglycan is a copolymer formed by linear glycan strands made by units of two different aminosugars, *N*-acetylglucosamine and *N*-acetylmuramic acid that are joint together by β-1 → 4 glycosidic links to form a carbohydrate backbone. Moreover, the *N*-acetylmuramic acid is linked to a pentapeptide made of different amino acid residues, the last two being usually D-Ala-D-Ala. This couple of unusual D-residues is essential for the formation of cross-links between two adjacent glycan strands, which confer mechanical resistance to the peptidoglycan. The most common type of cross-link is formed between the residue in position 3 of a pentapeptide of the first glycan strand and the D-Ala in position 4 of a pentapeptide of the flanking glycan strand, either directly or via an interpeptide bridge, with the loss of the final D-Ala (Vollmer et al. 2008). PBPs are involved mainly in the transpeptidation reaction that allows the formation of the cross-linking between the glycan strands, but they can also catalyze the transglycosylation reaction that allows the polymerization of the glycan



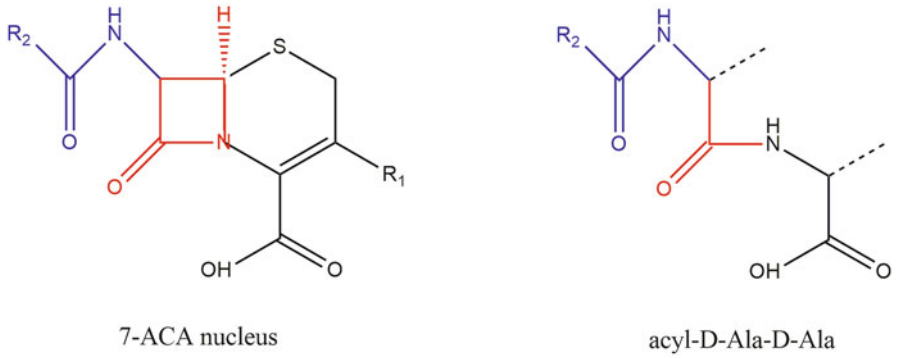
Cephalosporins, Fig. 2 Structure of peptidoglycan (Reproduced by permission by Creative Proteomics)

strand. Additionally, some PBPs can catalyze the hydrolysis of the last D-Ala of the pentapeptide, or the hydrolysis of the peptide bond connecting the two glycan strands (the inverse reaction of transpeptidation). The activity of these enzymes is higher when bacteria actively replicates, since the process of peptidoglycan synthesis is more relevant during these phases. However, the bacteria continuously remodel peptidoglycan during their life, therefore PBPs are active components of the fine balance between peptidoglycan synthesis and degradation. Thus, these enzymes represent an ideal pharmacological target, both because they are involved in a crucial process for the survival of the bacteria, and because there is no homologous enzyme in humans that could in turn be impaired by this class of antibiotics (Sauvage et al. 2008).

The key of the mechanism of action of cephalosporins (as well as of all β-lactam antibiotics) is the structural resemblance of the β-lactam ring with the natural target of PBPs, the D-Ala-D-Ala dipeptide involved in the transpeptidation reaction (Fig. 3).

In the presence of these antibiotics, PBPs are misled and identify them as the substrates for the transpeptidation reaction. The four-member ring binds covalently to the nucleophilic residue (usually, a Ser) in the active site of these enzymes and forms an acyl-enzyme that is unable to synthesize the cross-links between two glycan chains. Additionally, there are evidences, especially in cocci, that these antibiotics induce the release of endogenous substances that enhance the spontaneous process of peptidoglycan hydrolysis. This causes a weakening of the newly synthesized cell wall. Therefore, bacteria are no longer able to resist to the osmotic stress caused by the high pressure inside the cell and this results in their lysis (Murray and Moellering 1981).

Unfortunately, bacteria have evolved several mechanisms to neutralize the activity of β-lactam antibiotics, thus becoming resistant to these compounds. The main mechanism of resistance is the action of β-lactamases, a family of hydrolytic enzymes able to disrupt the β-lactam ring, thus inactivating these molecules (King et al. 2016). The first β-lactamase (penicillinase) was discovered soon after the introduction of penicillin in the clinics (Abraham and Chain 1940). In this regard, the discovery of cephalosporins was highly welcomed, because the 7-ACA nucleus was less susceptible of hydrolysis by penicillinase with respect to the β-lactam ring of penicillins (Abraham 1987). Regrettably, many β-lactamases progressively evolved by selective pressure, especially in Gram-negative bacteria, and were able to hydrolyze the β-lactam ring of cephalosporins, too. Therefore, the development of further generations of cephalosporins after the discovery of the founder molecules was made both to broaden the spectrum of action of these compounds, and to develop molecules resistant to β-lactamase hydrolysis.



Cephalosporins, Fig. 3 Structural resemblance of the 7-ACA nucleus with the D-Ala-D-Ala dipeptide

Other mechanisms of bacterial resistance include the down-regulation of membrane channels, such as porins, to limit the permeability of the cell wall and decrease the drug entry, or the active expulsion of the drug through efflux pumps. Moreover, several bacteria modified their PBPs with mutations in order to render them less susceptible to the irreversible acylation by the β-lactam ring (King et al. 2016). This is the case of the MRSA, identified in the early 1960s. Its resistance is caused by a specific PBP, PBP2a, whose expression by gene *mecA* is triggered by the presence of β-lactams. The kinetic comparison of the properties of PBP2a with respect to other β-lactam sensitive PBPs reveals that this enzyme is characterized by a slow acylation rate, because the active site cleft of this protein is distorted, causing a misalignment of the substrate with the catalytic Ser residue (King et al. 2016). Out of the five generations of cephalosporin, only the fifth generation has coverage against MRSA (Bui and Preuss 2020). In particular, ceftobiprole is a fifth-generation cephalosporin with in vitro activity towards a broad range of Gram-negative pathogens, including MRSA and other methicillino-resistant bacteria (King et al. 2016). Crystallographic studies showed that ceftobiprole irreversibly acylates the catalytic Ser403 of PBP2a with more favorable kinetic parameters, because this compound can perfectly fit into the narrow active site pocket of PBP2a forming interactions with the residues of the cavity. This facilitates the rearrangement required by the acylation reaction (King et al. 2016) (Fig. 4).

Another fifth-generation cephalosporin, ceftaroline, has up to 256-fold higher affinity for PBP2a than other cephalosporins (King et al. 2016). The mechanism of action of this compound seems different from that of ceftobiprole, since it involves the allosteric regulation of PBP2a in addition to the binding of this antibiotic in the active site of the enzyme (King et al. 2016) (Fig. 5).

Clinical Use (Including Side Effects)

All cephalosporins are bactericidal agents and are used to treat infections made by different bacteria sensitive to these antibiotics. Given their potent activity, general safety, low toxicity, and small cost, they are still very popular antibiotics, despite the development of bacterial resistance.

First-generation cephalosporins such as cefazolin and cephalexin are commonly used to treat infections of skin and soft tissue and of the upper respiratory tract caused by Gram-positive cocci such as *Staphylococci* spp., *S. pneumoniae, S. viridans*, and by Gram-negative bacteria sensitive to these compounds, such as *P. mirabilis, E. coli, K. pneumoniae.* Other indications include infections of bone, genitourinary tract, biliary tract, otitis, and surgical prophylaxis. Another possible indication is endocarditis prophylaxis for susceptible individuals (Deck and Winston 2012).

Second-generation cephalosporins show an increased activity towards Gram-negative bacteria such as *H. influenzae* and *Bacteroides* spp., but less activity against Gram-positive cocci, compared to the first generation compounds. Cefuroxime can be used to treat Lyme disease in

pregnant women, and can be used in combination with probenecid (a drug that increases uric acid excretion and can decrease the concentration of cephalosporins in urines) to treat noncomplicated gonorrhea. Because of its ability to cross the blood-brain barrier and to diffuse into cerebrospinal fluid, cefuroxime is used to treat meningitis in children. Cefoxitin is used as a preventive agent before pelvic or colorectal surgery, and can be administered to treat gonococcal infections caused by *N. gonorrhoeae* strains producing penicillinase. Cefonicid is the second-generation cephalosporin with the longest half-life and can be used as a single-dose administration to treat infections such as community-acquired pneumonia (Deck and Winston 2012).

Third-generation cephalosporins have an extended Gram-negative coverage and are often used to treat Gram-negative infections that show resistance to other β-lactam antibiotics. Ceftriaxone, one of the most popular third-generation cephalosporins, is able cross the blood-brain barrier and is a drug of choice to treat meningitis caused by *H. influenzae, N. meningitidis, and S. pneumoniae*, as well as to prevent the pharyngeal transmission of *N. meningitis*. It is also very active against *N. gonorrhoeae* and is frequently used for monotherapy against infections of the lower

respiratory tract, skin, bone and serious urinary infections. Its long half-life allows a daily administration, making this drug excellent for outpatient antibiotic therapy. Ceftazidime is another third-generation cephalosporin that shows activity against *P. aeruginosa*, a Gram-negative bacterium often associated with serious infections, such as hospital-acquired pneumonia, sepsis, and meningitis. This drug has an excellent ability to cross the blood-brain barrier, therefore it is also employed to treat meningitis caused by other Gram-negative species (Deck and Winston 2012).

Fourth-generation cephalosporin cefepime is an anti-Pseudomonal agent, active also against

ceftadizime-resistant strains. Its quaternary ammonium group allows it to penetrate the outer membrane of Gram-negative bacteria. Moreover, this drug is active against Gram-negative bacilli producing β-lactamase (but not MRSA). In order to reduce the spreading of resistance against this compound, it is reserved for systemic infections caused by multi-resistant bacteria (Deck and Winston 2012).

Finally, fifth-generation cephalosporins include the two compounds, ceftaroline and ceftobiprole, active against MRSA in addition to the broad spectrum of action against Gram-positive and Gram-negative bacteria typical of fourth-generation cephalosporins. Ceftaroline was originally approved for the treatment of community-acquired pneumonia and acute bacterial skin infections, but it has proved effective to treat infections caused by MRSA, with rapid bloodstream eradication even in patients non-responding to other therapies. Given the dramatic spreading of resistance (also due to the senseless and indiscriminate use of antibiotics outside the clinical environment), ceftaroline is considered a salvage treatment against MRSA and it should not be used as a first-line therapy for other pathologies (Zhanel et al. 2009). Ceftobiprole is another fifth-generation cephalosporin active against MRSA, *P. aeruginosa* and resistant strains of *S. pneumoniae*. It is administered intravenously as a prodrug, but it is almost immediately converted to the active form. It is well tolerated, safe, and effective, and in contrast to other cephalosporins, it presents a low risk of superinfection by *C. difficilis* leading to pseudomembranous colitis (Barbour et al. 2009).

Cephalosporins belonging to the first generation are mainly administered parenterally, but the following manipulation of the side chains of the 7-ACA allowed to produce semisynthetic derivatives in which pharmacokinetic properties could be modulated. Therefore, from the second generation, many cephalosporins can be administered orally, reaching adequate levels in the whole body. However, fourth- and fifth-generation cephalosporins must be administer parenterally. Cephalosporin derivatives are able to reach many different tissues, including the pleural, pericardial and synovial fluids. They can cross the placenta and be excreted in breast milk. As described before, several cephalosporins such as ceftriaxone, ceftadizime, cefotaxime, and cefuroxime can cross the blood-brain barrier, even in the presence of infected meninges.

Usually, these compounds do not undergo metabolic modification and are excreted unmodified in the urines, but some cephalosporins with an acetyl group in R′ position (Fig. 2) loose this acetyl group before being excreted. The half-life of the parenterally available compounds is often short, but some compounds such as cefuroxime, cefonicid, cefazolin, ceftazidime, and ceftriaxone have a longer half-life. Since the main route of excretion is renal, people with impaired renal function are at higher risk of accumulating cephalosporins and should reduce the dose.

Cephalosporins are generally well tolerated, being gastrointestinal manifestations, such as nausea, vomiting, and abdominal pain, the most common adverse effects especially after oral administration. Like penicillin, cephalosporins can induce a hypersensitivity reaction in about 2% of people, with skin rash, fever, hives, and swelling, but rarely this leads to anaphylaxis. First- and second-generation cephalosporins are more likely to induce hypersensitivity reactions, and to show cross-reactivity with penicillin. Some evidences of a potential increase in nephrotoxicity caused by cephaloridine and cephalotin, both alone and in combination with other classes of antibiotics such as aminoglycosides, were reported in literature in the past, but these reports have been questioned (Murray and Moellering 1981). Although few other cephalosporins (e.g., cefazolin and cefamandole) can produce nephrotoxic effects in animals, they are less likely to increase the risk of nephrotoxic events in humans. Ceftriaxone can frequently cause cholecystitis because of the precipitation of the calcium salt in the gallbladder; therefore, it must not be administered together with calcium additives or calcium-containing solutions. It can also displace bilirubin from albumin, increasing the risk of jaundice in newborns. Ceftriaxone and cefotetan are also associated to the development of drug-induced immune hemolytic anemia, caused by IgG against these drugs, which bind to the red blood cells that carry the drugs on their cell membrane, provoking hemolysis (Bui and Preuss 2020).

In conclusion, despite nearly 75 years of use, cephalosporins appear to be still a valid weapon against bacteria. Nevertheless, clinicians must keep the guard up and researchers must pursue the development of new generations of innovative representatives of this class of compounds, to be always ready to the fight against the threat of resistance against β-lactam antibiotics.

Chaperones

Richard Zimmermann
Medical Biochemistry and Molecular Biology, Saarland University, Homburg, Germany

Synonyms

Heat shock proteins (**Hsp**); Molecular chaperones (note: not all molecular chaperones are stress proteins); Polypeptide chain-binding proteins; Stress proteins (note: not all stress proteins are molecular chaperones, heat shock is one form of cellular stress, and glucose deprivation is another one)

Definition

Chaperones bind to exposed hydrophobic surfaces of polypeptide substrates and, through either ATP-dependent or ATP-independent mechanism, facilitate the folding/assembly, intracellular transport, and activity of polypeptides.

Basic Mechanisms

Molecular Chaperones

The term *molecular chaperone* was coined by Ron A. Laskey and coworkers in 1978 to describe the properties of the nuclear protein nucleoplasmin in assisting the in vitro assembly of nucleosomes from isolated histones and DNA (Laskey et al. 1978). Laskey introduced the term *molecular chaperone* to describe the function of nucleoplasmin because of the analogy with the human chaperone. The role of a human chaperone was to prevent incorrect interactions between pairs of human beings, without either providing a blueprint (or steric information) necessary for their correct interaction or the necessity to be present during their continued (functional) interaction. This concept was extended by Hugh R. B. Pelham in 1986 (Pelham 1986). Pelham proposed that members of the Hsp70 and Hsp90 protein families are involved in the assembly and disassembly of proteins in the cytosol, nucleus, and **endoplasmic reticulum** under non-stress conditions but are required in increased amounts during cellular stress – such as heat shock – conditions, both to unscramble protein aggregates and to prevent aggregation by binding to hydrophobic surfaces that are exposed as a result of the stress. In addition, Pelham proposed that all cells contain a variety of proteins that act as molecular chaperones, in preventing incorrect interactions during the operation of several basic cellular processes under normal growth conditions. These cellular processes are protein folding plus assembly and protein topogenesis in the course of protein biogenesis. More recently, it was appreciated that certain molecular chaperones can also act as modulators/regulators of the activity of folded proteins. Furthermore, these proteins have also been shown to facilitate protein degradation, thereby making them important integration points or sites of "triage" of the cellular pathways of protein folding, assembly, topogenesis, and degradation. Therefore, at a broad cellular level, molecular chaperones are some of the key quality control components of the cell.

Today, molecular chaperones are divided into three principle classes, according to their mode of action (Table 1). The first class comprises the chaperonins or Hsp60 protein family members. Chaperonins are oligomeric proteins, composed of two rings placed back to back, each one enclosing a cavity that allows protein folding in a secluded environment. The term "Anfinsen cage" was coined by R. John Ellis in 1994 to illustrate this mechanistic principle (Ellis 1994). They are divided in two groups, those found in eubacteria or endosymbiotic organelles and those found in archaea and the eukaryotic cytosol. The second class includes all the other Hsp protein families (sHsp, Hsp70, Hsp90) and their respective co-chaperones (such as Hsp40 and nucleotide exchange factors, NEF). These chaperones have highly diverse three-dimensional structures but share as a mechanistic principle that they aid protein folding plus assembly and protein transport by cycles of binding and release of exposed hydrophobic surfaces of polypeptides that, otherwise, would be prone to aggregation. This mode of action is described in detail below in the case of Hsp70. The third class, termed non-Hsp, represents polypeptide-binding proteins that appear to be more specialized for certain classes of substrate polypeptides, such as nascent polypeptides (NAC, nascent polypeptide-associated complex; SRP, signal recognition particle; TRC40, transmembrane recognition complex 40) or glycoproteins (calnexin, calreticulin) or even single-substrate proteins (nucleoplasmin, Hsp47, NDUFAF1, B172L).

The Hsp 70 is the most widely distributed chaperone system in the human cell (Fig. 1). The major molecular chaperone, Hsp70, consists of an N-terminal nucleotide-binding and ATPase domain (NBD) and a C-terminal substrate-binding domain (SBD). The affinity of Hsp70 for protein client is modulated by ATP binding and hydrolysis. In the ATP-bound state, affinity of the substrate-binding domain for the client protein is low, and exchange rates are high. Hydrolysis of ATP to ADP results in high affinity for the substrate and low exchange rates, effectively locking the substrate into the binding pocket. This integral step in assisted protein folding is directly modulated by the binding of Hsp40 proteins. Hsp40s are defined by the presence of an approximately

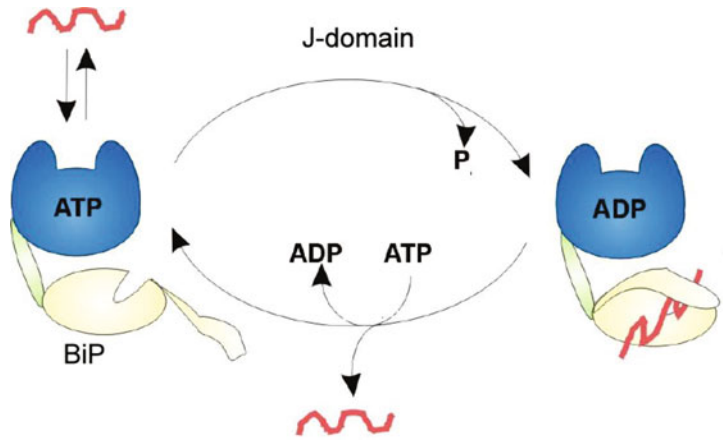
70-amino acid region known as the J-domain, which is essential for interaction with Hsp70. The J-domain is a highly conserved α-helical structure that interacts with the Hsp70 ATPase domain and possibly also with the Hsp70 substrate-binding domain. Hsp40s are divided into three groups based on their possession of domains in addition to the J-domain. Type I Hsp40s contain four domains: an N-terminal J-domain, a glycine/phenylalanine (GF)-rich region, a zinc finger domain, and a C-terminal domain. Type I Hsp40s have been shown to bind protein substrates at their C-terminal domain and to have independent chaperone activity by inhibiting denaturation and aggregation. Type II Hsp40s contain an N-terminal J-domain, a GF-rich region, and a C-terminal domain. Type III Hsp40s contain the J-domain, and this may occur at any position within the protein. Other than the J-domain, the type III Hsp40s are highly divergent in size, sequence, and structure and tend to serve highly specialized functions.

The various roles of a certain Hsp70 shall be described with respect to glucose-regulated protein 78 (Grp78, also called immunoglobulin heavy-chain-binding protein or BiP) (Fig. 2). BiP is the Hsp70 protein family member resident in the endoplasmic reticulum (ER). It is involved (i) in the import of polypeptides into the ER, working both as an allosteric modulator of the folded polypeptide-conducting Sec61 channel and as a molecular ratchet on the polypeptide in



Chaperones, Fig. 1 The functional cycle of Hsp70

transit through the channel, (ii) in the efficient gating of the open Sec61 channel to the closed state, (iii) in folding and assembly of proteins in the ER, (iv) in the export of misfolded polypeptides from the ER to the cytosol for degradation by the proteasome (ER-associated degradation, **ERAD**), and (v) and in the so-called unfolded protein response (**UPR**).

RNA Chaperones

As it is the case in polypeptide folding, non-specific or promiscuous RNA-binding proteins can prevent RNA misfolding and resolve misfolded RNAs, thereby ensuring that RNA is accessible for its biological function (Herschlag 1995). Certain DEAD-box proteins as well as some proteins that are involved in the assembly of ribonucleoparticles were shown to act as RNA chaperones.

Chaperone Diseases

There are a number of human diseases associated with mutations in genes encoding chaperones, and the functional failure of certain molecular chaperones has been linked to human diseases (Macario and Conway de Macario 2005). In addition, disease-linked mutations have been found in proteins that regulate the activity of Hsp70 (i.e., co-chaperones and NEF). To name just a few examples and in staying with the Hsp70 chaperone network in the ER (Fig. 2), Marinesco-Sjögren syndrome (MSS; OMIM 248800), polycystic kidney disease (PKD; OMIM 173900), diabetes mellitus (OMIM 616192), and polycystic liver disease (PCLD; OMIM 174050) have been linked to Sil1, ERj3, ERj6, and ERj2 (Sec63), a nucleotide exchange factor, and various Hsp40s, respectively, for BiP (Dudek et al. 2009). Furthermore, overexpression of various molecular chaperones as well as mutations in certain chaperone genes have been observed in a wide range of tumors (Dudek et al. 2009). In some cases, the chaperone overexpression was linked to poor prognosis and/or resistance to therapy. More recent work linked a human infectious disease to inactivation of the ER-resident chaperone BiP (Dudek et al. 2009). The AB_5 subtilase cytotoxin of certain pathogenic bacteria causes morbidity and mortality among children in developing countries by inactivating BiP (i.e., hemolytic uremic syndrome, HUS).

Pharmacological Intervention

Chemical Chaperones

A number of different low molecular weight compounds are known to stabilize proteins in their native conformation and, therefore, may be effective in correcting protein folding abnormalities in vivo. Relevant compounds are N-acetyl-L-lysine, L-carnitine, L-proline, betaine, ectoine, and hydroxy-ectoine (Welch and Brown 1996). Some of these **chemical chaperones** are already in clinical use to combat protein folding diseases,

such as cystic fibrosis (i.e., the combinations of Lumacaftor® plus Ivacaftor® and Tezacaftor® plus Ivacaftor®).

Drugs That Target Molecular Chaperones

Several small compounds have been discovered that alter expression or function of Hsp70 and Hsp90, respectively (Brodsky and Chiosis 2006). The proteasome inhibitor bortezomib (Velcade®) leads to accumulation of misfolded proteins and, therefore, stress response and subsequent induction of stress proteins, such as Hsp70; the natural compound celastrol and geranylgeranylacetone (GGA) were also shown to induce a stress response. Thus, these compounds may also be used to combat protein folding diseases. Furthermore, small molecules with structural similarity to 15-deoxyspergualin or NSC 630668.R/1 were described to inhibit the ATPase activity of Hsp70. Thus, these compounds may be able to combat certain cancers. Last but not least, based on the discovery of the Hsp70 inhibitors, screening for positive modulators is pursued. The established anticancer drug geldanamycin and its less toxic analogue 17-AAG, on the other hand, target Hsp90.

Definition

G-protein-coupled receptors (GPCRs) play a major role in regulating the overall homeostasis of complex organisms, like mammals, but are also found in primitive species like *Dictyostelium* (slime mold) and yeast (Fredriksson and Schioth 2005). The GPCR superfamily is quite diverse, and sequencing has revealed more than 850 genes comprising around 3% of the human genome. The diversity of the GPCRs is equally matched by the variety of ligands that activate them, which include odorants, taste ligands, light, metals, biogenic amines, fatty acids, amino acids, peptides, proteins, nucleotides, lipids, Krebs cycle intermediates, and steroids. Because of their central role

in regulating normal physiological responses, GPCRs have attracted considerable attention from the pharmaceutical industry as targets for disease. This large superfamily of proteins remains one of the most druggable targets accounting for more than 40% of all marketed therapeutics. Chemokine receptors are members of the GPCR superfamily, and seven CXC, ten CC, and one CX3C and XC chemokine receptors have been cloned so far (Pease and Horuk 2012). Receptor binding initiates a cascade of intracellular events mediated by the receptor-associated heterotrimeric G-proteins. These G-protein subunits trigger various effector enzymes that lead to the activation not only of chemotaxis but also to a wide range of functions in different leukocytes such as an increase in respiratory burst, degranulation, phagocytosis, and lipid mediator synthesis.

Basic Characteristics

Chemokines belong to a large family of small, chemotactic cytokines characterized by a distinctive pattern of four conserved cysteine residues (Baggiolini 1998). They are divided into two major (CXC and CC) and two minor (C and CX3C) groups dependent on the number and spacing of the first two conserved cysteine residues. Although originally identified on the basis of their ability to regulate the trafficking of immune cells, the biological role of chemokines goes well beyond this simple description of their function as chemoattractants; they have been shown to be involved in a number of biological processes, including growth regulation, hematopoiesis, embryologic development, angiogenesis, and HIV-1 infection (Fig. 1).

Chemokines have been shown to be associated with a number of autoinflammatory diseases including multiple sclerosis, rheumatoid arthritis, atherosclerosis, dermatitis, and organ transplant rejection. Evidence, reviewed below, is mounting that chemokines may play a major role in the pathophysiology of these diseases, and thus chemokine receptor antagonists could prove to be useful therapeutics in treating these and other proinflammatory diseases.

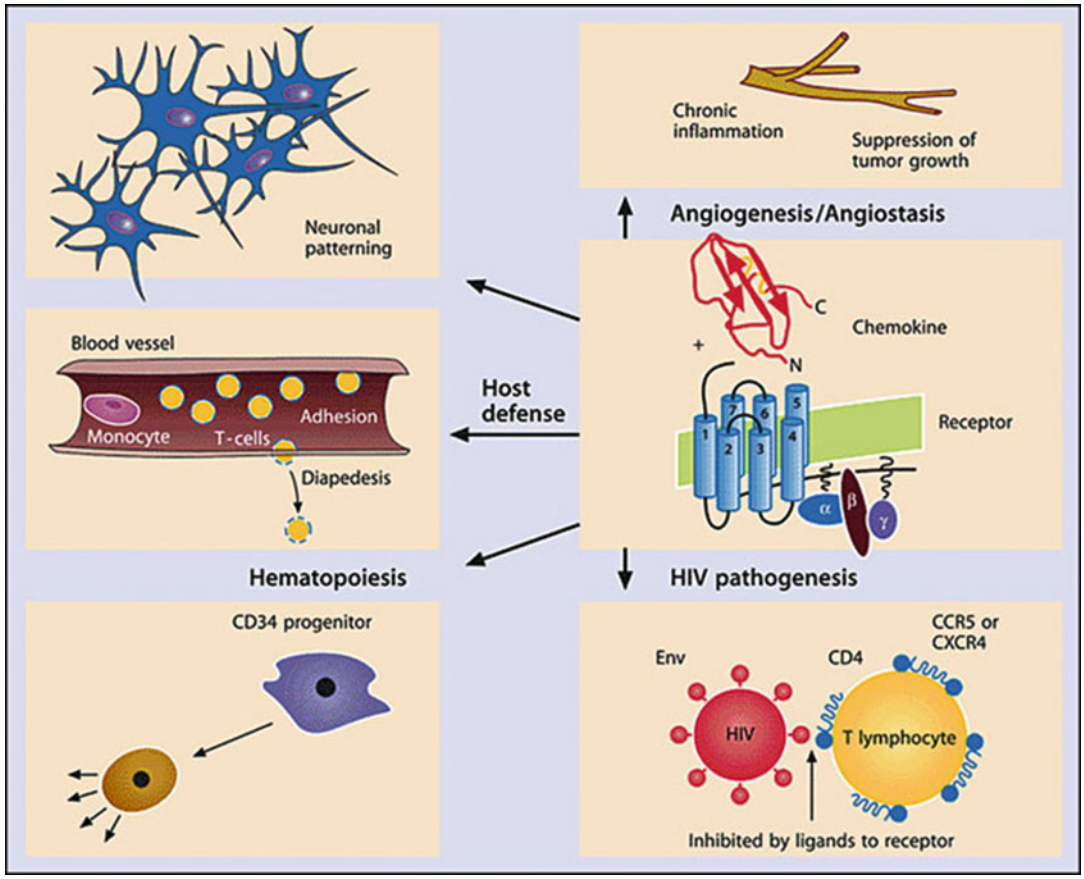
Chemokine Receptors

Although leukocytes continue to be the major site of expression of chemokine receptors, several studies have recently demonstrated chemokine receptor expression on neurons in the CNS.

A number of chemokine receptors including CXCR2, CXCR4, CCR1, CCR5, and DARC have been demonstrated in either adult or fetal brain. Not only were these receptors present on the cell surface but they were also functional. Clearly, the role of these receptors on CNS neurons must be very different from their role on immune cells. Given that human astrocytes can be stimulated with cytokines to upregulate the expression of chemokines, it is tempting to speculate that in vivo during CNS development, chemokines secreted by astrocytes might engage specific receptors expressed on neurons and may play a role in the directed migration of specific subsets of neurons to distinctive regions of the brain.

Genetic mutations of receptors, both natural and induced (by targeted gene disruption), can help to unravel their biological roles. Nature has been generous in this regard by providing us with two naturally occurring examples of gene inactivation for chemokine receptors. Humans homozygous for inherited inactivating mutations of the Duffy (*DARC*) gene and the *CCR5* gene have been identified and appear to be phenotypically normal and healthy. Indeed, these gene inactivations appear to be beneficial to their hosts, rendering them resistant to certain infectious diseases. For example, DARC-negative individuals are resistant to malaria induced by *Plasmodium vivax*, which utilizes DARC to attach to and enter erythrocytes. CCR5-negative individuals are resistant to HIV-1, which utilizes this chemokine receptor as a coreceptor for invasion (see section role of receptors in HIV infection).

The role of chemokine receptors on disease has been clarified not only by genetic mutations but also by receptor antagonists such as small molecules and neutralizing antibodies. For example, the pathophysiological role of CXCR4 has recently been expanded by the finding that it appears to be highly expressed in a number of human breast cancer cells, malignant breast



Chemokine Receptors, Fig. 1 Biological functions of chemokine receptors as exemplified by the chemokine receptor CXCR4

tumors, and metastases. This expression is complemented by the fact that the expression of the CXCR4 ligand CXCL12 is the highest in the lymph node, lung, liver, and bone marrow, distributions that exactly correspond to regions where one would expect to find breast cancer metastasis appearing. These findings point to an important role for CXCR4 in oncology. Data demonstrating that breast cancer cells signaling through CXCR4 can mediate activities such as actin polymerization and pseudopodia formation, functions that would support the ability of these cells to migrate and become invasive, further supports this. In support of these studies, a neutralizing antibody to CXCR4 was used in an animal model of carcinogenesis and was able to significantly impair the metastasis of breast cancer cells to regional lymph nodes and lung. These studies demonstrate that the chemoattractant properties of the CXCR4/CXCL12 interaction, which are so important during morphogenesis in helping to keep cells together to form blood vessels, can also have a darker side in helping to propagate and promote tumor growth. Finally, they highlight another therapeutic opportunity in which CXCR4 small molecule antagonists could be useful.

Role in Immune Response

Chemokines are potent chemoattractants that provide directional cues to summon leukocytes. Leukocyte recruitment is a three-step process that involves the formation of solid-phase chemokine gradients generated by the binding of chemokines to extracellular matrix proteins like

glycosaminoglycans, which decorate the cell surface of endothelial cells. These gradients then attract immune cells that first undergo selectin-mediated rolling along the endothelial cells. Chemokine-mediated upregulation of CD11/18 complexes then results in a much firmer adherence of immune cells to the endothelium, and this culminates in diapedesis of leukocytes across the endothelial space into tissues.

By regulating the movement of different subsets of leukocytes from the peripheral blood to extravascular sites such as organs, skin, or connective tissue, chemokines play a critical role in the maintenance of host defense as well as in the development of immune response. However, sometimes these molecules can inappropriately target immune cells to attack their own tissues and organs leading to inflammation and cellular destruction. Indeed, strong evidence supports the idea that chemokines play an important role in the pathogenesis of a number of autoimmune diseases such as multiple sclerosis and rheumatoid arthritis.

Rheumatoid arthritis is a chronic inflammatory disease characterized in part by a memory T lymphocyte and monocyte infiltrate. Recent studies using neutralizing antibodies have provided strong in vivo concept validation for the role of chemokines in animal models of rheumatoid arthritis. For example, a neutralizing monoclonal antibody against rat CCL2 was efficacious in a collagen-induced arthritis model. In addition, the CCR2 ligands CCL2 and CCL5 are elevated in the joints of patients with rheumatoid arthritis which promotes the recruitment of monocytes and T cells into synovial tissues. Furthermore CCR2 is strongly expressed on monocytes/macrophages in patients with rheumatoid arthritis compared to control patients. These and other studies strongly suggested that CCR2 plays an important role in monocyte recruitment and in Th1-type inflammatory diseases such as rheumatoid arthritis. Based on these findings, a number of companies have embarked on CCR2 antagonist programs, and some of these are still in active human clinical trials (see Table 1).

In contrast to the proinflammatory role of chemokine receptors discussed above, some appear to play a key role in noninflammatory settings. For example, CCR3 has been proposed as a target for asthma given its potential role in activating eosinophils, but a huge number of clinical trials targeting CCR3 in this indication have all failed. In contrast CCR3 may play a key role in a non-allergic setting, namely, choroidal neovascularization, and has been proposed as a target for "wet" age-related macular degeneration (AMD), a leading cause of blindness in the elderly. In "wet" AMD, abnormal development of blood vessels within the choroid (choroidal neovascularization or CNV) results in infiltration of the retina and potential for retinal detachment. Choroidal expression of CCR3 has been observed in both human tissue and also in animal models of AMD, which correlates with CNV. In line with these observations, blockade of CCR3 appears to be beneficial in some animal models of AMD and is being pursued as a drug target in this disease with recent positive phase II clinical trials (Table 1).

Based on the demonstrated role of chemokines in disease, the generation of small molecule chemokine receptor antagonists has received great interest from pharmaceutical companies as attractive therapeutic approaches. GPCRs like chemokine receptors have in the past been an extremely fertile source of biological targets in the pharmaceutical industry, and compound library screening has proven successful in the discovery of antagonists for a number of these receptors, i.e., CCK and neurotensin antagonists. Using similar approaches several drug companies have now identified potent small molecule antagonists of a number of chemokine receptors, which should find broad utility in a variety of acute and chronic inflammatory diseases.

Drugs

Insight into the physiological and pathophysiological roles of chemokine receptors have been provided by studies with potent antagonists for a number of receptors (Pease and Horuk 2012). However, despite multi-million dollar efforts by many academic groups and pharmaceutical

companies, only three chemokine receptor antagonists have been licensed for clinical use: Pfizer's small molecule CCR5 inhibitor, Maraviroc; Genzyme/Aventis small molecule CXCR4 inhibitor, Plerixafor; and Amgen's CCR4 neutralizing antibody, Mogamulizumab (Pease and Horuk

2012) (Table 1). All three antagonists show efficacy in the noninflammatory setting: inhibition of HIV-1 entry (Maraviroc), stem cell mobilization (Plerixafor), and treatment of T cell lymphomas (Mogamulizumab). In contrast, the inflammatory setting has been a graveyard for chemokine receptor drug discovery efforts, with multiple antagonists failing in a range of disorders, including multiple sclerosis, rheumatoid arthritis, asthma, and psoriasis. The reasons for such failures are likely to be many and varied. Recent studies have questioned whether some antagonists achieved sufficient target coverage in vivo, with the suggestion that over 90% of the target needs to be blocked to achieve efficacy in vivo. Alternatively, the target selection may not have been appropriate for treatment of the disorder; for example, despite numerous animal studies demonstrating that CCR3 plays a role in eosinophil recruitment and activation, blockade of this receptor in human clinical trials of asthma and allergy has failed miserably (Table 1) demonstrating that this receptor might not be a major driver for the human disease. Alternatively, given the potential redundancy of the chemokine/chemokine receptor system, it may be necessary to block more than one receptor in certain inflammatory settings (Pease and Horuk 2010). For example, the failures of human clinical trials targeting CCR3 in asthma may have failed because eosinophils can also be activated by CCL3 which is a CCR1 ligand. Thus targeting CCR1 and CCR3 with a dual antagonist might show benefit in asthma.

Chemokine Receptors in Pathogen Infection

A number of viruses, including those in the herpes and pox families, express chemokine-like or chemokine receptor-like molecules that presumably help them to survive immune attack and proliferate. In addition to these strategies, chemoattractant receptors have themselves been targeted as vehicles of cellular invasion by a wide variety of microbes. These range from the Duffy blood group antigen, a promiscuous chemokine receptor on human erythrocytes which serves as a binding protein for the malarial parasite *Plasmodium vivax*, to the fractalkine receptor, CX3CR1, which is a portal of entry for the respiratory syncytial virus, and the HIV-1 virus which utilizes the chemokine receptors CXCR4 and CCR5 as coreceptors for cellular entry. CCR5 is an entry cofactor for M-tropic isolates of HIV-1 and is important in the early proliferative part of the disease, while CXCR4 is a coreceptor for T-tropic isolates of HIV-1 whose emergence in infected individuals usually correlates with accelerated disease progression.

HIV-1 resistance exhibited by some exposed but uninfected individuals is due, in part, to a 32-base pair deletion in the *CCR5* gene (CCR5D32) which results in a truncated protein that is not expressed on the cell surface. About 1% of Caucasians are homozygous for the CCR5D32 allele and appear to be healthy with no untoward signs of disease. In fact, recent findings suggest that homozygosity for the CCR5D32 alleles confers other selective advantages to these individuals, rendering them less susceptible to rheumatoid arthritis and asthma and prolonging survival of transplanted solid organs.

Definition

Cholinesterases (ChEs), polymorphic carboxylesterases of broad substrate specificity, terminate neurotransmission at cholinergic synapses and neuromuscular junctions (NMJs). Being sensitive to inhibition by organophosphate (OP) poisons, ChEs belong to the serine hydrolases (B type). ChEs share 65% amino acid sequence homology and have similar molecular forms and active center structures (Soreq and Seidman 2001). Substrate and inhibitor specificities classify ChEs into two subtypes:

1. Acetylcholinesterase (EC 3.1.1.7) (AChE)
   Primarily hydrolyses esters with short acyl moiety, such as acetylcholine (ACh). It is the major ChE in human red blood cells, muscle cells, and brain cells. In the mammalian brain, AChE mRNA is 20-fold more abundant than BChE mRNA.
2. Butyrylcholinesterase (EC 3.1.1.8) (BChE or BuChE)
   Primarily hydrolyses esters with longer aliphatic (compared to AChE) or aromatic acyl moiety, such as butyrylcholine (BCh) and benzoylcholine (BzCh). BChE is the primary circulating ChE. It is threefold more abundant than AChE in human blood and is found in the liver, lungs, muscles, brain, and heart.

Basic Characteristics

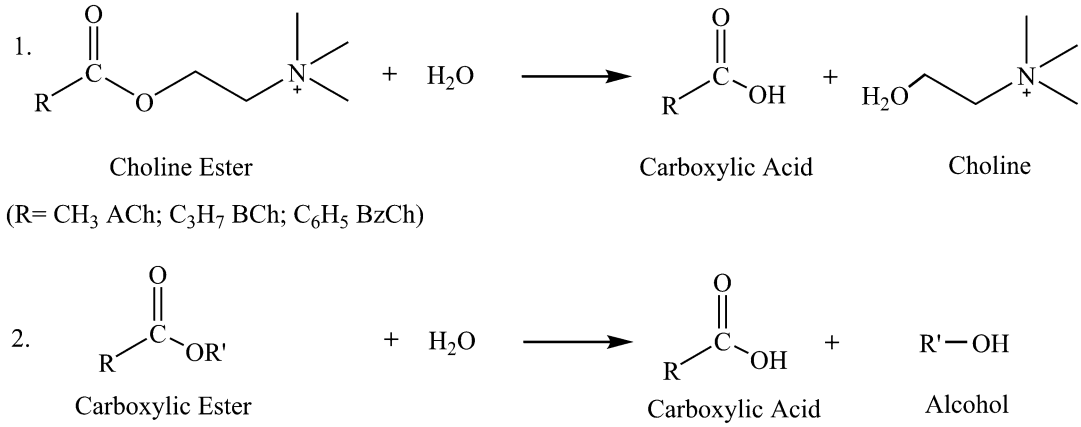
Cellular Processes

ChEs control the duration of ACh-mediated action on postsynaptic receptors in cholinergic synapses and have non-hydrolytic roles in nervous systems' development and plasticity.

Catalytic Activity

ChEs hydrolyze choline esters and carboxylic esters (1, 2, respectively, in Fig. 1).

Hydrolysis involves a Glu-His-Ser catalytic triad, similar to other serine hydrolases, through a "charge relay" process. The imidazole ring of His can relay electrons from Glu to Ser, and the hydroxyl oxygen of Ser becomes a nucleophile and attacks the ester bond of the substrate, yielding an acyl-enzyme intermediate releasing a choline moiety. A water molecule then hydrolyzes the acetylated Ser by nucleophilic attack. Carbamates and OPs chemically modify the active site Ser, slowing down the last hydrolysis step and irreversibly inhibiting hydrolysis.



Cholinesterases, Fig. 1 Hydrolysis of choline and carboxylic esters by cholinesterases

Cholinergic neurotransmission: ChEs terminate cholinergic transmission in the central nervous system (CNS), in NMJs, and in the autonomic system (the parasympathetic system, somatic motor nerves, and preganglionic sympathetic nerves) as well as in circulating blood cells expressing cholinergic proteins. A few sensory cells and the NMJ in nematodes also include ChEs.

Physiological roles: Both enzymes can catalyze ACh hydrolysis into acetic acid and choline, thus maintaining proper transmission of impulses between nerve cells or from neurons to muscles and gland or immune cells. The catalytic mechanism of AChE is extremely efficient, approaching diffusion-controlled rates (kcat/Km = 1.47×10^8 $M^{-1} \cdot s^{-1}$), considerably faster than BChE's hydrolysis rate of ACh. BChE deficiency, an uncommon genetic disorder, causes no pathology but increases carriers' susceptibility to prolonged apnea under muscle relaxant agents, such as succinylcholine or mivacurium, which are naturally destroyed by BChE. When administered under anesthesia to a susceptible person, these compounds are ineffectively removed, which prolongs muscle relaxation. Likewise, subjects with BChE deficiency are susceptible for adverse reactions to other anti-ChEs including commonly used pesticides.

Both ChEs show aryl-acylamidase activity, but BChE has a wider range of substrates; it hydrolyzes several choline esters from acetyl to heptanoylcholine, as well as other aliphatic esters. High BChE activity in many first contact tissues (e.g., lungs, skin, blood, and placenta) as well as high affinity toward a wide range of orally ingested toxic compounds and xenobiotics (e.g., cocaine, procainamide, acetylsalicylic acid) supports the hypothesis that BChE functions as a natural bio-scavenger by absorbing and degrading organophosphate (OP) poisons (e.g., nerve agents) before these lead to neurological damage.

Non-catalytic Activity

ChEs exist throughout the entire animal kingdom, and they also appear in locations where no ACh is released, suggesting that they possess additional non-hydrolytic functional properties, designated "nonclassical." These may depend on protein-protein interactions, compatible with ChE's structural homology with synaptic proteins such as neuroligins, which interact with other synaptic proteins – the neurexins. Also, AChE contains two helix-loop-helix motifs, each forming a calcium-binding site (EF-hand). These do not play a role in its catalytic activity but may participate in protein-protein interactions which are affected in mutated BChE variants.

Within the nervous system, ChEs are involved in membrane conductance and transmission of excitatory amino acids, learning and memory, neurite growth, neuritic translocation,

apoptosome formation, and acute stress reactions (Soreq 2015).

Reports of altered ChE levels in tumors, e.g., meningioma, glioma, acoustic neurinomas and lung cancers, megakaryocytopoietic disorders and leukemias, ovarian tumors, and neuroblastomas, suggest cell proliferation and differentiation activities. Inversely, altered BChE levels in neurodegenerative diseases may reflect systemic cholinergic impairments.

Structure

ChEs possess the α-/β-fold structure, which is shared with other esterases and non-catalytic proteins such as thyroglobulin, glutactin, neurotactin, gliotactin, and neuroligins, all of which include a single ChE domain. Both ChEs are ellipsoidal molecules of ~45·60·65 $Å^3$. Their structure consists of a central, highly twisted, 8–12-stranded β-sheet, in which most strands are parallel, flanked on both sides by α-helices. Studies have indicated three major domains within the protein: the active site, the aromatic gorge, and the peripheral active site.

The active site is composed of two subsites:

The esteratic subsite contains the catalytic machinery of the enzyme. The catalytic triad residues – Ser 200, His 440, and Glu 327 (the residue numbering in this section refers to *Torpedo californica acetylcholinesterase*, *Tc*AChE) – are identical in both enzymes and are basically located in the same positions.

The anionic subsite (Trp 84 and Phe 330) lies between the peripheral and acylation sites halfway down the gorge and accommodates the positively charged quaternary ammonium of the choline moiety. Trp 84 orients the charged part of the substrate to the active center. This subsite is involved in a "cross-talk" mechanism with the peripheral anionic site (PAS) (Silman and Sussman 2005).

