a LANGE medical book

CURRENT Diagnosis & Treatment Pediatrics

TWENTY-FOURTH EDITION

Edited by

William W. Hay, Jr., MD

Professor, Department of Pediatrics Section of Neonatology and Division of Perinatal Medicine University of Colorado School of Medicine and Children's Hospital Colorado

Myron J. Levin, MD

Professor, Departments of Pediatrics and Medicine Section of Pediatric Infectious Diseases University of Colorado School of Medicine and Children's Hospital Colorado

Robin R. Deterding, MD

Professor, Department of Pediatrics Chief, Section of Pediatric Pulmonary Medicine University of Colorado School of Medicine and Children's Hospital Colorado Medical Director, Breathing Institute Children's Hospital Colorado

Mark J. Abzug, MD

Professor, Department of Pediatrics Section of Pediatric Infectious Diseases Associate Vice Chair for Academic Affairs, Department of Pediatrics University of Colorado School of Medicine and Children's Hospital Colorado

and Associate Authors

The Department of Pediatrics at the University of Colorado School of Medicine is affiliated with Children's Hospital Colorado.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Contents

Authors Preface Selected Highlighted Topics in the		xix xxix
24	th Edition of CDT-P	xxxi
1.	Advancing the Quality	
	& Safety of Care	
	Daniel Hyman, MD	
	Introduction	1
	Current Context	1
	Strategies & Models for	
	Quality Improvement (QI)	4
	Principles of Patient Safety	
	(Incident Reporting, Just Culture,	
	Disclosure, FMEA, RCA,	
	Reliability, Checklists)	7
2	The Newborn Infant	10
2.	menewborn man	10
	Danielle Smith, MD Theresa Grover, MD	
	Introduction	10
	The Neonatal History	10
	Assessment of Growth & Gestational Age	10
	Examination at Birth	12
	Examination in the Nursery	13
	Care of the Well Neonate	15
	Feeding the Well Neonate	15
	Early Discharge of the Newborn Infant	17
	Hearing Screening	18
	Common Problems in the Term Newborn	18
	Neonatal Jaundice	18
	Hypoglycemia	25
	Nexthern Infort	26
	Newborn Infant	20
	Birth Trauma	20
	Infants of Mothers Who Abuse Drugs	20
	Multiple Births	29
	Neonatal Intensive Care	32
	Perinatal Resuscitation	32
	The Preterm Infant	36
	The Late Preterm Infant	45
	Cardiac Problems in the Newborn Infant	46
	Structural Heart Disease	46
	Persistent Pulmonary Hypertension	47
	Arrhythmias	48
	Gastrointestinal & Abdominal Surgical	
	Conditions in the Newborn Infant	48

Esophageal Atresia & Tracheoesophageal	
Fistula	48
Intestinal Obstruction	49
Abdominal Wall Defects	50
Diaphragmatic Hernia	51
Gastrointestinal Bleeding	51
Gastroesophageal Reflux	51
Infections in the Newborn Infant	52
Bacterial Infections	52
Fungal Sepsis	55
Congenital Infections	56
Perinatally Acquired Infections	58
Hematologic Disorders in the Newborn Infant	59
Bleeding Disorders	59
Anemia	60
Polycythemia	61
Renal Disorders in the Newborn Infant	62
Renal Failure	62
Urinary Tract Anomalies	62
Renal Vein Thrombosis	63
Neurologic Problems in the Newborn Infant	63
Seizures	63
Intracranial Hemorrhage	64
Metabolic Disorders in the Newborn Infant	65
Hyperglycemia	65
Hypocalcenna	65
Inborn Errors of Metabolism	65 66
Inborn Errors of Metabolism Quality Assessment & Improvement	65 66
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU	65 66 66
 Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior 	65 66 66 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior	65 66 66 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior Edward Goldson, MD	65 66 66 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior Edward Goldson, MD Ann Reynolds, MD	65 66 66 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior Edward Goldson, MD Ann Reynolds, MD Introduction	65 66 67 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior <i>Edward Goldson, MD</i> <i>Ann Reynolds, MD</i> Introduction Normal Development	65 66 66 67 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior <i>Edward Goldson, MD</i> <i>Ann Reynolds, MD</i> Introduction Normal Development The First 2 Years	65 66 67 67 67 67
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior <i>Edward Goldson, MD</i> <i>Ann Reynolds, MD</i> Introduction Normal Development The First 2 Years Ages 2–4 Years	65 66 67 67 67 67 67 73
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. Child Development & Behavior <i>Edward Goldson, MD</i> <i>Ann Reynolds, MD</i> Introduction Normal Development The First 2 Years Ages 2–4 Years Early School Years: Ages 5–7 Years	65 66 67 67 67 67 73 74
Inborn Errors of Metabolism Quality Assessment & Improvement in the Newborn Nursery & NICU 3. 12. Emergencies & Injuries *Kevin P. Carney, MD*