The aromatic gorge composed of 14 highly conserved aromatic residues is placed ~20 Å deep, penetrating halfway into the gorge, harboring the active site. In BChE, 6 of the 14 aromatic amino acid residues are replaced by aliphatic ones. Therefore, BChE's gorge is larger in volume and shows a distinct inhibitor sensitivity profile. Other crucial residue changes exist in the acyl-binding pocket, with the replacements of Phe 288 and Phe 290 of *Tc*AChE by Leu 286 and Val 288, respectively; these changes enable the binding of the bulkier butyrate substrate moiety in BChE.

The PAS is located at the rim of the aromatic gorge, on the protein's surface. It spans six AChE residues: Tyr 72, Tyr 124, Glu 285, and Trp 286, on one side of the gorge entrance, and Asp 74 and Tyr 341, on its opposite side. Its core is comprised of Trp 286 and Asp 74 and accommodates many distinct ligands. BChE also has a PAS, but its relatively aromatic content and the response upon ligand binding differ significantly from those of AChE.

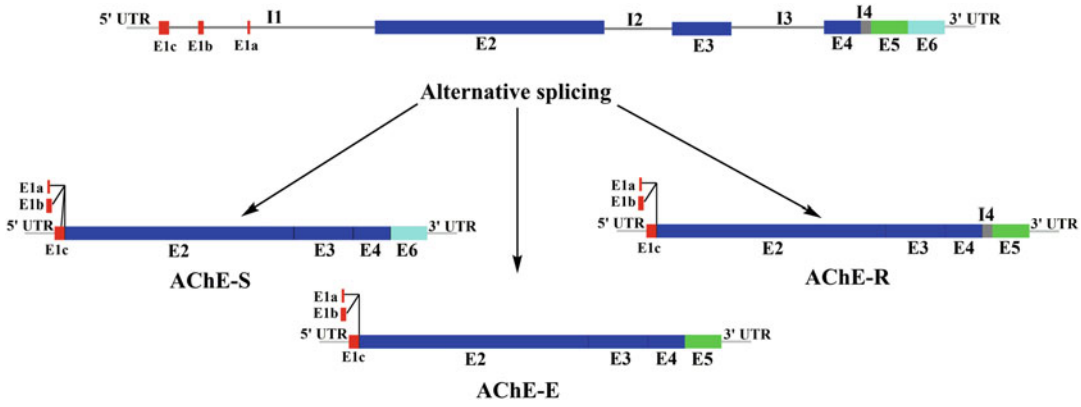
Molecular Mechanisms of Assembly

ChEs present a wide molecular diversity that modulates their function in cholinergic synapses and nonsynaptic contexts. This diversity arises at the genetic, posttranscriptional, and posttranslational levels.

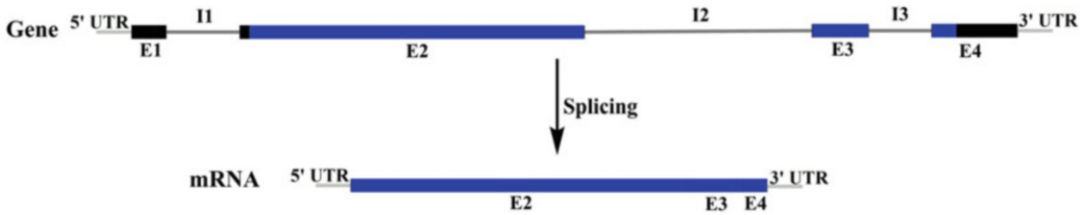
Genetics and Evolution

Genomic comparisons suggest evolutionary gene duplications creating new ChE encoding genes, which initiated before the divergence of nematodes and insects. Subsequent independent duplications lead, for example, to four *ACHE* genes in nematodes. Some families or species may in turn have lost copies of the duplicated genes (e.g., *Drosophila melanogaster*). The duplication that formed *ACHE* and *BCHE* occurred in the tetrapod lineage; thus, amphibians and reptiles but not fish have a *BCHE* homologue resembling *BCHE* of mammals or birds.

The human ACHE gene (7q22) is 7 kb long, and it encodes all variants of AChE (Fig. 2), which share a core domain, spanning the 543 amino acids encoded by exons E2, E3, and E4 of this gene (E1 is a noncoding exon). Posttranscriptional events modify the N′- and the C′-terminus, adding an extended N-terminal domain, exchanging the C-terminal domain, and causing differences in assembly and localization of the AChE multiple forms (Soreq 2015). A single nucleotide



Cholinesterases, Fig. 2 The human ACHE gene and its alternative mRNAs. Structure of the human ACHE gene. Exons are depicted as rectangles and introns as horizontal lines. Alternative splicing options of AChE mRNAs are shown with arrows. E1a, E1b, and E1c are alternative versions of human ACHE exon 1



Cholinesterases, Fig. 3 The human BCHE gene structure and its mRNA. BCHE exons are indicated in blue (coding) and black rectangles. Introns are marked as gray horizontal lines. The spliced form of BChE mRNA is shown by the arrow

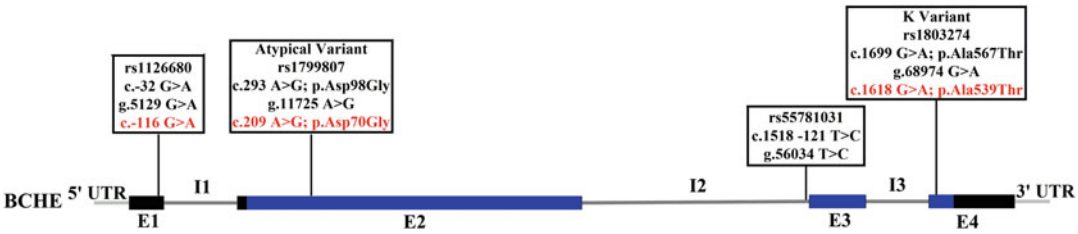
polymorphism (SNP) in position 353 (His353Asn) is responsible for the Yt blood group system; His-353 AChE corresponds to the Yt(a) and the rare Asn-353 AChE variant to Yt(b) blood group antigen.

The human BCHE gene (3q26.1-q26.2) includes 4 exons and 3 introns, yielding a somewhat longer protein, 602 amino acids long, also with an option for an N-terminal extension (Fig. 3). Human BChE has no any other alternatively spliced forms.

More than 70 natural mutations have been described for human BChE (Fig. 4). "Atypical" BChE (the dibucaine-resistant Asp70Gly) shows reduced activity, because Asp70 facilitates the initial binding of positively charged substrates to the active site gorge. The K (Ala539Thr), J (Glu497Val), and fluoride-resistant (Thr247Met or Gly390Val) variants also show reduced BChE activities. In Caucasian populations, the atypical variant and the K variant are the most common BChE variants. The atypical variant is carried in 1 out of 25 subjects, and the K variant allele is found in 1 out of 5 people. Also, 20 different "silent" genotypes have been recognized, with 0–2% of normal activity. Inversely, the Cynthiana and Johannesburg variants show higher activity than "usual" BChE.

Posttranscriptional Modifications

The *ACHE* gene includes sites for alternative splicing of its pre-mRNA product both at the 5′ and the 3′ ends. Three different carboxy termini exist: the "synaptic" or S variant also called "tailed," the "erythrocytic" or E variant, and the "readthrough" or R variant. These join the short and long N-termini to yield variants with the common or the "extended" N-terminus. In comparison, the *BCHE* gene mainly produces a transcript similar to the "synaptic" or S variant of AChE, yet



Cholinesterases, Fig. 4 Some of the important genetic variants in the human BCHE gene. BCHE exons (E) are indicated in blue (coding) and black (noncoding) rectangulars. Introns (I) are marked as gray horizontal lines. Residue numbers indicated in red follow the numbers in the mature BChE protein as present in the PDB database. In contradistinction, residue numbers indicated in black follow the genetics databases (gDNA NCBI Reference Sequence: NG_009031.1; cDNA NCBI Reference Sequence: NM_000055.2, protein NP_000046.1). Red-marked residues imply modified protein sequences

it as well may yield two different N-termini: a variant with the common or the "extended" N-terminus which may be produced due to the coding-altering SNP (c.-32G > A (rs1126680), Fig. 4).

Posttranslational Modifications

Both ChEs undergo several posttranslational modifications, including glycosylation and glycosylphosphatidylinositolation (GPI), phosphorylation, and carbamylation.

Glycosylation: AChE and BChE carry three and nine, respectively, N-glycosylation consensus sequences attaching carbohydrate residues to the core protein via asparagines. Different molecular forms of these enzymes in various tissues show different numbers and compositions of carbohydrate residues. N-glycosylation at all sites was shown to be important for effective biosynthesis, secretion, and clearance of ChEs from the circulation. Altered patterns of AChE glycosylation have been observed in the brain and the cerebrospinal fluid of Alzheimer's disease (AD) patients, with potential diagnostic value.

Glycosylphosphatidylinositolation: The glycophosphatidylinositol moiety anchor of AChE consists exclusively of diacyl molecular species. Over 85% of the molecular species are composed of palmitoyl, stearoyl, and oleoyl. The posttranslational process of glypiation takes place in the endoplasmic reticulum, after completion of the polypeptide chain; the newly synthesized protein interacts with a transamidase complex, which cleaves the chain upstream of the hydrophobic region and adds a preformed GPI anchor to the resulting C-terminal residue.

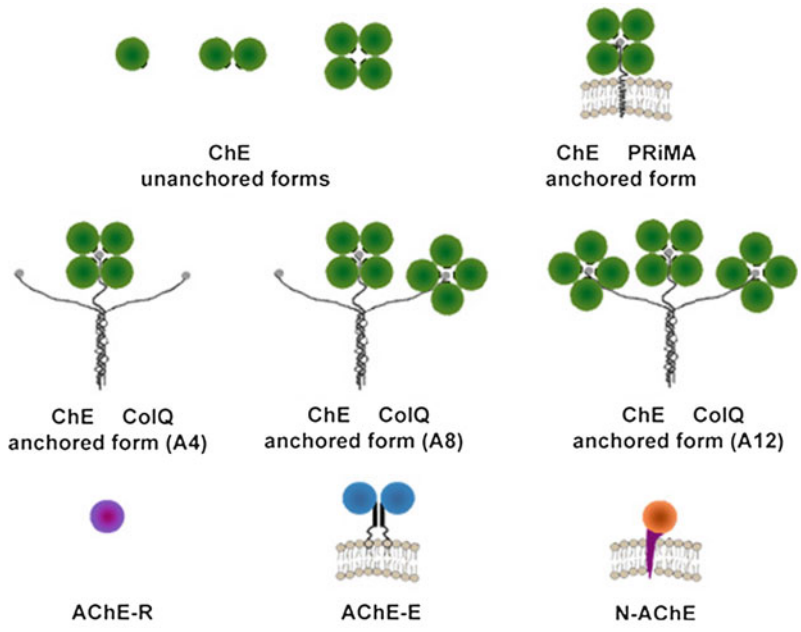
Disulfide bridges formation: ChEs contain eight to ten cysteines; six of these form three internal disulfide bridges. The cysteine that is located four amino acids upstream to the carboxyl terminus forms a disulfide bridge with a cysteine of an identical subunit, creating an interchain disulfide bridge, which stabilizes the dimeric structure.

Molecular Forms of ChEs

ChEs present several amphiphilic and soluble homo- and hetero-oligomeric molecular forms in tissues and body fluids, with different tissue distributions (Fig. 5).

BChE and AChE-S (1–4, in green).

1. Amphiphilic monomers and dimers (G1, G2): Abundant in mammalian brain, muscles, and intestine for both ChEs.
2. Soluble tetrameric form (G4): Composed of four identical monomers and stabilized by hydrophobic interactions of hydrophobic amino acids at the C-terminus of monomers. Abundant for brain AChE and BChE in mammalian body fluids and in the soluble fraction of tissue homogenates.
3. Hydrophobic-tailed tetramers: Abundant form in the mammalian CNS. Anchored to plasma membranes by a hydrophobic, 20 k dalton length polypeptide subunit named PRiMA (proline-rich membrane anchor).



Cholinesterases, Fig. 5 Shown are the seven subgroups of ChEs' molecular forms: top, in green – monomeric, dimeric, and tetrameric AChE-S forms (G1, G2, G4, and PRiMA). Middle, in green – ColQ tailed AChE-S forms (A4, A8, and A12). Parallel forms exist for BChE. Down – other AChE splicing variants (AChE-R, AChE-E, N-AChE) and N-BChE

4. Collagen-like (ColQ) tailed forms or asymmetric multimers: Characterized by triple helical structure of three collagen subunits Q, each associated with one (A4), two (A8), or three (A12) tetramers of ChEs, anchoring to the basal lamina. It is more abundant for AChE than BChE in NMJ.
5. AChE-R (in purple): Naturally rare, stress-induced variant, which lacks a hydrophobic domain and is incapable of binding to ColQ or PRiMA. Therefore, it remains soluble, and its secreted form shows greater mobility than AChE-S. AChE-R can intracellularly interact through its C-terminal tail with the protein kinase C receptor RACK1, a scaffold protein which modifies multiple cellular processes.
6. AChE-E (in blue): GPI-anchored dimers to plasma membranes in mammalian muscles, erythrocytes, and lymphocytes.
7. N-AChE (in purple): The N-terminus extension may serve as a transmembrane domain, enabling AChE-R anchorage to the membrane without ColQ/PRiMA. In principle, N-AChE-S, N-AChE-E, and N-AChE-R may exist. N-AChE (AY389977 is accession number within the GeneBank) shows a high predicted pI value (11.76), matching that of histones and other nucleic acid-binding proteins.
8. N-BChE (in turquoise): The N-terminal extension of BChE is likewise positively charged and may also enable membrane insertion of this protein. The corresponding SNP may change this value, indicating potential differences between the common and the modified variants. Predicted N-BChE amino acid sequence is 41 aa longer than wild-type (wt) BChE (Jasiecki et al. 2019). Based on this predicted sequence, computed pI value (https://web.expasy.org/compute_pi/) for N-BChE was found to be 8.64. To calculate the pI value for N-extended BChE, the following sequence was used: **MSVQSNLQAGAAAASCISPKYYMIFTPCKLCHLCCRESEIN**MHSKVTIICIRFL (extended aa sequence bolded, underlined sequence corresponds to the coding sequence of wt BChE).

Drugs

Alzheimer's disease (AD) is an age-related neurodegenerative disorder characterized by progressive cognitive impairment, a variety of neuropsychiatric and behavioral disturbances, and restrictions in activities of daily living. Both AChE and BChE are found in human neurons, glia, and in AD's plaques and tangles. AChE activity decreases, while BChE activity increases with age (>60 years), in a sex-related manner which is exacerbated in the AD brain. The cholinergic hypothesis attributes to decreased cholinergic transmission, a major role in the expression of cognitive, functional, and possibly behavioral symptoms in AD. Correspondingly, cholinesterase inhibitors (ChEIs) became a common treatment for dementia symptoms. Male carriers of both *BCHE-K* and the debilitated apolipoprotein E4 variant, when older than 75 years, show high risk for late-onset AD in some, but not all, studies.

Another pathway of influence in AD is the facilitation of amyloid-β (Aβ) aggregation through an interaction with the PAS of AChE but not of BChE. Inversely, the "usual" BChE (and more specifically its C-terminus) was shown to attenuate in vitro the formation of amyloid fibrils. Also, carriers of single nucleotide polymorphisms (SNPs) interrupting the interactions of cholinesterase mRNA transcripts with inhibiting microRNAs in noncoding regions of these transcripts show modified cholinesterase levels (Simchovitz et al. 2017).

Gulf War syndrome (GWS) is the name given to a variety of psychological and physical symptoms suffered by veterans of the 1991 Persian Gulf War. The symptoms have been remarkably wide-ranging, sometimes somewhat ill-defined. These symptoms were interpreted to reflect exposure to centrally acting anti-AChEs (Soreq and Seidman 2001).

Cholinesterase Inhibitors

Organophosphates (OPs) or carbamate esters are potent inhibitors of both AChE and BChE. These include drugs (e.g., for AD or myasthenia gravis, MG), pesticides, insecticides, and chemical warfare agents. Phosphorylation or carbamylation of the serine hydroxyl group in the substrate-binding domain inhibits the enzyme, causing ACh accumulation in synaptic clefts and overstimulation of cholinergic receptors. This induces various symptoms, including tension, anxiety, headaches, slurred speech, tremor, convulsions, muscle paralysis, seizure, and even death by asphyxiation.

Drugs

ChEIs represent the treatment of choice for AD therapy, currently including donepezil, rivastigmine, and galantamine. ChEIs vary widely in their pharmacological profiles and affinities for AChE and BChE. Donepezil and galantamine inhibit AChE by 1000- and 50-fold more than BChE, respectively, whereas rivastigmine inhibits both enzymes with similar affinity and in a semi-irreversible manner. ChEI treatments have been expanded also to include other dementias and CNS disorders, e.g., delirium, traumatic brain injuries, and memory impairments, as well as myasthenia gravis, glaucoma, and parasite infections.

Dementia with Lewy bodies (DLB) is considered the second most common cause of dementia after AD. The disorder is characterized by progressive fluctuating cognitive impairment, visual hallucinations, and motor features of Parkinsonism. Neocortical cholinergic activity is more severely depleted in DLB than in AD, and DLB also affects the caudate nucleus, the thalamus, and the brain stem. Tolerability of ChEI in DLB appears similar to AD, with some gastrointestinal effects and muscle cramps.

Parkinson's disease (PD) patients may suffer cognitive and behavioral impairments including apathy, personality changes, and visual hallucinations, with no currently recommended treatment. Their significant cholinergic deficits led to recommendation of ChEI therapeutics, but sex and genotype differences were not yet considered.

Vascular dementia (VD) accounts for ~20–30% of dementia cases, with clinical and pathological overlap with AD. Reductions in cholinergic biomarkers suggest cholinergic deficits in VD, and ChEIs increase ACh availability and improve their cerebral blood flow.

Down's syndrome (DS) carriers develop early-onset AD, likely due to the chromosomal origin of the amyloid gene on their triple chromosome 21, motivating the use of cholinergic therapy in this disorder.

Traumatic brain injury, *including concussion*, is the most common cause of death in subjects under the age of 40 and an important risk factor for AD. Loss of hippocampal cells and depletion of ACh and of muscarinic receptors can be attenuated in injured experimental animals, improve blood perfusion in ischemic areas, and increase cholinergic transmission in the cortex and hippocampus; the same mechanism invoked for treatment of vascular dementia.

Delirium, e.g., post-narcotic delirium, somnolence, or coma, is a common complication involving dementia, with fluctuating attention and consciousness and considerable morbidity. It is not always reversible, and there is no specific treatment. Some of the accompanying central cholinergic syndromes can be reversed by ChEIs.

Myasthenia gravis (*MG*) is an autoimmune disorder characterized by weakness of the face, tongue, and/or neck, which result in double vision or drooping eyelids, along with difficulty in chewing, swallowing, and talking. The most commonly used ChEIs in MG are the cholinesterase inhibitors pyridostigmine, neostigmine, and huperzine A. An AChE mRNA-targeted oligonucleotide agent, Monarsen, is under clinical trials for ameliorating MG symptoms, with significant advantages over ChEIs.

Chemical Warfare Agents, Pesticides, and Insecticides

Discovered in the late 1930s in Germany as improved poisonous insecticides, organophosphorus ChEIs were developed as chemical warfare agents (e.g., sarin, soman, and tabun) and were more recently employed in the 1995 terrorist attack in the Tokyo subway system and in the internal Syrian war (Taylor 2011).

Therapy against acute nerve gas toxicity includes pretreatment with pyridostigmine, a reversible carbamate ChEI, capable of inducing AChE overexpression. Postexposure treatment is continuous with administration of cholinolytic agents such as atropine, the oxime reactivator, pralidoxime chloride, and diazepam. Although multidrug combination therapy is effective in increasing survival, it must be administered immediately and cannot prevent the occurrence of postexposure toxic symptoms. A recently developing alternative involves the use of highly purified ChEs as therapeutic agents. Recombinant production systems for such proteins include transgenic goats producing human BChE in their milk or plant production of human AChE.

Definition

Chronic obstructive pulmonary disease (COPD) affects over 5% of the adult population, is the fourth leading cause of death worldwide, and is the only major cause of mortality that is increasing worldwide. It is a complex and heterogeneous inflammatory disorder of the lungs, caused mainly, but not exclusively, by cigarette smoking. Fifteen to twenty percent of smokers develop COPD.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD; (http://www.goldcopd.com) has defined COPD as follows: "COPD is a common, preventable, and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases. The chronic airflow limitation that characterizes COPD is caused by a mixture of small airways disease (e.g., obstructive bronchiolitis) and parenchymal destruction (emphysema), the relative contributions of which vary from person to person. Chronic inflammation causes structural changes, small airways narrowing, and destruction of lung parenchyma. A loss of small airways may contribute to airflow limitation and mucociliary dysfunction, a characteristic feature of the disease." The severity of COPD is classified on the basis of chronic symptoms (cough, sputum production), spirometric lung function tests, and the history of exacerbations.

Basic Mechanisms

During COPD the following symptoms occur, usually in the order mucus hypersecretion (associated with MUC5AC and MUC5B overexpression), ciliary dysfunction, airflow limitation, pulmonary hyperinflation, gas exchange abnormalities, pulmonary hypertension, and cor pulmonale. Acute exacerbations appear to be mainly triggered by bacteria, viruses, or environmental pollutants. They lead to a worsening of lung functions and reduced quality of life and mainly impact on long-term outcome. COPD is considered a systemic disease because cardiovascular disease, sarcopenia, osteoporosis, and diabetes are frequent comorbidities.

COPD is a chronic inflammatory disease that results from prolonged and repeated inhalation of particles and gases, chronic (or latent) infection, or an interaction of these factors. In many cases the inflammation persists even when the exposure (in most cases smoking) is stopped. The inflammation is found predominantly in the smaller airways and in the lung parenchyma. Prominent among the infiltrating leukocytes are neutrophils, **$CD8^+$** lymphocytes and **$CD68^+$** monocytic cells (Table 1). The chronic inflammation leads to small airway fibrosis causing airway narrowing and to lung parenchyma stiffening that promotes small airway collapse. Both mechanisms are irreversible and lead to air trapping. Superimposed are reversible cholinergic responses such as small airway contraction and mucus hyperproduction (Barnes 2017).

Oxidative stress is considered an important pathogenic factor. It may promote COPD by many factors such as induction of pro-inflammatory genes in many cells including epithelial and endothelial cells, inactivation of antiproteases, and key repair molecules such as sirtuin-1, which may contribute to the accelerated aging responses seen in COPD. **Reactive oxygen species** and other factors such as ceramide or blockade of vascular endothelial growth factor (VEGF) receptors may cause

Chronic Obstructive Pulmonary Disease, Table 1 Pathological changes in COPD

	Large airways	Small airways (<2 mm Ø)	Parenchyma	Products/consequences
Goblet cell hyperplasia/ metaplasia	+[a]	+	–	Mucus
Neutrophil infiltration	+[b]	+[b]	(+)[b]	ROS, elastase, MMP-8, MMP-9
$CD8^+$ T cells[c]	+	+	+	TNF, perforins, granzymes, activation of Fas-dependent apoptosis
Macrophages ($CD68^+$)	–	+	+	TNF, IL-8 cathepsins B, L, and S MMP-2, MMP-9, MMP-12
Airway wall fibrosis, thickening	–	+	–	Flow limitation
Smooth muscle	–	+	–	AHR?
Emphysema	–	–	+	Flow limitation

ROS reactive oxygen species, *AHR* airway hyperresponsiveness, *MMP* matrix metalloprotease
[a]Correlates with cough and chronic bronchitis
[b]Number increases with disease severity
[c]Correlates with amount of alveolar destruction and severity of airflow obstruction

emphysema by induction of apoptosis (in the case of reactive oxygen species also necrosis) in endothelial or epithelial cells. Furthermore, inefficient apoptotic cell clearance (efferocytosis) may also contribute to a probably genetically modulated progressive lung destruction with fibrosis.

The inflammation in COPD appears to be complex and heterogeneous. In general the immune response appears to be skewed – albeit not in a clear-cut manner – toward pro-inflammatory M1-like macrophages and Th1 as well as Th17 responses. Among the typical mediators and effectors found in the disease are TNF, IL-1, IL-8, IP10, LTB_4, and elastolytic enzymes such as matrix metalloproteases and cathepsins. The majority of drugs in development for COPD are based on anti-inflammatory concepts, e.g., antagonists for IL-33, CXCR2, IFNβ, IL-1β, IL-5, IL-13, IL-17A, TNF, or FGF and inhibitors for LOX5, MMP12, PI3Kδ, p38, IKK2, or iNOS (Barnes 2017).

Both elastase and MMPs have physiological antagonists, named α1AT (α1-antitrypsin) (the primary inhibitor of neutrophil elastase) and TIMP (tissue inhibitor of matrix metalloproteases), respectively. Smoke, presumably through oxidative stress, may inactivate these antiproteases. Consequently, it has been suggested that emphysema results from an imbalance of the protease and antiprotease ratio and indeed, hereditary α1AT deficiency is a rare but well-known cause of emphysema. In experimental animals, TIMP-3 deficiency leads to a combination of developmental airspace enlargement combined with progressive destructive emphysema in adults. However, almost certainly, no single protease/antiprotease alone is responsible for the development of COPD.

Today, COPD is regarded as a systemic disease. The different pathomechanisms do not only cause local lung injury and remodelling but also alter systemic structures and function. Relatively little is known about the low-grade systemic inflammation present in COPD that is considered the main cause for the systemic effects. These systemic effects of COPD include involuntary weight loss, muscle atrophy, impaired bone metabolism, reduced functional capacity and health status, and increased cardiovascular morbidity as an important resource-consuming comorbidity. Thus, COPD is multidimensional disease (Singh et al. 2019). To account for the multiple changes in COPD, the BODE index was introduced, a 10-point scale combining measures of BMI (B), the degree of airflow

obstruction (O) and dyspnea (D), and exercise capacity (E) (Celli et al. 2004).

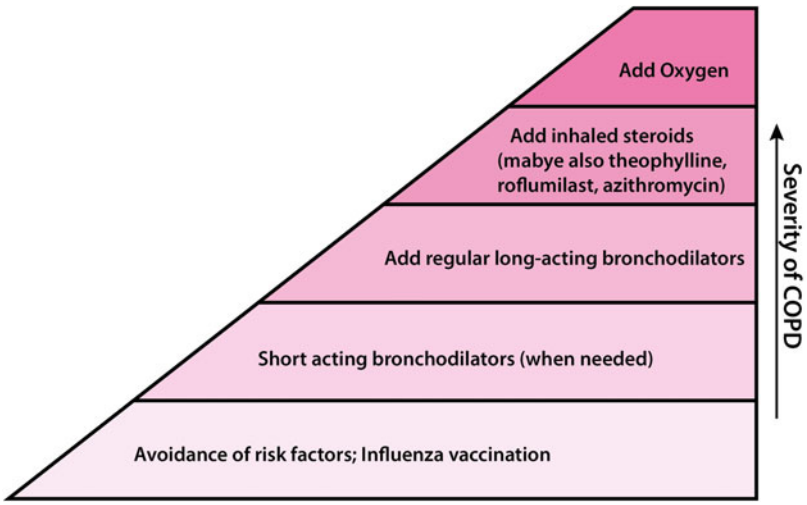
Pharmacological Interventions

Usually it takes years of toxin exposure to cause the pathological alterations seen in COPD. In most cases the disease is already well progressed when COPD is diagnosed. Reversal of established chronic inflammatory disease is always extremely difficult to achieve, and at present healing of COPD is impossible. Most of the pharmacological agents that are used in COPD (Fig. 1) have been developed for the treatment of asthma, where their benefit is clearly greater. The comparatively small effect of inhaled β-agonists on airway resistance is even used as a diagnostic criterion to distinguish COPD from asthma. The management of COPD is largely symptom-driven, and there is only an imperfect relationship between the degree of airflow limitation and the presence of symptoms. Currently, there is no effective therapy for the irreversible airflow obstruction that results from airway remodelling, fibrosis, and emphysema. Available pharmacotherapy can reduce or abolish symptoms, increase exercise capacity, reduce the number and severity of exacerbations, and improve health status. The inhaled route is preferred. The mainstay of therapy are anticholinergics, β2-agonists, and steroids, and much effort has been put into evaluating the benefits of single, double, and triple therapies of these three classes. In addition to these drugs, roflumilast or azithromycin may be used to treat exacerbations (van Haarst et al. 2019; Singh et al. 2016, 2019; Woodruff et al. 2015).

Bronchodilators

The primary aim of the current COPD therapy is to reduce airway resistance by reducing bronchial smooth muscle constriction and mucous plugging. β2-adrenoreceptor agonists and anticholinergics are the mainstay of therapy for symptomatic management. These bronchodilators improve symptoms and exercise tolerance and may reduce exacerbations but have little effect on inflammation and on the long-term decline in lung functions. β2-agonists and to some extent also anticholinergics may increase the risk of adverse cardiovascular events, although the cardiovascular risks of the latest drugs are quite low.

β2-adrenoreceptor agonists: β-agonists increase intracellular cAMP, which in turn leads to bronchodilation and improved lung emptying during breathing. Short-acting β-agonists (SABA, half-life <6 h: salbutamol, terbutaline, orciprenaline, fenoterol, albuterol), long-acting β-agonists (LABA, ~12 h: formoterol, salmeterol), and ultra-long-acting β-agonists



Chronic Obstructive Pulmonary Disease, Fig. 1 Pharmacotherapy of COPD

(uLABA, ~24 h: indacaterol, olodaterol) are used. Regular treatment with long-acting bronchodilators is more effective and convenient than treatment with short-acting bronchodilators. There is a relatively small and flat dose-response relationship with all β-agonists. Possible side effects are palpitations and premature ventricular contraction (resulting from stimulation of β_1 receptors in the heart), tremor, sleep disturbances, and hypokalemia (see also "► Asthma" entry).

Anticholinergics: Modern long-acting muscarinic receptor antagonists (LAMA) are tiotropium, aclidinium, umeclidinium, and glycopyrrolate. All show higher selectivity for M3-receptors compared to M2-receptors and in addition remain bound to M3-receptors longer than to M2-receptors. They have to be given once or twice daily. Older anticholinergics (e.g., ipratropium, oxytropium) that have to be given up to four times daily are often used as maintenance treatment. Possible side effects are dry mouth, metallic taste after inhalation, and very rarely close angle glaucoma. The effects of anticholinergics and β-agonists show some additive effects (combination therapy).

Anti-inflammatory Therapy

Inhaled corticosteroids. Inhaled steroids (commonly used are beclomethasone, budesonide, triamcinolone, fluticasone and its derivatives, flunisolide) are typically used in conjunction with LABAs and appear to attenuate the inflammatory response, to reduce bronchial hyperreactivity, to decrease exacerbations and to improve health status. Many patients appear to be resistant to steroids, and large, long-term trials have shown only limited effectiveness of inhaled corticosteroid therapy. They appear to work best in patients with frequent exacerbations and with eosinophilia; of note, the IL-5 antibody mepolizumab is currently under debate for use in eosinophilic COPD. Certainly, the benefit from steroids is smaller in COPD than in asthma. Topical side effects of inhaled steroids are oropharyngeal candidiasis and hoarse voice; in addition systemic side effects such as osteoporosis may develop.

Systemic steroids. Systemic steroids are used to treat acute exacerbations. Here, short-term use of 3–5 days is standard of care. Long-term use of systemic steroids should be avoided in order to prevent steroid-associated side effects. In addition, it has been shown that long-term use of systemic steroids is associated with negative long-term outcome.

Phosphodiesterase inhibitors: The phosphodiesterase-4 (PDE-4) inhibitor roflumilast is approved to reduce the risk of COPD exacerbations in patients with frequent COPD exacerbations despite bronchodilators and inhaled steroids. Its mechanism of action is considered to be largely based on its anti-inflammatory effects; as an example, it decreases TNF expression. Another albeit unspecific phosphodiesterase inhibitor that also hits other targets such as A1-receptors is theophylline; theophylline is a third-line bronchodilator drug in chronic COPD behind inhaled anticholinergics and β2-agonists, with slow-release forms of oral theophylline preferred. Methylxanthines have a narrow therapeutic margin; major side effects are ventricular and atrial dysrhythmias and convulsions. Possible side effects of PDE-4 inhibitors include headache, nausea, vomiting, diarrhea, and heartburn.

Anti-microbial Therapy

The use of antibiotics is not recommended, except for the treatment of infectious exacerbations of COPD and other bacterial infections. An exception are macrolides, in particular azithromycin, that do also have immunomodulatory effects. Azithromycin may be beneficial for older patients with milder disease and for ex-smokers. Known risks are hearing loss and prolonged QTc interval (Woodruff et al. 2015).

Anti-trypsin Augmentation Therapy

Approximately 2% of all COPD patients suffer from homozygous α1-AT deficiency. Intravenous infusion of replacement protein twice weekly in patients with established α_1-antitrypsin deficiency has been approved in both in the USA and in Europe.

Oxygen Therapy

Long-term oxygen therapy (>15 h per day) is introduced in very severe hypoxemic COPD and improves survival, exercise capacity, and cognitive performance. Oxygen therapy is also temporarily used for hospital treatment of hypoxemic COPD exacerbations. In addition to improving oxygenation, oxygen therapy is thought to be effective because it reduces pulmonary hypertension by opposing hypoxic pulmonary vasoconstriction.

Psychopharmacological Therapy

Up to 30% of COPD patients suffer from anxiety disorder or depression and should be treated with conventional pharmacotherapy (Woodruff et al. 2015).

Non-pharmacological Interventions (Singh et al. 2019)

Reduction of Risk Factors

Smoking is the single most important single-risk factor for COPD, and smoking cessation is the single most effective – and cost-effective – intervention to reduce the risk of developing COPD and to stop its progression. Other risk factors include open fire cooking.

Vaccination

Because infections are a common cause of exacerbations, age-appropriate vaccination against influenza and pneumococci is recommended.

Noninvasive Ventilation

Noninvasive ventilation is used to treat acute hypercapnic respiratory failure during an acute exacerbation. This treatment is administered in hospital. Nevertheless, current data have shown that NIV is able to treat chronic hypercapnic respiratory failure as well. Here, NIV is used mainly at home during nighttime for long-term treatment.

Pulmonary Rehabilitation

Pulmonary rehabilitation as add-on to medication and vaccination has proven to be much more efficient in motivated patients than medication alone. It is aiming at self-management and training but also includes nutritional, pharmacological, and psychosocial support. Training increases the proportion of type I (minimal fatiguable aerobic low-velocity fibers) versus type II fibers (vs. the high-velocity anaerobic), stimulates the release of endogenous opioids, provides psychological reinforcement during exercise, and improves self-confidence.

Lung Volume Reduction (Surgery and Endoscopic)

Lung volume reduction surgery is a treatment option for patients with severe emphysema. Endoscopic lung volume reduction using valves, coils, and other approaches are newly developed treatment options that can alternatively be used in COPD patients with severe emphysema.

Circadian Rhythms

Annabelle Ballesta
INSERM Unit 900; Institut Curie; University Paris-Saclay, Saint-Cloud, France
Honorary position, University of Warwick, Coventry, UK

Synonyms

Daily rhythms; 24h-rhythms

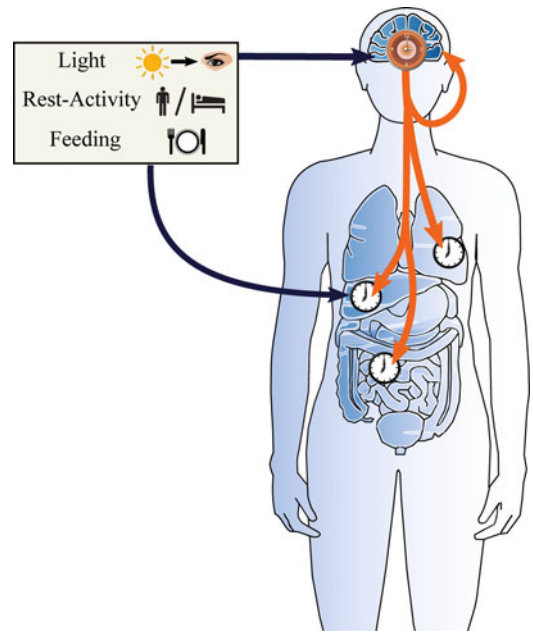
Definition

Most mammals display 24 h-rhythms in their activity and internal physiological functions also called circadian rhythms. The word "circadian" comes from the Latin words "circa" – "dies" which means around – a day, thus referring to phenomenon with a period comprised between 20 and 28 h. The 24 h-rhythms of the organism are governed by a hierarchical internal system called the circadian timing system (CTS) which aims to optimize the energy use and supply over the day and night cycles though the anticipation of the body needs. More than 30 years of research in the field of circadian rhythms have recently been acknowledged by the 2017 Nobel Prize of physiology and medicine awarded to Prof. Jeffrey C. Hall, Michael Rosbash, and Michael W. Young for their discoveries of the molecular mechanisms controlling the circadian clock. The daily oscillations are endogenous, meaning that they are created by the CTS itself and are sustainable in the absence of external synchronizers. However, the inner period of the rhythms is not exactly equal to 24 h and varies from one individual to another. Environmental cues such as light or social interactions entrain the body to a period of exactly 24 h, equal to that of the rotation of the Earth.

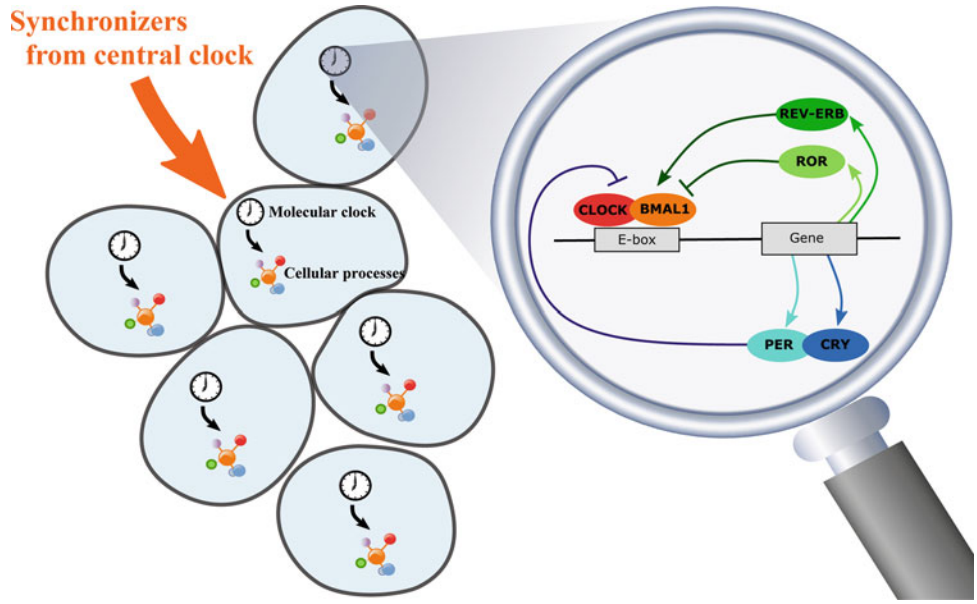
Basic Mechanisms

The Circadian Timing System

The mammalian Circadian Timing System (CTS) is constituted of a central pacemaker located in the hypothalamus – the suprachiasmatic nuclei – that spontaneously oscillates at its own period of nearly 24 h and is daily synchronized to an exactly 24 h-period by external time cues such as light-dark cycles, food intake, or socio-professional interactions (Levi and Schibler 2007). This central pacemaker transmits rhythmic physiological signals to molecular circadian clocks present in all nucleated cells of the peripheral organs, in various forms including hormone variations or temperature cycles (Fig. 1). Indeed, each nucleated cell is endowed with a molecular clock which is composed of approximately 15 genes involved in at least two interconnected feedback loops that spontaneously generate circadian oscillations (Fig. 2). More precisely, the central node of the clock is the complex formed by two clock genes: Clock and Bmal1. The CLOCK/BMAL1 complex attaches to Enhancer–boxes (E-boxes) and promotes the transcription of Period homolog 1, 2, and 3 (Per1, Per2, Per3), Cryptochromes (Cry1, Cry2), retinoic acid-related orphan receptors



Circadian Rhythms, Fig. 1 The circadian timing system. A central pacemaker located in the hypothalamus display rhythms of a period close to 24 h and is entrained by external cues such as light or feeding patterns to exactly 24 h. This central clock exerts a control on the cellular clocks of the peripheral organs in various forms including rhythmic hormone secretion or temperature cycles



Circadian Rhythms, Fig. 2 The molecular clocks in peripheral organs. In mammals, each nucleated cell is endowed with a molecular clock spontaneously oscillating with a circadian period as a result of interconnected transcriptional and translational feedback loops. The clock genes Clock and Bmal1 form dimers that attach to E-boxes to promote the transcription of Pers, Crys, Rors, and Rev-erbs genes. Per and Cry undergo post-translational modifications and associate to repress the transcriptional activity of Clock/Bmal1, thus decreasing their own transcription. After few hours, Per/Cry complexes are degraded which starts a new cycle of the oscillator. Another feedback loop involves the respective positive and negative action of REV-ERB and ROR proteins on Bmal1 transcription which increases the robustness of the oscillator. At the level of a tissue, cellular clocks are synchronized with each other through rhythmic physiological signals coordinated by the central pacemaker in the brain

(Rora, Rorb, Rorc), and Rev-Erb nuclear orphan receptors (Rev-Erbα, Rev-Erbβ). PER and CRY proteins undergo post-translational modifications in the cytoplasm followed by nuclear translocation probably under the form of a PER/CRY complex, and inhibit CLOCK/BMAL1 positive action on transcription, including their own. As a consequence, PER and CRY protein levels decrease, thus allowing CLOCK/BMAL complexes to be active again, thus starting a new cycle of the oscillator. A second feedback loop involves ROR and REV-ERB proteins which regulate BMAL1 transcription by respectively activating and inhibiting it (Levi and Schibler 2007). In vitro experiments have demonstrated that individual cells may oscillate with different periods, amplitudes, and phases in the absence of external synchronizers. The central pacemaker sends physiological signals to the peripheral organs to synchronize the cells. External synchronizers may also act independently from the central pacemaker, as for instance, meal timing modifies the systemic metabolic cues such as insulin or glucagon levels and impacts on local energy metabolism.

Circadian Rhythms of Key Intracellular Pathways

The CTS exerts multilevel controls on peripheral organs inducing 24 h-rhythms in major intracellular pathways governing cell fate. Recent genome wide studies have uncovered circadian regulation of general mechanisms such as chromatin remodeling, transcription, or translation (Takahashi 2017). As a result, more than 40% of the 20,000 protein-coding genes display circadian expression in at least 1 out of 12 mouse organs (Zhang et al. 2014; Robles et al. 2017). In baboons, approximately 80% of the detected protein-coding genes exhibited 24 h-rhythms in their

mRNA expression in at least one of the 64 studied tissues (Mure et al. 2018). These 24 h-rhythms in gene and protein expression translate into circadian variations of key intracellular pathways driving cellular processes such as energy metabolism, proliferation, or cell death (Fig. 2). In particular, extensive experimental and mathematical works have highlighted that the circadian clock and the cell cycle machinery are dynamically coupled through a robust phase locking mechanism in dividing cells involving both gene transcriptional control and direct protein–protein interactions (Ballesta et al. 2017). The 2015 Nobel Prize winner Aziz Sancar also evidenced daily variations in the Nucleotide Excision Repair pathway which is involved in repairing DNA damage caused by the exposure to irradiation or to various anticancer agents (Sancar et al. 2015).

Circadian Rhythms of Physiological Functions Governing Drug Absorption, Distribution, Metabolism, and Excretion (ADME)

The circadian organization of the body has great implications for drug response. Indeed, most physiological functions of the organism – including processes of drug Absorption, Distribution, Metabolism, and Elimination (ADME) – display 24 h-rhythms with differences of several folds between minimum and maximum activities. Daily variations have been demonstrated in laboratory animals and in humans for: gastric pH, gastric and small intestinal motility; plasma proteins levels, circulating blood cells and their membrane properties, blood flows though the main organs; liver metabolism, bile volume, and salt excretion; renal functions and urinary output (Levi and Schibler 2007). At the molecular level, numerous enzymes display circadian rhythms in their protein level and activity including phase I and phase II metabolism enzymes and phase III transporters (Bicker et al. 2020). In particular, the efflux pump P-glycoprotein (Abcb1), which is involved in the transport of many xenobiotics, display circadian rhythms in its hepatic and intestinal activity that vary according to sex and to feeding patterns (Bicker et al. 2020).

Inter-Individual Variabilities in Circadian Rhythms

Efforts have been made to monitor the CTS in individuals to decipher intersubject variabilities. Historically, questionnaires assessing diurnal preferences have been used to identify chronotypes and have demonstrated large interindividual variabilities. For instance, the time of midsleep on free days was equal to 4 a.m. local time on average and ranged from 11 p.m. to 11 a.m. in a population of 221,480 individuals from the Munich Chronotype Questionnaire database (Roenneberg et al. 2019). The mean value of the distribution of midsleep time is different with age, shifting later during adolescence, showing a peak around 19 years, and shifting earlier thereafter. Sex-related differences are also known as, on average, women go to bed earlier and get more total sleep than men (Bailey and Silver 2014). A large recent study in a US-based population revealed that men are typically later chronotypes than women before 40, but earlier types after 40 (Roenneberg et al. 2019).

However, such chronotype classification based on questionnaires may not precisely correlate with the underlying physiology and more molecular biomarkers have been investigated. The study of clock gene polymorphisms has been useful yet with limited results. For instance, PER3 polymorphisms have been associated with diurnal preferences (Hida et al. 2014). Next, melatonin is a hormone that is produced by the pineal gland with a strong circadian rhythms peaking at night. It can easily be measured either in the saliva or in the plasma of individuals. The time of Dim Light Melatonin Onset (DLMO) is considered as a relevant biomarker of the central clock. To measure it, the individual is subjected to dim light (approx. 10 lux) for few hours and blood samples are then collected over at least 12 h to assess melatonin plasma level and determine its onset time. This physiological measurement evidenced natural intra- and interindividual variability of internal time. In particular, sex differences in melatonin rhythms have been reported as women have a larger melatonin amplitude than men as well as an earlier onset (Bailey and Silver 2014). However, DMLO assessment requires dedicated

facilities and patient hospitalization which may not be amenable for everyday clinical practice.

Lately, the use of wearables has allowed to continuously monitor circadian biomarkers in individuals over several consecutive days in daily routine. When combined with suitable computer analysis techniques, wearable devices constitute promising tools for extracting insight from real-time monitoring of body rhythms (e.g., rest-activity, heart rate, skin temperature, . . .) and of external cues such as light. Rest-activity and skin surface temperature assessment has revealed up to 12 h intersubject differences regarding the circadian maxima of physical activity or skin temperature (Ballesta et al. 2017). The recording of rest-activity, position, and thoracic skin temperature of 55 healthy volunteers and 12 cancer patients of the InCasa study – named by the EU Commission as "one of the Top 25 influential projects in Information and Communication Technologies for Active and Healthy Ageing" – revealed that all participants displayed 24 h-rhythm in their rest-activity with maxima occurring from 12:09 to 20:25 (Komarzynski et al. 2018). The period of the temperature rhythm was around 24 h for only 51 out of 67 subjects, and around 12 h for the 13 others with maximum located at night for the majority of people, but during daytime for 18 out of 67 participants. Differences according to sex have also been found in between participants.

Efforts have also been made to assess peripheral clocks from patients' samples. In vitro analysis of skin fibroblasts or hair keratocytes isolated from individuals and subsequently cultured in vitro provided insights into the intersubject variability of the molecular clock although the relevance of such ex vivo experiments to predict the in vivo timing remains unclear (Levi and Schibler 2007).

Clock Disruption and Pathologies

Dysfunction of the CTS due to genetic alterations may be associated to various pathologies as, for instance, mutations in Per2 or Per3 clock genes are linked to sleep disorders. On the other hand, circadian disruption due to the exposure of mistimed environmental cues can be detrimental for health. Disruption of the CTS may occur for various reasons including sedentary lifestyle; mistimed eating patterns or unbalanced diet; suboptimal light-dark cycles including exposure to light at night; or shift work which implies work schedule changes on a week basis (Hatori et al. 2017; Sulli et al. 2018a). A well-known disruption of the CTS is caused by changing of time zones which induces jet lag usually associated to minor symptoms such as fatigue or dizziness. However, CTS disruption may be linked to the appearance of more severe pathologies as it is associated to a higher incidence of cancer, cardiovascular diseases, or metabolic disorders such as obesity or diabetes (Maury 2019; Ballesta et al. 2017). In particular, shift workers such as flying attendants or hospital nurses experience higher risk of sleep disorders, heart disease, respiratory disorders, and cancers (Sulli et al. 2018a).

Next, pathologies themselves may disrupt the internal timing system. Indeed, approximately 50% of cancer patients present disrupted circadian rhythms which are correlated to poor quality of life and overall survival (Ballesta et al. 2017). Furthermore, tumor cells often present disrupted circadian rhythms, including mutations of core clock genes, which has become a hallmark of cancer (Levi and Schibler 2007; Ye et al. 2018). This escape from the circadian control allows for increased proliferation (Levi et al. 2010) and may be associated with a decreased sensitivity to anticancer drugs (Ballesta et al. 2017). Tumor clock gene mutations or deregulated expression are associated with poorer patient survival in several cancer types including breast and renal cancers (Ye et al. 2018).

Pharmacological Intervention

The circadian control of the organism physiological functions has great implications for pharmacotherapies. First, the CTS itself can be seen as a target to pharmacological intervention in order to restore the Clock. Indeed, fighting against CTS disruption may be an indirect way to treat other pathologies which are under its control. On the other hand, both the efficacy and side effects of many drugs critically vary according to

administration timing over the 24 h span, to an extent which may be comparable to dose modifications. The concepts of chronoefficacy and chronotoxicity then relate to circadian rhythms in drug activity on diseased or healthy tissues respectively. Drug pharmacokinetics-pharmacodynamics (PK-PD) may vary as a function of dosing time, as shown for several hundreds of medications in laboratory animals and in patients (Levi et al. 2010). This may partly explain why systemic drug exposure after classical drug administration which does not account for circadian timing can vary by more than ten-fold in individual patients, despite dose adjustment to body weight or surface area. Chronotherapy relies on the optimization of drug timing based on the patient circadian rhythms to increase treatment efficacy and decrease side effects. It has been successful for several pathologies, yet with the challenge of inter-patient variability (Ballesta et al. 2017). However, it is still associated with technological and methodological challenges so that less than 1% of all reported clinical trials currently stipulate the time of the day.

Intervention to Restore Normal CTS Functions

The CTS in itself can be considered as a target for pharmacotherapies to restore normal circadian rhythms as an indirect treatment for pathologies affecting clock-controlled functions (Sulli et al. 2018a). Current strategies to restore normal circadian rhythms usually combine behavioral and pharmacological interventions.

Light – and in particular blue light – is considered as one of the stronger external cues affecting the CTS. Thus, clinicians have designed behavioral interventions jointly aiming to decrease evening light exposure and increase daytime light exposure. This has led to recommendations to avoid mistimed blue light exposure by limiting access to screens (phones, computers, . . .) before the resting phase for instance. In addition, bright light therapies using dedicated lamps can be used to increase light exposure at particular hours of the daytime and thus restore normal rhythms. For instance, bright light therapy is used to manage Delayed Sleep Phase Syndrome, a condition which shifts the normal sleeping pattern outside of what is considered the social norm.

Regarding pharmacological intervention, melatonin administration is now recognized as a possible treatment for CTS disruption. Oral administration of slow-release formulation of melatonin at bed time mimics natural shortens sleep onset latency defined as the amount of time it takes to go from being fully awake to sleeping. Hence, such therapies primarily treat sleep problems, which may indirectly improve other aspects of the daily rhythms leading to a better quality of life.

Time-restricted eating limiting the duration and circadian interval of food intake has emerged as another behavioral intervention to strengthen circadian rhythms in peripheral organs, even in the absence of a functioning circadian clock. Animal studies suggest that meal timing may improve brain health in Huntington's disease and reduce tumor progression, although clinical trials are needed to confirm these findings in patients and design optimize eating cycles (Ballesta et al. 2017; Sulli et al. 2018a).

Chronotherapies of Selected Pathologies

Rheumatology

Rheumatology diseases involve the immune system which is under the control of the CTS. As a result, the intensity of symptoms of such conditions including rheumatoid arthritis and osteoarthritis display 24 h-variations. The symptoms of rheumatoid arthritis, which is an inflammatory disease associated with joint pain and stiffness, tend to be more severe in the morning. Such rhythms have been correlated with the night increase in circulating proinflammatory cytokines levels that achieve their maximum value in the early morning. This result led to the development of modified-release formulations of the glucocorticoid prednisone in order to achieve drug exposure starting at the middle of the night span, after an administration at bedtime. Clinical trials in rheumatoid arthritis patients confirmed a better pain and stiffness control of modified-release prednisone as compared with the conventional prednisone formulation taken in the morning.

Other disease-modifying drugs such as methotrexate were also shown to present fewer side effects and be more effective in rheumatoid arthritis patients, following evening dosing (Ballesta et al. 2017).

Cardiovascular Pathologies

The cardiovascular system presents robust circadian rhythms at multiple levels including heart rate, blood pressure as well as clock gene expression in the heart and the arteries (Portaluppi and Hermida 2007; Smolensky et al. 2016). As a consequence, the occurrence of many cardiac events, such as myocardial infarction, or sudden cardiac death displays a circadian rhythm with their occurrence being greater in the morning. Next, side effects of heart surgery were lower during the afternoon as compared to morning surgery (Montaigne et al. 2018). Various drugs against cardiovascular pathologies may also present chronoefficacy rhythms. Indeed, the beta-blocker talinolol is a very good substrate of the efflux transporter P-glycoprotein which presents a circadian activity thus inducing circadian rhythm in talinolol pharmacokinetics. Next, most drugs against hypertension achieved both greater improvement of blood pressure and lower risks of cardiovascular events, after their oral intake at bedtime as compared with morning administration (Smolensky et al. 2016).

Anticancer Chronotherapies

Among the therapeutics strategies which have proven a benefit for cancer patients in the past decades, **cancer chronotherapy** – that is adjusting antitumor drug delivery to the patient's 24-h biological rhythms – is considered as very promising. The temporal differences between tumor tissues and healthy organs constitute an important domain of host-tumor differences and offer possibilities to specifically target times of best tolerability and/or best efficacy which coincides in animal models (Levi et al. 2010). Clinical trials in colorectal cancer patients have shown that proper chemotherapy timing decreases the incidence of severe toxicities by up to five-fold and nearly doubles efficacy (Levi et al. 2010). However, a large impact of sex on optimal timing has been demonstrated both in mouse and human studies (Ballesta et al. 2017; Innominato et al. 2020), which highlighted the need for personalized chronotherapies.

Such precision medicine approach relies on a mechanistic understanding of circadian determinants of drug chronoefficacy, which requires the development of dedicated technological and mathematical tools. This work has been initiated for irinotecan, an anticancer drug active against digestive malignancies. The molecular basis of the chronotoxicity of irinotecan was deciphered though a systems pharmacology study which concluded that irinotecan chronotoxicity rhythm mainly originated from the daily variations of both the drug activation enzymes (carboxylesterases) and the detoxification enzymes (UGT1As). This provided a preclinical argument to further investigate those two protein families as possible clinical biomarkers for chronotherapy individualization (Ballesta et al. 2017).

Another clock-related anticancer strategy that has recently appeared consists in directly targeting the clock of tumor cells as the circadian clock is a natural regulator of key cellular processes. Two agonists of the clock genes REV-ERBs – SR9009 and SR9011 – have been proven to be efficient against cancer cells, even in the absence of functional p53 or under hypoxic conditions, while having no effect on normal tissues (Sulli et al. 2018b). These findings open the way to new anticancer strategies consisting of pharmacological modulation of circadian regulators.

Anion channels; Chloride channels

Definition

Chloride channels are membrane proteins that allow for the passive flow of anions across

biological membranes. As chloride is the most abundant anion under physiological conditions, these channels are often called chloride channels instead of anion channels, even though other anions (such as iodide, nitrate, bicarbonate, or larger organic anions) may also permeate them. A major family of chloride channels, the CLC proteins, comprises Cl^- channels as well as Cl^-/H^+-exchangers. Both will be reviewed here.

Basic Characteristics

Chloride channels are membrane proteins with several transmembrane domains, which form a pore that allows for the passive flow of anions along their electrochemical gradient. Like other channels, chloride channels can be opened or closed by a process called gating. Gating can be influenced by several factors, e.g., by the transmembrane voltage in voltage-gated chloride channels, by intracellular Ca^{2+} in Ca^{2+}-activated chloride channels, by extracellular ligands such as glycine or GABA as in ligand-gated chloride channels, by cAMP-dependent phosphorylation, by cell swelling, or by extracellular acidification. Chloride channels may be present in the plasma membrane or in the membranes of intracellular organelles. Several intracellular CLC proteins that were previously thought to be Cl^- channels turned out to rather be electrogenic Cl^-/H^+ exchangers. They will be included in this entry.

Classification of Chloride Channels

Chloride channels can be classified by their biophysical characteristics (e.g., single-channel conductance), regulation (e.g., voltage-dependent, ligand-gated, swelling-activated, Ca^{2+}-activated), or by their sequence (gene families).

Gene Families of Chloride Channels

Chloride channels are highly heterogeneous, with several phylogenetically unrelated genes or gene families encoding anion-selective channel proteins with strikingly different functional properties and physiological roles. The following molecular classes of mammalian chloride channels are well established: CLC chloride channels and Cl^-/H^+ exchangers, ligand-gated chloride channels (GABA and glycine receptors), TMEM16/ANO Ca^{2+}-activated chloride channels and phospholipid scramblases, the cystic fibrosis transmembrane conductance regulator CFTR, bestrophin Ca^{2+}-activated chloride channels, LRRC8/VRAC volume-regulated anion channels, and TMEM206/ASOR acid-activated anion channels.

CLC chloride channels form a large gene family with members in bacteria, archaea, and eukaryotes. Many CLCs gate in a voltage-dependent manner. In mammals, there are nine different genes encoding CLC proteins. While bacterial CLC proteins appear to exclusively function as Cl^-/H^+ exchangers, roughly half of vertebrate CLCs are Cl^-/H^+ exchangers that reside mainly in intracellular membranes; the other half are plasma membrane Cl^- channels. They function as dimers, with each monomer having its own pore ("double-barreled" channels). Some CLC channels or transporters have accessory β-subunits.

$GABA_A$ and glycine receptors are ligand-gated chloride channels that belong to the superfamily of pentameric ligand-gated channels or Cys-loop receptors which also include cation-selective channels (e.g., nicotinic acetylcholine receptors, $5\text{-}HT_3$ receptors). Ligand-gated chloride channels are involved in synaptic transmission and mostly exert inhibitory signals in the adult nervous system due to the direction of the chloride concentration gradient. These channels are important pharmacological targets, but will not be discussed in detail here (refer to the following entries: ▶ GABAergic System, ▶ Glycine Receptors).

TMEM16/ANO is a large family of proteins that mediate Ca^{2+}-activated phospholipid scrambling and in some cases ionic currents in the plasma membrane or membranes of intracellular organelles. A subset of TMEM16 proteins comprises selective plasma membrane chloride channels activated by intracellular Ca^{2+} which play roles in a wide variety of physiological processes. Similar to the unrelated CLC channels, TMEM16 proteins form dimers with one ion permeation pathway or scrambling domain per monomer.

The cystic fibrosis transmembrane conductance regulator (CFTR) is the only member of the large ABC-transporter gene family known to function as a chloride channel. Mutations in CFTR underlie **cystic fibrosis**, a potentially lethal disease affecting the lungs and other tissues such as the intestine and kidney where CFTR-mediated chloride excretion or resorption is important. Reflecting its heritage as a transporter, the permeation pathway of CFTR is formed within a monomer.

Bestrophins are a comparatively understudied family of plasma membrane Ca^{2+}-activated chloride channels, comprising four members (Best1–4). Mutations in Best1 cause macular degeneration, but little is known about the other isoforms. Bestrophins form pentameric channels.

LRRC8 volume-regulated anion channels (*VRACs*) are encoded by a gene family encompassing five members (LRRC8A-E) found in vertebrates. These ubiquitously expressed channels mediate the efflux of chloride and small organic molecules upon cell swelling, thereby facilitating cell volume regulation. The finding that VRACs also transport other substrates including drugs and signaling molecules such as neurotransmitters suggests their involvement in other physiological and pathological processes beyond volume regulation. LRRC8 proteins assemble as hetero-hexamers around a central pore.

TMEM206/ASOR acid-activated anion channels are the most recent addition to the known chloride channels. They appear to be ubiquitously expressed in all vertebrate cells and play a role in acid-induced cell death. Further physiological functions of these enigmatic channels remain to be discovered. The architecture of TMEM206 channels is not yet clear, but they may assemble to trimers akin to the structurally similar ENaC/degenerin or ASIC cation channels.

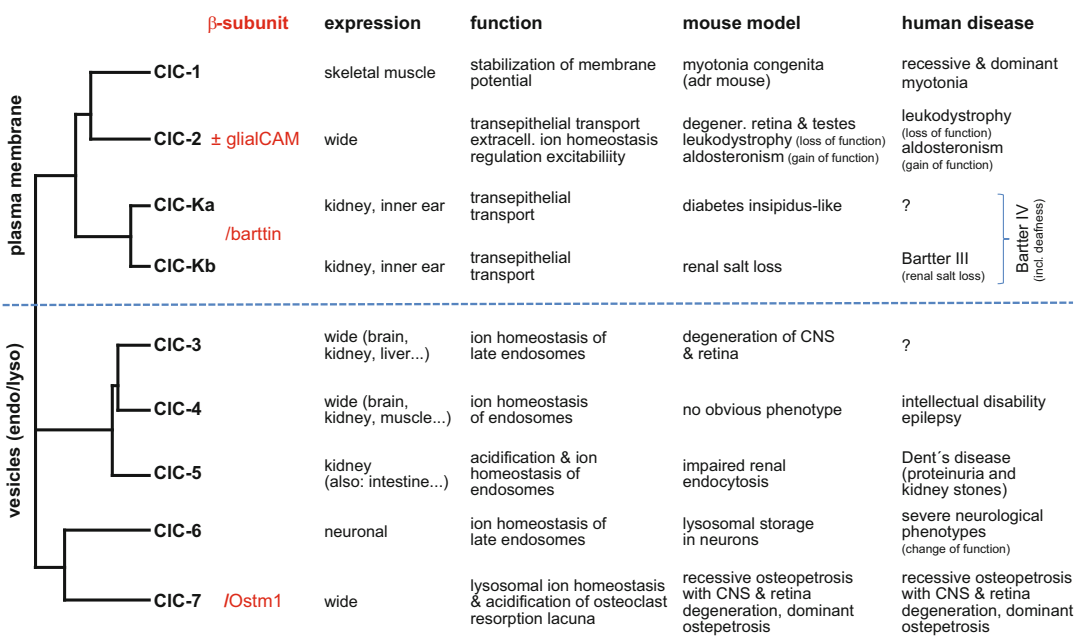
It has to be noted that several other transport proteins beyond those listed here have been shown to conduct chloride to some extent. For instance, pannexins which serve as a major pathway for cellular ATP release appear to be mostly anion-selective. Likewise, several members of the large SLC family of solute carriers can mediate passive chloride fluxes, including excitatory amino acid transporters (EAATs) and the prostaglandin transporter SLCO2A1, which has recently been reported to mediate the long-elusive Maxi-Cl currents.

The CLC Family of Chloride Channels and Transporters in Mammals

There are nine different CLC isoforms in mammals; the physiological roles of which are apparent from human diseases or mouse models in which these genes are disrupted (Jentsch and Pusch 2018). Based on homology, they can be classed into three branches (Fig. 1). The first branch includes the plasma membrane chloride channels ClC-1, ClC-2, ClC-Ka, and ClC-Kb.

ClC-1 is a skeletal muscle chloride channel, mutations in which lead to **myotonia**, a muscle stiffness that is associated with a hyperexcitability of the muscle plasma membrane. Thus, the high resting chloride conductance in muscle is necessary for its electrical stability. ClC-1 shows a distinct voltage-dependence and is activated by depolarization.

ClC-2 is a broadly expressed chloride channel that mediates an inwardly rectifying current slowly activated by hyperpolarization. It can also be activated by cell swelling and by moderate extracellular acidification. In mice, disruption of ClC-2 leads to leukodystrophy, infertility, and blindness. Likewise, ClC-2 loss-of-function mutations in humans cause leukodystrophy, a form of neurodegeneration restricted to the white matter of the brain, and were associated with infertility and visual impairments in few patients. The observed tissue degeneration may be caused by a defective regulation of extracellular ion homeostasis. In glial cells, ClC-2 associates with the cell adhesion molecule GlialCAM, which stabilizes and directs ClC-2 to cell-cell contacts and increases its current amplitudes by virtually abolishing its voltage-dependent gating. Loss of GlialCAM, disruption of its interaction with ClC-2, or loss of MLC1, another interaction partner, also led to leukodystrophy in patients and mouse models. Gain-of-function mutations in ClC-2 have recently been shown to cause primary aldosteronism in mice and man by causing a depolarization of adrenal glomerulosa cells.



Cl^- Channels and Cl^-/H^+ Exchangers, Fig. 1 The family of mammalian CLCs and associated proteins. In mammals, three homology branches can be identified (shown in dendrogram at left). Whereas members of the first branch function as plasma membrane voltage-gated anion channels, proteins of the two other branches are rather Cl^-/H^+ exchangers that reside predominantly on endosomes and lysosomes. ClC-1 and the two ClC-K isoforms show highly specific tissue expression patterns, whereas ClC-2 and the vesicular Cl^-/H^+ exchangers (with the exception of ClC-5/6) are widely and probably even ubiquitously expressed across tissues. Both ClC-K isoforms and ClC-7 need specific auxiliary proteins (β-subunits) for functional expression and protein stability. ClC-2 can function without a β-subunit but associates with the cell adhesion molecule GlialCAM in glia, which changes its localization, stability, and biophysical properties. These differential requirements for ancillary proteins are symbolized by "/" and "±", respectively. The main phenotypes of *Clcn* mouse models or human diseases caused by *CLCN* mutations are indicated. The loss of the common β-subunit barttin, or the loss of both ClC-K isoforms, leads to a combination of severe renal salt loss and congenital deafness, which in humans is known as Bartter syndrome type IV

ClC-Ka and ClC-Kb are highly homologous epithelial chloride channels that require the β-subunit barttin for proper function. Both channels are expressed specifically in different parts of the kidney and the inner ear, where they facilitate transepithelial chloride transport. Mutations in ClC-Kb lead to a form of **Bartter syndrome** (type III), a disease associated with severe renal salt loss. The disruption of the mouse ortholog of ClC-Ka causes a syndrome resembling nephrogenic diabetes insipidus. Mutations in the β-subunit barttin entail the loss-of-function of both, ClC-Ka and ClC-Kb, resulting in the more severe Bartter syndrome type IV with deafness. Considering the important role of the ClC-K/barttin channels in renal salt and fluid reabsorption, they are attractive candidate targets for the development of alternative diuretics that may also be useful in conditions of renal failure.

In contrast to the CLC channels, the two other branches of the CLC family including ClC-3 through ClC-7 are Cl^-/H^+ exchangers that reside in intracellular membranes of the endocytic pathway. Their function on those vesicles is presumably to facilitate H^+-ATPase-mediated acidification by providing an electrical shunt. Somewhat counterintuitively, this can be achieved more efficiently by a Cl^-/H^+ exchanger than by a pure chloride channel. However, alterations in endolysosomal pH were not consistently observed in knockout mouse models for intracellular CLCs and are absent in some (e.g., ClC-7). Cl^-/H^+

exchangers accumulate intravesicular chloride, resulting in an inside-negative electrical potential, both of which may be required for the biological function of endocytic organelles. The antiport stoichiometry of most CLC exchangers has been shown to be $2Cl^-:1H^+$.

The second CLC homology branch includes ClC-3 through ClC-5, which are ~80% identical (Fig. 1). The expression of ClC-3 and ClC-4 appears to be broad, while ClC-5 is predominantly expressed in the kidney.

ClC-3 mainly localizes to endosomes but can also be detected in a subset of synaptic vesicles. Surprisingly, the disruption of *Clcn3* in mice resulted in a drastic degeneration of the hippocampus and the retina, but the underlying mechanism remained obscure.

Even less is known about ClC-4, which also appears to be present in endosomal compartments. *Clcn4*$^{-/-}$ mice display no obvious phenotype, but several loss-of-function mutations in *CLCN4* have been linked to syndromic intellectual disability associated with behavior and seizure disorders in humans. As for ClC-3, the molecular mechanism remains enigmatic. A recent study suggests intimate functional interactions between ClC-4 and ClC-3, which form heteromers in which ClC-3 stabilizes ClC-4. ClC-4 can partially compensate for loss of ClC-3 activity, as illustrated by the more severe phenotype of double knockout animals.

ClC-5 is predominantly expressed in the kidney proximal tubule, where it localizes to endosomes. Disruption of ClC-5 leads to a defect in endocytosis in mouse models as well as in human Dent's disease, a disorder associated with proteinuria and kidney stones. The deficiency in endocytosis leads to secondary changes in calciotropic hormones, resulting in tertiary changes such as hyperphosphaturia, hypercalciuria, and the formation of kidney stones.

ClC-6 and ClC-7 define the third branch of the CLC family (Fig. 1). These proteins are only about 45% identical to each other. Whereas ClC-7 is very broadly expressed, the ClC-6 protein seems to be restricted to the nervous system.

ClC-6 is a late endosomal Cl^-/H^+ exchanger. Its disruption in mice led to mild neuronal lysosomal storage disease, whereas *CLCN6* missense mutations were found in patients with developmental delay and severe neurological symptoms.

ClC-7 is expressed in late endosomes and lysosomes. It needs Ostm1 as β-subunit. The disruption of either ClC-7 or Ostm1 in mice and man leads to severe osteopetrosis, retinal degeneration, and lysosomal storage disease. ClC-7/Ostm1 is highly expressed in osteoclasts, which degrade calcified bone in strongly acidic lysosome-derived structures called resorption lacunae. In mice lacking ClC-7, resorption lacunae fail to form adequately. Accordingly, it was assumed that ClC-7/Ostm1 is required for efficient acidification of lysosomes and the resorption lacuna. However, lysosomal pH was found to be unchanged in several ClC-7/Ostm1 mouse models. Lysosomal pathologies may instead be caused by an observed reduction in lysosomal $[Cl^-]$. Failure to acidify the resorption lacuna may be explained by perturbed formation of the acid-secreting ruffled border by lysosomal exocytosis. ClC-7 may be an interesting target for the treatment of osteoporosis as its partial inhibition might increase bone mass. This notion is indirectly supported by the observation that patients that are heterozygous for dominant negative ClC-7 mutations (a situation expected to lead only to a partial inhibition of ClC-7) present with a milder form of osteopetrosis in which retinal degeneration is absent.

TMEM16/ANO Ca^{2+}-activated Chloride Channels

The *TMEM16/ANO* gene family comprises ten members in humans (TMEM16A, B, C, D, E, F, G, H, J, and K), of which only two encode bona fide plasma membrane chloride channels activated by intracellular Ca^{2+} (TMEM16A and B). The other family members are thought to be Ca^{2+}-activated phospholipid scramblases, which may also mediate ionic currents of varying selectivity (Falzone et al. 2018). These will not be discussed here. TMEM16A and B differ in their expression profiles and biophysical properties, with TMEM16A being much more sensitive to Ca^{2+}. Whereas TMEM16A is expressed a variety of

cells types including epithelial, neuronal, and smooth muscle cells, TMEM16B expression appears to be more restricted to neurons.

TMEM16A has been shown to be essential for epithelial fluid secretion, e.g., in the salivary gland. In respiratory and digestive organs, it may support secretory functions in conjunction with CFTR, making it an interesting alternative drug target for cystic fibrosis. TMEM16A is also involved in contractibility of vascular smooth muscle cells and plays a role in blood pressure regulation. In interstitial cells of Cajal, TMEM16A is responsible for the generation of slow wave activity, which serves as pacemaker for stomach peristalsis. Curiously, TMEM16A is also upregulated in many cancer types and has been suggested as a diagnostic marker.

In neuronal cells, Ca^{2+}-activated chloride channels may serve excitatory or inhibitory roles, depending on the intracellular chloride concentration. TMEM16A, which is steeply temperature-dependent, has been suggested to be responsible for sensing heat in a subset of nociceptive neurons. Expression of both, TMEM16A or B, has been demonstrated in visual and olfactory systems. TMEM16A amplifies signal transduction in olfactory neurons, without, however, having a significant effect on olfaction in mice. Although expression of TMEM16B in brain is generally very low, some studies have reported neuromodulatory roles of TMEM16B in several brain regions including amygdala, lateral septum, and medulla oblongata.

CFTR

CFTR is considered a "broken" ABC-transporter as it is the only channel in this protein family, which comprises ATP-dependent pumps for a large variety of substrates. It is activated by the cAMP-dependent protein kinase A, which phosphorylates CFTR. Phosphorylated CFTR is gated by ATP binding. The channel is expressed in many epithelia, e.g., in apical membranes in the lung, pancreas, and intestine where it is essential for fluid secretion. Loss-of-function mutations in CFTR underlie cystic fibrosis, a potentially lethal and fairly common (~1 in 3,000) disease with impaired production of mucus, digestive fluids, and sweat. In addition to working as a chloride channel, several other functions such as the regulation of other ion channels or being a receptor for bacteria have been attributed to CFTR.

Bestrophins

Bestrophins represent another family of Ca^{2+}-activated chloride channels (Hartzell et al. 2008). There are four different bestrophin isoforms (Best1–4) in humans. Mutations in Best1 cause vitelliform macular dystrophy (**Best's disease**), but the underlying molecular mechanism is still not fully understood. A moderately wide expression pattern of Best1 may hint at physiological roles beyond those in the retina. Little is known about Best2–4 expression and function. All four human isoforms induce chloride currents when expressed heterologously. Although they show a dependence on intracellular calcium, their biophysical properties differ from Ca^{2+}-activated chloride channels of the unrelated TMEM16 family. Mutations in Best1 altered biophysical properties of currents induced by overexpression, lending support to the hypothesis that bestrophins themselves are Cl^- channels. This was confirmed by recent high-resolution structures of Best1.

LRRC8/VRACs: Volume-Regulated Anion Channels

VRACs (volume regulated anion channels) are a relatively recent addition to the known chloride channel proteins, having been identified as LRRC8 (leucine-rich repeat 8) heteromers in 2014 (Jentsch 2016). VRACs are found in all vertebrate cell types, appear mostly inactive under iso-osmotic conditions, and open upon cell swelling or a reduction in intracellular osmolarity. Extrusion of chloride and organic osmolytes through VRACs drives water loss and volume regulation in swollen cells. Functional VRACs are formed when the obligatory subunit LRRC8A heteromerizes in hexameric complexes with at least one of the other members of the protein family (LRRC8B-E), which determine permeation properties of the resulting channels. For instance, channels containing LRRC8D are permeable for organic compounds such as taurine, lysine or the neurotransmitters GABA, and

glutamate. The stoichiometry of LRRC8 heteromerization is poorly understood but may be quite flexible and thus enable the formation of a large variety of VRACs with different substrate specificities. Disruption of LRRC8A in mice leads to high pre- and postnatal lethality and tissue abnormalities in many organs. LRRC8A-dependent chloride currents have been shown to be involved in apoptosis induction, insulin release, adipocyte function, and cell volume regulation in developing spermatozoa. Besides their roles based on chloride and osmolyte extrusion upon cell swelling, the transport of signaling molecules and drugs by VRACs implicates these channels in several other (patho)physiological processes. For instance, commonly used platin-based anti-cancer drugs enter cells in part through LRRC8D-containing VRACs. By conducting the second messenger cGAMP (cyclic-GMP-AMP), LRRC8/VRAC channels also have a role in innate immunity. Astrocytic VRACs mediate tonic non-vesicular glutamate release, thereby tuning glutamatergic synaptic transmission. Mice lacking LRRC8A in astrocytes exhibited learning and memory deficiencies but were protected against excitotoxic cell death in a cerebral stroke model, corroborating earlier findings that (unspecific) VRAC inhibitors improved outcomes in such models. VRACs were reported to mediate pulsatile GABA secretion from pancreatic beta cells, an important autocrine and paracrine process regulating homeostasis in islets of Langerhans. However, it is unclear why release through VRACs should be pulsatile.

TMEM206/ASOR Acid Activated Anion Channels

A chloride current induced by strong extracellular acidification below pH 5.5 has been described to be universally present in mammalian cells. The corresponding channel was termed ASOR (acid-sensitive outward rectifier) or PAORAC (proton-activated outwardly rectifying anion channel), but its molecular correlate has only been identified in 2019 by two independent groups (Ullrich et al. 2019; Yang et al. 2019). TMEM206 (also named PAC for proton-activated chloride; or PACC1 for proton-activated chloride channel 1) is a ubiquitously expressed membrane protein that is necessary and sufficient to form functional ASOR channels. Disruption of TMEM206 protects cells against acid-induced cell death, which may occur under ischemic conditions. Accordingly, mice lacking TMEM206 were partially protected in a model for ischemic cerebral stroke. However, the physiological functions of TMEM206/ASOR remain unresolved to date.

Drugs

The pharmacology of chloride channels is still poorly developed. Specific and highly useful inhibitors or modulators (e.g., strychnine, picrotoxin, diazepams) are only available for ligand-gated chloride channels, but these are covered in a different chapter (see ▶ GABAergic System and ▶ Glycine Receptors). Another exception in this regard is CFTR, which has been the target of intense drug development to enable treatment of cystic fibrosis. Depending on the underlying mutation, drugs with different mechanisms of action may be used, including activators facilitating channel opening (e.g., ivacaftor), potentiators aiding correct folding and trafficking (e.g., lumacaftor, tezacaftor, elexacaftor), and compounds termed amplifiers which increase CFTR mRNA levels (e.g., nesolicaftor).

For other targets, there are several "chloride channel inhibitors" such as the stilbene disulfonates DIDS and SITS, 9-anthracene-carboxylic acid (9-AC), arylaminobenzoates such as DPC and NPPB, niflumic acid and derivatives, sulfonylureas, and zinc and cadmium. All of these, however, are not particularly specific. Several of them (e.g., DIDS) inhibit many chloride channels only partially even at millimolar concentrations and have effects on other types of transport proteins. CLC channels are quite insensitive to DIDS but can often be inhibited by Zn^{2+} or Cd^{2+} in the submillimolar range. 9-AC is a quite specific inhibitor for the muscle channel ClC-1, which can also be inhibited by clofibric acid derivatives. Inhibitors with affinities below 10 μM are

available for ClC-K channels, and inhibitors with nanomolar affinities are being developed for ClC-2.

Lubiprostone, a drug used for treating obstipation, has been claimed to be an activator of ClC-2. This was based on a paper showing activation by lubiprostone of currents thought to represent ClC-2. These currents, however, differ starkly from typical ClC-2 currents. Furthermore, ClC-2 is located in basolateral membranes of the intestine. This localization is incompatible with the hypothesis that its activation increases intestinal chloride and fluid secretion. Thus, the claim that lubiprostone is a chloride channel activator must be subject to considerable doubt. Being a prostone, it might rather affect ion transport by stimulating prostaglandin receptors.

TMEM16/ANO Ca^{2+}-activated chloride channels are sensitive to niflumic acid and derivatives, which also inhibit VRACs. More specific inhibitors of TMEM16A-mediated currents, such as T16Ainh-A01, CaCCinh-A01, and MONNA, have been developed. Activation of TMEM16A was proposed as an alternative strategy in cystic fibrosis therapy. Denufosol (INS37217) and duramycin (Moli-1901) have been employed to this end, but clinical trials have yielded disappointing results.

LRRC8/VRAC channels can be inhibited by tamoxifen, carbenoxolone, and DCPIB, all of which are quite unspecific. Likewise, no specific inhibitors of TMEM206/ASOR are available. However, these channels can be blocked by micromolar concentrations of pregnenolone sulfate. Development of potent and specific drugs targeting these channels may be beneficial for the acute treatment of ischemic stroke.

Connexin Hemichannels

Mathieu Vinken
Entity of In Vitro Toxicology and Dermato-Cosmetology, Department of Pharmaceutical and Pharmacological Sciences, Vrije Universiteit Brussel, Brussels, Belgium

Synonyms

Gap junction hemichannels

Definition

Homeostasis is controlled by a myriad of extracellular, intracellular, and intercellular communication mechanisms. Typically, extracellular signals trigger intracellular signal transduction cascades. Several of these intracellular signals are subsequently propagated to adjacent cells. Such intercellular connections are formed by arrays of gap junctions. They are composed of two hemichannels of neighboring cells, which in turn are built up by six connexin (Cx) proteins (Fig. 1). More than 20 different connexin species have been identified. They are all designated based upon their molecular weight as predicted by cDNA sequencing and are expressed in a cell-type-specific way (Table 1). Among those, Cx43, with a molecular weight of 43 kDa, is the most widespread connexin species in vertebrate cells. Connexins share a similar structure consisting of four transmembrane domains, two extracellular loops, one cytosolic loop, one cytosolic carboxyl-terminal tail, and one cytosolic aminotail (Fig. 1) (Vinken 2015; Maes et al. 2015).

Gap junctions mediate the passive intercellular diffusion of small and hydrophilic molecules (Fig. 2). Numerous physiological processes are regulated by substances that are intercellularly exchanged via gap junctions, and hence gap junctional intercellular communication is considered as a key mechanism in the control of tissue homeostasis. In the last decade, it has become clear that connexin hemichannels also provide a pathway for communication independent of gap junctional intercellular communication, albeit between the intracellular compartment and the extracellular milieu. The messengers that are involved in this type of extracellular communication are, however, very similar to those exchanged through gap junctions (Fig. 2). Unlike gap junctions, connexin hemichannels are closed in physiological conditions. They only open up in stress conditions, and by doing so, they facilitate processes such as inflammation and cell death in plethora of diseases, including in the brain, spinal cord, heart, blood vessels, intestine, liver, pancreas, lungs, kidneys, skin, eyes, muscles, and bones (Willebrords et al. 2016; Decrock et al. 2009). This renders connexin hemichannels very

Gap junctions and connexin hemichannels provide a pathway for the passive flux of small and hydrophilic substances between two neighboring cells and between an individual cell and its extracellular environment, respectively

attractive pharmacological targets, as their pharmacological closure may counteract the clinical manifestation of many pathologies. However, clinical exploration in this area is currently impeded by the lack of specific inhibitors of connexin hemichannels. Indeed, the vast majority of the connexin hemichannel inhibitors also suppress other channel types, including gap junctions. An exception in this respect are a number of peptides that reproduce specific amino acid sequences in the primary structure of connexin proteins (Willebrords et al. 2017) (Fig. 3).

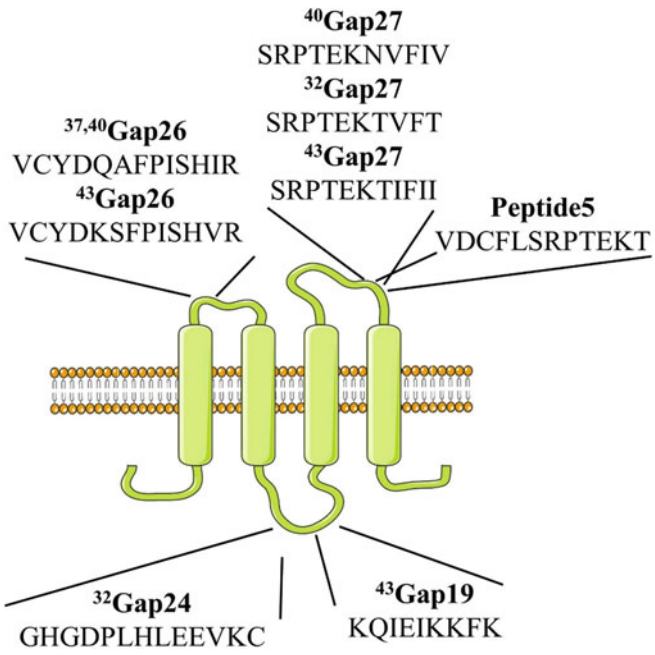
Basic Characteristics

Life Cycle

Most connexins are synthetized by membrane-bound ribosomes and co-translationally integrated into the endoplasmic reticulum, where six proteins oligomerize to form a connexin hemichannel. Connexin hemichannels packaged into vesicles are transported to the plasma membrane. They may remain uncoupled or dock with a connexin hemichannel of an adjacent cell, thereby creating a narrow extracellular space, a so-called 2–3 nm "gap." Connexin proteins usually display rapid turnover rates in comparison with other plasma membrane proteins. Both in vitro and in vivo, the half-lives of Cx26 and Cx32 have been found to be 2 and 3 h, respectively, whereas the turnover times of other integral membrane proteins generally range from 17 to 100 h. Upon degradation, gap junctions are internalized by one of the two opposing cells, resulting in the formation of "annular" gap junctions. These structures are further degraded by both lysosomes and proteasomes, although the precise degradation pathway depends on the identity of the connexin species and cell type (Vinken 2015; Maes et al. 2015).

Regulation

Short-term control of gap junction and connexin hemichannel opening is driven by a number of factors, including pH, transmembrane voltage,



Connexin Hemichannels, Fig. 3 *Connexin mimetic peptides*. Connexin mimetic peptides that inhibit connexin hemichannels reproduce amino acid sequences in the extracellular loop or cytoplasmic loop regions of connexin proteins

and calcium concentration. Posttranslational modifications, such as S-nitrosylation, sumoylation, and phosphorylation, also directly regulate their opening. Phosphorylation mainly occurs at the cytosolic carboxyl-terminal connexin tail. The regulation of gap junction and connexin hemichannel opening by phosphorylation is complex, as the outcome of this posttranslational modification depends on the nature of the kinase and connexin as well as on the cellular context. Furthermore, phosphorylation may have an opposing effect on gap junctions versus connexin hemichannels consisting of the same connexin species. Cx43 is a substrate for many kinases, including protein kinases A and C, members of the mitogen-activated protein kinase family, casein kinase 1, the cyclin-dependent kinase 1/cyclin B complex, and v-Src. Different from other connexins, shifts in electrophoretic mobility occur upon phosphorylation of Cx43. Usually, three bands appear during sodium dodecyl sulfate-polyacrylamide gel electrophoresis analysis, representing the fast-migrating non-phosphorylated Cx43 isoform and two slow-migrating phosphorylated Cx43 isoforms.

Long-term control of gap junction and connexin hemichannel opening involves regulation at the transcriptional level of connexin expression. The architecture of most connexin genes is simple, consisting of a first exon that harbors the 5′-untranslated region, which is separated by an intron of varying length from a second exon, bearing the complete coding sequence, and the 3′-untranslated region. Connexin gene promoters show binding affinity for several general transcription factors, including activator protein 1, Yin Yang 1, and specificity protein 1. In parallel, a number of cell-type-specific transcription factors control connexin gene transcription. In the last decade, epigenetic mechanisms, including histone acetylation and DNA methylation, have also joined in as master regulators of connexin expression (Vinken 2015; Maes et al. 2015).

Drugs

Peptides Targeting the Connexin Extracellular Loop

Given its ubiquitous presence in a wide spectrum of cells, most efforts to produce connexin mimetic peptides have been focused on Cx43. Among the first peptides were ^{43}Gap26 and ^{43}Gap27, which reproduce amino acid sequences in the first and

second extracellular loops of Cx43 (Fig. 3). These peptides are thought to interact with complementary sites within the extracellular loop regions of Cx43 of opposing connexin hemichannels and thereby to prevent their docking and hence the formation of gap junctions. In course of time, it has been found that they also affect channels consisting of Cx32, Cx40, and Cx37. In vitro, both ^{43}Gap26 and ^{43}Gap27 inhibit connexin hemichannel-mediated adenosine triphosphate release and dye uptake upon short exposure, while longer exposures also result in the suppression of the corresponding gap junction activity. Additionally, exposure of cells to ^{43}Gap27 may have effects on Cx43 phosphorylation, especially occurring at serine368, and therefore could influence Cx43 channel activity. Both peptides have been used extensively in studies of the immune system, vascular system, heart, lung, brain, skin, and liver. In order to generate more specific inhibitors, a modified Gap27 peptide, namely, ^{40}Gap27, was developed. This peptide incorporates a sequence in the second extracellular loop of Cx40 and has also proven useful in vascular tissues. The same was performed for a part of the second extracellular loop of Cx32, generating ^{32}Gap27 (Fig. 3), which showed inhibition of adenosine triphosphate release in primary hepatocytes and no effect on gap junction activity.

^{43}Gap26M is a modified version of ^{43}Gap26 that has an acylated aminoterminus and shows greater solubility and stability. ^{43}Gap26M significantly increased migration rates across scrapes in keratinocytes and fibroblasts by blocking gap junction functionality.

Peptide5 is a peptide that shifted five amino acids in aminoterminal direction compared to Gap27 (Fig. 3). It inhibits connexin hemichannels at low (5–10 μM) concentration, while equally inhibiting gap junctions at higher concentration (100 μM). In vitro, peptide5 has been used to study a variety of cellular processes, such as dynamic calcium signals, release of neurotransmitters as well as propagation of cell death. In vivo, peptide5 reduces tissue damage secondary to spinal cord injury and attenuates vascular permeability increase following retinal ischemia/reperfusion insult (Willebrords et al. 2017).

Peptides Targeting the Connexin Cytoplasmic Loop

The L2 peptide, corresponding to a sequence in the cytoplasmic loop moiety of Cx43, inhibits its connexin hemichannel opening without affecting gap junctions independent of time of exposure. Based on this observation, the hypothesis was raised that prevention of the interaction between the carboxyl-terminal tail and the cytoplasmic loop areas of Cx43 leads to connexin hemichannel closure, which means that this interaction is necessary for connexin hemichannel opening. By contrast, carboxyl-terminal tail-cytoplasmic loop interaction results in the closure of gap junctions. Indeed, physical binding of the carboxyl-terminal tail and the L2 region of Cx43 in the cytoplasmic loop induces a residual state with very low conductance.

It has been shown that Gap19, a synthetic nonapeptide derived from the cytoplasmic loop region of Cx43, inhibits its connexin hemichannel activity without influencing the corresponding gap junction activity over time. Connexin hemichannel inhibition is due to the binding of Gap19 to the carboxyl-terminal tail area of Cx43, thereby preventing intramolecular carboxyl-terminal tail-cytoplasmic loop interactions. By doing so, Gap19 was found to inhibit Cx43 hemichannels in Cx43-overexpressing C6 rat glioma cells, cultured primary mouse astrocytes, and murine hippocampal slices. Blocking Cx43 hemichannels has been recently investigated as a therapeutic intervention for various diseases, including cardiac ischemia/reperfusion insults, myocardial infarction, cardiac arrhythmia, wound healing, Parkinson's disease, spinal cord injury, acute liver failure, liver fibrosis, and nonalcoholic steatohepatitis.