Kelley Roswell, MD		
Introduction to Pediatric		
Emergencies & Injuries	309	
Initial Approach to the Acutely Ill		
Infant or Child	309	
The ABCs of Resuscitation	310	
Management of Shock	314	
Summary of Initial Approach to the		
Acutely Ill Infant or Child	315	
Emergency Pediatric Drugs	316	
Approach to the Pediatric Trauma Patient	316	
Mechanism of Injury	317	
Initial Assessment & Management	317	
Primary Survey	317	
Secondary Survey	319	
Head Injury	321	
Burns	323	
Thermal Burns	323	
Electrical Burns	325	
Disorders due to Extremes of Environment	326	
Heat-Related Illnesses & Heat Stroke	326	
Hypothermia	326	
Submersion Injuries	327	
Lacerations	328	
Animal & Human Bites	329	
Dog Bites	329	
Cat Bites	330	
Human Bites	330	
Pain Management & Procedural Sedation	330	

13. Poisoning

Richard C. Dart, MD, PhD Barry H. Rumack, MD George Sam Wang, MD	
Introduction	332
Pharmacologic Principles of Toxicology	332
Preventing Childhood Poisonings	333
General Treatment of Poisoning	333
Initial Telephone Contact	333
Initial Emergency Department Contact	336
Definitive Therapy of Poisoning	336
Management of Specific Common Poisonings	337
Acetaminophen (Paracetamol)	337
Alcohol, Ethyl (Ethanol)	339
Amphetamines & Related Drugs	
(Stimulants, Methamphetamine, MDMA)	340
Anesthetics, Local	340
Antihistamines & Cough & Cold	
Preparations	341

Barbiturates & Benzodiazepines	342
Belladonna Alkaloids (Atropine, Jimsonweed,	
Potato Leaves, Scopolamine, Stramonium)	342
β-Blockers & Calcium Channel Blockers	343
Carbon Monoxide	343
Caustics	344
Central α_2 -Adrenergic Agonist	344
Cocaine	345
Cosmetics & Related Products	345
Cyclic Antidepressants	345
Digitalis & Other Cardiac Glycosides	346
Diphenoxylate with Atropine	
(Lomotil) & Loperamide (Imodium)	346
Disinfectants & Deodorizers	347
Disk-Shaped "Button" Batteries	347
Ethylene Glycol & Methanol	348
γ-Hydroxybutyrate, γ-Butyrolactone,	
Butanediol, Flunitrazepam, & Ketamine	348
Hydrocarbons (Benzene, Charcoal	
Lighter Fluid, Gasoline, Kerosene,	
Petroleum Distillates, Turpentine)	349
Ibuprofen	349
Insect Stings (Bee, Wasp, & Hornet)	349
Insecticides	349
Iron	350
Lead	351
Magnets	352
Marijuana	352
Mushrooms	352
Nitrites, Nitrates, Aniline,	
Pentachlorophenol, & Dinitrophenol	353
Opioids & Opiates	353
Oral Anti-Diabetics	
(Sulfonylureas, Metformin)	354
Antipsychotics (Typical & Atypical)	355
Plants	355
Psychotropic Drugs	355
Salicylates	357
Scorpion Stings	358
Serotonin Reuptake Inhibitors	358
Snakebite	358
Soaps & Detergents	359
Spider Bites	360
Vitamins	360
Warfarin (Coumadin) & Newer Oral	
Anticoagulants (NOAC)	361
	0.01

14.	Critical Care	362
	Todd C. Carpenter, MD	
	Amy Clevenger, MD, PhD	
	Angela S. Czaja, MD, MSc	
	Eva N. Grayck, MD	
	Cameron F. Gunville, DO	
	Leslie Ridall, DO	
	Carleen Zebuhr, MD	
	Introduction	362
	Respiratory Critical Care	362
	Acute Respiratory Failure	362
	Conventional Mechanical Ventilation	366
	Other Modes of Respiratory Support	369
	Major Respiratory Diseases in the	
	Pediatric ICU	370

	Hypoxic-Ischemic Encephalopathy	387
	Acute Kidney Injury & Renal Replacement	
	Therapy	388
	Fluid Management & Nutritional Support	
	of the Critically III Child	389
	Sedation & Analgesia in the Pediatric ICU	391
	End-of-Life Care & Death in the PICU	395
	Quality Improvement Initiatives	200
	in the PICU	398

15. Skin

Lori D. Prok, MD	
Carla X. Torres-Zegarra, MD	
General Principles	399
Diagnosis of Skin Disorders	399
Treatment of Skin Disorders	399
Disorders of the Skin in Newborns	401
Transient Diseases in Newborns	401
Pigment Cell Birthmarks, Nevi,	
& Melanoma	402
Melanocytic Nevi	402
Vascular Birthmarks	403
Epidermal Birthmarks	404
Connective Tissue Birthmarks	
(Juvenile Elastoma, Collagenoma)	404
Hereditary Skin Disorders	405
Common Skin Diseases in Infants,	
Children, & Adolescents	406
Acne	406
Bacterial