^{32}Gap24, which mimics a sequence in the cytoplasmic loop region of Cx32 (Fig. 3), specifically inhibits Cx32 hemichannels and not their full channel counterparts. ^{32}Gap24 completely blocked calcium-triggered adenosine triphosphate responses in ECV304 bladder cancer epithelial cells. It is believed that ^{32}Gap24 acts in a mechanistically similar way as Gap19 (Willebrords et al. 2017).

Synonyms

Hormonal contraceptives; Oral contraceptives

Definition

Hormonal contraceptives belong to the most widely prescribed and most efficacious drugs that have a profound impact on western societies since their inauguration in the 1960s. In women, oral hormonal contraceptives are used to prevent fertilization or implantation in cases of unplanned pregnancies. Apart from these primary objectives, there are significant additional medical benefits contributing to a substantial improvement of reproductive health in women.

Mechanism of Action

The most frequently used oral contraceptives are composed of varying combinations of estrogens and progestins, which belong to the large family of steroid hormones. Steroids interact with intracellular receptors functioning as ligand-activated transcription factors to control the expression of a wide array of specific genes. The receptors for estrogens and progestins are members of a superfamily of approximately 50 structurally related nuclear receptors that bind ligands such as steroid hormones, retinoids, vitamin D_3, eicosanoids, and thyroid hormones (Fuentes and Silveyra 2019). Members of this receptor superfamily share a common architecture of mainly four conserved functional domains: The N-terminal transactivation domain (activation function, AF-1) is the most variable in the superfamily of receptors. The subsequent DNA-binding domain also participates in receptor dimerization, whereas nuclear localization is determined by the neighboring hinge region. The C-terminal hormone-binding domain comprises a ligand-dependent transcriptional activation function (AF-2) and provides the sites for the binding of chaperones like heat shock proteins that prevent dimerization and DNA binding of unliganded receptors.

Upon hormone binding, steroid hormone receptors undergo a conformational change, dissociate from heat shock proteins, and translocate into the nucleus where they interact as dimers with specific DNA regulatory sequences of target genes. The transcriptional regulation by steroid hormone receptors is mediated by co-regulatory proteins that either positively (co-activators) or negatively (co-repressors) influence steroid hormone-induced transcriptional activity. A complementary mode of steroid hormone receptor action relies on direct protein–protein interactions with other transcription factors such as AP-1, Sp-1, and NF-κB, thus providing an explanation for the well-known observation that steroid hormone receptors are able to regulate genes lacking consensus response elements in their noncoding 5′ region (Turgeon et al. 2006).

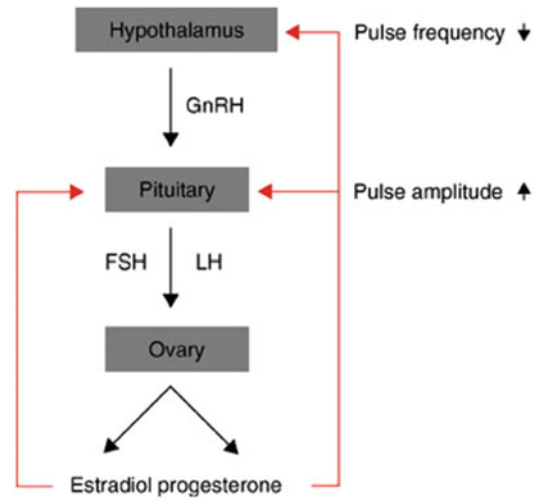
Most nuclear receptors are phosphoproteins, and their function can be influenced by

phosphorylation events that are initiated by membranous receptors like receptor tyrosine kinases or G-protein-coupled receptors. Thus, steroid hormone receptors are embedded in complex signaling networks that may give rise to ligand-independent activation of nuclear receptors. In addition to the well-understood nuclear events set in motion by steroid hormones, rapid nongenomic effects have been reported for estrogens and progesterone. These rapid effects of sex-steroids that are often initiated at the plasma membrane may result from steroid effects on membranous receptors other than classical steroid hormone receptors, for example, the G protein-coupled estrogen receptor (Prossnitz and Arterburn 2015). In particular, the rapid engagement of the MAP kinase cascade by estrogen has been studied in great detail, and it is quite likely that cardinal estrogenic effects like cell proliferation and survival are not primarily brought about by genomic actions of classical nuclear receptors but by rapid, nongenomic mechanisms.

At present, two distinct nuclear estrogen receptors, ERα and ERβ, are known. The receptors differ in their tissue distribution, ligand binding profile, and transcription activation functions in that ERβ is devoid of AF-1. In cells, that express both estrogen receptors, ERβ appears to oppose the transcriptional activity of ERα. Due to two distinct estrogen-dependent promoters in the single progesterone receptor (PR) gene, two isoforms of the progesterone receptor, PR-B and the N-terminally shortened PR-A, are generated. The biological activities of PR-A and PR-B are distinct and depend on the target tissue in question. In the reproductive system, progesterone acting through its respective nuclear receptors, PR-A and PR-B, serves the role of a physiological negative regulator of estrogen action by causing depletion of estrogen receptors. In addition, the major role of PR-A may be to inhibit transcriptional activity of other steroid receptors like ERα. Although one aspect of the biological relationship between estrogen and progesterone may be called functional antagonism, a concerted, sequential action of estrogen and progesterone is required in reproductive tissues like the endometrium and the breast to yield the desired complex biological response.

Estrogen and progesterone play a central role in the neuroendocrine control of the female menstrual cycle. In the early follicular phase, estrogen exerts an inhibitory effect on the pulsatile secretion of gonadotropins from the pituitary (Fig. 1). Thus, the gradual increase in the peripheral estradiol concentration during the follicular phase is accompanied by a reduced release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the gonadotropes. At midcycle, a different set of regulatory interactions becomes dominant. A sustained elevation of estradiol (150–200 pg/ml for approximately 36 h) induces a positive feedback on the anterior pituitary to trigger the ovulatory surge of LH. The underlying mechanism is a sensitization of the pituitary gonadotropes towards hypothalamic gonadotropin-releasing hormone (GnRH). Progesterone decreases the frequency of GnRH release from the hypothalamus resulting in a marked decrease of the frequency of gonadotropin pulses in the luteal phase (Fig. 1). At the same time, progesterone increases the amount of LH released per pulse (i.e., the pulse amplitude).

Estrogen exerts a negative feedback on the pituitary and decreases the secretion of FSH and LH during most of the menstrual cycle. Yet, it triggers the LH surge at midcycle by sensitizing the pituitary to hypothalamic GnRH. Progesterone increases the amplitude of gonadotropins



Contraceptives, Fig. 1 Regulation of hypothalamic and pituitary function by ovarian steroid hormones

released from the pituitary and at the same time decreases the GnRH pulse frequency at the level of the hypothalamus. These feedback controls give rise to fairly frequent LH pulses of low amplitude during the follicular phase of the cycle and less frequent pulses with a higher amplitude in the luteal phase.

The main mechanism of action of a combination oral contraceptive (a combination oral contraceptive contains both an estrogenic and a progestational component to achieve contraception) is to prevent ovulation by inhibiting gonadotropin secretion via an effect on both pituitary and hypothalamic centers. The progestational component primarily suppresses the surge-like LH release required to induce ovulation, while the estrogenic agent suppresses FSH secretion and thus prevents selection of a dominant follicle. Therefore, both estrogenic and progestational components of an oral contraceptive synergistically contribute to the contraceptive efficacy. However, even if follicular growth were not sufficiently inhibited, the progestational agent alone would suffice to abrogate the ovulatory LH surge. The estrogenic component, however, serves at least two other important purposes. It is responsible for the stability of the endometrium, thus minimizing events of irregular and unwanted breakthrough bleeding. In addition, estrogen action provides for a sufficient concentration of progesterone receptors. In aggregate, a small pharmacologic estrogen level is necessary to maintain the efficacy of the combination oral contraceptive.

As under most circumstances progesterone action will hold primacy over estrogenic effects, the cervical mucus, endometrium, and probably the fallopian tubes reflect progestational stimulation. The cervical mucus becomes thick and viscous and thus impervious to spermatozoa. The endometrium is in a state that is not receptive for implantation of a fertilized egg. Probably, the progestational impact on the secretory activity and peristalsis in the fallopian tubes also assists the general contraceptive effect. It is difficult, however, to assess the relative contribution of the various effects to the contraceptive efficacy, because combination oral contraceptives suppress ovulation very effectively.

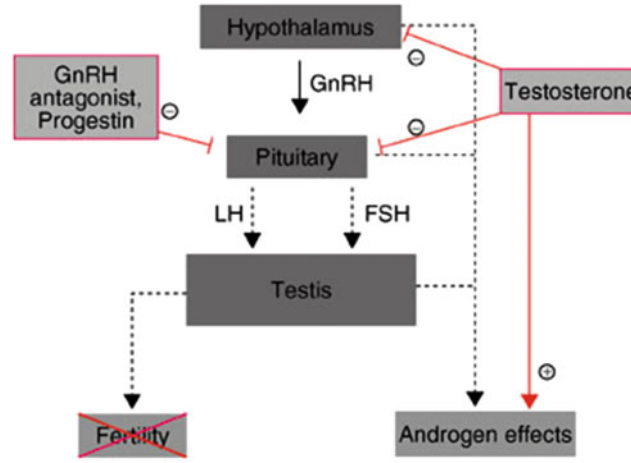
The progestin-only minipill contains a low-dose of a progestational agent which is sufficient to block ovulation in only 60–80% of cycles. The contraceptive effect is largely dependent on endometrial and cervical mucus effects, as gonadotropins are not reliably suppressed. Because of the low-dose of progestins, the minipill must be taken every day at the same time with great accuracy.

Long-acting methods of hormonal contraception are even more effective than oral methods. Two effective systems are available: a sustained-release method of levonorgestrel or etonogestrel using implanted steroid-permeable silastic tubing and depot injections of medroxyprogesterone acetate. The mechanism of action is similar to the progestin-only minipill. However, in addition, the long-acting methods yield progestin plasma levels high enough to prevent ovulation in basically all patients.

High doses of progestins are used for emergency postcoital contraception. A high dose of the progestin levonorgestrel (1,500 μg) can be used for postcoital emergency contraception. Administration of a total dose should be started within 12 h of unprotected sexual intercourse to achieve contraceptive protection of approximately 95%. Nausea and lower abdominal and breast pain as well as retarded menstruation have been reported as untoward effects. It is important to note that emergency contraceptives are not used as medical abortifacients to interrupt an established pregnancy defined to begin with implantation.

Ulipristal acetate is a new selective progesterone receptor modulator that has been approved for emergency contraception within 5 days of unprotected sexual intercourse. Thus, ulipristal acetate is longer acting compared to levonorgestrel providing reliable protection for only 3 days. The main action of 30 mg ulipristal acetate is to prevent ovulation similar to levonorgestrel. Main side effects are gastrointestinal and menstrual disturbances.

In recent years, strategies for hormonal male contraception have also been devised. Quantitatively and qualitatively normal spermatogenesis critically depends on neatly orchestrated LH and FSH release from the pituitary. In hormonal approaches to male contraception, gonadotropin secretion and intratesticular testosterone



Contraceptives, Fig. 2 Principles of hormonal male contraception

production need to be suppressed as efficiently as possible. Because androgens are key determinants of virilization and thus the male phenotype, but also strongly suppress gonadotropin release when applied exogenously, androgen preparations are essential components of all experimental approaches to male contraception (Fig. 2). Notably, the use of long-acting testosterone esters such as testosterone undecanoate causes azoospermia in only 30% of Caucasian men, while androgen-only regimens are highly effective for East Asian men. As additional agents, various combinations of androgens with progestins or GnRH antagonists have been evaluated in clinical trials. Testosterone administered in combination with various progestins such as depot medroxyprogesterone acetate, norethisterone enanthate, desogestrel or etonogestrel has yielded promising efficacy.

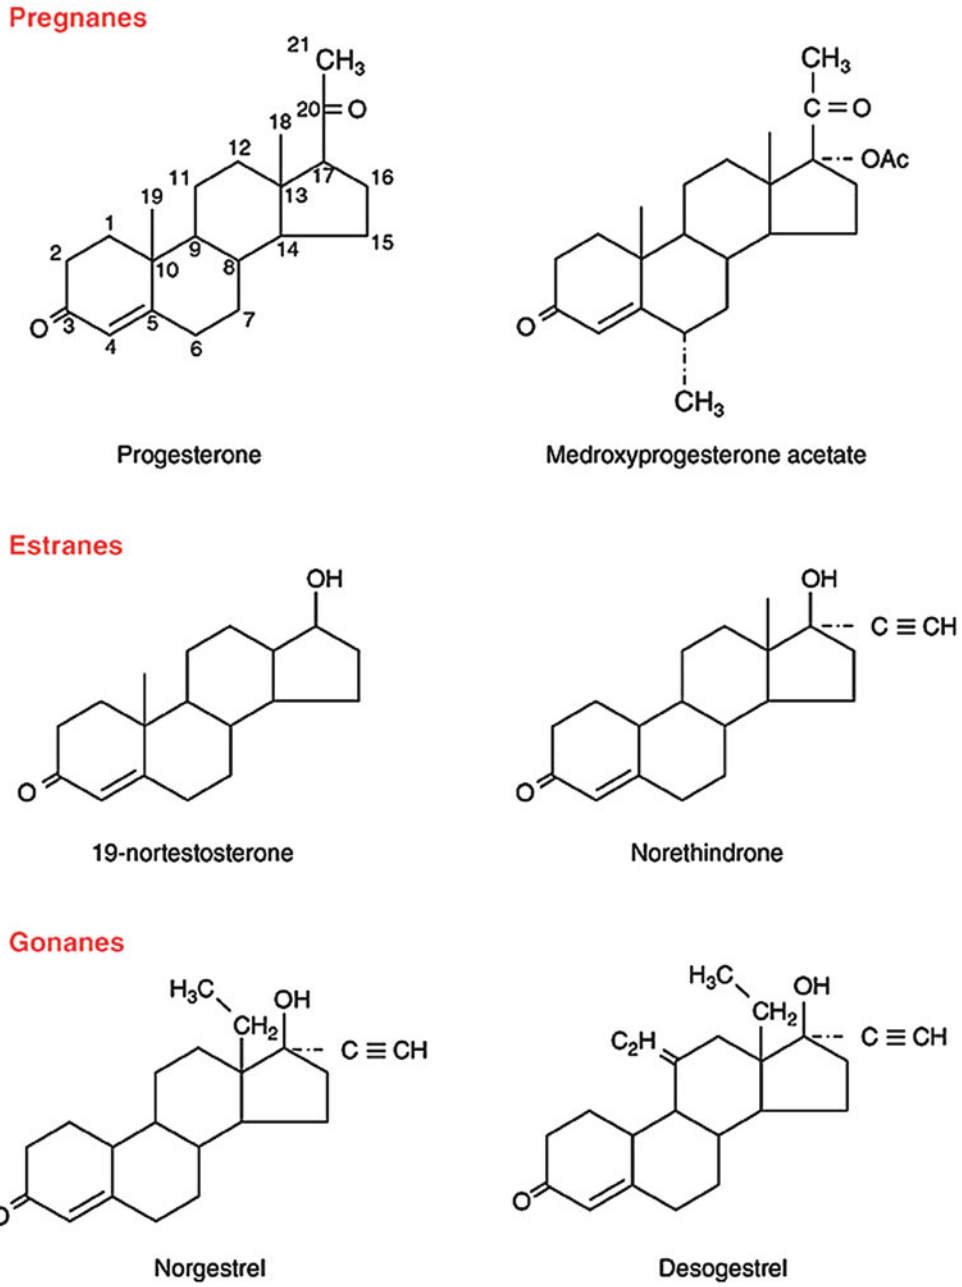
Testis function is regulated by hypothalamic and pituitary feedback circuits. The application of exogenous testosterone in conjunction with progestins or GnRH antagonists suppresses gonadotropin secretion from the pituitary and intratesticular testosterone production while maintaining extratesticular androgen effects. Such regimen reliably induced azoospermia and infertility.

Clinical Use (Including Side Effects)

After the seminal observation by Gregory Pincus and colleagues in the 1950s that progestins prevented ovulation in women, initial trials on humans were conducted using progestins like norethynodrel that were contaminated with about 1% mestranol. When subsequent efforts to provide a more pure progestin lowered the estrogenic component but provoked breakthrough bleeding, it was decided to keep the estrogen. Thus, the principles of combined estrogen–progestin oral contraception were established.

A major obstacle to the use of naturally occurring estrogens for the purpose of contraception was extensive first-pass hepatic metabolism and hence inactivation of the compounds when given orally. The addition of an ethinyl group at the 17 position made estradiol orally active. Ethinyl estradiol is a potent oral estrogen and represents one of the two forms of estrogens used in oral contraceptive pills. The other estrogenic compound is the 3-methyl ether of ethinyl estradiol, mestranol which is converted to ethinyl estradiol in the body.

The progestins used in oral contraceptives are 19-nor compounds of the estrane and gonane series (Fig. 3). Each compound possesses various degrees of androgenic, estrogenic, and antiandrogenic activities, thereby determining the scope of side effects. Animal and human studies showed, however, that only norethindrone, norethynodrel, and ethynodiol diacetate have estrogenic activity. Replacement of the 13-methyl group of norethindrone with a 13-ethyl moiety gives rise to the gonane norgestrel, which is a potent progestin with reduced androgenic activity (Fig. 3). More

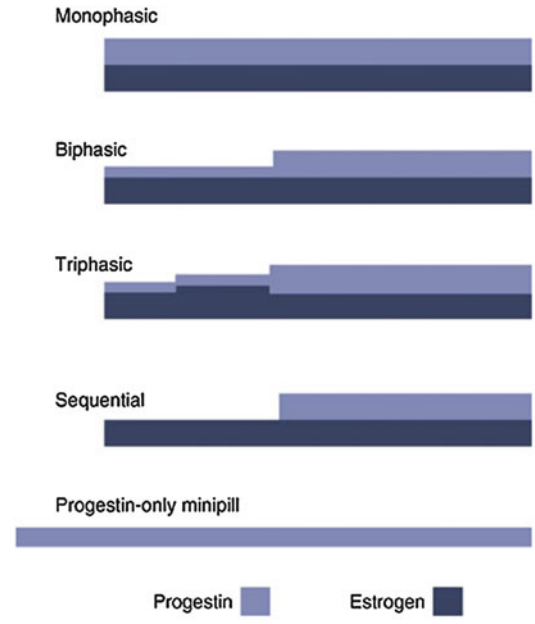


Contraceptives, Fig. 3 Examples of progestins derived from progesterone (pregnanes), 19-nortestosterone (estranes), and norgestrel (gonanes)

recently developed compounds like desogestrel (Fig. 3), norgestimate, gestoden, and etonogestrel display the least androgenic characteristics when compared with other 19-nor substances. Although norgestimate is a "newer" progestin, its activity is believed to be largely mediated by levonorgestrel or related metabolites. Therefore, epidemiologists do not generally include combination contraceptives containing norgestimate in the group of third generation compounds.

In epidemiologic studies, all products containing less than 50 μg ethinyl estradiol per pill are summarized as low-dose oral contraceptives. The first generation of oral contraceptives includes products with 50 μg or more of ethinyl estradiol. The second generation of oral contraceptives comprises formulations of norgestrel (0.3–0.5 mg), levonorgestrel (0.1–0.15 mg), norgestimate (0.25 mg), ethynodiol diacetate (1 mg), and other members of the norethindrone family in conjunction with 30 or 35 μg ethinyl estradiol. Desogestrel (0.15 mg) or gestodene (0.075 mg) are progestins in third generation contraceptives that are combined with 20 or 30 μg ethinyl estradiol. Most notably, the first oral contraceptive available contained 150 μg mestranol and 10 mg norethynodrel. It is nowadays commonly believed that the formulations of third generation oral contraceptives are very close to the lowest hormone levels which can be used without sacrificing contraceptive efficacy.

Combination oral contraceptives are the most frequently used agents and are characterized by a high therapeutic efficacy. Carefully controlled clinical studies with highly motivated subjects achieve an annual failure rate of 0.1%. The typical use effectiveness, however, amounts to 97–98%. Combination oral contraceptives are used as monophasic, biphasic, triphasic, and sequential preparations. In monophasic preparations (Fig. 4), a fixed estrogen/progestin combination is present in each pill which is administered daily for 21 consecutive days followed by a 7-day hormone-free period (usually the pills for the last 7 days of a 28-day pack contain only inert ingredients). In the bi- and triphasic preparations (Fig. 4), varying amounts and ratios of estrogen to progestin are present in order to mimic most closely the sex-steroid levels throughout a normal menstrual cycle. In addition, the total amount of steroids administered can be reduced when taking multiphasic oral contraceptives. Sequential preparations (Fig. 4) contain only estrogens for the first 7–11 days followed by a fixed estrogen/progestin combination in the remainder of the 21-day hormone application period. Phasic- and sequential-preparations were developed mainly to reduce the amount of progestins due to their untoward effects on the cardiovascular system.



Contraceptives, Fig. 4 Principal composition of various forms of oral contraceptives

Since a few years, a transdermal system received worldwide approval for hormonal contraception. In addition to ethinyl estradiol it contains norelgestromin as a progestational component. Norelgestromin is the active metabolite of norgestimate and is structurally related to 19-nortestosterone. Norelgestromin has negligible androgenic activity and may thus be suitable for women suffering from symptoms caused by androgen excess. The contraceptive efficacy of the transdermal patch is similar to that of oral contraceptives, but the transdermal system has the additional benefit of a once-weekly administration. In addition, transdermal delivery of hormones abolishes variability in gastrointestinal absorption and circumvents hepatic first-pass metabolism. It should be noted, however, that under steady-state conditions the area under the curve (AUC) describing plasma estrogen concentrations is 60% higher than corresponding levels resulting from a daily

oral application of 35 μg ethinyl estradiol. Two independent cohort studies recently demonstrated an increased risk of venous thromboembolism when using transdermal systems or vaginal rings (see below). Compared to levonorgestrel containing oral preparations the risk of venous thromboembolism nearly doubles.

Another fairly recent development in the field of hormonal contraception are combined contraceptive vaginal rings (NuvaRing) releasing 120 μg etonogestrel and 15 μg ethinyl estradiol daily. The small silastic ring is replaced weekly for 3 weeks followed by a ring-free period of 7 days. NuvaRing is well-tolerated and accepted by women, allows for a good control of the menstrual cycle, and has a therapeutic efficacy comparable to oral contraceptives.

Progestin-only contraceptives (Fig. 4) contain low-doses of progestins (e.g., 350 μg norethindrone or 75 μg norgestrel) that have to be administered daily without interruption. The lowest expected failure rate during the first year of use is 0.5%, while the typical failure rate amounts to 3%. Subdermal implants of norgestrel (216 mg) for sustained release provides for long-term (for up to 5 years) contraceptive effects characterized by failure rates of only 0.05%. Reliable contraception for 3 months can be achieved by an intramuscular injection of a crystalline suspension of 150 mg medroxyprogesterone acetate (Fig. 3) (failure rate 0.3%).

The main purpose of healthy women taking oral contraceptives is to prevent unwanted pregnancies. "Primum non nocere" applies particularly to preventive health care measures and therefore, untoward effects of oral contraceptives have to be monitored and assessed with great scrutiny. Shortly after the introduction of oral contraceptives approximately 40 years ago they soon became one of the most widely used drugs throughout the world. Hence, it is not surprising that reports on adverse effects began to appear rather quickly. Most of the untoward effects appeared to be dose-dependent, thus spurring on researchers to develop the current low-dose preparations. The most worrying adverse effects can be summarized in two main categories: the cardiovascular system and cancer.

Synthetic estrogens like ethinyl estradiol have a profound effect on the production of fibrinogen and clotting factors VII, VIII, X, and XII in the liver. In parallel, the concentrations of anticoagulation factors like protein C, S, and antithrombin III are diminished. This pro-coagulatory effect leads to an increased risk of thromboembolism in healthy women taking oral estrogens (Gialeraki et al. 2018). More than 20 years ago, several studies reported on a twofold increase in the risk of venous thromboembolism when third generation oral contraceptives containing desogestrel and gestoden were compared with older preparations mostly containing levonorgestrel. A number of independent recent studies clearly showed that drospirenone containing oral contraceptives are characterized by a three-fold increased risk of thromboembolism when compared to preparations containing levonorgestrel as a progestin. This does not come as a surprise, because drospirenone is characterized by partial agonism at the mineralocorticoid receptor in addition to its progestational activity. In summary, third generation oral contraceptives containing desogestrel, gestoden, or drospirenone as well as those with cyproterone acetate as a progestin have a 70% higher risk of thromboembolism compared to levonorgestrel based preparations. Because of the fairly low absolute risk in young women, a systematic search for cardiovascular risk factors is mandatory before prescribing a hormonal contraceptive.

The effects of oral contraceptives on thrombosis can be surmised as follows: All low-dose oral contraceptives, regardless of the type of progestin, have an increased risk of venous thromboembolism. Smoking has no effect on the risk of venous thrombosis. However, smoking and estrogen administration have an additive effect on the risk of arterial thrombosis.

Oral contraceptive-induced hypertension was previously observed in users of higher dose pills. An increased risk of clinically significant hypertension, however, has not been reported for low-dose oral contraceptives, including those containing the third generation progestins. Preexisting hypertension

is an important additive risk factor for stroke in oral contraceptive users. Most notably, recent clinical studies fail to find any substantial risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age, who take low-dose oral contraceptives. The vast majority of myocardial infections and strokes in oral contraceptive users occur when women over the age of 35 and cardiovascular risk factors take high-dose products (more than 50 μg ethinyl estradiol per pill).

In 1996 already, a meta-analysis of 54 epidemiologic studies indicated that women had a slightly increased risk of breast cancer while taking oral contraceptives when compared to nonusers (relative risk = 1.24). The increased risk diminished steadily after cessation of medication and was not found elevated 10 years after discontinuation. A more recent population-based case-control study of more than 4,500 women with breast cancer and nearly 4,700 controls showed no association between past and present use of oral contraceptives (Marchbanks et al. 2002). Due to the large study, subgroups of women, for example, those taking a formulation with a high estrogen content, duration of oral contraceptive use, initiation of use during adolescence, history of breast cancer in a first-degree relative, could be analyzed. None of these subgroups had a significantly increased risk of breast cancer. More broadly speaking, a large cohort study in the UK did not observe any association between oral contraception and an increased overall risk of cancer (Hannaford et al. 2007). On the contrary, a recent population-based study in Denmark following 1.8 million women for more than 10 years corroborated the 1996 figures and showed that the risk of breast cancer was higher among women who currently or recently used hormonal contraceptives (relative risk between 1.20 and 1.38). After discontinuation of contraception, the risk of breast cancer still remained higher among women who had used hormonal contraceptives for 5 years or more than among never users. However, it should be noted that absolute increases in risk were small (13 per 100,000 person years) (Morch et al. 2017).

The flip side of the coin is that hormonal contraceptives indisputably have significant health benefits. The use of oral contraceptives for at least 12 months reduces the risk of developing endometrial cancer by 50%. Furthermore, the risk of epithelial ovarian cancer in users of oral contraceptives is reduced by 40% compared with that on nonusers. This kind of protection is already seen after as little as 3–6 months of use. Oral contraceptives also decrease the incidence of ovarian cysts and fibrocystic breast disease. They reduce menstrual blood loss and thus the incidence of iron-deficiency anemia. A decreased incidence of pelvic inflammatory disease and ectopic pregnancies has been reported as well as an ameliorating effect on the clinical course of endometriosis.

Future efforts should be directed at optimizing current formulations to finally come up with an ideal oral contraceptive which would reduce the risk of breast, ovarian, and endometrial cancer without any cardiovascular complications.

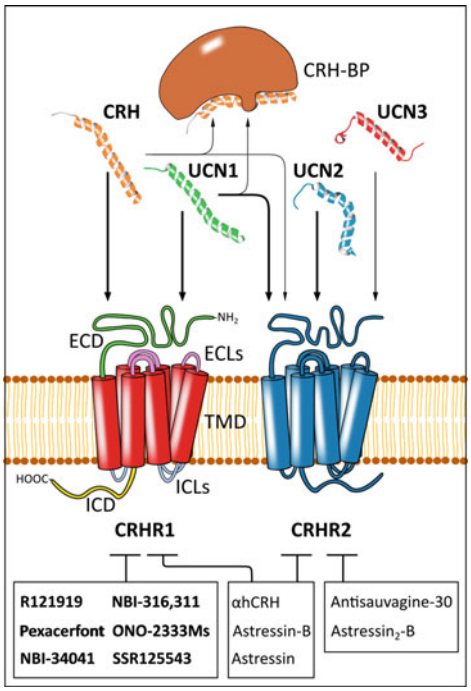
Corticotropin-releasing factor (CRF) system

Definition

The corticotropin-releasing hormone (CRH) system plays a prominent role in shaping the stress response. It acts through two receptors: the corticotropin-releasing hormone receptor type 1 (CRHR1) and 2 (CRHR2), which are differentially activated by four peptide ligands: CRH, urocortin 1 (UCN1), urocortin 2 (UCN2), and urocortin 3 (UCN3) (Fig. 1). CRH was originally discovered as the initiator of the hypothalamic-pituitary-adrenal (HPA) axis – the neuroendocrine limb of the stress response. In addition, the central CRH system is well-known for its capacity to modulate adaptive behavioral and autonomic responses to stress. Since its discovery, a dysregulation of the CRH system has been associated with different stress-related diseases including major depressive disorder (MDD) and anxiety disorders. Accordingly, the CRH system holds great expectations as a potential target for the treatment of stress-related disorders.



Corticotropin-Releasing Hormone System, Fig. 1 Ligand-receptor interaction within the corticotropin-releasing hormone (CRH) system: CRH binds to the CRH receptor 1 (CRHR1) and with lower affinity to the CRH receptor 2 (CRHR2). Urocortin 1 (UCN1) is also bound by both receptors, but with comparable affinity. CRH and UCN1 both bind to the CRH-binding protein (CRH-BP). Urocortin 2 (UCN2) and urocortin 3 (UCN3) are exclusive ligands of the CRHR2. Structural domains of CRHRs are illustrated for CRHR1: extracellular domain (ECD, green), transmembrane domain (TMD, red), extracellular loops (ECLs, pink), intracellular loops (ICLs, blue), and intracellular domain (ICD, yellow). Basic Characteristics

CRH and Its Related Neuropeptides

Members of the CRH-Related Neuropeptide Family

In 1981, the 41 amino acid (AA) neuropeptide corticotropin-releasing hormone (CRH) was isolated from the ovine hypothalamus by Wylie Vale and his team (Vale et al. 1981). In humans the *CRH* gene is located on chromosome 8 and is made up of two exons separated by an 800 bp intron. Exon 2 encodes the entire prepropeptide of 196 AAs. The N-terminal 24 AA signal sequence and the proregion are proteolytically processed by prohormone convertases. Its maturation is completed by C-terminal amidation. In mammals, the CRH-related neuropeptide family consists of three additional members, UCN1, UCN2, and UCN3, which were identified between 1995 and 2001. CRH shares 43% sequence identity with UCN1, 34% with UCN2, and 26% with UCN3. All of the CRH family members show a similar gene structure comprising two exons, with exon two encoding the prepropeptide. All mature peptides share a similar structure containing an N-terminal receptor activation domain and a C-terminal receptor-binding domain. In the case of CRH and UCN1, a sequence that conveys binding to the CRH-binding protein (CRH-BP) is flanked by the receptor-binding and activation domains (Dedic et al. 2018; Deussing and Chen 2018).

Expression Pattern

In the human brain, gene expression can only be inferred from postmortem studies, and the availability of human brain tissue is limited. Therefore, most of the findings concerning ligand expression were gathered in rodent models. All members of the family can be found in the brain, but also in peripheral tissues. Among the family of CRH-related neuropeptides, CRH shows the most widespread expression within the brain. It is mainly expressed in the paraventricular nucleus of the hypothalamus (PVN), the central amygdala, different divisions of the bed nucleus of the stria terminalis (BNST), in the lateral part of the interstitial nucleus of the posterior limb of the anterior commissure (IPACL), in the hippocampus, in the piriform cortex, as well as throughout the neocortex. Although the identity of CRH expressing neurons has only partially been revealed so far, it is known that the majority of CRH neurons are γ-aminobutyric acid (GABA)-ergic in nature, with a few exceptions in the piriform cortex as well as the PVN, where they express the glutamatergic marker VGLUT2. The expression of UCN1 is much more restricted and can mainly be found in the Edinger-Westphal nucleus, but also in the supraoptic nucleus and lateral superior olive. UCN2 and UCN3 are also present in discrete brain regions but are more prevalent in peripheral structures like the skin, skeletal muscle, pancreas, or gastrointestinal tract (Dedic et al. 2018).

CRH-Binding Protein

The first polypeptide described to bind CRH was the CRH-binding protein (CRH-BP). Its discovery was fostered by the observation that the massive increase of circulating CRH levels during pregnancy neither increases adrenocorticotropic hormone (ACTH) nor cortisol levels. Sequestration of CRH by the CRH-BP was identified as the underlying mechanism preventing a massive activation of the HPA axis during pregnancy. The 37 kDa glycoprotein is found in the placenta, liver, circulation, pituitary and brain. It is able to bind CRH as well as UCN1, but not UCN2 nor UCN3 (Fig. 1). CRH-BP regulates the availability of CRH and UCN1 and therefore serves as endogenous buffer, which can inhibit the biological activity of CRH as well as UCN1, thereby preventing any unwanted activation, e.g., of the HPA axis. Despite this modulatory impact of CRH-BP on HPA axis regulation as well as on central CRH circuits, the physiological relevance connected to this polypeptide remains largely unclear (Deussing and Chen 2018).

CRH Receptors

The two CRH receptors – CRHR1 and CRHR2 – are heptahelical G protein-coupled receptors (GPCRs) of the class B (secretin-like) family (Fig. 1). Both receptors show 70% AA sequence homology, with lowest identity in the N-terminal extracellular domain (ECD) (40%) and highest in

the transmembrane helices as well as in the C-terminal intracellular domain (ICD) (80–90%).

Splice Variants

The human genes encoding CRHRs comprise 14 (CRHR1) and 16 (CRHR2) exons, which span approximately 50 kb on chromosome 17 and 7, respectively. In humans, eight alternative CRHR1 splice variants have been characterized to date, of which only CRHR1α is biologically active and present in the central nervous system (CNS). All other splice variants, which were primarily isolated from peripheral tissues, are truncated forms that do not signal upon CRH binding. Expression of these splice variants directly competes with expression and thus availability of CRHR1α. In addition, CRHR1α might form hetero-oligomers with these splice variants, thereby changing receptor properties such as localization, ligand affinity, and receptor signaling. Three CRHR2 splice variants have been isolated in humans so far. Variants CRHR2α, CRHR2β, and CRHR2γ are all spliced at the 5′ end, thereby maintaining identical seven-transmembrane as well as C-terminal domains. One additional splice variant, which has only been identified in the mouse so far, is a soluble form of the CRHR2α (sCRHR2α). This splice variant exclusively encodes the extracellular ligand-binding domain of the receptor and terminates before the first TMD. This soluble variant might act as a decoy receptor. However, its exact role remains unclear as it is efficiently translated but not necessarily secreted.

Expression Pattern

Both CRHRs are expressed in the CNS, albeit CRHR1 being the predominant receptor in the brain. CRHR1 is expressed throughout the brain with highest levels, e.g., in the olfactory bulb, neocortex, hippocampus, subnuclei of the amygdala, ventral tegmental area, substantia nigra, red nucleus, and cerebellum. CRHR2 expression is more limited to specific brain areas, e.g., lateral septum, ventromedial hypothalamus, medial amygdala, BNST, dorsal raphe, and choroid plexus. In humans, the CRHR2 splice variants CRHR2β and CRHR2γ are mainly expressed in the brain, whereas CRHR2α is more prominent in peripheral tissues like the skin, heart, or skeletal muscle (Dedic et al. 2018; Deussing and Chen 2018).

Receptor Interactions

Ligand-Receptor Interaction

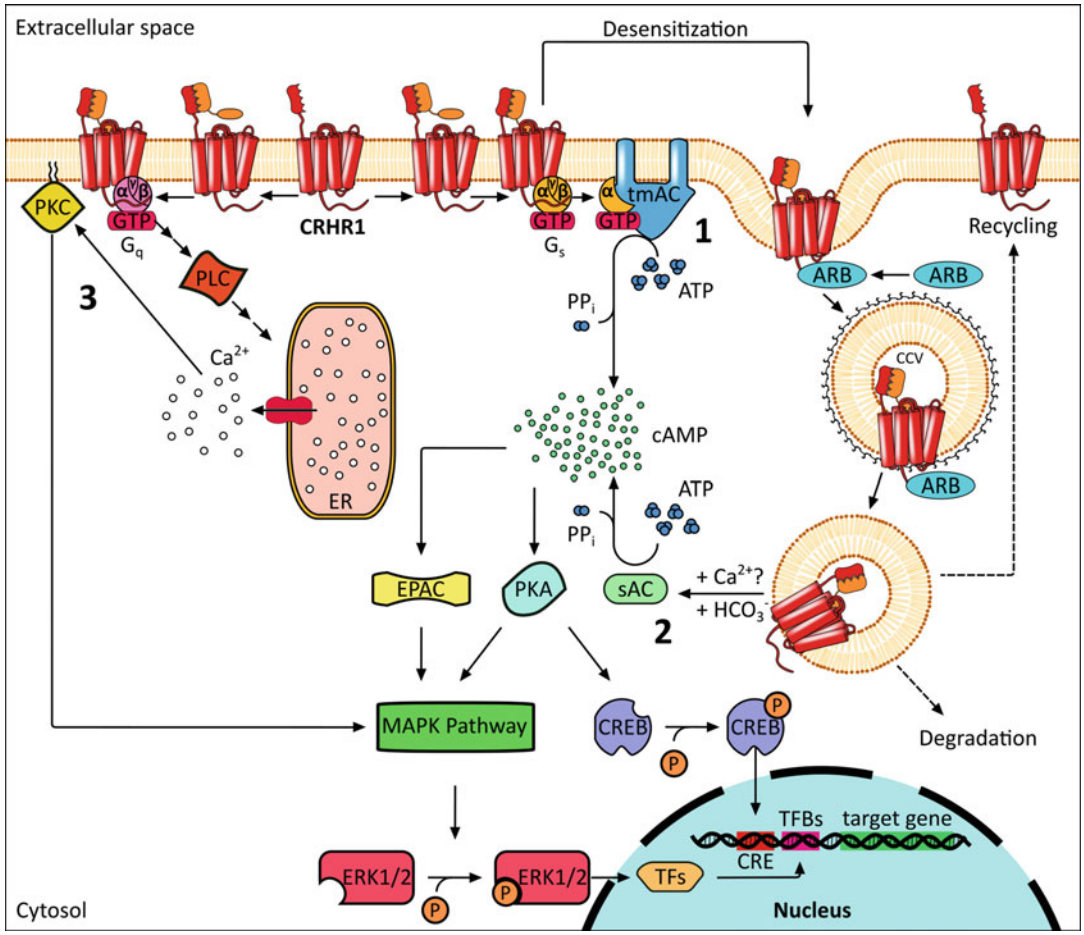
The four ligands of the CRH system (CRH, UCN1, UCN2, UCN3) bind with different affinities to the two CRHRs (Fig. 1). The main ligand for CRHR1 is CRH, which can also bind CRHR2, but with lower affinity. UCN1 shows equal affinity for both receptors, whereas UCN2 and UCN3 are exclusively bound by CRHR2. Ligand specificity is mainly determined by the N-terminal part of the receptor. The recently proposed two domain model for ligand-receptor interaction can be best described using the structure of CRH family ligands. The mature peptide consists of two receptor-interacting domains. The C-terminal domain interacts with the ECD of the receptor thereby determining the affinity and specificity of the ligand for the receptor. Once the peptide's C-terminus is bound, its N-terminal domain binds to the receptor's juxtamembrane portion and thereby activates the receptor (Deussing and Chen 2018; Inda et al. 2017).

Receptor-Receptor Interaction

CRHR1 was one of the first class B GPCRs reported to form homooligomers at the plasma membrane and in intracellular compartments. CRHR2β also forms oligomers, whereas CRHR2α only acts as a monomer. The dimer/monomer states of the receptors are proposed to play a role in G protein selectivity and thus intracellular signaling. The CRHR1 contains a C-terminal PDZ-binding domain, which is absent in the CRHR2. This domain conveys interactions with PDZ domain containing proteins such as members of the membrane-associated guanylate kinase (MAGUK) family, which serve as scaffolds for the assembly and compartmentalization of signaling complexes. Along these lines, it has been demonstrated that the PDZ-binding domain is capable of promoting the cross talk with other GPCRs such as the 5-hydroxytryptamine 2A receptor (Deussing and Chen 2018).

CRH-Dependent Signaling

CRHR-dependent signaling has been extensively studied for the CRHR1 and to lesser extent for CRHR2. Upon binding of the ligand to the CRHR, the third intracellular loop (ICL3) is bound by a heterotrimeric G protein consisting of an alpha, beta, and gamma subunit, which in turn leads to a stabilization of the receptor-ligand complex (Fig. 2). The catalytically active alpha subunit dissociates from the beta and gamma subunits and activates a membrane bound adenylyl cyclase (tmAC), which, in its activated state, generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) (Fig. 2(1)).



Corticotropin-Releasing Hormone System, Fig. 2 CRHR1-induced intracellular signaling cascades: Activation of the receptor induces G protein binding (canonically Gs), which triggers the generation of cyclic adenosine monophosphate (cAMP) by membrane bound adenylyl cyclase (tmAC) (**1**). Recruitment of β-arrestin (ARB) leads to receptor internalization. Signaling continues by a yet unknown mechanism in which soluble adenylyl cyclase (sAC) generates cAMP depending on Ca^{2+} and HCO_3^- (**2**). Increased cAMP levels ultimately lead to changes in transcription by activation of Ca^{2+}/cAMP response element-binding protein (CREB) and the mitogen-activated protein kinase (MAPK) pathway. Both pathways (**1** and **2**) contribute to increased cAMP levels in the early phase of ERK1/2 activation, but only sAC (**2**) is responsible for its activation at later stages. Besides the Gs-dependent pathway transcription can also be influenced in a protein kinase C (PKC)-dependent manner induced by binding of Gq to the activated receptor, which also triggers the activation of the MAPK pathway (**3**). Receptor desensitization involves its internalization, which can result in degradation or recycling of the receptor. CCV, clathrin-coated vesicle; EPAC, exchange protein activated by cAMP 2; PLC, phospholipase C; PKA, protein kinase A; CRE, cAMP-response element; TFs, transcription factors; TFBs, TF binding sites

The second messenger cAMP can then activate different signaling pathways, ultimately modulating downstream gene expression. cAMP binds to the regulatory subunit of the protein kinase A (PKA) leading to the release of the catalytic subunit, which can phosphorylate different target proteins in the cytosol or nucleus such as the $Ca2^{+}$/cAMP response element binding-protein (CREB). Activated CREB binds to cAMP-response elements (CREs) in the promotor region of target genes, like c-*fos* to induce their expression. Besides this pathway, PKA can also activate the mitogen-activated protein kinase (MAPK) pathway by activating the MAPKKK Rap1/2. The MAPK pathway is also activated via a PKA-independent pathway. In this case, cAMP activates the exchange protein activated by cAMP 2 (EPAC2), which in turn activates Rap1/2, thereby triggering the MAPK pathway. By subsequent activation of downstream kinases (B-Raf, MEK1/2), the extracellular signal regulated kinase ERK1/2 is phosphorylated. ERK1/2 activates different transcription factors (TFs), thereby promoting the expression of genes like proopiomelanocortin (POMC).

An alternative signaling pathway leading to the activation of the MAPK pathway is triggered by the binding of a Gq protein to the ICL3 region of CRHR1 (Fig. 2(3)). The alpha subunit of the G protein activates the phospholipase C (PLC), which in turn cleaves the phosphatidylinositol-4,5-biphosphate (PIP_2) into inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 accumulates in the cytosol and activates the IP_3 receptor stimulating the release of Ca^{2+} into the cytosol. The accumulation of cytosolic Ca^{2+} from intracellular stores activates different calcium-dependent proteins including Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and protein kinase C (PKC), leading to the phosphorylation of c-Raf, thereby activating ERK1/2, which leads to the previously described changes in TF activation and gene expression.

A common mechanism of GPCR regulation is their desensitization, which is primarily accounted for by phosphorylation of intracellular residues by GPCR kinases (GRKs). The phosphorylation of the ICD of the CRHRs by GRK3 and GRK6 leads to the recruitment of β-arrestin (ARB), a small GPCR-binding protein. ARB leads to the termination of the receptor-G protein interaction and also serves as an adaptor protein for components of the clathrin-dependent endocytic machinery, such as clathrin or ß2-adaptin (AP-2). AP-2 is bound to the receptor and leads to its endocytosis and internalization. Upon internalization, Ca^{2+} and bicarbonate trigger the activation of the atypical soluble adenylyl cyclase (sAC), which in turn generates cAMP leading to the activation of EPAC and ERK1/2 (Fig. 2(2)).

The activation of ERK1/2 upon CRHR1 activation can be separated into two phases, the early and the late phase. The previously described G protein-dependent activation of the tmAC and the G protein-independent activation of sAC are the sources of cAMP within the early phase of ERK1/2 activation (Fig. 2(1 and 2)), but only cAMP from sAC leads to the sustained activation in the late phase (Fig. 2(1)). Although the process of sAC activation has been shown to be dependent on CRHR internalization, presence of Ca^{2+} and bicarbonate is believed to be G protein-independent; however the exact mechanisms controlling its activation are still unclear.

The intracellular signaling of CRHRs is highly dependent on the equipment of a given cell, e.g., with different G proteins, kinases, other enzymes, and transcriptional regulators. In addition, the binding of different ligands might promote a bias toward specific downstream signaling pathways. It is of note that the experimental evidence for the described signaling pathways was gathered from different cell lines, not necessarily expressing CRHRs endogenously. Hence, the components of the signaling machinery in these cells might differ from the in vivo situation, i.e., cells, expressing CRHRs endogenously. Therefore, these pathways have to be further validated in primary cells as well as in the in vivo context (Deussing and Chen 2018; Inda et al. 2017).

The CRH System and Its Connection to Stress

Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is a neuroendocrine system crucially involved in regulating homeostasis and an

integral part of the organism's stress response system. Its circadian regulation and activation in response to internal or external challenges are specifically controlled by CRH. CRH is expressed in parvocellular secretory neurons with glutamatergic identity in the PVN where it is stored in large dense core vesicles. As a consequence of physical or psychological stressors, CRH is released from axon terminals in the external zone of the median eminence into the portal vasculature. The release of CRH results in a local activation of CRHR1 in anterior pituitary corticotrophs, which triggers the release of ACTH into the general circulation. Upon its arrival at the adrenal cortex, it activates the ACTH receptor, stimulating the synthesis and secretion of glucocorticoids (human, cortisol; mouse, corticosterone). The effects of glucocorticoids are manifold leading to an increase in the catabolic metabolism by promotion of gluconeogenesis in the liver, lipolysis in fat, and amino acid mobilization in muscle tissue. Glucocorticoids also create an anti-inflammatory environment in peripheral tissues. The whole stress response via the HPA axis is a self-regulated process in which glucocorticoids act in a negative feedback loop inhibiting further generation and secretion by acting on glucocorticoid receptors (GRs) in the anterior pituitary and different brain regions. The CRHR2 plays also a role in HPA axis regulation and is particularly involved in the initiation and termination of HPA axis activity. In contrast to CRH, the contribution of UCNs to HPA axis regulation is rather limited (Deussing and Chen 2018; Dedic et al. 2018).

Behavioral Stress Responses

Besides its elementary role in HPA axis, regulation the CRH system is also involved in modulating complex behavioral responses upon stressful stimuli as elucidated from a wealth of studies involving genetic mouse models or behavioral pharmacology. CRH and the CRHR1 are both widely expressed throughout the brain including nuclei not connected to the HPA axis implying an additional role of this system in brain physiology. The central application or overexpression of CRH in rodents causes reactions resembling the behavioral and physiological stress response. In contrast, the disruption of CRH/CRHR1 signaling by pharmacological or genetic means promotes anxiolytic effects. The anxiolytic consequences of CRH/CRHR1 loss-of-function approaches as well as the stress-like phenotypes originating from gain-of-function experiments support a prominent role of the extrahypothalamic CRH system with regard to the behavioral reaction to stressors. In recent years, it has become clear that the central CRH system is more complex than originally envisioned. The original concept of a dualism of a stress-initiating/anxiogenic CRHR1 and a stress recovery-related/anxiolytic CRHR2 has largely been revised. The function of CRHRs and their ligands is critically determined by their cellular localization and previous stress exposure or experiences. To fully understand the role of CRH-related neuropeptides and their receptors in brain physiology requires more detailed understanding of related neurocircuits and their dynamics (Deussing and Chen 2018).

Therapeutic Potential of the CRH System in Stress-Related Disorders

In 1999, the CRH hypothesis of depression was proposed, based on the following findings regarding the CRH system in MDD patients: (i) elevated levels of CRH in the cerebrospinal fluid, (ii) increase in CRH secreting neurons in the PVN, (iii) reduction of CRH-binding sites in the frontal cortex secondary to elevated CRH levels, and (iv) elevated urinary cortisol levels due to increased ACTH and cortisol pulses. All of these findings, together with the potential role of CRH in emotional behaviors, support the assumption that the HPA axis and CRH itself are causally involved in the etiology of MDD and other stress-related disorders. Therefore, the CRHR1 was seen as a promising target for the development of new antidepressants, which led to the generation of different small molecule antagonists that have been tested in clinical trials (Holsboer 1999; Spierling and Zorrilla 2017).

Drugs

The two domain model of ligand-receptor interaction states that there are two potential targets for

the inhibition of the CRHR1, the N-terminal ECD, and the juxtamembrane domain. For these two targets, different drug types are suitable: (i) peptides for preventing ligand-receptor interaction and (ii) non-peptide antagonists for the inhibition of receptor activation.

An example for a peptide antagonist is the N-terminally truncated CRH analogue alpha-helical CRH (αhCRH), which shows approximately the same binding affinity to CRHRs as the full-length CRH. However, since it cannot cross the blood-brain barrier, it needs to be applied at the location of interest in the brain. Accordingly, peptide antagonists for the inhibition of CRHRs are mainly used in basic research, but not for therapeutic purposes in human subjects. Therefore the development of non-peptide antagonists, so-called small molecules, was necessary for their use in clinical trials (Fig. 1 and Table 1).

All currently available small molecules with high affinity and selectivity for CRHR1 share a common structure of one or two aliphatic top units and a nitrogen in the core ring, which can directly interact with a histidine in the third transmembrane domain and in that way occupy the hydrophobic pocket of the receptor. Their structure has somewhat hampered the development of small molecule antagonists for clinical trials because of their inherent lipophilic properties, resulting in poor water solubility.

Small molecules for the inhibition of CRHR1 have been extensively tested in different mouse models of anxiety, depression, and addictive disorder, showing promising results and leading to their use in different clinical trials.

The first clinical study of a CRHR1 antagonist was a phase 2a open-label study to assess safety and efficacy of NBI-30775/R121919 (Table 1). The patients showed an improvement in the Hamilton Depression Rating Scale (HDRS) scores and no major impact on the HPA axis (tested by the CRH challenge test). The study was still discontinued because of elevated levels of liver enzymes in healthy patients. A phase 1 study with NBI-34041 showed no influence on HPA axis while demonstrating safety and tolerability, also improving resistance to psychosocial stress. In a phase 2b double-blinded, placebo-controlled study in patients with recurrent MDD using the antagonists NBI-316,311, there was no improvement in the HDRS scores and it was prematurely stopped. Similarly Pexacerfont was unable to

Corticotropin-Releasing Hormone System, Table 1 Selected clinical trials of small molecule CRHR1 antagonists (based on Spierling and Zorrilla 2017)

Indication	Drug name	Study type	Outcome	Reference (year of completion)
Major depression	R121919	Phase 2a, open label	Improvement in HDRS; discontinued: elevated liver enzyme levels	Zobel et al. (2000)
	Pexacerfont	Phase 1, double-blinded, placebo-controlled	No results reported	NCT00135421 (2007)
	PF-00572778	Phase 1, single-blinded, placebo-controlled	discontinued: elevated liver enzyme levels	NCT00580190 (2008)
	CP-316,311	Phase2b, double-blinded, placebo-controlled	No improvement in HDRS, prematurely stopped	NCT00143091 (2006)
	ONO-2333Ms	Phase 2b, quadrupole-blinded, placebo-controlled	Lacked efficacy	NCT00514865 (2008)
	SSR125543	Phase 2, triple-blinded, placebo-controlled	Lacked efficacy	NCT01034995 (2011)
Generalized anxiety disorder	Pexacerfont	Phase 2b, double-blinded, placebo-controlled	No therapeutic effect	NCT00481325 (2008)
Post-traumatic stress disorder	Verucerfont	Phase 2b, double-blinded, placebo-controlled	Lacked efficacy	NCT01018992 (2014)

National Clinical Trial Identifier (NCT)

show any therapeutic effect in a large, randomized, and placebo-controlled clinical trial of patients with generalized anxiety disorder. Other compounds like SSR125543 lacked efficacy in controlled trials and therefore were stopped. Also Verucerfont, a CRHR1 antagonist for the treatment of post-traumatic stress disorder did not show any improvement in disease-related symptoms compared to placebo.

Since none of the small molecule CRHR1 antagonists were able to enter a phase 3 clinical trial yet, the expectations of CRHR1 inhibition for treatment of stress-related psychiatric disorders were largely unmet. In this regard, CRHR1 inhibitors share the fate of many other drugs that were specifically developed for the treatment of psychiatric disorders.

The underlying reasons for the lack of translation from animal models to patient treatment are manifold. Firstly, disturbances of the CRH/CRHR system are observed in only a subset of patients. Astonishingly, this has not been taken into account in previous clinical trials but could easily be overcome, e.g., by patient stratification to select patients suitable for treatment. Moreover, the predictive sensitivity of preclinical models is good, while they are lacking sufficient specificity. Another reason for the poor performance of these antagonists may be their relatively limited binding to the receptor, as a long duration of receptor occupancy might be crucial for their efficacy. Additionally, all of the antagonists developed to date bind to the atypical allosteric binding site, with none binding at the orthosteric binding site. Studies on other GPCRs have shown that the administration of a double antagonist, against both the allosteric and orthosteric binding sites, showed the highest receptor inhibition. Besides these model- and compound-specific questions, it has to be emphasized again that different neuronal subpopulations are involved in the CRH/CRHR1 system-related behavioral stress responses. In addition, CRHR1 signaling depends highly on the components of the signaling machinery, which might differ between different neuronal populations. Thus, a general inhibition of CRHR1, without discriminating between specific CRH/CRHR1 circuits might be less effective for the treatment of psychiatric disorders. Therefore, a better understanding of the involved cellular subpopulations and related signaling pathways is crucial for the understanding of how treatment of these diseases can be improved (Deussing and Chen 2018; Spierling and Zorrilla 2017).

CNP; Vascular natriuretic peptide

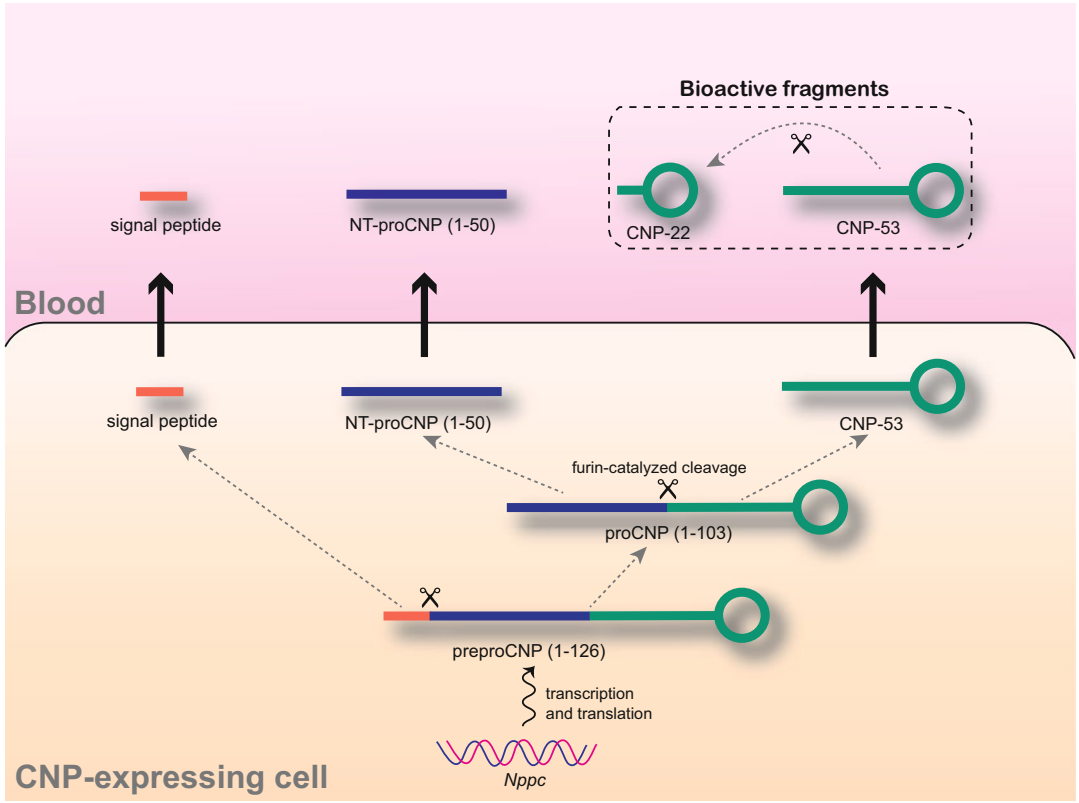
Definition

C-type natriuretic peptide (CNP) is a paracrine/autocrine peptide belonging to the family of natriuretic peptides. All natriuretic peptides share a structurally related C-terminus that constitutes the receptor-binding site in the molecules. The intracellular signaling of CNP is mediated through a specific CNP receptor, e.g., natriuretic peptide receptor B (NPR-B) as well as via the common natriuretic peptide receptor C (NPR-C), which acts both as a clearance receptor and as a trigger of intracellular signaling. CNP is synthesized in many tissues and cell types, and the CNP system accordingly plays a role in several physiological processes – including bone growth and vascular homeostasis. Different targets of the CNP system have been in recent focus for drug development, and these pharmacological interventions have shown a promising clinical potential.

Basic Characteristics

C-Type Natriuretic Peptides

In 1990, C-type natriuretic peptide was reported as the third peptide of the family of the natriuretic peptides – in addition to Atrial and B-type natriuretic peptide (ANP and BNP) (Zois et al. 2014). Subsequently, Dendroaspis Natriuretic Peptide (DNP) was isolated from the venom of the green mamba and was also included in the peptide family (Singh et al. 2006). The commonality of the members is a preserved intramolecular ring structure of 17 amino acids formed by a single disulfide bridge. Extending from cystyl residues forming the disulfide bridge, the different natriuretic peptides have variable N- and C-terminal regions. Bioactive CNP does not possess a C-terminal extension stemming from the ring structure and is found in two major forms, CNP-22 and CNP-53, with a differently sized N-terminal region (5 and 36 amino acid residues, respectively) (Prickett and Espiner 2012). Located on chromosome 2, the human CNP gene, *NPPC*, is often considered the genetic ancestor of the natriuretic peptide family (Prickett and Espiner 2012; Takei 1999). Notably, the CNP gene is extremely conserved between species, indicating a vital biological function of CNP (Lippert and Goetze 2010). From *NPPC,* the first translational product, pre-proCNP, is synthesized, and cotranslatory cleavage by the signal peptidase forms the first prostructure, proCNP, together with a hydrophobic signal peptide (103 and 23 amino acid residues, respectively) (Pemberton et al. 2014). Further intracellular processing by the endoprotease furin leads to the formation of CNP-53 and an N-terminal proCNP fragment (50 amino acid residues). After release from the cell, CNP-53 can be further processed to CNP-22 by unknown mechanisms (Prickett and Espiner 2012). Both bioactive CNP, NT-proCNP, and the signal peptide are measurable in the human circulation (see Fig. 1 and "Measurement of C-Type Natriuretic Peptides in Human Plasma"). The half-life of CNP-22 in the human circulation is estimated to be 2–3 min (Prickett and Espiner 2012).



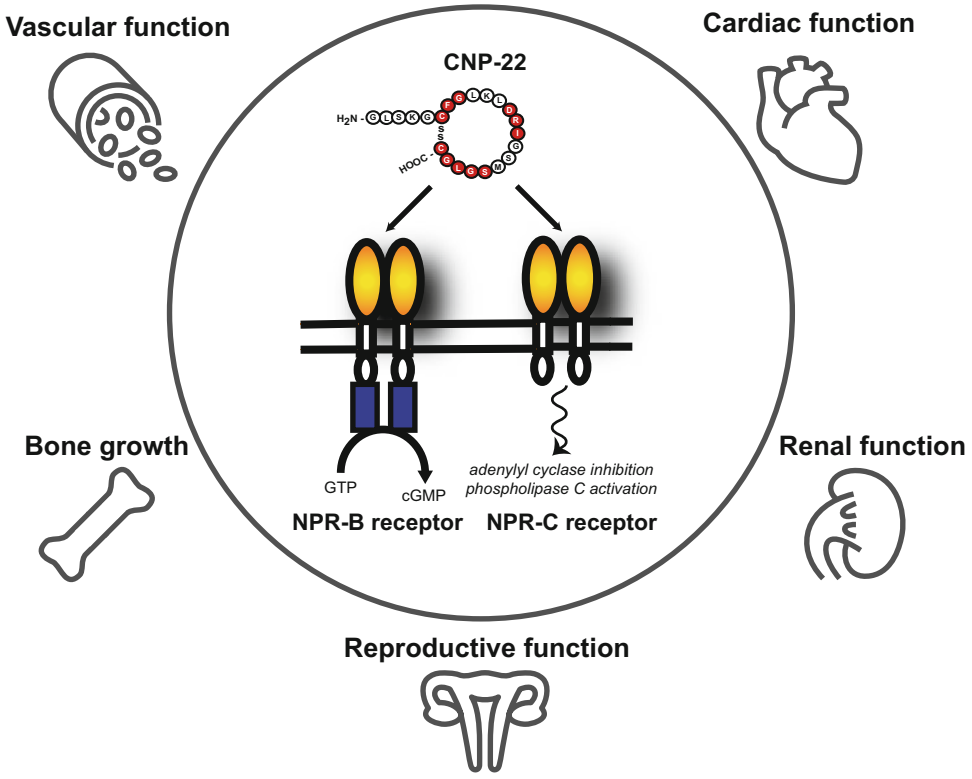
C-Type Natriuretic Peptide and Its Receptors, Fig. 1 Expression of CNP from gene transcription to circulating CNP-fragments

C-Type Natriuretic Peptide Receptors and Enzymes

From a functional point of view, CNP differs markedly from ANP and BNP. The CNP system has two types of membrane-bound receptors (see Fig. 2), where natriuretic peptide receptor B (NPR-B), also known as guanylyl cyclase B, is CNP specific. Binding of CNP leads to NPR-B receptor activation that catalyzes the intracellular conversion of guanosine triphosphate to cyclic guanosine monophosphate (cGMP) as second messenger. The other CNP receptor, natriuretic peptide receptor C (NPR-C), has affinity for all natriuretic peptides and holds both an intracellular signaling function and a clearance mechanism (NPR-C is often referred to as a clearance receptor). Intracellular signaling from the NPR-C receptor is mediated through inhibitory G-proteins and, hence, inhibition of adenylyl cyclase and phospholipase C activation (Zois et al. 2014). Furthermore, natriuretic peptides including CNP are all substrates for degradation by the broadly expressed enzyme, membrane-bound metallo-endopeptidase (EC 24.11, neprilysin) (Potter 2011), which is the target of a newly introduced treatment in heart failure (see "Inhibition of Neprilysin").

Sites of Expression and Biological Roles

In contrast to ANP and BNP – both mainly secreted from cardiomyocytes – CNP is expressed in a variety of tissues and cell types including chondrocytes, vascular endothelial cells, cardiomyocytes, reproductive tissues, and renal tissue, as well as high concentrations in the pituitary gland and brain of the central nervous system (Sellitti et al. 2011) (see Fig. 2). The blood-borne concentrations of bioactive CNP are too low for activation of the CNP receptors through the circulation. Thus, CNP is regarded as a paracrine/



C-Type Natriuretic Peptide and Its Receptors, Fig. 2 The CNP system illustrated with CNP-22, its receptors, NPR-B and NPR-C, and the organs, where the CNP system has a regulatory function (CNP-53 is not shown for illustrative purposes)

autocrine regulatory peptide (Prickett and Espiner 2012). Accordingly, CNP has been ascribed separate biological roles in different organs with functions in bone growth, vascular homeostasis/protection, and reproduction being the most extensively studied.

Reports on rare human mutations of genes specifically related to the CNP system point to a crucial role in the regulation of longitudinal bone growth, where CNP and NPR-B expressed in chondrocytes promote endochondral ossification. Loss of function of NPR-B has been shown to cause severe growth retardation, and overexpression of *NPPC* leads, correspondingly, to a phenotype with clinical resemblance to the Marfan syndrome, including tall stature. In mice, genetic manipulations of the CNP system have consolidated the pivotal role in bone growth (Prickett and Espiner 2012). It has also been shown that the intracellular signaling cascade from the activated NPR-B converges with the signaling from the Fibroblast Growth Factor 3 receptor (FGFR3), which is pharmacologically utilized in trials of treatment of achondroplasia (see "CNP Analogs").

In the cardiovascular system, implications of a complex interplay between CNP and the receptors, NPR-B and NPR-C respectively, to maintain cardiovascular homeostasis have emerged during the recent years from preclinical studies. In general, these investigations have been based on thorough experiments of tissue-specific and global knock-out of CNP and the two receptors. It has been shown that CNP produced in the vascular endothelium exerts a vasodilatory function through receptors in smooth muscle cells and pericytes of the vascular tree, where both NPR-B- and NPR-C-signaling seem instrumental. Moreover, the CNP system is mediating a cardioprotective process including reduced

endothelial dysfunction, inflammation, and atherosclerosis, as well as enhanced angiogenesis (Moyes and Hobbs 2019). Recently, it was shown that CNP-signaling mediated by NPR-C activation is important for organizing structural and functional elements in cardiac tissue, where endothelial cells, cardiomyocytes, and fibroblasts are all local sources of CNP (Moyes et al. 2019). Whether this essential cardiovascular role of the CNP system is also applicable to humans is still uncertain, but measurement in plasma indicates an independent association between CNP and heart disease.

The role CNP and its receptors in reproductive physiology represents another branch of the diverse action of CNP. Studies in female rodents have shown high concentrations of CNP mRNA in ovaries and uterus. In addition, both CNP and NPR-B follow a time-dependent expression over the estrous cycle, and estradiol rapidly upregulates CNP synthesis in the uterus (Walther and Stepan 2004). In the male reproductive tissues, the CNP system is involved in testicular regulation and penile erection (Walther and Stepan 2004). Interestingly, the CNP system has been found to play a role at another level of reproductive biology. In a recent report, pulsatile gonadotropin-releasing hormone stimulation in gonadotropic cells of the anterior pituitary gland induced enhanced expression of CNP and NPR-B and, also, CNP upregulated gonadotrope transcription factors (Mirczuk 2019). Thus, CNP and its receptors seem to be involved in multiple and distinct cellular processes of reproductive function.

Measurement of C-Type Natriuretic Peptides in Human Plasma

In spite of the low circulating concentrations, several methods exist for quantification of CNP and its molecular precursor in plasma. Radioimmunoassays for measurement of CNP-22 have been developed, and plasma concentrations for healthy adult individuals are typically in the range of ~1 pmol/L (Prickett et al. 2013). In this context, it should be recapitulated that the related peptides ANP and BNP circulate in much higher concentrations, and cross-reactivity should always be taken into account. Radioimmunoassays and enzyme-linked immunosorbent assays (ELISAs) for measurement of the more stable N-terminal proCNP fragment have revealed approximately 10–20-fold (~15 pmol/L) higher concentrations in plasma when compared with CNP-22 (Prickett et al. 2013). In addition, a modified radioimmunoassay for proCNP-derived peptides has been developed, where the assay principle and the specific molecular target ensure detection of various forms of proCNP and, therefore, measured plasma concentrations are higher than that of N-terminal proCNP concentrations, typically 30–50 pmol/L in reference individuals (Lippert et al. 2010). Lastly, an immunoassay for the signal peptide from preproCNP has shown that this "by-product" of peptide processing is also present in the human bloodstream and in remarkably high plasma concentrations of 60–90 pmol/L with no apparent correlation to N-terminal proCNP concentrations (Pemberton et al. 2014).

Although the vascular endothelium is thought to be a major source for proCNP-derived peptides in plasma, it is largely unknown in what proportion the different CNP-producing tissues contribute to the venous plasma concentrations. Nevertheless, measurement of circulating CNP and its molecular precursors as biomarkers has been the scope of different clinical studies, predominantly within cardiovascular research. In particular, N-terminal proCNP has been shown to be an informative molecular target for subgroups of patients with heart disease. High concentrations of N-terminal proCNP in plasma are associated with an unfavorable prognosis with increased risk of disease progression and death in patients with unstable angina pectoris (Prickett et al. 2017) and in patients with heart failure with preserved ejection fraction (Lok et al. 2014). Notably, this predictive potential of N-terminal proCNP measurement was beyond established cardiovascular risk factors including other natriuretic peptides (ANPs and BNPs). It remains to be clarified which risk factor(s) high concentrations of CNPs in plasma potentially reflect, and if these

biomarkers add unique information with substantial value in the clinical setting.

Drugs

CNP Analogs

The genetic disorder achondroplasia is the most common variant of dwarfism caused by a gain-of-function mutation in the FGFR3-receptor that leads to increased and unregulated intracellular signaling. Since the discovery that CNP/NPR-B-signaling inhibits the Raf-MEK½ step of the ERK½ pathway (a MAPK cascade initiated by the activated FGFR3 receptor), CNP analogs have been in focus as a drug target to attenuate the constitutively active FGFR3-signaling (Legeai-Mallet 2016). Due to the rapid removal of bioactive CNP in the human circulation, CNP treatment is challenged by the need of prolonged release and/or stabilized forms of CNP analogs. Different CNP analogs have been developed and are currently at different stages of clinical testing (Savarirayan et al. 2019; Breinholt et al. 2019). Recently, a clinical report showed promising results from a phase 2 dose-finding trial on the treatment with the CNP agent Vosoritide, in 35 children with achondroplasia aged 5–14 years. Vosoritide treatment was administrated subcutaneously once daily, the side effects were generally mild, and, most importantly, the growth velocity was increased for up to 42 months. Ongoing phase 3 studies will further clarify the effect of Vosoritide on height growth in a broader age span and evaluate the safety of the treatment (Savarirayan et al. 2019).

Other Ligands of CNP Receptors

Different pharmaceutical strategies are pursued to develop drugs to activate the CNP system as potential treatment of cardiovascular diseases. As a means to activate both the NPR-A (the ANP/BNP-specific receptor) and the NPR-B-receptor, a fused drug, Cenderitide, has been designed. The molecular structure of Cenderitide is a CNP-22 molecule, where a C-terminal extension, identical to the 15 amino acid sequence in DNP, has been attached. Thus, the drug works as a dual ligand and triggers intracellular signaling from both NPR-A and NPR-B. The clinical scope of this agent is treatment of heart failure with both reduced and preserved ejection fraction. Cenderitide has been tested by infusion in 12 patients with stable heart failure, and a safe, well-tolerated treatment was reported as well as increased cGMP plasma concentrations (Kawakami et al. 2018). Another approach is to activate the NPR-C-signaling by designing agents specific to this common natriuretic peptide receptor that seems to mediate a cardioprotective function of the CNP system. A specific NPR-C agonist, cANF4–23, has been developed, and the drug has been tested in an experimental model of secondary pulmonary hypertension due to left ventricle heart failure, where a reduction in pulmonary artery systolic pressure and enhancement of cardiac performance has been observed. To our knowledge, cANF4–23 has so far not been tested in human trials (Egom et al. 2017).

Inhibition of Neprilysin

As mentioned, neprilysin is abundantly expressed in the human organism and degrades a wide range of regulatory peptides. In particular, neprilysin has a high affinity for natriuretic peptides (CNP $\geq$ ANP $>$ BNP) (Potter 2011). Inhibition of neprilysin has been introduced in the treatment of chronic heart failure with the aim to utilize the beneficial effect of increased endogenous natriuretic peptide concentrations. Since neprilysin also degrades the potent vasoconstrictor angiotensin II (Ang II), treatment with inhibition of neprilysin by sacubitril is combined with the angiotensin-receptor blocker valsartan, in order to antagonize a potential vasoconstrictive effect of diminished Ang II degradation. Sacubitril/valsartan is currently an approved drug in the treatment of chronic heart failure with reduced ejection fraction (HFrEF) and has been shown to lower both the risk of death and the hospitalization rate compared with treatment of angiotensin-converting-enzyme-inhibition alone (McMurray et al. 2014). Moreover, a recent trial found a positive effect of sacubitril/valsartan treatment in

subgroups of patients with heart failure with preserved ejection (HFpEF) (Solomon et al. 2019). The mechanism of sacubitril is thought to be mediated by an increased bioavailability of endogenous ANP and BNP. Still, given the versatile activity of neprilysin, it remains more or less unresolved if changed activities of other peptide systems, including the CNP-system, contribute beneficially. Considering the high affinity of bioactive CNP to neprilysin and the marked vasoprotective effects of CNP in preclinical studies, there is an urgent need of examining the effect of neprilysin inhibition on the CNP system in humans.

Cyclin-dependent kinase inhibitors

Definition

A subset of cyclin-dependent kinases (CDKs), including CDK1, CDK2, CDK3, CDK4, and CDK6, control progression through the cell division cycle by phosphorylating specific substrate proteins in an ordered, temporal sequence. Since cancer is a disease of uncontrolled cell proliferation, CDK inhibitors may be useful as anticancer therapeutics. The rationale for using small-molecule CDK inhibitors as anticancer drugs is further supported by the observation that natural CDK inhibitor proteins p15, p16, p18, p19, p21, and p27 suppress cell proliferation, and in certain contexts function as tumor suppressors (Lee and Yang 2001).

Inhibitors of Cell Cycle CDKs

Most efforts to develop anticancer CDK inhibitors have focused on CDK2, CDK4, and CDK6 due to their roles in phosphorylating the retinoblastoma tumor suppressor protein, Rb, and in driving cells through the G1 to S-phase cell cycle transition and through S-phase. The cell cycle CDKs show extensive functional redundancy as demonstrated by mouse gene knockout models (Berthet and Kaldis 2007; L'Italien et al. 2006). Only CDK1 is essential for mouse development (Diril et al. 2012). The high sequence identity (65%) between CDK1 and CDK2 has made the development of CDK1- and CDK2-selective inhibitors challenging. RO-3306 is one of the few compounds that exhibits selectivity for CDK1 over CDK2 (Vassilev et al. 2006).

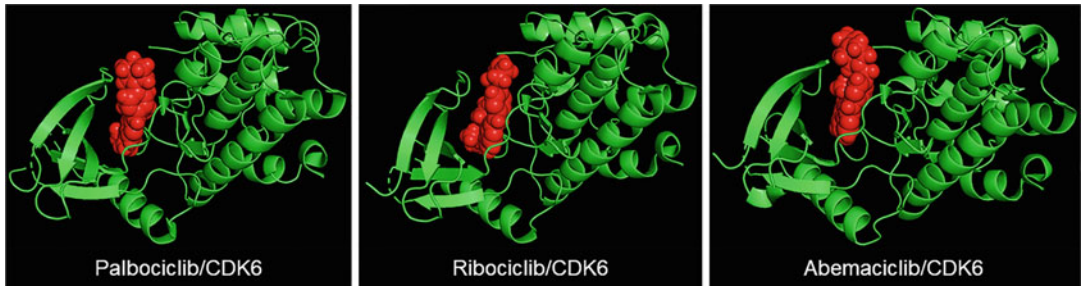
Inhibitors of Non-Cell Cycle CDKs

Non-cell cycle CDKs, including CDK5, CDK7, CDK8, CDK9, CDK11, CDK12/13, and CDK19 may also be important targets for anticancer therapeutics due to their roles in transcription, RNA processing, the DNA damage response, and the regulation of cell signaling proteins (reviewed in (Fisher 2019; Liu et al. 2017; Dannappel et al. 2018; Lui et al. 2018)).

Modes of CDK Inhibition

CDK inhibitors may function in several distinct ways as reviewed previously (Law et al. 2015). These inhibitory mechanisms are not mutually exclusive and some CDK inhibitors act via combinations of these modes.

- ATP-competitive: Most of the CDK inhibitors that have been investigated act by occupying the ATP-binding pocket of the kinases. Analysis of crystal structures of various CDKs bound to their inhibitors has shown a variety of binding modes within the ATP-binding site, including binding at the Ribose pocket, the hydrophobic region, the solvent region, and the phosphate pocket. The dual CDK4/6-specific drugs Palbociclib (Ibrance), Ribociclib (Kisqali), and Abemaciclib (Verzenio) are FDA-approved CDK inhibitors used to treat subsets of breast cancer. The structures of



Cyclin-Dependent Kinases as Therapeutic Targets, Fig. 1 X-ray crystal structures of CDK4/6 inhibitors Palbociclib, Ribociclib, and Abemaciclib (red spheres) bound to CDK6 (green ribbon diagrams)

these drugs bound in the ATP pocket of CDK6 is shown in Fig. 1 (PDB#s: 5L2I, 5L2S, and 5L2T; (Chen et al. 2016)).

- Covalent

  The potential for developing irreversible CDK inhibitors is illustrated by the identification of an inhibitor that reacts with C312 of CDK7 (Christensen et al. 2014; Kwiatkowski et al. 2014), and a compound that bonds with C218 of CDK14 (Ferguson et al. 2019).
- Allosteric

  Allosteric kinase inhibitors are an attractive option since allosteric sites may be less conserved between kinases than the ATP and substrate-binding pockets. Some precedence exists for identifying allosteric CDK inhibitors and targetable allosteric sites (Pellerano et al. 2017; Betzi et al. 2011).

Revelations from the Clinical Use of CDK4/6 Inhibitors

Expectations were that CDK4/6 inhibitors would block tumor growth by inducing cell cycle arrest. However, results from clinical studies and preclinical models have shown that these drugs act through additional, non-cell cycle mechanisms. First, CDK4/6 inhibition can induce senescence selectively in cancer cells (Rader et al. 2013; Valenzuela et al. 2017; Chen and Pan 2017; Tao et al. 2017). These "additional" mechanisms of anticancer activity result in part from CDK4/6-dependent phosphorylation of substrate proteins, including FOXM1, SMAD3, and NFAT, in addition to RB, in cancer cells (Anders et al. 2011; Deng et al. 2018; Liu et al. 2014; Liu 2006; Zelivianski et al. 2010), and the effects of inhibiting CDK4/6 in immune cells and other cell populations in the tumor microenvironment (Teh and Aplin 2019; Schaer et al. 2018; Klein et al. 2018).

COX; Prostaglandin G/H Synthases; Prostaglandin-endoperoxide H Synthases (PGHSs)

Definition

The cylooxygenases (COX)-1 and COX-2 are two distinct isoenzymes encoded by separate genes that catalyze the first two enzymatic steps in the biosynthesis of prostanoids from ω3 and ω6 20- and 22-carbon essential fatty acids (Smith et al. 2011). Bioactive prostanoids comprise prostaglandins (PGs) PGD, PGE, PGF, as well as prostacyclins (denoted PGIs) and thromboxanes (TXs), which display numerous physiological and pathophysiological effects mediated by specific G protein-coupled receptors (Table 1). The

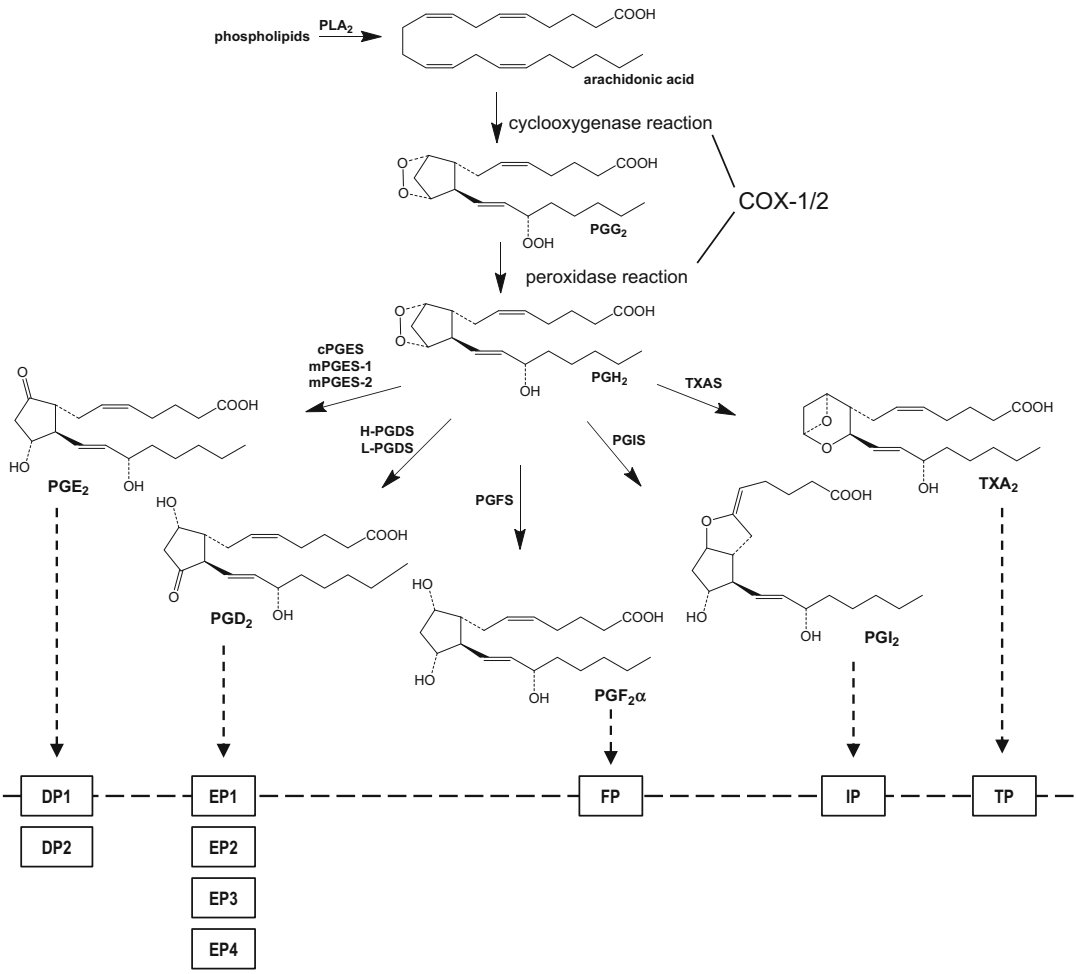
Cyclooxygenases, Table 1 Targets and biological function of prostanoids

Prostanoid	Prostanoid receptor	Target cells and tissues	Biological actions/(patho-)physiological effects
PGD_2	DP1, DP2	Mast cells, airways, brain	Vasodilatation, anti-platelet aggregation. Sleep induction, relaxation of intestinal smooth muscles.
PGE_2	EP1, EP2, EP3, EP4	Platelets, macrophages, vascular smooth muscle cells, kidney, brain	Vasodilatation, bronchodilatation, anti-platelet aggregation. Inflammation, fever, pain, protects gastric mucosa.
$PGF_{2\alpha}$	FP	Vascular smooth muscle cells, airways, eye, uterus	Vasodilatation/vasoconstriction, bronchoconstriction. Labor induction, uterus contraction, ovulation and parturition, contraction of intestinal smooth muscles.
PGI_2	IP	Platelets, endothelial cells, kidney, brain	Vasodilatation, bronchodilatation, anti-platelet aggregation. Decrease in blood pressure, mediates pain, antithrombogenic, protects gastric mucosa.
TXA_2	TP	Platelets, macrophages, vascular smooth muscle cells, kidney	Platelet aggregation, vasoconstriction, bronchoconstriction. Haemostasis, hypertension.

arachidonic acid (AA)-derived eicosanoids of the "2-series" compounds with two double bonds and 20 C-atoms are the most abundant and prominent prostanoids that are involved in inflammation, pain, fever, hemostasis and thrombosis, regulation of renal function, cytoprotection of the mucosa in the stomach, induction of labor, angiogenesis, and cancer (Smyth et al. 2009). The nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, ibuprofen, diclofenac, or indometacin elicit their pharmacological effects by inhibition of COX enzymes (Patrignani and Patrono 2015). COX-1 is constitutively expressed in most tissues and mainly confers the biosynthesis of prostanoids involved in basic housekeeping functions throughout the body. In contrast, COX-2 is primarily an inducible enzyme in a variety of cells in response to endotoxins, cytokines, and mitogens, but is also constitutively expressed, for example, in the endothelium, brain, and kidney (Smyth et al. 2009). Therefore, the anti-inflammatory effect of classical NSAIDs is essentially due to inhibition of COX-2, while the ulcerogenic side effects are proposed to arise mainly from inhibition of COX-1, explaining the serious gastrointestinal toxicity of NSAIDs due to their nonselective inhibition of COX-1 and COX-2. Selective COX-2 inhibitors ("coxibs") display equivalent efficacy to traditional NSAIDs, with reduced gastrointestinal side effects but increased risk for gastrointestinal adverse events (Grosser et al. 2017; Schjerning et al. 2020).

Basic Characteristics

In eicosanoid biosynthesis, the bifunctional COXs catalyze two distinct sequential reactions (Fig. 1) that occur at physically different sites within the catalytic domain: after release of AA by a phospholipase (PL)A_2, the first reaction is a bis-oxygenation, where two O_2 molecules are inserted into the carbon backbone of AA at C11 and C15 yielding the cyclic peroxide PGG_2 (cyclooxygenase reaction); the second step (peroxidase reaction) is the reduction of the 15-hydroperoxyl group of PGG_2 leading to PGH_2 (Smith et al. 2011; Simmons et al. 2004). The highly instable PGH_2 is quickly converted by tissue-specific prostaglandin synthases: the hematopoietic PGD_2 synthase (H-PGDS) and lipocalin-type (L-)PGDS form PGD_2; the cytosolic PGE_2 synthase (cPGES) and the microsomal (m)PGES-1 and -2 generate PGE_2; the PGF synthase (PGFS)



Cyclooxygenases, Fig. 1 Biosynthetic pathway of prostanoids and their receptors. Upon release of arachidonic acid by a phospholipase (PL)A_2, COX-1 and COX-2 bis-oxygenate AA in a first step to the endoperoxide PGG_2 (cyclooxygenase reaction) and in a second step to the corresponding alcohol PGH_2 (peroxidase reaction). Specific prostanoid synthases then convert instable PGH_2 to the bioactive prostanoids PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2 (prostacyclin) and TXA_2 that essentially mediate their biological effects via their cognate GPCRs

makes $PGF_2\alpha$; the PGI synthase (PGIS) produces PGI_2 (also named prostacyclin); the TXA synthase (TXAS) forms TxA_2 (Smith et al. 2011).

Structural Features

COX-1 and COX-2 from the same species possess about 60–65% amino acid identity and a high degree of structural homology. They both exist as heme-containing, monotopic membrane proteins, forming homodimers with a molecular mass of approx. 70 kDa per monomer, where human COX-1 consists of 576 and COX-2 of 581 amino acids. Each monomer consists of three distinct structural domains: (i) an N-terminal epidermal growth factor (EGF) domain, (ii) an α-helical membrane-binding motif, and (iii) a C-terminal catalytic domain, the latter accounting for about 80% of the monomer, containing the cyclooxygenase and peroxidase active sites on either side of the heme (Kurumbail et al. 2001). Both COXs carry three high mannose oligosaccharides, one of them facilitates the folding of the protein, and for COX-2 a fourth oligosaccharide regulates its degradation.

The cyclooxygenase active site lies on the opposite side of the heme from the peroxidase active site at the top of an L-shaped, long hydrophobic substrate-binding channel and a smaller amphipathic side pocket (Kurumbail et al. 2001). This channel originates in the membrane binding domain and extends toward the interior of the enzyme. The mouth of the channel consists of a large volume that narrows to a constriction, formed by Arg120, Tyr355, and Glu524, and must open for entry of substrates or inhibitors into the channel. When AA enters this channel, the C-20 methyl group is accommodated at the narrow terminus of the channel, while the carboxyl group lies at the constriction. This directs C-13 of AA for hydrogen abstraction in close proximity to the catalytically active Tyr-385. The peroxidase active site is located on the surface of the protein near the heme cofactor. The cyclooxygenase active site is composed of the L-shaped, mainly hydrophobic, substrate-binding channel and a smaller amphipathic side pocket. Since the three-dimensional structures of COX-1 and COX-2 are very similar, and both the cyclooxygenase active and the peroxidase active sites are highly conserved, it is not surprising that the two isoenzymes have comparable kinetic parameters (V_{max} and K_M) for the enzymatic conversion of AA. However, the volume of the COX-2 active site is about 20% larger than that of the COX-1, causing different properties between the isoenzymes: (i) increased promiscuity of COX-2 for fatty acid substrates, (ii) distinct susceptibilities for inhibition by aspirin that acetylates COX-1 at Ser530 and completely abrogates enzyme activity, whereas acetylation of COX-2 (also at Ser530) prompts for formation of 15*R*-hydroxyeicosatetraenoic acid instead of PGH_2, and (iii) the presence of the larger Ile523 in COX-1 versus Val523 in COX-2 limits the size of the side pocket, thus hindering the accommodation of space-demanding inhibitors, selective for COX-2.

Reaction Mechanisms

Conversion of AA to PGG_2 is initialized by the abstraction of the pro-S hydrogen atom from C-13, followed by steps that are consistent with nonenzymatic lipid peroxidation (Smith et al. 2011). Cyclooxygenase catalysis requires enzyme activation which depends on the peroxidase activity: a two-electron reduction of a peroxide substrate causes oxidation of the ferric heme to an oxo-ferryl porphyrin radical cation. The transfer of an electron from Tyr-385 to the heme generates a tyrosyl radical which is in perfect position to abstract the pro-S hydrogen from C-13 of AA. Reduction of the peroxyl radical to the hydroperoxide to form PGG_2 regenerates the tyrosyl radical. Subsequent after the cyclooxygenase reaction, the peroxidase reduces the 15-hydroperoxy group of PGG_2 to the corresponding alcohol of PGH_2.

Roles in Physiology and in Pathophysiology

COX-1 and COX-2 share the same catalytic activities and generate the same product, but they display numerous structural and functional differences with significant consequences for physiology and pathophysiology (Smyth et al. 2009). COX-1 is widely distributed and constitutively expressed in most tissues, and its gene, Ptgs-1, codes for a 2.8 kb mRNA that is relatively stable. The COX-2 gene, Ptgs-2, in contrast, is an immediate early gene that can be induced by various inflammatory and proliferative stimuli, and the 4 kb COX-2 mRNA is rather instable leading to rapid turnover. Moreover, the translation rates for the two isoenzymes differ, being superior for COX-2 over COX-1, due to differences in the signal peptides at the N-terminus, that is, 22-24 for COX-1 and 17 for COX-2. The differences in the pattern of gene expression suggest that COX-1-derived prostanoids are required for homeostatic functions, for example, gastric cytoprotection and hemostasis, whereas COX-2 predominantly may play a pathophysiological role in PG formation particular during inflammation but also during tumorigenesis (Simmons et al. 2004). In fact, COX-2 is frequently expressed in many types of cancers exerting pleiotropic and multifaceted roles in carcinogenesis and cancer cell resistance to chemo- and radiotherapy. It induces cancer stem cell-like activity and promotes apoptotic resistance, proliferation, angiogenesis, invasion, and metastasis of cancer cells (Wang and Dubois 2010). Administration of

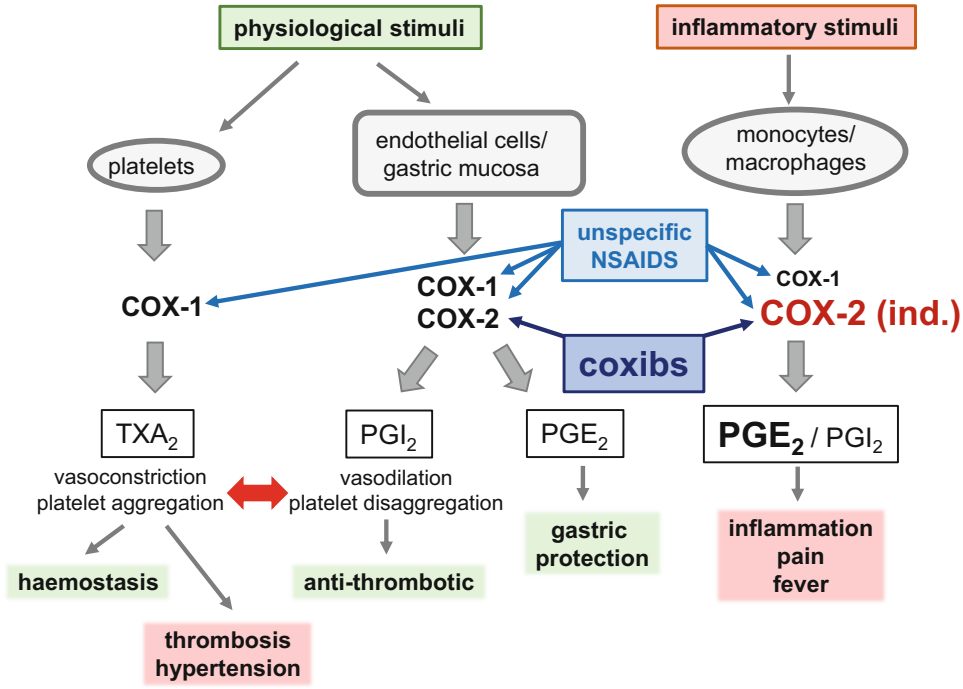
COX-2 inhibitors in a preoperative setting could reduce the risk of metastasis in cancer patients and sensitizes cancer cells to treatments like radio- and chemotherapy (Hashemi Goradel et al. 2019).

The simplified pattern of beneficial and detrimental roles of COX-1 and COX-2, respectively, is a matter of ongoing debate for several reasons. Selective pharmacological and genetic inhibition of COX-1 or COX-2 as well as clinical use of COX-2 selective inhibitors do not confirm this paradigm of COX function (Grosser et al. 2017; Schjerning et al. 2020; Patrono and Baigent 2017). In humans, COX-1 is uniformly expressed in almost all tissues, most prominently in platelets, blood vessels, smooth muscle cells, interstitial cells, and mesothelial cells. But also the COX-2 protein was found in nearly all organs, such as in brain, kidney, thymus, stomach, and the female reproductive tract, mainly localized to parenchymal cells. Genetic deletion of COX-2 indicates crucial roles of the isoenzyme in kidney development and female fertility, and prolonged therapeutic use of COX-2 selective inhibitors confirms homeostatic functions of COX-2 in the cardiovascular system. Moreover, COX-2 may play a significant role in resolution of inflammation which is particularly important in the healing of gastric ulcers, and inhibition of COX-2 can even cause exacerbated inflammation. On the other hand, COX-1 is constitutively expressed in resident inflammatory cells and can be induced during endotoxin-evoked inflammatory responses and during cellular differentiation. Moreover, pharmacological or genetic inhibition of COX-1 did not result in increased susceptibility to gastric ulceration. In fact, mRNA and protein levels of both COX-1 and COX-2 are co-expressed in circulating inflammatory cells and in the inflamed synovium of rheumatoid arthritis patients. Thus, both COX-isoenzymes may contribute to the acute inflammatory response where COX-1-derived prostanoids may be generated in the initial phase, while COX-2 upregulation is delayed for several hours being the dominant pathway in the chronic phase of the inflammatory response.

Beside the distinct tissue-specific gene expression of COX-1 and COX-2, there are additional reasons why the isoenzymes are not functionally interchangeable at the protein level (Patrignani and Patrono 2015; Smith et al. 2011). First, COX-1 and COX-2 differentially couple to downstream prostanoid synthases, for example, COX-2 with PGIS or with mPGES-1. Second, COX-2 requires lower amounts of activating hydroperoxides than COX-1 and thus COX-2 can function at lower AA concentrations than COX-1. Third, COX-2 exhibits a more promiscuous substrate specificity and can metabolize also EPA, α- and γ-linolenic acid, or linoleic acid, but also ester and amide derivatives of AA, such as the endocannabinoids 2-arachidonoyl-glycerol or arachidonoylethanolamide that are only poor substrates for COX-1. Metabolites of these endocannabinoids display a variety of physiological activities mediated by orphan GPCRs, eicosanoid receptors, or nuclear lipid receptors. Finally, acetylation of Ser530 by aspirin in the active site inhibits prostanoid formation of both isoenzymes but retains the ability of COX-2 to oxygenate AA to 15*R*-hydroperoxy-eicosatetraenoic acid instead of PGG_2. In conjunction with lipoxygenases, acetylated COX-2 can generate aspirin-triggered lipoxins, protectins, and resolvins that are inflammation-resolving lipid mediators that actively terminate inflammation and promote tissue regeneration, potentially explaining the clinical benefits of aspirin (Serhan et al. 2015).

Drugs

With the discovery that aspirin and aspirin-like drugs mediate their anti-inflammatory properties by inhibiting PG formation in 1971, COX was revealed as the major drug target of NSAIDs. Although several off-target effects of NSAIDS have been reported, most of them occurred at supratherapeutic concentrations in cell culture experiments. Today, COX inhibitors are divided into the class of traditional NSAIDs that inhibit both COX-1 and COX-2 and into the class of COX-2-specific inhibitors, referred to as coxibs (Patrignani and Patrono 2015). The serious gastrointestinal toxicity of traditional NSAIDs and the initial assumption that COX-2 is the exclusive source of prostanoids in inflammation and cancer,



Cyclooxygenases, Fig. 2 Physiological and pathophysiological roles of COX-1 and COX-2 and targeting by NSAIDs or coxibs. Physiological stimuli cause moderate formation of TXA_2, PGI_2 and PGE_2 by ubiquitously and constitutively expressed COX-1 and COX-2, mediating normal haemostasis, blood pressure regulation and gastric protection. Under inflammatory conditions, COX-2 is strikingly induced in monocytes and macrophages producing substantial PGE_2 that causes inflammation, fever and pain. Unselective NSAIDS that inhibit COX-1 and COX-2 block the formation of all prostanoids and suppress inflammatory pain and fever but may cause gastrointestinal toxicity devoid of serious cardiovascular hazards. Coxibs and COX-2-preferring NSAIDs (e.g. diclofenac) effectively block inflammation sparing some of the gastric side effect but cause cardiovascular complications due to superiority of COX-1-derived production of pro-thrombotic TXA_2 versus anti-thrombotic PGI_2

without sufficient understanding of COX-2 biology, stimulated the intensive development of coxibs with the expectation that selective COX-2 inhibition provides analgesia devoid of gastrointestinal complications. Later it was found that these actively advertised "safer NSAIDs" revealed cardiovascular adverse events, including heart attacks, which is currently the major obstacle related to the use of COX-2-selective drugs (Schjerning et al. 2020). Together, the commonly accepted rule of thumb is that COX-2 inhibition is required and sufficient for NSAIDs to exert the anti-inflammatory, analgesic, and antipyretic effects, while the variable degrees of COX-1 and COX-2 inhibition contribute to the toxicities affecting the gastrointestinal tract, the kidneys, and the cardiovascular system, eventually providing a rational for developing COX-2 selective inhibitors (Fig. 2).

Among the multiple NSAIDs, aspirin is unique as this drug is the only one that covalently and irreversibly inhibits COX-1/2 by acetylation of Ser530. All the other NSAIDs bind noncovalently as either (a) rapidly and time-dependent AA-competitive inhibitors (e.g., naproxen) or (b) time-independent tightly binding inhibitors (e.g., indomethacin) that slowly form very stable complexes with COX and are highly potent. Interestingly, no structural differences are apparent in complexes of COX-1 with a competitive inhibitor or a slow tight-binding inhibitor (Kurumbail et al. 2001).

The chemical structures of NSAIDs are diverse but exhibit the common features of fatty acid-like molecules with a hydrophobic backbone

consisting of an aromatic nucleus and an acidic head group:

- Salicyclic acids, for example, aspirin or sulphasalzine
- Phenylacetic acids, for example, diclofenac, felbinac, or bufexamac
- Hereoaryl acetic acids, for example, indomethacin or etodolac
- Arylpropionic acids, for example, ibuprofen, flurbiprofen, naproxen, dexketoprofen or thiaprofenic acid
- Anthranilic acids, for example, mefenamic acid or flufenamic acid
- Enolic acids/oxicames, for example, meloxicam, lornoxicam, or piroxicam

The crystal structure of COX-1 with various NSAIDs such as diclofenac, ibuprofen, or flurbiprofen revealed that the aromatic portion of the molecules lies in the hydrophobic substrate-binding channel of the enzyme while the acidic moiety forms hydrogen bond to the hydroxyl of Tyr338 and the guanidinium group of Arg120. The NSAID-binding site in COX-2 is identical to the one in COX-1, except the presence of the Val523 and Arg513 in COX-2 versus the more space-demanding Ile523 and His513 in COX-1. The smaller amino acids in the COX-2 active site cause a slightly larger volume of the drug-binding cavity and allow, in contrast to COX-1, the accommodation of the sulfone or sulfonamide group of coxibs (e.g., celecoxib, etoricoxib, parecoxib). This eventually enabled the development of selective COX-2 inhibitors with 10- to 100-fold superior potencies to COX-2 versus COX-1 enzymes. Notably, the ratio of COX-1/COX-2 selectivity of a given inhibitor can strikingly differ, depending on the assay system, that is, cell-free versus cell-based assays. For example, the binding affinities of celecoxib are up to 3200-fold higher for COX-2 over COX-1, while in cell-based systems (human whole blood assay) there was no marked selectivity for COX-2. Similarly, aspirin inhibits the activities of isolated COX-1 and COX-2 enzymes with similar potencies but is about 60-fold more against COX-1 in isolated human platelets as compared to COX-2 in isolated human monocytes (Patrignani and Patrono 2015).

NSAIDs block the biosynthesis of all types of prostanoids due to unselective inhibition of COX−1/2 and are efficacious therapeutics with antipyretic, anti-inflammatory and analgesic effects. However, due to inhibition of prostanoids with homeostatic functions, they are also afflicted with severe side effects. The most common on-target side effects are as follows:

- Gastrointestinal toxicity: ulceration, bleeding, perforation, erosion, and dyspepsia, mainly due to reduced PGE_2 levels
- Nephrotoxic effects: Na^+ and water retention, edema, and acute kidney failure, essentially due to lower PGI_2 and PGE_2 levels
- Cardiovascular toxicity: higher bleeding tendencies (in particular with aspirin) due to impaired TXA_2 and elevated blood pressure, heart attack, stroke, and heart failure, mainly due to increased ratio of TXA_2 to PGI_2 formation

Note that NSAIDs that even only moderately prefer COX-2 over COX-1, such as meloxicam, nimesulide, and etodolac, induced less stomach toxicity than other representatives like indomethacin or naproxen that dominate in COX-1 inhibition. In fact, the COX-1-dependent gastrointestinal toxicity of NSAIDs favored the clinical development of the COX-2-selective coxibs, in order to limit its burden. As expected, the COX-2-selective coxibs display reduced toxic effects in the stomach despite potent anti-inflammatory efficacy, but still are not entirely devoid of gastrointestinal complications. Thus, using selective inhibitors or genetic deletion of COX-2 revealed an important role of COX-2 in the healing of preexisting ulcers, suggesting that both COX-isozymes are a source of cytoprotective prostanoids. Therefore, simultaneous inhibition of COX-1 and COX-2 that profoundly suppresses prostanoid biosynthesis might be a hazard for the gastrointestinal system consistent with the finding that in mice inhibition of both COX-1 and COX-2 is required for the induction of gastric lesions.

The most problematic obstacle with coxibs is their modest but consistent increase in cardiovascular risk under chronic use (particularly under long-term use, > 1.5 years) in a small percentage of patients, which led to the withdrawal of rofecoxib (in 2004), valdecoxib (in 2005), and lumiracoxib (in 2007) from the market after slightly higher incidences of myocardial infarctions and thromoembolic events in risk patients. The increased risk of cardiovascular events under coxib treatment is seemingly due to the preferential inhibition of systemic (and renal) vasodilatory and platelet-inhibitory PGI_2 produced by constitutively expressed COX-2 in the endothelium versus platelet-derived prothrombotic TXA_2 generated by COX-1 in platelets (Fig. 2). Nevertheless, other factors may contribute including intra- and inter-subject variability in the extent of COX isozyme inhibition and COX-2 selectivity achieved at therapeutic doses of coxibs related to heterogeneity in the pharmacokinetics and pharmacodynamics.

Conclusions and Future Perspectives of COX Inhibitors

The COX-1 and COX-2 isoforms are the key enzymes in the biosynthesis of prostanoids and are the targets of NSAIDs that are effective, widely used analgesics. The ubiquitous constitutive expression of COX-1 and the inducible expression of COX-2 led to the hypothesis that COX-1 produces homeostatic PGs, while PGs produced by COX-2 are primarily pathophysiological contributing to inflammation, fever, pain, and cancer. Recent discoveries question this paradigm and reveal more complex functionalities for both isoenzymes.

After initial attempts to eliminate the gastrointestinal toxicity of unselective COX-1/2 inhibitors, considerable attention has then been focused on the cardiovascular safety of COX-2-selective drugs given the increased risks of heart failure, elevated blood pressure, and thrombotic events in a very small number of patients. Today it is accepted that gastrointestinal toxicity is evident for all NSAIDs, also for COX-2-selective drugs. The greatest risk of cardiovascular hazards concerns coxibs but also nonselective NSAIDs with strong COX-2 inhibition such as diclofenac. Thus, the use of NSAID is generally discouraged in cardiovascular risk patients but pain-relief medication is often required, but the use of NSAIDs is still likely to rise. Future studies should focus on optimizing the safe use of NSAIDs using measures of drug exposure and biochemical markers of drug activity, carefully monitored for blood pressure and renal function as functional markers of COX-2 inhibition and measurements of symptom relief. Careful risk-benefit evaluation might help at identifying those patients for which COX-2-selective inhibitors should remain the drug of choice, versus traditional NSAIDs.

Cytokines

Michael Kracht[1] and Helmut Holtmann[2]
[1]Rudolf Buchheim Institute of Pharmacology, Justus Liebig University Giessen, Giessen, Germany
[2]Medical School Hannover (emeritus in 2017), Hannover, Germany

Synonyms

Chemokines; Growth factors; Interferons; Interleukins; Lymphokines; Monokines

Definition

Cytokines are a large and heterogeneous group of small polypeptides, most of them with a Mr between 8 and 30 kDa (Table 1). They are mostly soluble extracellular mediators (some exist in membrane-associated form) and function through high-affinity cell surface receptors. Released by cells of hematopoietic origin (reflected in the terms "lymphokines" and "monokines") as well as by a wide variety of non-hematopoietic cells, cytokines are critical for the normal functioning of the immune defense, which they coordinate by communicating between participating cells.

"My private metaphor was that of a zoo of factors in a jungle of interactions surrounded by deep morasses of acronyms and bleak deserts of synonyms" (Ibelgaufts 2020).

Basic Characteristics

Historically, many cytokines were discovered by means of their immunoregulatory properties, hence, the term interleukins. However, cytokines

Cytokines, Table 1 Structural/functional groups of cytokines (examples)

Interferons	IFN-α, β, γ
Hematopoietic cytokines/colony-stimulating factors	IL-3, IL-7, erythropoietin (EPO), GM-CSF, G-CSF, M-CSF, thrombopoietin (THPO)
IL-1 family	IL-1α, IL-1β, IL-18, IL-1Ra, IL-33, IL-37
TNF family	TNFα (cachectin, TNFSF2), lymphotoxin-alfa (TNFβ,TNFSF1), CD40 ligand (TRAP, TNFSF5), CD95 ligand (FAS ligand, TNFSF6), TRAIL (Apo2 ligand, TNFSF10)
Chemokines	IL-8 (CXCL8), GROα/β/γ (CXCL1/2/3), MIP1α (CCL3), MIP3α (CCL20), MCP1 (CCL2), IP-10 (CXCL10), I-TAC (CXCL11)
Immunoregulatory cytokines	IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-17, IL-23

regulate not only functions of the specific immune system but also many aspects of infection and inflammation. At the cellular level, they control proliferation, differentiation, functional activity, and apoptosis. As a whole, they are synthesized by a broad variety of different cell types. This also holds true for many cytokines individually (e.g., IL-6, IL-8, IFN-β, for further information on individual cytokines, see Ibelgaufts 2020), whereas synthesis of others is restricted to one or few cell types (e.g., IL-2, IL-4, IL-17, IFN-γ). In general, their biosynthesis is rapidly and highly inducible by changes of the cell's microenvironment. Cytokines often have a short half-life, and production is restricted to potentially pathological conditions. Uncontrolled synthesis results in the systemic inflammatory response syndrome ("cytokine storm") but more often in chronic inflammatory or other diseases. All cytokines act locally in an autocrine or paracrine manner, but some may also act systemically. Examples for the latter are the induction of fever by IL-1 and TNF and the induction of acute phase proteins in the liver by IL-6. Cytokines can therefore also be regarded as hormones. Cytokines are pleiotropic, that is, they control multiple biological responses. There is considerable functional overlap between certain cytokines (e.g., TNF and IL-1 both induce inflammation). In general, activation of a cell by a cytokine results in reprogramming of the cell's gene expression profile.

Mechanism of Action

Most cytokines – in particular the ones that are targeted in the clinics – bind to high-affinity receptors on the plasma membrane. These receptors fall into different classes, those with enzymatic tyrosine kinase activity (e.g., the receptors of certain hematopoietic growth factors (M-CSF, SCF), G-protein-coupled receptors (chemokine receptors), and several groups that bind to a variety of intracellular adaptor proteins (IL-1, TNF, interferon, and hematopoietic cytokine receptor families)). Ligand-dependent receptor clustering activates several intracellular signaling pathways. These pathways consist of consecutive interactions between protein components that in part involve enzymatic activities. The activity of many proteins in a given cytokine-activated pathway is regulated by reversible phosphorylation and by non-degradative ubiquitinylation. The NF-κB, MAP kinase cascades, and JAK-STAT signaling pathways are intensively studied examples. Certain receptors (of the TNF-R family) can activate caspases, a family of proteases that executes programmed cell death. Other protein synthesis-independent effects of cytokines include cytoskeletal changes and modulation of cell surface receptors and adhesion molecules. Most cytokine-activated intracellular pathways ultimately turn on expression of genes whose products change the biological function of the same or a neighboring cell. These include further cytokines (hence the term "cytokine network"), cell surface receptors and adhesion molecules, enzymes involved in degradative processes (e.g., collagenases), and in formation of small molecular weight mediators (e.g., cyclooxygenases, NO synthases).

Cytokines and Therapy

Knowledge on cytokines has been exploited to improve the therapy of many diseases, basically in two ways:

1. Application of cytokines as drugs. A few relevant examples will be given below. In general, treatment with cytokines turned out to be problematic due to their pleiotropic nature of function. Thus tumor necrosis factor, apart from its antitumoral effect, has severe sepsis-like systemic side effects as manifestations of its activity, which largely precludes its use as anticancer drug. Similar toxicity has been observed for several other inflammatory cytokines, in particular IL-1 family members. Selected recombinant cytokines are being used to boost immune reactions during infection and cancer (interleukin-2, interferons) or to substitute cytokine deficiencies (hematopoietic growth factors, erythropoietin).
2. Interference with cytokine action. Inhibition of cytokine synthesis has turned out to be a major

component of the activity of anti-inflammatory drugs, with glucocorticoids being the most prominent example. Because for many cytokines the molecular mechanisms of their actions have been worked out in detail, rational strategies for interfering with their biological activities have been developed. The action of cytokines can be suppressed pharmacologically by different means: (i) inhibition of their synthesis by drugs (cyclosporin → IL-2 synthesis); (ii) prevention of their interaction with cell surface receptors by soluble receptors (TNFR1 extracellular domain), by neutralizing anti-cytokine (α-TNF) or anti-cytokine receptor (α-IL-2R) antibodies, or by natural antagonists (IL-1R antagonist); and (iii) blockade of specific events in the intracellular signaling pathways by protein kinase inhibitors such as JAK inhibitors. Extracellularly acting clinically used cytokines or cytokine antagonists are proteins. Repeated application, especially for those of nonhuman origin, bears the risk of recognition by the immune system and of antibody production against them with subsequent loss of efficacy or systemic or local adverse reactions. Therefore, the proteins are nowadays genetically engineered, that is, humanized to be as homologous as possible or to be even identical to human proteins. Variants of classical antibodies include antibody (Fab) fragments, polyethylene glycol (PEG)-modified Fab fragments, single chain nanobodies, bispecific antibodies, or antibody Fc fragments fused to extracellular receptor domains. Increasingly, biosimilars are produced which mimic the protein structures and activities of approved antibodies (Shepard et al. 2017).

Clinical Use (Including Side Effects)

Examples of Recombinant Cytokines Currently in Use

Interferons

Interferon alfa-2a (Roferon A®) and interferon alfa-2b (Intron A®) are applied in the treatment of chronic hepatitis B and some malignancies, especially hairy cell leukemia. IFNα proteins induce the expression of antiviral, antiproliferative, and immunomodulatory genes. Interferon beta-1a (Avonex®, Rebif®) and interferon beta-1b (Betaferon®, Extavia®) are applied in multiple sclerosis to reduce both frequency and severity of disease incidents. In multiple sclerosis, IFNβ proteins modulate the destruction of myelin in the cause of the autoimmune reaction. Interferon gamma-1b (Imukin®) is used to reduce the incidence of infections in the treatment of chronic granulomatosis and osteopetrosis. Common side effects of interferons are flu-like symptoms, fever, myelosuppression, and skin reactions.

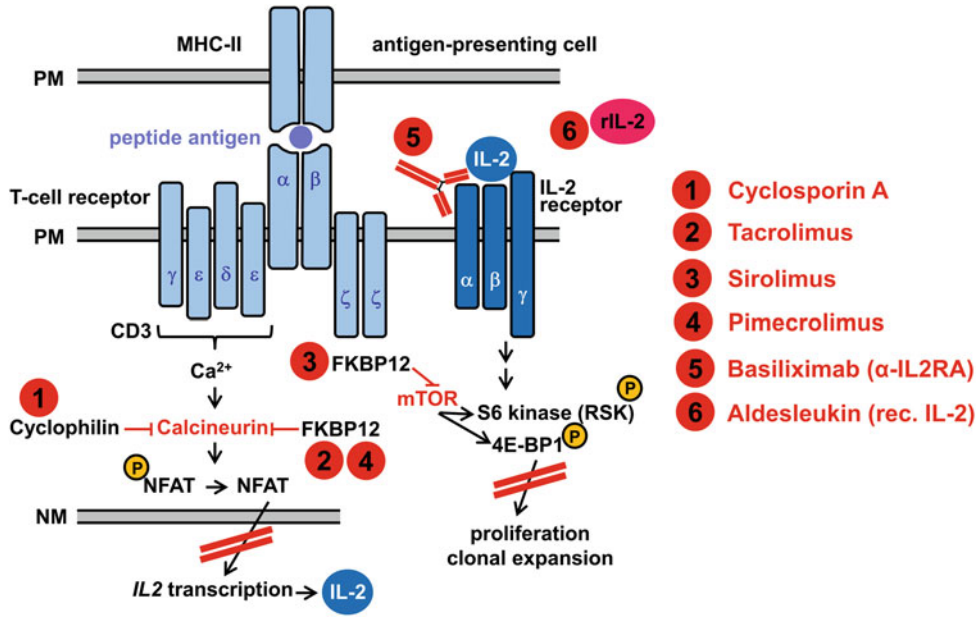
The recombinant forms of granulocyte colony-stimulating factor (G-CSF), such as filgrastim (r-metHuG-CSF, Neupogen®) and its biosimilars (Accofil®, Nivestim®, Grastofil®), or pegylated filgrastim and lenograstim (rHuG-CSF, Granocyte®), promote the differentiation of pluripotent bone marrow stem cells to leukocytes. GM-CSF (molgramostim) induces proliferation of cells of the macrophage, neutrophil, and eosinophil lineages, while G-CSF acts primarily on neutrophil precursors. They are effective in treatment of congenital and acquired neutropenias during chemotherapy of cancer or bone marrow transplantation. G-CSF is also applied to donors to increase peripheral blood progenitor cells for allogeneic bone marrow transplantation. Side effects include bone pain, fever, and myalgia. Interleukin-2 (Aldesleukin, Proleukin®) is a major growth factor and activator of cytotoxic and other T-lymphocytes. It is applied in the therapy of metastasing renal carcinoma. Side effects include hypotension, arrhythmias, edema, pruritus, erythema, central nervous symptoms, fever, and many others. Erythropoietin is physiologically produced in the kidney and regulates proliferation of committed progenitors of red blood cells. Recombinant versions (darbepoetin alfa, epoetin alfa, beta, theta, zeta) are used to substitute erythropoietin in severe anemias due to end-stage renal disease or treatment of cancer with cytostatic agents. Side effects include hypertension and increased risk of thrombosis.

Inhibitors of Cytokine Action

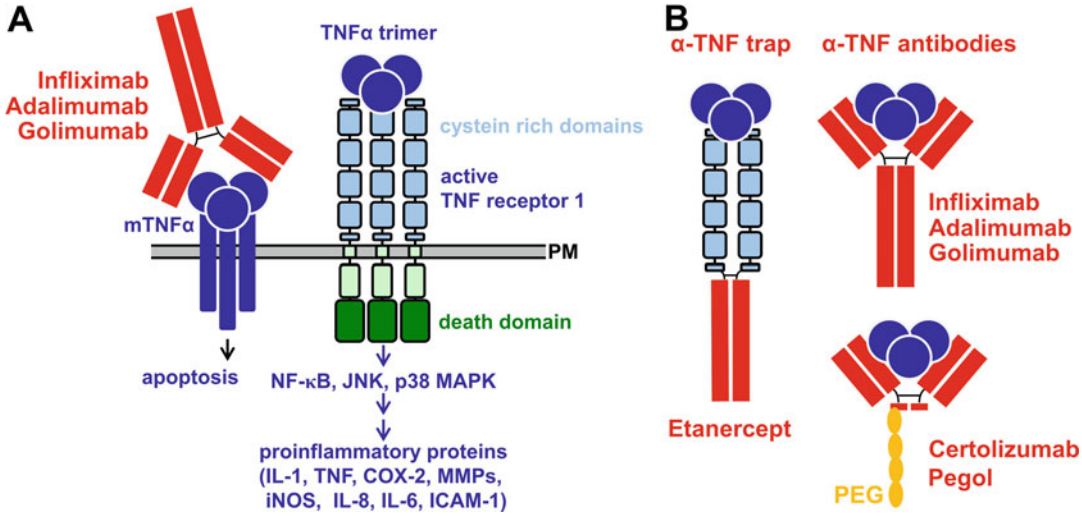
The humanized recombinant anti-IL-2 receptor antibody basiliximab (Simulect®) binds with high affinity to the IL-2 receptor alfa chain on T-lymphocytes and prevents activation and clonal expansion of anti-allograft T-lymphocytes by endogenous IL-2 during acute (kidney) allograft rejection. The main side effects are severe immunosuppression and cytokine release syndrome.

In intracellular inhibition of IL-2 production and activity, the immunosuppressants cyclosporin A (Sandimmune®), tacrolimus (Prograf®), (topical) pimecrolimus (Elidel®), and sirolimus (Rapamune®) are used for the prophylaxis of allograft rejection, for severe forms of autoimmune diseases, and for external treatment of inflammatory skin diseases (atopic dermatitis). Cyclosporin binds to the intracellular protein cyclophilin, and tacrolimus/pimecrolimus bind to the intracellular protein FK506-binding protein (FKBP) 12. The resulting complexes inhibit a serine-threonine phosphatase, calcineurin, which is required for T-lymphocyte activation and for IL-2 gene expression. Sirolimus also binds to FKBP12. However, the complex inhibits a different enzyme, the protein kinase mTOR (mammalian target of rapamycin), which is a major regulation of protein synthesis. Thereby, it inhibits IL-2 receptor-dependent progression of activated T-lymphocytes through the cell cycle. All four drugs suppress clonal expansion of antigen-activated T-lymphocytes. Cyclosporin and tacrolimus are nephrotoxic, and sirolimus causes hyperlipidemia (Fig. 1).

The monoclonal anti-TNF antibodies infliximab (Remicade®), adalimumab (Humira®), golimumab (Simponi®), and certolizumab pegol (Cimzia®) bind with high selectivity to human TNFα and neutralize its activity. Thereby, they decrease the effects of enhanced TNF levels during inflammatory disease such as production of



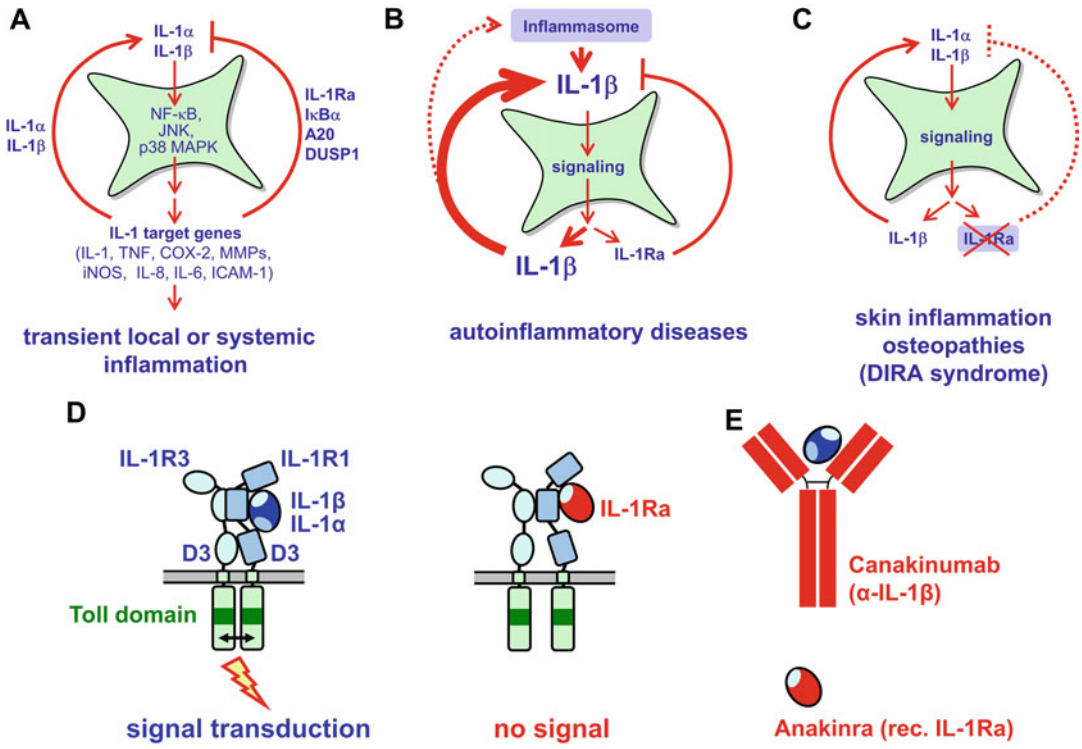
Cytokines, Fig. 1 Modulation of cytokine synthesis and function during activation of the specific immune system: antigenic activation of the multi-subunit T-cell receptor induces IL-2 synthesis which promotes clonal T-cell proliferation through the IL-2 receptor. IL-2 delivery or IL-2 receptor blockade activates or suppresses this process. The calcineurin antagonists cyclosporin A, tacrolimus, and pimecrolimus inhibit activation of cytoplasmic NFAT, a transcription factor essential for activation of the IL-2 gene (see entry ▶ "NFAT Family of Transcription Factors"). The mTOR antagonist sirolimus interferes with mTOR complex 1 (mTORC1) signaling and protein biosynthesis and thereby inhibits IL-2-dependent proliferation. *4E-BP1* eukaryotic translation initiation factor 4E-binding protein 1, *MHC* major histocompatibility complex, *NFAT* nuclear factor of activated T cells, *NM* nuclear membrane, *P* phosphorylation, *PM* plasma membrane, *rec.* recombinant, *RSK* ribosomal S6 kinase



Cytokines, Fig. 2 Modulation of TNFα: (**a**) scheme of the active trimeric TNF receptor 1 bound by a TNFα trimer upon inflammatory cell activation. Membrane-bound mTNFα can induce paracrine or reverse signaling and can be bound by α-TNFα antibodies to induce apoptosis. (**b**) Summary of TNFα antagonists. *NF-κB* nuclear factor "kappa-light-chain-enhancer" of activated B cells, *JNK* JUN N-terminal kinase, *mTNFα* membrane TNFα, *MAPK* mitogen-activated protein kinase

matrix metalloproteinases (MMPs), chemokines, adhesion molecules, cyclooxygenase-2 (COX-2) products (i.e., prostaglandins), inducible NO-synthase (iNOS), and proinflammatory molecules such as interleukin-1 and interleukin-6. The antibodies also recognize membrane-bound (m) TNFα on lymphocytes and other immune cells. These cells may subsequently become apoptotic or are eliminated via Fc-receptor-mediated phagocytosis. The anti-TNF antibodies are used to treat Crohn's disease, psoriasis (including psoriasis arthritis), spondylitis ankylosans, and rheumatoid arthritis. Side effects include immunosuppression and increased risk of infections. The recombinant soluble TNFR1-IgG1 fusion protein etanercept (Enbrel®) is a chimeric molecule consisting of the extracellular domain of the TNF receptor 1 (TNFR1) and the Fc portion of human IgG1. Two Fc domains are bound to each other via disulfide bonds, thereby yielding dimers with two binding sites for the TNF trimer. Such a construct is also called cytokine trap. Etanercept binds with high affinity to extracellular TNF and reduces TNF activity. Etanercept is not effective in Crohn's disease, possibly because it does not lead to destruction of membrane TNFα expressing cells or reverse mTNFα-mediated signaling. Indications and side effects are similar to those of infliximab and adalimumab (Fig. 2).

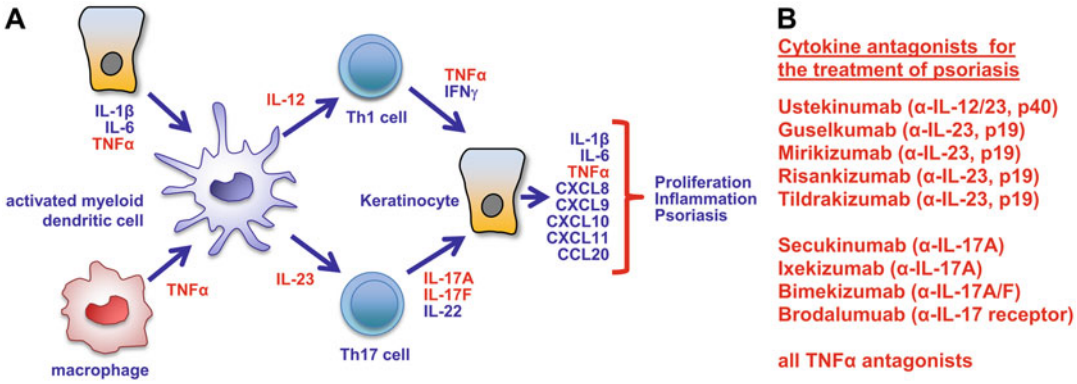
The recombinant human IL-1 receptor antagonist (anakinra, Kineret®) blocks the biological activity of both interleukin-1α and interleukin-1β by competitively inhibiting IL-1 binding to the interleukin-1 type I receptor (IL-1R1), which is expressed in most tissues and organs. The antibody canakinumab (Ilaris®) blocks secreted IL-1β. Both agents broadly reduce the proinflammatory activities of IL-1 including fever, cartilage destruction, and bone resorption and are highly effective in the treatment of gout and a number of auto-inflammatory syndromes which are mainly driven by cells of the myeloid compartment rather than by T or B cells (e.g., familial Mediterranean fever (FMF), cryopyrin-associated periodic syndrome (CAPS), and systemic juvenile idiopathic arthritis). Mild side effects include an increased risk of infections and neutropenia. The efficacy, therapeutic index, and safety of Anakinra allow using a single injection to diagnose IL-1-dependent disease (Fig. 3) (Mantovani et al. 2019).



Cytokines, Fig. 3 Modulation of the IL-1 system: (**a**) besides their own expression (as a feedforward loop), IL-1α and IL-1β induce the expression of multiple inflammatory proteins through the NF-κB, JNK, and p38 signaling pathways. The inflammatory reaction is self-limiting due to the simultaneous induction of a range of anti-inflammatory proteins, including the IL-1 receptor antagonist IL-1Ra. (**b**) Mutations in proteins of the IL-1β-releasing inflammasome complex amplify the feedforward loop, thus driving a range of the so-called auto-inflammatory disease. (**c**) Loss-of-function mutations in the IL-1Ra gene cause severe systemic inflammation including skin and bone disease by affecting negative control of endogenous IL-1 cytokines. (**d**) Scheme of the active IL-1 receptor heterotrimer composed of two subunits IL-1R1 and IL-1R3 (formerly called IL-1 receptor accessory protein, IL-RAcP) plus IL-1α or IL-1β ligands. Ligand binding causes a conformational change in the D3 domain of the IL-1R1 which promotes spatial proximity of the intracellular Toll domains to induce signaling. Binding of IL-1Ra to the IL-1R1 prevents formation of the active receptor structures. (**e**) Recombinant IL-1Ra and anti-IL-1β antibodies are highly effective in blocking IL-1-dependent diseases. *DIRA* deficiency of IL-1Ra syndrome, *A20*, also called *TNFAIP3* tumor necrosis factor alpha-induced protein 3, *DUSP* dual-specificity phosphatase, *IκBα* inhibitor of NF-κB alfa

While TNFα and IL-1α/IL-1β can be considered as master regulators of multiple proinflammatory diseases, the disruption of the IL-23/IL-17 network by antibodies has proven to be highly effective in the treatment of psoriasis and also inflammatory bowel diseases (Nestle et al. 2009). The antibodies ustekinumab (Stelara®), guselkumab (Tremfya®), risankizumab (Skyrizi®), tildrakizumab (Ilumetri®), secukinumab (Cosentyx®), ixekizumab (Taltz®), and brodalumab (Kyntheum®) interfere with this network at several levels and are in clinical use, while mirikizumab and bimekizumab are awaiting approval (Fig. 4).

Antibodies against IL-5 (mepolizumab (Nucala®), reslizumab (Cinqaero®)) or the IL-5 receptor (benralizumab (Fasenra®)) on eosinophils block differentiation and activation of these white blood cells and are used to reduce the



Cytokines, Fig. 4 Modulation of the IL-23/IL-17 cytokine network: (**a**) cell types and cytokine/chemokine mediators driving the uncontrolled keratinocyte proliferation and inflammation in psoriatic skin disease. (**b**) Approved antibodies with efficacy in blocking the actions of IL-23 and IL-17 type cytokines in psoriasis in addition to all TNFα antagonists. Note that IL-23 is composed of two subunits, p19 and p40, the latter is shared with IL-12. (**b**) Interference with the cytokine network is highly effective for treating psoriasis, a common chronic inflammatory skin disease with multiple systemic manifestations, including arthritis

severity and frequency of asthma attacks that are resistant to standard therapy.

The IL-6 receptor antibody tocilizumab (Roactemra®) is combined with methotrexate to treat severe rheumatoid arthritis, while the anti-IL-6 antibody siltuximab (Sylvant®) is used to treat Castleman disease, a lymphoproliferative disorder.

The JAK protein kinase inhibitors baricitinib (Olumiant®) and tofacitinib (Xeljanz®) suppress activation of JAK-STAT signaling and thereby the downstream effects on multiple inflammatory cytokines simultaneously. Baricitinib has a preference for JAK1 and JAK2, whereas tofacitinib preferentially targets JAK1 and JAK3. Both compounds suppress STAT1, 3, 5 phosphorylation and subsequent gene expression events. Both inhibitors affect the (patho)physiological functions of IL-2, IL-4, IL-7, IL-9, IL-10, IL-15, IL-21, IL-22, IFNα/β/γ, GM-CSF, EPO, TPO, and IL-6. Tofacitinib also suppresses IL-12 and IL-23 signaling. These drugs are alternative treatments for rheumatoid arthritis in case the abovementioned monoclonal antibodies or conventional disease-modifying antirheumatic (DMARDs) drugs fail. Tofacitinib is additionally approved for the treatment of psoriasis and colitis ulcerosa.

Outlook: Anti-cytokine therapy is now firmly established in the clinics and offers multiple new options for personalized therapy of common but also rare chronic inflammatory diseases. Improvements will involve variants of genetically engineered proteins with altered specificities and pharmacokinetic properties such as bi-specific antibodies or nanobodies (Shepard et al. 2017). Future developments will involve a better understanding of combination therapies targeting several components of cytokine networks simultaneously and the development of allosteric and irreversible (rather than ATP-competitive reversible) inhibitors of intracellular cytokine pathways (Gaestel et al. 2009).

Definition

Deubiquitylating enzymes (DUBs) are the peptidases that can remove ubiquitin from substrate

S. Offermanns, W. Rosenthal (eds.), *Encyclopedia of Molecular Pharmacology*,
https://doi.org/10.1007/978-3-030-57401-7

proteins, edit ubiquitin chains, or cleave ubiquitin precursors. Human genome encodes about 100 DUBs that can be classified into six families based on similar sequence and conserved domains. These DUB families include ubiquitin-specific proteases (USPs), ubiquitin carboxyl-terminal hydrolases (UCHs), Machado-Josephin domain-containing proteases (MJDs), ovarian tumor proteases (OTUs), motif interacting with ubiquitin-containing novel DUB family (MINDYs), and JAB1/MPN/MOV34 metalloenzyme family (JAMMs). The first five DUB families are cysteine peptidases with the catalytic triad of cysteine, histidine, and asparagine/asparagine residue, whereas JAMMs are zinc metallopeptidases. DUBs exhibit strong substrate selectivity in targeting individual proteins and structural motifs. This specificity is imparted via the key domain of DUBs, i.e., a zinc finger ubiquitin-specific protease domain (ZnF-UBP domain) (Dou and Zonder 2014; Farshi et al. 2015; Harrigan et al. 2018).

Basic Characteristics

Characteristics of Ubiquitylation

Ubiquitylation exhibits vital enzymatic reactions for post-modification and turnover of substrate proteins in cellular processes. Ubiquitin, a 76-residue polypeptide, is conjugated to different residues of a variety of target proteins. In humans, approximately 600 ubiquitin E3 ligases have been identified to ensure the specificity of substrate selection. Linear ubiquitin chains exist in several formats depending on the linkage of the internal ubiquitin lysine residue (Lys6, Lys11, Lys27, Lys29, Lys33, Lys48, or Lys63). Similarly, polyubiquitin chains have different linkages that are involved in linkages between ubiquitin and ubiquitin-like proteins (UBLs) such as small ubiquitin-like modifier (SUMO) and neuronal precursor cell-expressed developmentally down-regulated protein 8 (NEDD8). Based on different types of ubiquitin and UBL modifications, the target proteins exhibit specific and diverse effects on cellular physiology. Such modifications of target protein are found in the ubiquitin proteasome system (UPS). Mostly, proteins polyubiquitylated via E3 ligases are recognized and then degraded by multimeric 26S proteasome complex; thus the ubiquitin moieties are recycled by the UPS. Currently, protein ubiquitylation process commonly exists in eukaryotic cells and is well investigated. Ubiquitylation plays a central role in regulating protein interactions, localization, and enzymatic activities and is involved in regulating DNA transcription, DNA damage and repair, cell cycle progression, endocytosis, apoptosis, and other cellular processes (Farshi et al. 2015).

Characteristics of Deubiquitylating Enzymes

Protein ubiquitylation is a reversible process conducted by DUBs. Just like phosphatases reversing protein phosphorylation, DUBs trim or remove ubiquitin chains linked to the substrate protein, act as vital regulatory components for posttranslational modifications, and add to the complexity and sensitivity of the UPS. The complex nature of UPS modulation helps the cell to accurately respond to various physiological states and stimuli through modulating the stability of key molecules in the cells.

DUBs selectively cleave ubiquitin chains to release ubiquitin. Through this critical process, DUBs modulate the degradation or activation of target proteins. Thus, diverse processing or removal of polyubiquitin moieties or chains on proteins regulated by DUBs determines the fate of targeted proteins into degradation by proteasome or another function (such as traveling to a differential subcellular localization). Importantly, DUB-mediated cleavage of polyubiquitylated chains works in a similar manner as a protein phosphatase to release phosphorylated groups in the kinase-phosphatase network. Thus, DUBs and E3 ligases determine protein fates in a similar way that kinases and phosphatases regulate protein activities. Specific cleavage along the ubiquitin chains in different locations can have differential effects on the fates of ubiquitylated proteins, which provides the cells with a complex and dynamic system to modulate protein turnover, activity, expression, and localization. In addition, DUBs regulate gene expression, apoptosis, cell cycle, DNA repair, and signaling (Harrigan et al. 2018).

DUBs in Cellular Signaling

Regulation of p53 Signaling

Deubiquitylation has emerged as a crucial process of p53 stability regulation. Several DUBs are involved in modulating the E3 ligase MDM2 (Murine double minute 2) that is a negative regulator of p53 stability. For example, OTUB1 can abrogate p53 ubiquitylation and increase p53 stability and activity via inhibiting MDM2 cognate ubiquitin-conjugating enzyme (E2) UbcH5. Through binding to E2 enzyme Ubc13, OTUB1 also modulates the K63-ubiquitylated chromatin induced by DNA damage. By cleaving ubiquitin chains on MDM2, USP7 can inhibit proteasomal degradation of MDM2 protein, leading to accumulation of MDM2 and suppression of p53 through increased ubiquitylation and degradation of p53. So, USP7 inhibition should trigger MDM2 degradation, p53 stabilization, and ultimately activation of apoptotic pathways in tumor cells. USP42 is another DUB important for p53 stability. p53 can be directly deubiquitylated by USP42 that reverses its ubiquitylation by MDM2. USP42 forms a direct complex with p53 and controls its activation in response to cellular stress; as a result it regulates p53-dependent transcription and cell cycle arrest. In addition, other DUBs such as USP2 and USP15 have been characterized to bind with p53 and deubiquitylate MDM2, thereby impeding expression of p53 (Harrigan et al. 2018).

Regulation of NF-κB Signaling

Ubiquitylation of key signaling molecules by E3 ubiquitin ligases has emerged as an important regulatory mechanism for nuclear factor-kappa B (NF-κB) signaling. DUBs counteract E3 ligases and therefore play a crucial role in the downregulation of NF-κB signaling and homeostasis. An important molecule A20, which was first identified as a zinc finger protein, can negatively regulate NF-κB signaling pathway by modifying receptor-interacting protein (RIP) with K63-ubiquitin chain and targeting RIP for degradation. Further investigating the mechanisms of NF-κB downregulation by specific DUBs such as A20 and CYLD (cylindromatosis) may provide therapeutic opportunities for the treatment of chronic inflammatory diseases and cancer (Harhaj and Dixit 2011).

Regulation of TGF-β Pathway

Transforming growth factor-β (TGF-β) pathway has a tumor suppressor role in normal and premalignant cells but promotes oncogenesis in advanced cancer cells. Several DUBs like USP4, USP11, USP15, USP18, USP9X, A20, AMSH, CYLD, and UCH37 can regulate TGF-β signaling pathway. UCH37 interacts with SMAD7 (mothers against decapentaplegic homolog 7) and deubiquitylates TβR-I (transmembrane serine/threonine kinase receptors type I) and therefore stabilizes the type I receptor and acts as the counterpart of SMAD ubiquitin regulatory factors (SMURFs) in regulating expression of TβR-I. UCH37 also increases early signaling and plays a role in TGF-β-induced migration. USP15 binds to the SMAD7-SMURF2 complex and deubiquitylates and stabilizes the type I TGF-β receptor, leading to enhanced TGF-β signaling. USP15 in glioblastoma has been identified to stabilize TβR-I and activate oncogenesis through the activation of TGF-β signaling. In addition, USP15 regulates TGF-β signaling by deubiquitylating mono-ubiquitylated receptor-regulated SMADs (R-SMADs) as well. CYLD acts as an inhibitor against JNK (c-Jun amino-terminal kinase) and NF-kB signaling and regulates TGF-β signaling in T cells. CYLD preferentially hydrolyzes or cleaves K63-linked ubiquitin chains and regulates TGF-β signaling. CYLD inhibits the TGF-β-induced development of regulatory T cells through deubiquitinating SMAD7 that inhibits the activation of transforming growth factor receptor-β-activated kinase 1 (TAK1) and p38. AMSH (associated molecule with the SH3 domain of STAM) and AMSH-LP (AMSH-like protein) bind to inhibitory SMADs (I-SMADs) and inhibit their function to enhance TGF-β and bone morphogenetic protein (BMP) signaling. Mono-ubiquitylation of SMAD4 at K519 blocks binding of SMAD4 to phospho-SMAD2; FAM/USP9x reverts this negative modification and re-empowers SMAD4 function. These findings provide a novel molecular target for the

design of inhibitors with therapeutic potential in various diseases (Iyengar 2017).

Cytokine-Inducible Deubiquitinating Enzymes

Currently, the well-characterized cytokine-inducible DUBs in murine include DUB-1, DUB-1A, DUB-2, DUB-2A, and DUB-3, which exert regulatory functions in cell proliferation and apoptosis in lymphocytes. For example, IL-3, IL-5, and GM-CSF stimulate DUB-1 expression, thereby arresting growth in the G_1 phase of the cell cycle. Essentially, the inhibitory effect of DUB-1 is specific to hematopoietic cells. Like DUB-1, DUB-2 is also stimulated by IL-2 and expressed in T lymphocytes that exhibited constitutive activation of the IL-2 signaling pathway. Interestingly, expression of DUB-2 in Ba/F3 cells can enhance the survival of these cells through strongly inhibiting apoptosis induced by cytokine withdrawal. In addition, DUB-3 induced by IL-4 and IL-6 can regulate cell growth and survival and, when constitutively expressed, results in growth suppression and apoptosis. Since cytokine-inducible DUBs play the vital role in various immune-related cells, it might be interesting to investigate cytokine-inducible human DUB homologues and define cytokine signal transduction and molecular mechanisms through the discovery of DUB inhibitors (Lim et al. 2013).

DUBs as Clinical Markers of Cancers

Several mutated DUBs serve as oncogenes (e.g., USP6 and USP28) or tumor suppressors (e.g., CYLD and A20). Moreover, activities and expression levels of DUBs frequently alter in a variety of malignant tumors. These findings exhibit the clinical relevance of DUBs in cancer development and offer valuable markers for predicting responses of cancer patients to chemotherapeutic drugs.

Somatic mutations in USP6 and USP28 have been detected in various human malignancies. For example, the overexpression of USP6 (Tre-2) is triggered by chromosomal rearrangements in the osteoblast cadherin 11 gene (CDH11) promoter region, which turns USP6 into an oncogene associated with neoplastic aneurismal bone cysts. Mutated USP28 and CYLD are widely found in cases of lobular breast cancer and familiar cylindromatosis, respectively. In several lymphoma subtypes, the chromosomal deletions and inactivating mutations of A20 have been detected as well.

A variety of DUBs are linked to cancer through altered expression patterns. For instance, the DUB dysregulation of human cancers can be screened through in situ hybridization on tissue microarrays. In non-small cell lung carcinomas, the significantly elevated expression levels of JOSD1, CSN5, UCHL1, and USP9X are observed, whereas USP10, USP11, USP22, USP48, and CSN5 are upregulated in malignant melanoma. USP10, USP11, and USP22 levels are significantly higher in metastatic melanoma compared with benign nevi and primitive tumors. Therefore, these DUBs might offer useful indicators for diagnostic/prognostic evaluation or as new therapeutic targets. Similarly, USP22 is overexpressed in several cancers including colorectal carcinomas, liver and breast cancer, as well as oral squamous carcinoma and esophageal squamous cell carcinoma; therefore this DUB serves as a new molecular marker to predict the prognosis of human metastatic cancers. Interestingly, USP2 expression is downregulated in breast carcinomas. Conversely, USP2 is overexpressed in ovarian and prostate carcinomas and is associated with lesions of poor prognosis. Moreover, overexpression of USP2 protects prostate cancer cells from apoptosis and confers them resistance to chemotherapeutic agents through decreasing p53 stability, suggesting that USP2 has dual properties (protumor or antitumor) exhibited in a tissue-specific manner. USP8 levels are upregulated in cervical squamous cell carcinoma (CSCC) tissue samples compared to healthy tissues. Importantly, elevated levels of USP8 promote cell proliferation, migration, and invasion of CSCC cell lines. Thus, high expression of USP8 correlates with tumor stage and might be used as an independent prognostic marker for CSCC. USP7 overexpression in prostate cancer is also connected with tumor aggressiveness. USP4 is overexpressed in several types of human cancer, but

downregulated in small-cell lung cancer cell lines. Moreover, elevated expression levels of USP17 have been identified in primary lung, colon, esophagus, and cervix tumor biopsies. Furthermore, USP15 is downregulated in paclitaxel-resistant ovarian cancer, and reduced expression of CYLD is found in melanoma and other malignant tumors. USP28 can stabilize the levels of Myc through an interaction with FBW7α (F-box and WD40 domain-containing protein 7α) and is highly expressed in colon and breast carcinoma. In addition, USP14 expression is high in different cancers including ovarian and colorectal cancer. The upregulated USP14 expression levels in colorectal cancer are associated with the pathologic stages as well as liver and lymph node metastases. CXCR4 (C-X-C motif chemokine receptor 4) degradation and chemotaxis are controlled due to its deubiquitylation by USP14. In gastric cancer, USP14 also serves as a novel prognostic indicator to encourage cisplatin resistance via Akt/ERK (serine-threonine kinase/extracellular signal-regulated kinase) signaling pathways (Fraile et al. 2012; Harrigan et al. 2018).

In addition, DUBs serve as the key regulatory components in various tumor metastatic events. These events in the metastatic progression include epithelial mesenchymal transition (EMT), the extracellular matrix (ECM) degradation, cell fate regulation, as well as resistance of apoptosis in the circulation. Currently, several well-characterized DUBs such as USP4, UCHL1, UCHL3, USP22, and USP47 are involved in modulating EMT process. USP6, USP22, USP2, and USP42 participate in matrix metalloproteinase (MMP) regulation as well. USP21, USP13, USP1, PSMD14, USP7, USP15, and USP21 are important regulatory DUB members found in cell fate determinants. Furthermore, DUBs like USP9X and ataxin-3 exhibit regulatory activities in cell apoptosis process (detailed review in citation (He et al. 2017)).

DUBs in Immunity and Inflammation

Mutations in specific DUBs are associated with chronic inflammation, autoimmunity, infectious disease, cancer, and neurodegeneration. Several DUBs such as A20, CYLD, and OTULIN are well characterized as vital regulators of inflammatory signaling and cell death (Harrigan et al. 2018).

A20 exhibits negative feedback of NF-κB activation in response to various proinflammatory stimuli including TNF, IL-1, LPS (lipopolysaccharide), T-cell and B-cell receptor antigens (e.g., pathogens), and nucleotide-binding oligomerization domain-containing protein 2 (NOD2) ligands. A20 specifically removes K63-linked polyubiquitylation chains from multiple NF-κB signaling factors including NF-κB essential modulator (NEMO), receptor-interacting serine/threonine protein kinase 1 (RIPK1), and tumor necrosis factor (TNF) receptor-associated factor 6 (TRAF6), thereby restricting the Toll-like receptor (TLR) signaling and maintaining immune homeostasis. In addition, A20 binds to polyubiquitin chains via its seventh zinc finger motif (ZnF7) and then is recruited to NEMO. This A20-NEMO interaction impairs the IκB kinase (IKK) phosphorylation by its upstream kinase TAK1, thereby reducing NF-κB activation. Furthermore, A20 exerts crucial roles in controlling inflammatory responses and might be an important determinant for multiple autoimmune diseases. In macrophages, A20 regulates IL-1β/IL-18 release by controlling NLRP3 (nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3) inflammasome activity and CXCL9/CXCL10 (C-X-C motif chemokine 9/10) production through STAT1 (signal transducer and activator of transcription 1) signaling. In essential, the autoinflammatory arthritis phenotype is restricted by these pathways. In dendritic cells, A20 regulates the expression of co-stimulatory molecules (e.g., CD80/CD60), proinflammatory cytokines (e.g., IL-6), and anti-apoptotic proteins, thereby exhibiting in vivo T-cell and B-cell homeostasis. A20 regulates necroptosis and autophagy in $CD4^+$ T cells, as well as necroptosis, IL-2, and IFNγ release in $CD8^+$ T cells. Furthermore, A20 perturbs regulatory T-cell development. A20 in B cells governs co-stimulatory molecule expression, IL-6

production, and Bcl-x survival protein expression, thereby blocking autoreactive B-cell generation leading to an autoimmune phenotype such as systemic lupus erythematosus.

CYLD is a negative regulator of RIG1 (retinoic acid-inducible gene-1-like receptor 1)-mediated antiviral response. CYLD can bind to RIG1 and thereby inhibit ubiquitylation and signaling functions of RIG1. CYLD also inhibits the ubiquitylation of TBK1 (TANK-binding kinase 1) and IKKε, which are implicated in the negative regulation of IFN responses. In dendritic cells, CYLD deficiency triggers constitutive activation of TBK1 and IKKε. Furthermore, CYLD-deficient cells and mice are more sensitive to viral infection due to downregulated interferon (IFN) receptor signaling and antiviral gene expression stimulated by IFNβ. Interestingly, CYLD-deficient mice exhibit disorder of thymocyte development and activation of T cells associated with bowel inflammation and autoimmune responses. In essential, CYLD interacted with lymphocyte-specific protein tyrosine kinase (LCK). The active LCK is recruited to its substrate, zeta-chain-associated protein kinase 70 (ZAP70), and then activates downstream T-cell receptor (TCR) signaling events. Also, CYLD exerts key regulatory effects on B-cell function. Lack of CYLD expression can induce constitutive activation of the canonical NF-kB signaling cascade in B cells. Furthermore, CYLD-deficient B cells exhibit defects in B-cell maturation and homeostasis. These defects are characterized by hyperproduction of marginal zone B cells and expansion of B cells in peripheral lymphoid organs. Similarly, abnormalities of B-cell function have been observed in $CYLD^{ex7/8}$ knock-in mice with a shorter isoform of CYLD (sCYLD).

Modification of proteins with M1-linked polyubiquitin chains exerts important roles in regulating immune and inflammatory signaling cascades. M1-linked polyubiquitin chains can form from the linear ubiquitin chain assembly complex (LUBAC). This assembly complex consists of heme-oxidized IRP2 ubiquitin ligase 1 (HOIL1, also known as RBCK1), HOIL1-interacting protein (HOIP, also known as RNF31), and SHANK-associated RH domain-interacting protein (SHARPIN). Importantly, LUBAC can be recruited to a wide range of immune receptors and ubiquitylate target proteins, especially RIPK1, RIPK2, MYD88, interleukin-1 receptor-associated kinases (IRAKs), and NEMO. Furthermore, deficiency of M1-linked ubiquitin chains perturbs immune signaling in LUBAC component-deficient mice. To date, OTULIN has been identified to specifically cleave M1 linkages. Knockdown of OTULIN results in M1-ubiquitinated protein accumulation. Conversely, overexpression of OTULIN attenuates TNF-induced NF-κB activation and proinflammatory signaling. Furthermore, phosphorylation-dependent regulation of interaction between OTULIN and HOIP governs the functions of OTULIN and offers a subtle control for M1-linked polyubiquitin signaling. The roles of A20, CYLD, and OTLIN in NF-κB signaling and cell death are so similar, but the nonredundant functions of these DUBs are determined by the cellular context. The cross talk between these DUBs needs to be further investigated.

In addition, USP4 can stabilize the nuclear receptor retinoid-related orphan receptor γt (RORγt) in TH17-activated T cells and offer a potential therapeutic target for rheumatoid arthritis. In dendritic cells, TRABID is required for TLR-mediated expression of the inflammatory cytokines IL-12 and IL-23. USP18 regulates the TAK1-TAB interaction, which is required for TH17 cell differentiation and the autoimmune response. The DUB cellular zinc finger anti-NF-κB protein (CEZANNE, also known as OTUD7B) is participant in T-cell receptor signaling. It binds to ZAP70, thereby perturbing the interaction of ZAP70 with negative regulatory phosphatases. USP10 can deubiquitylate and stabilize T-bet, leading to enhanced secretion of IFNγ. Moreover, elevated expression of USP10 is found in peripheral blood mononuclear cells from patients with asthma compared with healthy donors. Thus, the expression of DUBs in various immune cells will be a new area for further investigation.

DUBs in Infectious Diseases

DUBs can function as potential therapeutic targets for various infectious diseases including viral infections, bacterial infections, and parasitic infections (Harrigan et al. 2018). For example, both severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) are highly pathogenic human coronaviruses, which contain papain-like cysteine proteases termed SARS-CoV PLpro and MERS-CoV PLpro, respectively. These proteases have structural similarity to the USP family of DUBs based on their X-ray structures. SARS-CoV papain-like proteases (PLPs) negatively regulate antiviral defenses by disrupting the STING (stimulator of interferon genes)-mediated IFN induction. Bacterial effectors often target kinase cascades involved in inflammation or the eukaryotic Ub system to promote bacterial pathogenicity. DUBs in *Shigella* (ShiCE) and *Rickettsia* (RickCE) showed strong preference for the K63-linked ubiquitin chains. Therefore, bacterial DUBs are potential therapeutic targets. The deubiquitylating enzyme PfUCH54 identified from *Plasmodium falciparum* has deubiquitylating activity and can remove adducts of the UBL NEDD8. Similarly, PfUCHL3 identified from *Toxoplasma gondii* has the dual specificity of the enzyme that is orthologous to mammalian UCHL3 and found to be required for parasite survival. Taken together, it will be interesting to further investigate DUB inhibitors with anti-infective activities.

Drugs

The development of selective small molecule inhibitors that targeted DUBs might be encouraging for anticancer therapeutics. Bortezomib is the first 20S proteasome inhibitor (PI) approved by the FDA in 2003 for the treatment of multiple myeloma (MM) and mantle cell lymphoma. However, the extended treatments of bortezomib result in several adverse effects due to its nonselectivity. Researchers have been looking for strategies to improve PI-based therapies. A variety of DUBs such as USP4 (UNP), USP6 (Tre-2), USP8 (UBPY), USP14, USP28, and UCHL5 (UCH37) have been found to function as crucial modulators in cancer development and progression. Moreover, the crystal structures of USP and UCH subfamilies (e.g., USP2, USP7, USP8, USP14, and USP21) have been well characterized, thereby attracting molecular recognition profiling investigations of these DUBs in their active states. These types of investigations have helped the rationale to design and develop DUB inhibitors. Thus, targeting specific upstream components of the UPS such as DUBs and E3s will be able to improve the current therapeutic treatments for cancer and other diseases (Dou and Zonder 2014; Farshi et al. 2015; Fraile et al. 2012; Harrigan et al. 2018; Komander et al. 2009; Ndubaku and Tsui 2014).

A small molecule PR-619 with moderate inhibitory activity is selective for DUBs over other cysteine proteases. HBX 41,108 originally identified as a USP7 inhibitor is a nonselective DUB inhibitor. HBX 41,108 can stabilize p53 in HEK293 cells and lead to caspase-3 and poly (ADP-ribose) polymerase (PARP) cleavage in both p53þ/þ and p53/HCT-116 cells. But HBX 41,108 can also inhibit USP5, USP8, UCH-L3, and caspase-3 with a potency (70–200 nmol/L) greater than its activity against USP7 (530 nmol/L). Considering the key regulatory roles played by USP7 in the cell physiological processes, there is growing interest in investigating USP7-specific inhibitors. The novel small molecule USP7-specific inhibitor P5091 identified by Progenra can stabilize p53, can impede cancer cell proliferation, and is also an effective antitumor agent in various tumor models. For example, P5091 can trigger cell apoptosis in multiple myeloma cells resistant to conventional and bortezomib therapies. Interestingly, P5091 is well-tolerated in animals, inhibits tumor growth, prolongs survival, and enhances synergistic anti-multiple myeloma activity in combination with other chemotherapeutic agents such as lenalidomide, histone deacetylase (HDAC) inhibitor, or dexamethasone. Hit-to-lead optimization identified additional

analogs of P5091 (e.g., aqueous soluble derivative P045204) that increases the steady-state levels of p53 and its transcriptional target p21 in a time-dependent manner in HCT-116 cells.

b-AP15 (or VLX1500) is characterized as a member of a unique class of proteasome inhibitors. It has potent inhibitory effects on the 19S regulatory particle-associated UCHL5 and USP14. Importantly, b-AP15 triggers apoptosis in tumor cells regardless of their p53 or BCL2 accumulation and potently blocks tumor progression and dissemination in multiple solid tumor mouse models and an in vivo AML model.

The molecules like pimozide, GW7647, and ML323 are potent inhibitors of the USP1-UAF1 complex. Pimozide or GW7647 can non-competitively bind with the USP1-UAF1 complex and then exhibit in synergy with cisplatin to inhibit cell proliferation in cisplatin-resistant non-small cell lung cancer (NSCLC) cells. In addition, pimozide induces degradation of USP1 substrate ID1 and therefore attenuates leukemic cell growth. ML323 exerts excellent selectivity for DUBs. In non-small cell lung cancer and osteosarcomas, ML323 potentiates cisplatin-induced cytotoxicity. ML323-mediated inhibition of USP1 inhibits deubiquitylation of Fanconi anemia group D2 protein (FANCD2) and proliferating cell nuclear antigen (PCNA) and compromises translesion synthesis (TLS) and Fanconi anemia (FA) pathways. Thus, ML323 may provide a means to sensitize cancer cells to platinum-based therapies.

The small molecule inhibitor WP1130, also known as Degrasyn, is derived from a compound with JAK2 (the Janus kinase 2) kinase inhibitory activity. WP1130 rapidly induces accumulation of polyubiquitylated proteins, resulting in induction of apoptosis. WP1130 is a partially selective inhibitor that directly inhibits the deubiquitylating activity of USP9X, USP5, and USP14, all of which regulate survival protein stability and proteasome function. In particular, WP1130-mediated USP9X inhibition induces apoptosis by reducing MCL-1 levels and increasing tumor cell sensitivity to chemotherapy. Moreover, USP9X inhibition by WP1130 can inhibit the growth of ERG-positive tumors in vitro and in mouse xenograft models of prostate cancer.

Diabetes Mellitus

Annette Schürmann and Hans-Georg Joost
Department of Experimental Diabetology, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany
German Center for Diabetes Research (DZD), München-Neuherberg, Germany

Definition

Diabetes mellitus is defined as hyperglycemia (fasting >7 mM and/or 2 h postprandial >11.1 mM) due to absolute or relative lack of insulin. The most common forms are type 1 diabetes (prevalence ~0.5%), with absolute lack of

insulin, and type 2 diabetes (prevalence ~8.5%) which is due to the combination of insulin resistance and insufficient insulin secretion. Among people diagnosed with diabetes ~5.5% have type 1 diabetes and ~ 90% type 2 diabetes.

Basic Mechanisms

Type 1 Diabetes (Previously Insulin-Dependent Diabetes Mellitus, IDDM, or Juvenile Diabetes)

Progredient destruction of insulin-secreting β cells by an autoimmune mechanism during a period of several years (Jahromi and Eisenbarth 2006). The diagnosis is confirmed by detection of antibodies against β-cell proteins (glutamic acid decarboxylase, tyrosine phosphatase IA-2, insulin). Islet cell destruction is probably mediated by activated T lymphocytes. There is a genetic susceptibility to type 1 diabetes, and several predisposing loci (e.g., the MHC locus) and alleles of genes associated with the disease risk (the insulin gene, PTPN22, CTLA-4) have been identified (Jahromi and Eisenbarth 2006). In addition, genetic and epidemiological data indicate a strong environmental factor in the pathogenesis.

Type 2 Diabetes (Previously Non-Insulin-Dependent Diabetes Mellitus, NIDDM)

Type 2 diabetes is a frequent consequence of the metabolic syndrome (obesity, insulin resistance, dyslipidemia, hypertension). Obesity causes insulin resistance which is initially compensated by hyperinsulinemia, mediated via increased insulin biosynthesis and insulin secretion and/or a β-cell proliferation. In the course of insulin resistance and under specific genetic and epigenetic predisposition, the β-cell function deteriorates and insulin secretion is reduced, leading to relative insulinopenia. In particular, the initial response (first phase insulin secretion) of islets to a glucose load is impaired during the first stages of the disease. Fasting hyperglycemia is preceded by a variable period of impaired glucose tolerance (IGT) during which secondary complications (micro- and macrovascular) start to develop. Thus, in many type 2 diabetics, secondary complication can be diagnosed at the time of the detection of hyperglycemia; these are accelerated and aggravated by other components of the metabolic syndrome (dyslipidemia, hypertension).

Obesity and insulin resistance appear to be due to a heterogeneous combination of genes involved in the control of appetite and thermogenesis. Several genes have been identified that are involved in the regulation of food intake and of body weight (e.g., leptin, the leptin receptor, melanocortin receptors; see chapter on appetite control). However, an increasing number of genes responsible for the polygenic obesity have been identified by genome wide association studies (GWAS), as well as by exome and whole genome sequencing. Currently about 300 obesity (Goodarzi 2018) and 400 diabetes genes (Mahajan et al. 2018) are known which in each case lead to the disease by a different set and combination of genes. Data obtained from rodent models indicate that islet cell failure is produced only under conditions of obesity. This interaction of two different genetic constellations (obesity and diabetes genes) explains the heterogeneity of the type 2 diabetes with regard to its association with body weight.

The molecular pathology of the β-cell destruction in the course of insulin resistance is not fully understood. It has been suggested that the constant hyperstimulation of the β cell by glucose ("glucose toxicity"), elevated fatty acids ("lipotoxicity"), or a combination of both ("glucolipotoxicity") may lead to cell damage, for example, via ER stress, reactive oxygen species, and hypoxia (Fonseca et al. 2011; Gerber and Rutter 2017).

Pharmacological Intervention

Type 1 diabetes requires a lifelong treatment with insulin. The goal of therapy is to maintain near-normoglycemia, to avoid acute complications, and to prevent long-term micro- and macrovascular complications. Insulin can be administered subcutaneously by a range of insulin types (rapid, short, intermediate, and long-acting, see Table 1) and delivery methods, for example, via multiple daily injections (MDI) and continuous

Diabetes Mellitus, Table 1 Pharmacokinetic characteristics of the most commonly used insulin preparations and analogs

	Onset of action	Maximum	Duration of action
Rapid and short-acting insulins:			
Insulin lispro	15 min	½–1 h	2–5 h
Insulin aspart	15 min	½–1 h	2–5 h
Insulin glulisine	15 min	½–1 h	2–5 h
Regular insulin	30 min	1–2 h	5–8 h
Long-acting insulins:			
NPH insulin	30–60 min	2 h	11–20 h
Insulin glargine	60 min	4 h	12–30 h
Insulin detemir	60 min	5–8 h	12–22 h

subcutaneous insulin infusion (CSII), also designated insulin pump therapy (Malik and Taplin 2014). Both therapies have to be supported by comprehensive education and depend on self-monitoring of blood glucose and/or continuous glucose monitoring (CGM) to avoid hypoglycemia and glucose variability. Recent advances in diabetes technology have resulted in the development of a commercially available, hybrid artificial pancreas (AP), also known as the closed-loop system or automated insulin delivery, which is already applied in the United States and several countries in Europe. The AP incorporates a sensor for CGM, an insulin pump to deliver insulin and an algorithm connecting the two devices, which directs the pump to deliver insulin based on the real-time glucose readings from the sensor (Ramli et al. 2019).

To achieve an optimal glycemic control, several different insulin analogs were developed which allow to simulate endogenous insulin secretion under changing circumstances (Table 1). When patients are treated by MDI, basal insulin requirements are given as an injection of long- or intermediate-acting insulin analogs (e.g., insulin glargine), while of rapid-acting insulin analogs (e.g., insulin lispro) are injected after a meal. CSII provides a 24 h preselected but adjustable basal rate of rapid-acting insulin, along with patient-activated mealtime bolus doses and thereby avoiding periodic injections.

Insulin preparations (Table 1): Recombinant human insulin is used predominantly. Retarded preparations are generated by addition of protamine (*NPH insulin*, neutral protamine Hagedorn) which may provide the "basal" supply in both MDI and CSII. Five insulin analogs with altered amino acid sequence and different pharmacokinetic characteristics are available: *insulin lispro* (swap of B28 proline and B29 lysine), *insulin aspart* (exchange of aspartate for B28 proline), and *insulin glulisine* (exchange of lysine for asparagine B3 and glutamate for lysine B29) exhibit a more rapid onset and a shorter duration of action because of a faster dissociation of the hexameric insulin–zinc–phenol complex. *Insulin glargine* is a long-acting analog which is soluble at low pH because of two additional arginines at the C terminus of the B chain. After injection, the analog precipitates from its solution and forms a long-acting depot with a steady absorption kinetic. *Insulin detemir* lacks threonine B30 and is myristoylated at lysine B29. Binding of the analog to serum albumin is responsible for its longer duration of action which is comparable to that of *insulin glargine*.

Type 2 diabetes: After clinical diagnosis, weight loss by hypocaloric diets and exercise, and to quit of smoking may normalize glucose homeostasis for a period of several years. Most successful weight reduction strategies are food substitution by formula diets for 3–5 months and sustained and intensive counseling over 6–12 months. Aerobic exercise, resistance training, and the combination of both are effective to improve glycemic control. However, because the "lifestyle changes" are difficult to maintain, and because of the progression of the islet cell failure, pharmacological intervention will usually become inevitable and has to be intensified

throughout the course of the disease. Initially, normalization of blood sugar can be accomplished with oral antidiabetics. Later on, a combination of oral antidiabetics with insulin or insulin alone (similar to treatment of type 1 diabetes) will be required.

The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) developed guidelines for treatment of type 2 diabetes and recommend to start pharmacological treatment with metformin. A treatment with sodium-dependent glucose transporter 2 (SGLT2) inhibitors or glucagon-like peptide 1 (GLP-1) receptor agonists is recommended for patients with clinical cardiovascular disease because of a proven cardiovascular benefit. For patients with risk of chronic kidney disease (CKD) or clinical heart failure and atherosclerotic cardiovascular disease (ASCVD) an SGLT2 inhibitor is recommended. GLP-1 agonists are generally suggested as first injectable medication. If further intensification is required or one of the abovementioned drugs not tolerated, a dipeptidyl-peptidase-4 (DPP4) inhibitor is recommended followed by basal insulin, a thiazolidinedione (TZD) and a sulfonylurea (SU) (Davies et al. 2018).

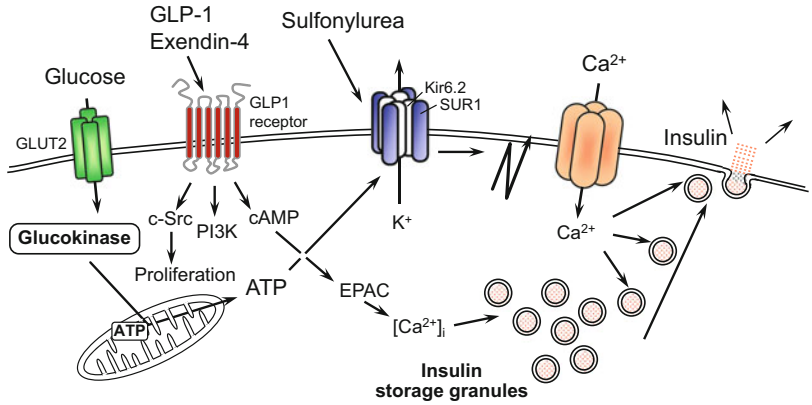
Metformin: The biguanide metformin lowers blood sugar mainly by inhibition of glucose output from the liver. It is generally accepted that this effect reflects a marked inhibition of gluconeogenesis and lipogenesis, presumably mediated by a stimulation of the AMP-dependent kinase (Zhou et al. 2001). Other effects of metformin (stimulation of glucose transport in muscle, inhibition of intestinal glucose absorption) require higher concentrations and appear to contribute little to the in vivo effect.

Under certain circumstances, and very rarely, the inhibition of gluconeogenesis by metformin may suppress lactic acid metabolism and precipitate a potentially fatal lactic acidosis. Impairment of renal function, liver disease, alcoholism, and conditions that give rise to increased lactate production (e.g., congestive heart failure, infections) are therefore contraindications for the application of metformin.

Oral formulations of metformin are rapidly and completely absorbed. The agent is poorly bound to plasma proteins; its duration of action is determined exclusively by renal elimination. Higher concentrations of metformin than in most tissues are found in the intestinal mucosa, giving rise to common side effects (irritation, diarrhea, etc.). Because of its high efficacy in lowering HbA1c, good safety profile, and low cost, metformin is the first-line medication for type 2 diabetes treatment (Davies et al. 2018).

SGLT2-inhibitors: The structure of SGLT2 inhibitors is based on phlorizin, a natural phenolic O-glucoside that competitively inhibits human SGLT2 and SGLT1 (Vallon 2015). They are oral medications that lower plasma glucose by enhancing urinary glucose secretion by about 75–120 g per day. This can be translated into a calorie loss of 308–490 kcal per day. SGLT2 inhibitors reduce HbA1c by 0.7–0.8%, lower body weight by ~5% and reduce systolic and diastolic blood pressure by an average of 4.0–4.7 mmHg and 1.9 mmHg, respectively (Seufert 2015). Furthermore, the SGLT2 inhibitors empagliflozin and canagliflozin have cardiac and renal benefits in patients diagnosed or at high risk of ASCVD and do not increase the risk for hypoglycemia. SGLT2 inhibitors are associated with a risk for mycotic genital infections and an increased risk of acute kidney injury, dehydration, and orthostatic hypotension.

GLP-1 receptor agonists: Glucagon-like peptide 1 (GLP-1) is an incretin released by enteroendocrine L-cells in response to nutrient ingestion. The activation of the GLP-1 receptor via GLP-1 receptor agonists increases glucose-dependent insulin secretion, induces β-cell proliferation and neogenesis, enhances resistance to β-cell apoptosis (Fig. 1), and reduces glucagon secretion by α cells. It also improves satiety (Baggio and Drucker, 2007). Because native GLP-1 is degraded rapidly, degradation-resistant GLP-1 receptor agonists have been developed for the treatment of type 2 diabetes. Exendin-4 is a 39 amino acid peptide originally isolated from the venom of the *Heloderma suspectum* lizard, exhibits 53% amino acid identity with native GLP-1, and is a potent agonist at the mammalian



Diabetes Mellitus, Fig. 1 Mechanism of insulin secretion and its stimulation by GLP-1 receptor agonists and β-cytotropic agents. Glucose enters the β cell via GLUT2, is phosphorylated by glucokinase, and generates ATP. Rise in the ATP-ADP ratio results in closure of ATP-dependent K^+ channels, membrane depolarization, and opening of voltage-gated Ca^{2+} channels. Ca^{2+} influx activates the exocytosis of insulin-containing secretory granules. The ATP-dependent K^+ channel consists of Kir6.2 (a K^+ inward rectifier) and SUR (sulfonylurea receptor). Sulfonylureas block the ATP-dependent K^+ channels by enhancing the effect of ATP. GLP-1 receptor-dependent intracellular signal transduction activates insulin secretion and β-cell proliferation

GLP-1 receptor. Exenatide, the synthetic peptide of exendin-4, mimics the GLP-1 effects in stimulating glucose-dependent insulin secretion from β cells and inhibiting glucagon secretion from α cells (Baggio and Drucker 2007). Exenatide is injected subcutaneously twice daily, other related peptides like liraglutide and lixisenatide are administrated once daily, and dulaglutide and semaglutide are available as a once-weekly formulation. All GLP-1 receptor agonists improve glycemic control in type 2 diabetics and cause a significant reduction of body weight. Liraglutide and Semaglutide have been shown to improve cardiovascular outcomes. The most common side effects of GLP-1 receptor agonists are nausea, vomiting, and diarrhea; however, these effects tend to diminish over the time. They also exhibit a minimal effect of hypoglycemia and may increase the hypoglycemic potential when combined with insulin or sulfonylureas (Davies et al. 2018).

DPP-4 inhibitors: Inhibition of the dipeptidyl peptidase 4 (by sitagliptin or vildagliptin) prolongs the duration of action of endogenous GLP-1, and thereby increases insulin secretion, reduces glucagon secretion, and improves glycemic control, either alone or in combination with other antidiabetic agents (Holst 2006; Henness and Keam 2006). DPP-4 inhibitors are oral medications that are well tolerated, have a neutral effect on body weight and minimal risk of hypoglycemia when applied as monotherapy. In combination with sulfonylurea DPP-4 inhibitors increase the risk for hypoglycemia by 50% in comparison to sulfonylurea alone (Davies et al. 2018).

Thiazolidinediones (PPARγ-agonists): Thiazolidinediones (TZDs; pioglitazone, rosiglitazone) are oral medications that increase insulin sensitivity and lower blood glucose levels in insulin-resistant patients. They are agonists of the peroxisome proliferator-activated receptor γ (PPARγ). Because they enhance the effect of insulin and reduce serum insulin levels in insulin-resistant patients, TZDs are usually referred to as "insulin sensitizers." PPARγ is a transcription factor which controls the expression of enzymes and proteins involved in fat and glucose metabolism, and thereby facilitates differentiation of mesenchymal stem cells into adipocytes, promotes lipogenesis in peripheral adipocytes, decreases hepatic and peripheral triglycerides, decreases activity of visceral adipocytes, and increases adiponectin. It is believed that the formation of additional, small fat cells lowers ectopic fat

storage in the liver, skeletal muscle, myocardial muscle, and endothelial cells, thereby correcting insulin resistance (Lebovitz 2019). TZDs increase HDL-cholesterol and pioglitazone was shown to reduce cardiovascular end points and hepatic steatohepatitis. The use of TZDs has been limited because some studies indicated safety concerns in respect to fluid retention, congestive heart failure, weight gain, and bladder cancer. However, recent studies indicated that cardiovascular toxicity with rosiglitazone and increase in bladder cancer with pioglitazone are no longer significant issues (Lebovitz 2019).

Sulfonylureas: Sulfonylureas are oral inexpensive medications (Aguilar-Bryan and Bryan 1999) that bind to the sulfonylurea receptor 1 (SUR1) which regulates the activity of the ATP-dependent potassium channel of the pancreatic β-cell (Kir 6.2). Binding of ATP, or of a sulfonylurea, to SUR reduces the potassium current and causes membrane depolarization, subsequently opening of voltage-gated calcium channels, and calcium-stimulated exocytosis of insulin-containing granules. Thereby, sulfonylureas stimulate insulin secretion and lower blood glucose (Fig. 1).

The commonly used sulfonylureas are the long-acting derivatives glibenclamide (US synonym: glyburide), glipidzide, gliclazide, and glimepiride. They are associated with weight gain and a risk for hypoglycemia, which is however lower than with insulin. Sulfonylureas remain a reasonable choice among glucose-lowering medications, particularly, when costs play an important role (Davies et al. 2018).

Definition

The DNA damage response (DDR) involves a complex network of genes responsible for sensing and responding to specific types of DNA damage, comprising specific machineries mediating DNA repair, cell cycle regulation, replication stress responses, and apoptosis. Defects in the DDR give rise to genomic instability in cells which leads to cancer initiation and progression via mutation accumulation. This also provides targetable vulnerabilities relatively specific to cancer cells which can then be utilized for clinical benefit with the use of DDR inhibitors.

Basic Mechanisms

DNA damage occurs constantly in cells due to a number of exogenous and endogenous stressors. Consequently, cells have evolved a complex and coordinated DNA damage response (DDR) that involves several interdependent signaling pathways and machineries. The importance of the DDR in preserving cell viability and preventing neoplasia is emphasized by the vital additional roles these pathways play in regulating the cell cycle, chromatin remodeling, metabolism, immunogenicity, and apoptosis (Roos et al. 2016). For instance, the detection of DNA damage results in the activation of checkpoints that induce cell cycle arrest to provide the time necessary for DNA repair before cell division. DDR pathways are also closely linked with the apoptotic pathway in order to enable the elimination of cells with unrepaired DNA damage. The DDR pathways, therefore, facilitate cell survival in the face of genomic instability and replicative stress or direct irreparably damaged cells to undergo senescence or programmed death (Pilié et al. 2019).

Genomic instability is a key hallmark of cancer that arises owing to defects in the DDR and/or increased replication stress. These alterations promote the clonal evolution of cancer cells via the accumulation of driver aberrations (including gene copy-number changes, rearrangements, and mutations), generation of tumor heterogeneity, and evasion of apoptosis (Tubbs and Nussenzweig 2017). DNA damage most commonly manifests as single-stranded breaks (SSBs), although double-strand breaks (DSB) also occur and are more lethal to cells, requiring

prompt countermeasures in order to ensure cell survival (Table 1). Consequently, modern DDR-directed therapies target the signaling and repair mechanisms associated with DSBs, increase replication stress and thereby the frequency of DSBs, or inhibit cell cycle checkpoints that facilitate DSB repair (Fig. 1).

Defects in certain DDR mechanisms, including DSB repair processes involving homologous recombination (HR), increase genomic instability and lead to a greater reliance on compensatory, and often error-prone, DDR and survival pathways (Brown et al. 2017). These same defects, however, also create vulnerabilities that are relatively specific to cancer cells, which theoretically can then be exploited, to improve the efficacy of anti-cancer treatments and thus improve patient outcomes.

Historically, these vulnerabilities have been exploited in anticancer therapies through the use of DNA-damaging chemotherapy and radiation. More recent strategies include the rapid development of potent and selective molecularly targeted agents against key components of different DDR pathways (herein termed DDR inhibitors). Here, we focus on novel therapeutic strategies targeting promising DDR targets and discuss clinical efforts to develop combinatorial strategies to optimize therapeutic targeting of the DDR.

Pharmacological Intervention

Targeting the DNA Damage Response

Various inhibitors of DDR components are in preclinical and clinical development. In order to fully exploit the potential of DDR inhibitors, and to ensure their long-term clinical success, a thorough understanding of DDR pathway complexities must be combined with lessons learned from the successful registration of PARP inhibitors to date. Beyond PARP inhibitors, there is now a sizeable array of potent and relatively selective inhibitors in clinical trial testing against key targets involved in the DDR, including *ATR*, *ATM*, *CHK1/2*, *WEE1*, and *DNA-PK*. These agents are being developed for patients with molecularly selected tumors and in rational combinations with other molecularly targeted agents and immune checkpoint inhibitors.

Single-Agent Strategies Targeting DNA Damage Sensor Proteins

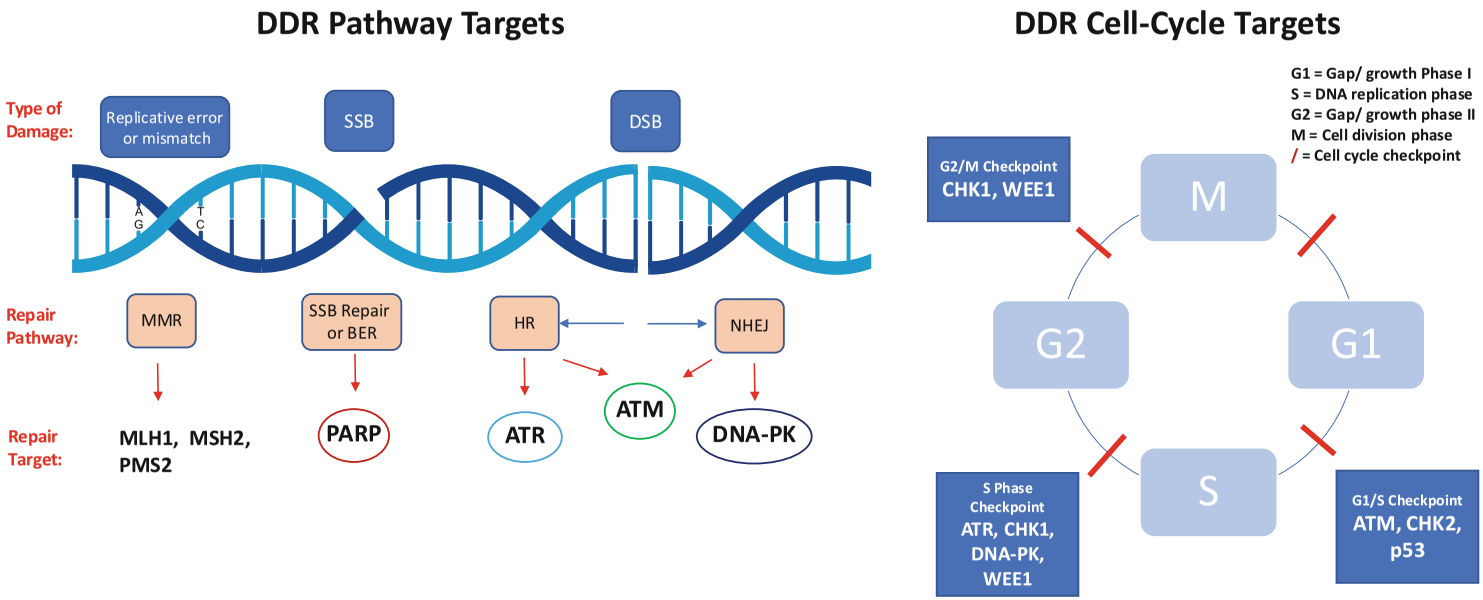
PARP Inhibitors

A well-recognized sensor of DNA damage is the protein poly(ADP-ribose) polymerase (PARP). The PARP family comprises a group of nuclear proteins that are activated upon binding to damaged DNA and have crucial roles in various aspects of the DDR (Fig. 1). Their main function is to detect DNA single-stranded breaks (SSBs) and double-stranded breaks (DSBs), recruit the DNA repair machinery, and stabilize replication forks (Helleday 2011) (Fig. 1). There are 17 PARP family members, and PARP1 has the predominant role in DNA repair. PARP2, and to a lesser extent PARP3, function in fewer, overlapping, DNA repair processes (De Vos et al. 2012).

PARP catalytic function is activated on binding to single-stranded DNA breaks, DNA nicks, or DSBs, to generate extensive poly(ADP-ribose) chains (PAR chains) on itself and proteins in the vicinity of DNA damage. These PAR chains and PARP itself then promote the recruitment of critical SSB repair proteins, such as XRCC1, to SSBs and modify chromatin structure to facilitate DNA repair. PARP auto-PARylation is also required for the dissociation of PARP from DNA damage sites (Helleday 2011). Enzymatic inhibition by PARP inhibitors therefore results in both the suppression of SSB repair and base-excision repair (BER), which molecularly converges with SSB repair in its downstream stages. Inhibition results in the trapping of PARP to SSBs, causing the stalling and subsequent collapse of DNA replication forks, resulting in replication-dependent DNA DSBs (Helleday 2011). These DSBs would typically be repaired by homologous recombination (HR); however, in HR-deficient cells, such as *BRCA1/2*-mutated tumors, less effective methods of repair are used; this leads to unsustainable levels of damage, chromosomal fusions/translocations, and ultimately cell death (Ceccaldi et al. 2016).

DNA Damage Response, Table 1 Predominant DNA repair pathways. (Adapted from Brown et al. 2017)

Double-stranded break repair pathways	
Classic (c)-NHEJ	Predominant DNA DSB repair pathway in human cells, functioning throughout the cell cycle Involves the relatively rapid ligation of broken DNA ends, mediated by the core NHEJ complex, including DNA-PK, XRCC4, LIG4, XLF, and PAXX, among others DNA end processing and DNA polymerase action may be required before ligation can occur, making NHEJ inherently error-prone NHEJ maintains genome stability, however, by rapidly repairing DSBs in circumstances where recombinogenic events would likely result in gross chromosomal rearrangements; in noncycling or G1 cells, for example
Homology-directed repair	
Homologous recombination (HR)	Relatively slow and restricted to late-S phase/G 2, as it generally relies on a homologous sister chromatid DNA strand for repair Extensive DNA end resection by helicases and exonucleases, such as DNA2, BLM, WRN, and EXO1, results in a 3′–ssDNA overhang, committing the break to repair by HR Replication protein A (RPA) coats and stabilizes the ssDNA, leading to ATR activation and subsequent signaling events BRCA2, with the help of BRCA1 and PALB2, loads RAD51 onto the RPA-coated ssDNA, leading to strand invasion, with a number of factors negatively regulating this process to prevent hyperrecombination, such as POLQ, PARI, RECQL5, FANCJ, and BLM
Alternative (alt)-NHEJ or MMEJ	Ligation pathway for DSBs when c-NHEJ is genetically compromised Occurs following limited DNA end resection Contributes to the excessive genomic deletions and chromosomal translocations seen in tumors and may also provide a backup repair pathway in HR-deficient cells
Single-stranded annealing (SSA)	Mutagenic, RAD51-independent repair pathway, involving annealing of short or longer complimentary DNA sequences on resected DNA with subsequent deletion of the intervening DNA sequence. The detailed mechanism has yet to be defined in mammalian cells
Other repair pathways	
SSB repair	SSBs usually arise following the removal of a damaged nucleotide PARP1 is the DNA damage sensor protein for DNA strand breaks. PARP1 localizes to sites of DNA damage, generating extensive PAR (poly ADP-ribose) chains Ribosylated PARP1 promotes recruitment of SSB-repair proteins to DNA damage sites
BER	DNA glycosylases recognize and remove damaged bases leading to basic sites that are processed by APE1 Results in SSB generation, repaired using SSB repair pathways
Mismatch repair (MMR)	MSH2, MSH3, and MSH6 recognize base-base mismatches and insertion/deletion loops, where they recruit MLH1 and PMS2 to damaged sites. The concerted actions of the MMR proteins engage EXO1 to remove the mismatch and then POLD and LIG1 to fill the gap and seal the nick, respectively
Interstrand cross-link (ICL) repair	ICLs cause DNA replication fork stalling and collapse, resulting in DNA DSBs ICLs are recognized by the FANCONI core complex, which engages HR, TLS, and NER pathways to repair the DNA lesion
Translesion synthesis (TLS)	DNA damage tolerance pathway that helps prevent replication fork stalling Engages low-fidelity DNA Y-family polymerases (e.g., REV1, POLH, POLI, and POLK) that accommodate the damaged lesion, replicating past it, at the expense of increased mutagenesis
Nucleotide excision repair (NER)	Removes helix-distorting lesions from DNA, in particular the UV-induced photo lesions Involves removal of a short oligonucleotide, including the damaged lesion using structure-specific endonucleases and subsequent restoration of the DNA sequence by DNA polymerases



DNA Damage Response, Fig. 1 DNA damage response pathways being targeted in the clinic. Specific types of DNA damage – mismatches due to replication, single-stranded DNA breaks (SSBs), or double-stranded DNA breaks (DSBs) – result in the activation of specific signaling and repair cascades. DNA damage response (DDR) pathways mitigate replication stress and repair DNA; thus, deficiencies in these pathways result in the accumulation of SSBs and DSBs and increased immunogenicity owing to the generation of neoantigens from mutant proteins. Poly(ADP-ribose) polymerase (PARP) enzymes are key to activating a host of downstream repair mechanisms and are primary proteins involved in SSB repair or base-excision repair (BER). The repair of DSBs occurs predominately through the rapid, error-prone nonhomologous end joining (NHEJ) repair pathway in conjunction with the much slower higher-fidelity, error-free homologous recombination (HR) repair pathway. DNA replication is a necessary component of DNA repair, and thus cell cycle regulation and replication stress responses are intertwined with DDR pathways. The kinases ATR and ATM have crucial roles in DDR signaling and in maintaining replication fork stability while also working together via their downstream targets, CHK1 and CHK2, respectively, to regulate cell cycle control checkpoints. The kinase activity of DNA-PK is essential for NHEJ and V(D)J recombination. WEE1 is a distinct nuclear kinase that regulates mitotic entry and nucleotide pools in coordination with DDR

The discovery that selected HR-deficient (HRD) tumors, initially those with germline *BRCA1* or *BRCA2* mutations, are exquisitely sensitive to PARP inhibition has pioneered a new era of research on biomarker-driven synthetic lethal treatment strategies for different cancer subtypes. This concept of "synthetic lethality" between *BRCA1/2* genetic defects and pharmacologic PARP inhibition was first presented in 2005, when the first preclinical data suggested that there may be single-agent activity with this class of agents. In "synthetic lethality," the combination of a functional genetic defect in an HR-related gene and pharmacological inhibition of a compensatory DDR pathway component, such as PARP, causes insurmountable genomic instability, mitotic catastrophe, and cell death (Lord and Ashworth 2017).

PARP inhibitors are the best-studied class of DDR inhibitors, with robust preclinical and clinical data. Indeed, several PARP inhibitors have now been FDA-approved or are undergoing testing in late phase clinical trials as single agents in various disease and treatment settings.

Current Licensed PARP Inhibitor Indications

All PARP inhibitors currently used in the clinic have a similar capacity to inhibit the catalytic activity of PARP because they share a nicotinamide moiety that competes with NAD+ for binding to this enzyme. There are differences, however, with regard to (1) the dose required to inhibit PARP activity and (2) the relative selectivity for different PARP family members. The PARP-trapping abilities of the five most-studied PARP inhibitors – niraparib, rucaparib, talazoparib, olaparib, and veliparib – also vary greatly, in contrast with their ability to inhibit protein poly ADP-ribosylation (PARylation). Talazoparib, for instance, has the greatest PARP-trapping ability observed preclinically and has cytotoxic potency in the nanomolar range. In contrast, veliparib results in less PARP trapping and is inactive at 100 mM. Furthermore, the maximum tolerated dose (MTD) of these PARP inhibitors mirrors their respective PARP-trapping ability, rather than their capacity to inhibit PARP catalytic activity (Pilié et al. 2019).

Aside from veliparib, the other PARP inhibitors – olaparib, niraparib, talazoparib, and rucaparib – all have comparable single-agent activity against the advanced-stage cancers evaluated in clinical trials to date (Gelmon et al. 2011; Kaye et al. 2012; Sandhu et al. 2013; Litton et al. 2018). However, it is important to note that there have been no head-to-head comparison studies and that the heterogeneous clinical characteristics of the patient populations in these separate trials make cross-study comparisons challenging (Fong et al. 2009; Gelmon et al. 2011; Kaye et al. 2012; Sandhu et al. 2013; Coleman et al. 2017; Litton et al. 2018).

In general, PARP inhibitors have shown a favorable side-effect profile as single agents, with a shared toxicity profile including fatigue, myelosuppression, and gastrointestinal symptoms (Fong et al. 2009; Gelmon et al. 2011; Kaye et al. 2012; Sandhu et al. 2013; Coleman et al. 2017; Litton et al. 2018). Patients treated with PARP inhibitors do have a theoretical risk of secondary malignancies due to DNA damage and genomic instability generating further mutational events, consistent with patients with DDR-deficient cancers treated using DNA-damaging chemotherapies. In practice, however, the risk of secondary malignancies, such as acute myeloid leukemia, in patients treated with PARP inhibitors has generally been low (reported as $<1\%$). Accordingly, regular complete blood counts should be undertaken during therapy, with timely referral of patients with persistent cytopenias to hematology specialists.

Ovarian Cancer

The development of PARP inhibitors for the treatment of ovarian cancer has provided clear clinical proof of concept and paved the way for the development of selective DDR inhibitors in cancer care. There are now three FDA-approved agents in different therapeutic settings – olaparib, rucaparib, and niraparib.

Maintenance Setting

Olaparib was first approved in 2014, for maintenance treatment of patients with platinum-sensitive, relapsed, germline, or somatic *BRCA1/2*-mutant ovarian cancers in complete or partial remission after platinum-based chemotherapy, based on data from the randomized phase II study 19 trial (NCT00753545), which demonstrated improved progression-free survival (PFS) in olaparib versus placebo (Ledermann et al. 2012). This finding was confirmed in this population in the follow-on, placebo-controlled, phase III SOLO2/ENGOT-Ov21 study, in which the median PFS was 19.1 months in the treatment group compared with 5.5 months in the placebo group (hazard ratio [HR], 0.3), with a tolerable adverse effect profile and no detrimental effects on quality of life. In 2017, the FDA approved olaparib for the maintenance treatment of ovarian cancer, irrespective of *BRCA*1/2-mutation status, on the basis of data from these trials.

In the ARIEL3 and NOVA trials, rucaparib and niraparib, respectively, have been explored in the maintenance setting for relapsed ovarian cancer, in patients with germline or somatic *BRCA* mutations and those with wild-type *BRCA*, with patient stratification by *BRCA* mutations (Mirza et al. 2016; Coleman et al. 2017), in an effort to define the wider homologous recombination deficiency (HRD) group of these cancers. ARIEL3 prospectively used the Foundation Medicine loss of heterozygosity test established in the ARIEL2 study to stratify patients with wild-type *BRCA1/2* into HRD-positive and HRD-negative groups (Coleman et al. 2017), while the NOVA study prospectively stratified patients using the myChoice HRD test (Myriad Genetics, Salt Lake City, UT), which was initially established in triple-negative breast cancer.

ARIEL3 demonstrated a PFS advantage in all patient groups over placebo, with the greatest benefit observed in the *BRCA*-mutant group (16.6 vs. 5.4 months; HR 0.23). A benefit was also observed in the HRD (13.6 vs. 5.4 months; HR 0.32) and intention-to-treat (10.8 vs. 5.4 months; HR 0.36) populations (Coleman et al. 2017). In the NOVA study, PFS was significantly increased in all patient groups; the median PFS was 21.1 versus 5.5 months (HR 0.27) in the germline *BRCA* cohort, 12.9 versus 3.8 months (HR 0.45) in the HRD group, and 9.3 versus 3.9 months (HR 0.45) in the overall non-germline *BRCA* group. There are subtle differences between the patient groups in the studies – the NOVA trial deployed a somewhat stricter entry criteria and required patients to have excellent disease response and no measurable disease greater than 2 cm following chemotherapy. Regardless, these data are clear: maintenance treatment with a PARP inhibitor significantly prolonged PFS in all patient groups over placebo, although overall survival (OS) data are pending. Based on these data, olaparib, rucaparib, and niraparib are now approved by the FDA in this setting in the United States. Talazoparib and veliparib are currently in late phase trials in patients with newly diagnosed ovarian cancer (NCT02470585) and in other advanced-stage cancers, mainly in combination with chemotherapies for the latter agent.

Upfront Setting

In 2018, the phase III SOLO1 trial set a new standard of care with maintenance olaparib substantially extending PFS in newly diagnosed *BRCA1/2*-mutated advanced-stage ovarian cancer (Moore et al. 2018). In this study, 391 patients with advanced, high-grade, *BRCA*-associated serous or endometrioid ovarian cancer who had a complete or partial response to frontline, platinum-based chemotherapy were randomly assigned to maintenance with olaparib or placebo (Moore et al. 2018). At a median follow-up of 41 months, olaparib resulted in a lower 3-year rate of disease progression or death compared with placebo (60 vs. 27%; HR for disease progression or death 0.30, 95% CI 0.23–0.41). Recently presented data have shown that, after 5 years of follow-up, 48.3% of patients treated with olaparib have not experienced disease progression and are still living with stable disease vs. 20.5% of those taking placebo (Banerjee et al. 2020); median PFS was 56 vs. 14 months in the olaparib group, and among patients in complete response (CR) at baseline, risk of disease

recurrence or death was reduced by 63%. These data have confirmed that as a first-line therapy, olaparib can have substantial benefit for patients earlier in the cancer pathway.

The PRIMA trial established niraparib as maintenance therapy in the first-line setting, irrespective of tumor *BRCA* status (González-Martín et al. 2019). In the PRIMA trial, patients with advanced ovarian cancer who had responded to first-line, platinum-based chemotherapy were randomly assigned to niraparib or placebo for 36 months. For the subgroup with *BRCA*-associated cancers, niraparib prolonged PFS compared with placebo (22.1 vs. 10.9 months; HR 0.40, 95% CI 0.27–0.62).

Recurrent Setting

Studies have also shown that patients with advanced ovarian cancer and a germline *BRCA* mutation may respond to olaparib if they have experienced progression on multiple previous lines of chemotherapy, in platinum-sensitive or platinum-resistant disease (Matulonis et al. 2016; Kaufman et al. 2015), which has led to FDA approval in this setting. In a meta-analysis of phase I and II trials including 273 patients with advanced, *BRCA*-associated ovarian cancer naïve to PARP inhibition, in the cohort of 205 patients who had received $\geq$3 lines of chemotherapy,[32] the tumor response rate was 31% (95% CI 25–38), and median duration of response was 7.8 months (95% CI 5.6–9.5).

Rucaparib has also been FDA-approved for use in advanced ovarian cancer patients who have received two or more chemotherapies and who have deleterious germline or somatic *BRCA* mutations, in either platinum-resistant or platinum-sensitive disease. The data to support this approval come from a pooled analysis of two phase II studies in which 106 patients with *BRCA*-mutated, high-grade ovarian cancer who had received at least two chemotherapy regimens and no prior PARP inhibition were treated with rucaparib (Oza et al. 2017). In this population, the objective response rate (ORR) was 54%, and the duration of response was 9.2 months; the ORR was 25% for those with platinum-resistant disease and 66% for platinum-sensitive disease.

Beyond Ovarian Cancer

BRCA1 and *BRCA2* are the two most studied genes in the HR repair pathway. Germline variants of these genes were initially discovered in patients with hereditary breast or ovarian cancer; however, somatic and germline *BRCA1/2* mutations, as well as aberrations affecting other HR genes including *ATM*, *ATR*, *BARD1*, *BRIP1*, *CHK1*, *CHK2*, *PALB2*, *RAD51*, and *FANC*, are increasingly being detected in patients with other tumor types through NGS of paired tumor and nonmalignant DNA samples (Pritchard et al. 2016).

Breast Cancer

The first studies exploring the possible effects of PARP inhibition on patients with germline BRCA cancer included patients with both breast and ovarian cancer, and responses were also observed in breast cancer patients. Rationally, it was initially proposed that triple-negative breast cancer, being a "BRCA-like" cancer with sensitivity to platinum-based chemotherapy, may also be sensitive to PARP inhibition, though early studies did not bear this out, and clinical trials with single-agent PARP inhibitors have focused on germline *BRCA1/2* patients.

The OlympiAD, a randomized phase III study of olaparib versus placebo for patients with metastatic breast cancer with germline BRCA mutation, confirmed activity PARP inhibitors in these patients, as a doubling of the ORR, a significant PFS benefit, and a more favorable safety profile for olaparib versus single-agent chemotherapy (not including platinum-based agents) were seen in patients with germline *BRCA1/2*-mutant, HER2-negative, metastatic breast cancer (Table 1). Olaparib is now FDA approved as a treatment following chemotherapy and appropriate hormonal therapy.

The ABRAZO phase II study with talazoparib also demonstrated promising activity for this patient group, which was confirmed in the phase III EMBRACA study, in which the primary analysis showed a PFS advantage for talazoparib over placebo (8.6 vs. 5.6 months; HR 0.54,

$P < 0.0001$) in all subgroups, including those with central nervous system disease (Litton et al. 2018). Importantly, the talazoparib-treated patients in this study also had improvements in quality of life and delayed clinically meaningful deterioration compared to patients treated with standard chemotherapy, which led to the FDA approval of talazoparib as a treatment option for patients with germline *BRCA1/2*-mutated advanced HER2-negative breast cancer. Updated data from the EMBRACA trial have shown that talazoparib did not produce a statistically significant OS benefit for these patients; however, OS results may have been confounded by subsequent treatments, as most patients included in the study went on to receive subsequent systemic therapies. Nevertheless, previous data showing talazoparib improved patient-reported quality-of-life measures over available chemotherapies with an acceptable safety profile were confirmed, and thus, talazoparib remains an option for patients with advanced *BRCA1/2*mutant, HER2negative breast cancer. A randomized trial of investigator's choice chemotherapy versus niraparib (NCT01905592) is ongoing.

Substantial efforts are also being applied to early-stage clinical testing of PARP inhibitors in the neoadjuvant setting. In contrast to other agents, encouraging data have recently been reported utilizing talazoparib in the neoadjuvant setting in patients with *BRCA1/2*-mutant, HER2-negative breast cancer, with 10 of 19 patients (53%) achieving a pathologic CR (pCR) (Litton et al. 2020). Perhaps more potent PARP inhibition of *BRCA1/2*-mutant tumors in an earlier setting, when driver mutations are perhaps more limited, might prove to be particularly effective.

Emerging Monotherapy Indications

It is clear that, for patients with a deleterious germline *BRCA*1/2 mutation, there is activity across a range of cancer types beyond breast and ovarian cancers, including prostate, pancreatic, and biliary cancers. In the TOPARP-A phase II study in metastatic CRPC, all 49 patients provided a fresh tumor sample before treatment for genomic analysis. The ORR to olaparib in this patient group was 33%, and 14 of 16 patients with disease response were in the biomarker-positive group with identified deleterious deletions or mutations in DDR genes (*BRCA1*, *BRCA2*, *ATM*, *BRIP1*, *BARD1*, *CDK12*, *CHEK1*, *CHEK2*, *FANCL*, *PALB2*, *PPP2R2A*, *RAD51B*, *RAD51C*, *RAD51D*, and *RAD54L*) (Mateo et al. 2015). These data resulted in olaparib receiving breakthrough therapy designation in prostate cancer from the FDA. The TOPARP-B study confirmed the antitumor activity of olaparib in metastatic prostate cancer with defective DNA repair secondary to either germline or somatic gene inactivation, as confirmed composite response was achieved in 25 (54.3%; 95% CI 39.0–69.1) of 46 evaluable patients in the 400 mg cohort and 18 (39.1%; 25.1–54.6) of 46 evaluable patients in the 300 mg cohort. The PROfound trial led to the recent FDA approval of olaparib for patients with mCRPC after treatment with enzalutamide and/or abiraterone. This prospective, randomized phase III trial examined the efficacy of olaparib in men with mCRPC and DDR mutations in 15 genes associated with DDR; PFS was significantly longer in patient receiving olaparib than control patients (de Bono et al. 2020). Other phase III clinical trials are evaluating niraparib and talazoparib, alone or in combination with AR signaling inhibitors.

Rucaparib was granted breakthrough therapy designation by the FDA based on initial efficacy and safety results from the TRITON2 study. Preliminary published data from this study shows promising results, with 43.9% of *BRCA* patients achieving a confirmed radiographic response, with the majority of responses lasting longer than 24 weeks. Interestingly, although a high response rate was observed for patients with *BRCA1/2*-mutant CRPC, responses were not reported in those harboring tumors with *ATM* and *CDK12* mutations. Similarly, in the PROfound trial, a hazard ratio of 0.74 for radiographic PFS with wide confidence limits was noted for patients with CDK12 alterations treated with olaparib (de Bono et al. 2020; Mateo et al. 2020). Studies of other PARP inhibitor treatments

in patients with *CDK12* mutations are similarly disappointing, and alternative agents are needed in this subset of patients. These findings do suggest that patients with *ATM*-mutant or *CDK12*-mutant metastatic CRPC may require alternative therapies, such as chemotherapy, or ATR inhibitors given as monotherapy, or in combination regimens.

Pancreatic ductal adenocarcinoma is also an emerging area of potential use for PARP inhibition. The POLO (Pancreas Cancer Olaparib Ongoing) phase III trial evaluated the efficacy of olaparib as maintenance therapy in patients who had a germline *BRCA1/2* mutation metastatic pancreatic cancer and disease that had not progressed during first-line platinum-based chemotherapy and demonstrated PFS was significantly longer in the olaparib group than in the placebo group (7.4 months vs. 3.8 months; HR 0.53; 95% CI 0.35 to 0.82; $P = 0.004$). In addition, after 2 years, 22.1% of patients had no disease progression versus 9.6% of those who received placebo, and the median duration of response was 24.9 months in the olaparib arm versus 3.7 months with placebo. This has led to FDA approval of olaparib for metastatic pancreatic adenocarcinoma with germline *BRCA1* or *BRCA2* mutation – the only approved targeted medicine in biomarker-selected patients with advanced pancreatic cancer.

Beyond Monotherapy Approaches

The heterogeneous responses to PARP inhibitors, even in *BRCA1/2*-mutant tumors, indicate the existence of complex inherent and acquired resistance mechanisms. Several novel mechanisms have been suggested, such as secondary mutations in both *BRCA1 and BRCA2* that restore, at least partially, HR capabilities and allow tumors to escape inhibition by PARP inhibitors, mitigation of replication stress, promoter demethylation of *BRCA1/2* genes, point mutations in PARP1, and drug-efflux pumps affecting drug pharmacokinetics (Pilié et al. 2019). Thus, strategies to overcome such resistance mechanisms have included the development of multiple drug combinations, which can also synergize antitumor efficacy.

Combination Strategies

Combination strategies using PARP inhibition have included multiple chemotherapeutic agents, molecularly targeted agents, and immunotherapeutics. Mechanisms resulting in synergy or additive activity of PARP inhibitor and chemotherapy combinations are multifactorial and depend on the specific combination and tumor in question. For example, chemotherapy can increase DNA damage, while PARP inhibitors can diminish the ability of PARP enzymes to repair DNA damage. Early promising efficacy has been observed with these combinations; however, tolerability of such regimens has been mixed. For example, although the concurrent addition of olaparib to carboplatin and paclitaxel for patients with advanced ovarian cancers showed an improved PFS in the combination group (12.2 months vs. 9.6 months), grade 3 neutropenia was reported for 43% of patients in the combination arm versus 35% in the chemotherapy-only arm, and a substantial proportion of patients required dose reductions or treatment delays as a result of myelosuppression (Pilié et al. 2019).

Combinations with Other DDR Pathway Inhibitors

The pairing of PARP inhibitors with other DDR pathway inhibitors, such as ATR and WEE1 inhibitors, is a rational approach currently under investigation. Preclinical studies have shown that olaparib-resistant cancer models may be resensitized to olaparib when combined with a WEE1 inhibitor or an ATR inhibitor (Pilié et al. 2019). There are also other potent inhibitors that target different key nodes along the DDR cascade in clinical development, including *CHK1/2*, *DNA-PK*, *ATM*, and *POLθ,* which may represent other potential combination partners for PARP inhibitors (Pilié et al. 2019). In view of the likely overlapping mechanism-based bone marrow toxicity with such agents, careful thought must be given to the concurrent development of such combinations, especially with regard to the doses, schedules, and sequences.

Combinations with Immune Checkpoint Blockade

There is now convincing preclinical evidence supporting the combination of DDR pathway inhibitors and immune checkpoint inhibitors as a rational antitumor strategy. PARP inhibition has been shown in preclinical models to inactivate GSK3β and upregulate PD-L1, suppressing T-cell activation and increasing cancer cell killing (Jiao et al. 2017). In addition to this, PARP inhibition generates cytosolic double-stranded DNA, which activate cGAS-STING signaling and its associated transcription programs, and induces IFN-mediated antitumor immune responses. These critical changes amplify STING signaling and promote tumor infiltrating lymphocytes and antitumor immunity, which can then be further enhanced through immune checkpoint blockade (ICB) (Shen et al. 2019). PARP inhibitor treatment has also been shown to enhance tumor susceptibility to ICB, regardless of the *BRCA1/2* status, in vitro and in vivo (Shen et al. 2019).

In the recently reported MEDIOLA phase II basket trial investigating olaparib and the PD-L1-inhibitor durvalumab in advanced solid tumors, in patients with advanced germline *BRCA1/2* mutation breast cancer, 24 out of 30 patients had disease control at 12 weeks, and 50% had disease control at 28 weeks. In the platinum-sensitive *BRCA1/2* mutation relapsed ovarian cancer cohort of the MEDIOLA study, ORR was 63%, while disease control rate (DCR) at 12 weeks was 81%. The combination of olaparib and durvalumab was safe and well-tolerated, with a low incidence of grade 3 and all-grade immune-related toxicities.

These data are in keeping with the TOPACIO study, the first study to report the safety and efficacy of combining PARP inhibitors and immuno-oncology checkpoint therapy in patients with metastatic TNBC, with or without *BRCA1/2* mutations. Here, Vinayak et al. investigated niraparib in combination with pembrolizumab in patients with advanced or metastatic TNBC and demonstrated promising antitumor activity, with numerically higher response rates in patients with *BRCA1/2* mutations: the ORR included 7 of 15 patients with *BRCA1/2* (47%; 90% CI, 24%–70%), and the DCR, 12 of 15 (80%; 90% CI, 56%–94%), with 2 confirmed complete responses, 5 confirmed partial responses, and 5 with stable disease. Among the 27 patients without *BRCA1/2* mutations, the ORR included 3 (11%; 90% CI, 3%–26%) and the DCR included 9 (33%; 90% CI, 19%–51%), with 3 complete responses and 6 with stable disease.

In the phase I/II TOPACIO/KEYNOTE-162 study, the clinical activity and safety of the niraparib and pembrolizumab combination in patients with platinum-resistant ovarian cancer were investigated. Overall efficacy data showed ORR of 18% (90% CI, 11%–29%), with a disease control rate of 65%, including 3 (5%) patients with complete responses, 8 (13%) with partial responses, 28 (47%) with stable disease, and 20 (33%) with progressive disease. The ORR was consistent across subgroups based on platinum sensitivity, prior bevacizumab, and tumor *BRCA1/2* or HRD status. Specific to advanced TNBC, the TOPACIO study showed a 28% ORR and PFS of 8.3 months with the combination of niraparib and pembrolizumab for patients with *BRCA1/2*-mutated tumors. Interestingly, responses were also seen in non-*BRCA* advanced TNBC patients, with and without HRD.

Conclusion

Over the past decade, significant advances have been made in successfully targeting the DDR in cancer medicine, with multiple selective and potent DDR inhibitors being developed in the clinic. PARP inhibitors have emerged as a well-tolerated single-agent strategy for the treatment of ovarian cancer, germline *BRCA*-mutant breast cancers, and now pancreatic and prostate cancer. Future efforts will aim at developing more inclusive and functionally based predictive biomarker assays, improving our understanding of resistance mechanisms and optimizing treatment strategies through the use of genomic-driven innovative, longitudinal trial designs to truly personalize antitumor DDR therapies, ultimately leading to improved outcomes for cancer patients.

DNA topoisomerase II inhibitors

Definition

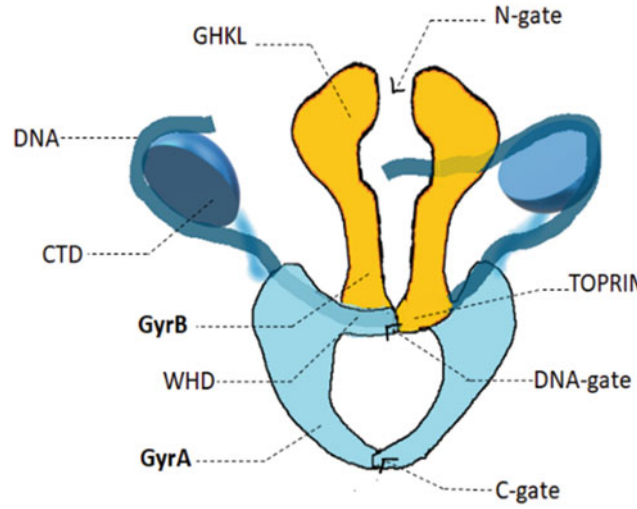
The emerging bacterial resistance makes several existing antibiotic therapies ineffective. As per the World Health Organization (WHO), approximately 7,00,000 people die annually due to drug-resistant diseases and the WHO has named bacterial resistance as one of the three major public health crises of the twenty-first century (World Health Organization 2018). To combat this, novel molecular targets are being explored for discovery of new antibacterial agents. One of the molecular targets is the prokaryotic topoisomerase that is implicated in several biological processes such as transcription, replication of DNA, and gene expression. The first topoisomerase was discovered by James Wang in 1971, followed by the discovery of *E. coli* DNA gyrase in 1976. DNA gyrase is a type II topoisomerase mainly present in prokaryotes; it overhauls the bacterial chromosome by introducing negative supercoils in the DNA via an ATP-dependent reaction. DNA gyrase introduces breaks in the two helices of the double stranded DNA. It plays an imperative role in compacting genome and resolves topological challenges related to transcription, recombination, and replication of DNA (Barančoková et al. 2018). DNA gyrase is not found in eukaryotes; hence, it is an attractive target for design and development of new chemical entities as potential antibacterial agents. This chapter presents some of the important clinically used DNA gyrase inhibitors along with an overview of new chemical entities targeting DNA gyrase.

DNA Gyrase Inhibitors

DNA gyrase inhibitors belong to three major families: quinolones, coumarins, and cyclothialidines. There is an emerging new class of DNA gyrase inhibitors in clinical trials for bacterial resistance strains. The mechanism of action of the various classes of DNA gyrase inhibitors is summarized below.

Mechanism of DNA Supercoiling by DNA Gyrase

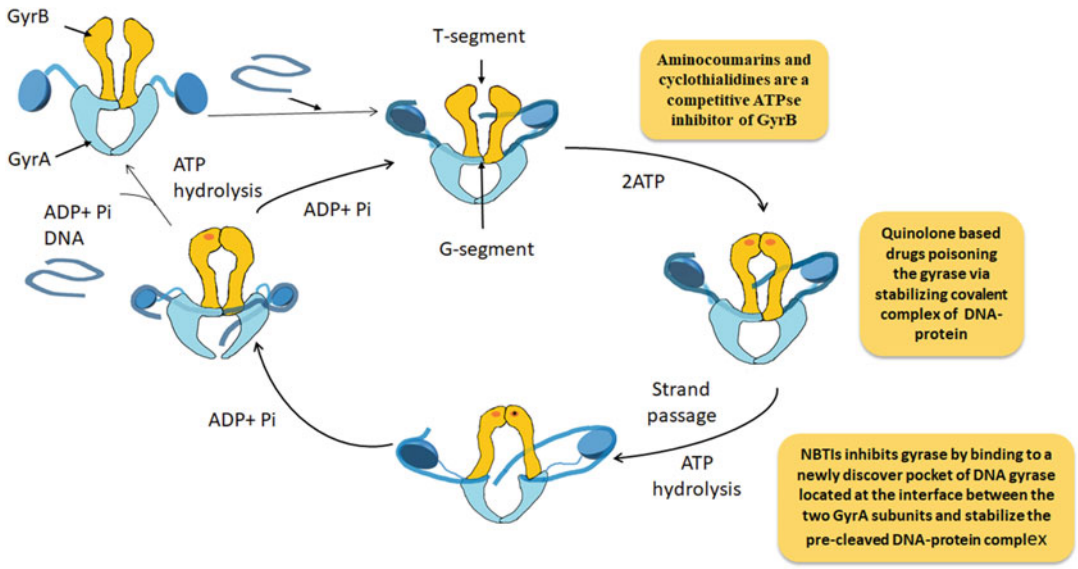
DNA gyrase is an A2B2 heterotetramer, comprised of two subunits, that is, A (encoded by *gyrA*, 97 KDa in *E-coli*) and B (encoded by *gyrB*, 90 KDa in *E-coli*). It has three domains like GyrB, GyrA, and C-terminal domain. GyrB belonging to GHKL family (GyrB, heat shock protein 90 (Hsp90)-histidine kinase/serine protein kinase, the DNA mismatch repair protein *MutL*), contains N-terminal domain for ATPase function (Fig. 1). The C-terminal domain (CTD) of GyrA forms six blades propeller kind of closed circular structure with blades 1 and 6 were connected by GyrA box. In the DNA-DNA gyrase complex, three major protein-protein interfaces forms called as gates. The gates can momentarily close and reopen for allowing passage of double-stranded DNA. The N-gate is formed by the N-terminal ATP-binding GHKL domain of GyrB that acts as an ATP-operated clamp for allowing the entry of double-stranded DNA. The central DNA gate is formed by GyrB and GyrA, specifically



DNA Gyrase Inhibitors, Fig. 1 Structure of DNA gyrase

C-terminal TOPRIM (topoisomerase primase) of GyrB along with N-terminal of WHD domain (Winged helix domain) of GyrA. This enables the catalytic tyrosine for DNA strand cleavage. Besides this, the C-terminal or exit gate is formed by GyrA (Gubaev et al. 2016).

The strand passage mechanism involves synchronized opening and closing of the N-, central DNA-, and C gate. Here, the GyrA subunit implicated in breakage and reseal of double stranded DNA while the GyrB subunit catalyzes the binding and hydrolysis of ATP. The segment of double stranded DNA intended to be cleaved known as G segment that binds at the central DNA gate encompassing the active site tyrosine that creates a transient 5′-phosphotyrosylprotein-DNA linkage in the cleaved state. A second segment of DNA is called as the T or transfer segment which pass through the upper cavity gap of GyrB, that is, N-gate. Consequently, the two catalytic gates of the DNA gyrase enzyme have been established specifically the N-terminal ATP gate and the central DNA-cleavage gate, each targeted by several antibacterial agents (Fig. 2) (Gubaev et al. 2016). Wrapping of the 140 base pairs segment of DNA around enzyme is facilitated by the C-terminal tail domain (CTD) of the GyrA protein resulted into a positive supercoil and binds to the central DNA-gate. N-terminal domains of GyrB form an ATP dependent protein clamp that closes due to nucleotide induced dimerization upon binding of ATP. Thus, the enzyme captures T segment of DNA in the upper cavity by N- or DNA gate and transfers it through the cleave in the G-segment of DNA forming DNA–phosphotyrosyl bonds 4 bp apart, thus creating a double-strand break resulting in covalent attachment of the active site tyrosine residues (Tyr122 in *E. coli* GyrA) from the two GyrA subunits to the 5′-phosphate groups on the cleaved ends via phosphodiester bonds with the help of Mg2+ ions coordinated by the TOPRIM domains of GyrB. The T segment of DNA is passed through the open central DNA gate and the broken G segment of DNA gets ultimately exit through the exit or C gate. DNA gyrase enzyme is resets for the next supercoiling cycle when the ATP gets hydrolyzed and released ADP opens the upper cavity N-gate for entry of next DNA. One DNA gyrase cycle of supercoiling facilitates two negative supercoils into the double stranded DNA molecule at the expenditure of 2 ATPs molecule. One thing is realized that DNA gyrase supercoiling cycle gives plenty targets for the inhibitors to show antibacterial activity via targeting ATP binding site of GyrA and interferes with the binding of DNA, stabilizing the DNA-protein complex in at cleaved DNA state. Thus, two major mechanisms can be liable for the antibacterial agents for targeting DNA gyrase functions. The first one is the inhibition of the ATPase enzymatic activity of GyrB and the second includes



DNA Gyrase Inhibitors, Fig. 2 Catalytic cycle of DNA gyrase and mode of action of DNA gyrase inhibitors

stabilization of the covalent binding of DNA gyrase–DNA complex, or poisoning of DNA gyrase (Gubaev and Klostermeier 2011).

Mechanism of Action of DNA Gyrase Inhibitors

Quinolones are a class of broad-spectrum bactericidal antibiotics that inhibit both gram- negative and gram-positive bacteria. The first-generation quinolones like nalidixic acid and oxalinic acid possessed weak activity, and development of fluoroquinolones such as norfloxacin and ciprofloxacin (second generation), levofloxacin (third generation), moxifloxacin, and gemifloxacin (fourth generation) expanded the armamentarium of antibiotics with potent activity and have enjoyed tremendous clinical success. They exert their action via binding to the cleavage binding site in a noncovalent manner and poison the gyrase by stabilizing the cleaved DNA-enzyme complex. The quinolones inhibit the replication process leading to cell death in bacteria (Collin et al. 2011).

The aminocoumarins class includes drugs like novobiocin, clorobiocin, and coumermycin A_1 which are naturally occurring DNA gyrase inhibitors isolated from *Streptomyces species*. Their binding site and mode of action differs from the quinolone class of DNA gyrase inhibitors. They are competitive inhibitors of the enzyme and binds at the ATP binding site of GyrB subunit inhibiting the ATPase activity of the gyrase. Besides these three classical aminocoumarins, only one natural aminocoumarin has been discovered – simocyclinones. The two binding sites identified for simocyclinones include the N-terminal domain of GyrA and C-terminal domain of GyrB. One binding pocket interacts with aminocoumarin moiety and the other binding pocket with angucyclinone moiety of the antibiotic. Therefore, occupancy of either site by an inhibitor would prevent DNA binding. These two binding sites are adjacent and not overlapping the binding site of fluoroquinolones (Khan et al. 2018).

Cyclothialidines are produced by *Streptomyces filipinensis*. The resorcinol ring of cyclothialidines is involved in a similar binding interaction as the adenine ring of ATP. They inhibit DNA gyrase activity via binding to the ATP binding site of GyrB (Khan et al. 2018).

Amycolamicin isolated from a soil *Amycolatopsis species* shows potent activity

against both gram-negative and gram-positive bacteria. Kibdelomycin is a broad spectrum, gram-positive antibacterial agent isolated from the genus *kibdelosporangium species*. It has a unique dual arm, U-shaped binding mode and is different from the binding modes of other gyrase inhibitors. Hence, they show no cross-resistance to known gyrase inhibitors such as quinolones, novobiocin, and coumermycin. They carry dichloropyrrole carboxylic acid moiety which acts as dual inhibitor of topoisomerase IV and GyrB subunit of gyrase (Barančoková et al. 2018).

CcdB and microcin B17 are plasmid-encoded toxins. These proteins stabilize the DNA gyrase-DNA covalent complexes leading to double-strand breaks in the genome (Collin et al. 2011).

Gepotidacin (GSK2140944), a traizaacenaphthylene, inhibits the gyrase by binding to the interface between the two GyrA subunits in the DNA-protein complex and targets the pre-cleaved conformation and zoliflodacin (ETX0914/AZD0914) is a spiropyrimidinetrione that stabilizes the DNA-protein complex after the DNA molecule has been cleaved. These two molecules constitute the novel bacterial type II topoisomerase inhibitors (NBTIs) class and have successfully completed phase II clinical trial for the treatment of *Neisseria gonorrhoeae* infections. These molecules possess nonquinolone binding sites of DNA gyrase to avoid cross resistance or over-lapping binding with existing known gyrase inhibitors such as quinolones or coumarins. They comprise of two heterocycles joined via an aliphatic linker, commonly containing a basic nitrogen. NBTIs form hydrophobic contacts with the gyrase via π-π interaction between two bases of the DNA. The linker part of NBTIs also shows hydrogen bonding with the side chain of Asp83 of gyrase at the binding site. For example, Gepotidacin contains a pyranopyridine and a tricyclic ring that are joined via amino-piperidine linker. It is also being studied for treatment of respiratory infections, skin infections, and urinary tract infections (Durcik et al. 2019).

The misuse and abuse of these antibiotics has led to development of quinolone-resistant bacterial strains. A vast majority of clinically observed resistance to quinolones arises due to mutations in single amino acids. These mutations are localized at the N-terminal domains of GyrA which extends from amino acids 67 to 106 in *E. coli*. Predominantly, mutations are observed at residues 67, 81, 82, 83, 84, and 106 in *E. coli*. Besides, resistance mutation is also localized at active site tyrosine positioned at 122, where DNA is bound. This domain of DNA gyrase is known as quinolone resistance determining region (QRDR). Novobiocin, marketed as Albamycin, was used clinically against *methicillin-resistant S. aureus* (MRSA). Some issues related to toxicity, poor oral absorption, low activity against gram negative bacteria, and development of resistance in coumarin sensitive organisms were observed with novobiocin. Hence, the use of novobiocin declined sharply during 1960s, although it was not officially withdrawn from the market until 2011 (Pham et al. 2019). However, in recent years many pharmaceutical industries have succeeded in overcoming the problems associated with classical aminocoumarins by designing and developing new ATPase inhibitors, for example, Quorex's indazole derivatives, AstraZeneca's aryl aminopyrimidines, vertex's pyrazole based inhibitors, and ethyl urea moiety containing DNA gyrase inhibitors have been reported by several companies such as benzimidazole ethyl urea by vertex, benzothiazole ethyl urea by Prolysis, pyridylurea by AstraZeneca, ethylurea imidazopyridines, and triazolopyridines by Pfizer (Table 1). All the known ATP-competitive inhibitors have similar interaction at the active site of DN gyrase. They contain a hydrogen bond donor and acceptor motif that interacts with Asp73, along with this essential water molecules and aromatic part forms π-π interaction with arginine residues. Except for benzimidazole and benzothiazole ethyl ureas, the progress of all the other ATP-competitive inhibitors mentioned above has been terminated. Moreover, AstraZeneca later developed azaindole and pyrrolamide classes of inhibitors with two of their pyrrolamides being the only ATPase inhibitors to reach clinical trials after novobiocin. The clinical development of pyrrolamides was later terminated, and in 2011, AstraZeneca withdrew all its efforts on development of GyrB inhibitors.

Clinical Use

DNA gyrase inhibitors are broad-spectrum antibiotics used in a variety of clinical indications. Despite the increased rate of resistance leading to re-adjustment of therapeutic strategies and applications of these inhibitors, fluoroquinolones have been used as key drugs in the treatment of urinary tract (UTIs), digestive tract, and respiratory system infections. Excessive prescription of quinolones has led to the rapid development of quinolone resistance, leading to a loss in therapeutic effectiveness of this class. Globally, high levels of resistance to *E. coli*, the predominant cause of UTIs, have led to replacement of quinolones by third-generation cephalosporins

(**d**) Structure of quinolones. (**e**) Structure of amycolamicin and kibdelomycin. (**f**) Structure of gepotidacin and zoliflodacin

for this indication. Fluoroquinolones are still used in the treatment of typhoid caused by *Salmonella* owing to resistance to earlier first line agents like chloramphenicol, trimethoprim/sulfamethoxazole, and ampicillin. Nevertheless, resistance to quinolones in *Salmonella* is rapidly being reported in South Asia, Africa, and America. Thus, *Salmonella* is now graded as a high urgency pathogen for research and development of new antibacterial agents. For respiratory tract infections, especially community-acquired pneumonia, quinolones are not recommended for first-line treatment but are reserved for serious cases. To decrease the probability of fluoroquinolone resistance development, it is recommended to limit the use of this class in the treatment of patients with less severe infections. Though it is a powerful antibiotic for treating children's infections such as diarrhea or gram-negative meningitis, the toxicity (arthralgia) of this class combined with the issues of increased resistance has reduced its use for this group. The recently reported potential of aortic rupture and dissection side effects also raises safety concerns for the use of quinolones in elderly patients, wherein they may lead to serious bleeding or even death. In addition, there are probable teratogenic and mutagenic effects, so prescription of fluoroquinolones in pregnant and breast-feeding women is limited. The use of aminocoumarins class of antibiotics has been constrained due to problems related to water solubility, activity against gram negative bacteria and toxicity. Hence, there is research impetus to explore nonquinolone binding sites of DNA gyrase to avoid cross resistance or over-lapping binding with existing known gyrase inhibitors. Until now, several molecules of the NBTIs class are under clinical trials that utilized distinct mechanism for trapping the DNA-protein complex. Two types of NBTIs have been discovered that we have discoursed in above chapter. Type 1 NBTIs inhibit the activity of the DNA gyrase via binding to the interface between the two GyrA subunits in the DNA-protein complex and target the precleaved conformation while type II NBTIs stabilize the DNA-protein complex after the DNA molecule has been cleaved (Table 2; Fig. 3).
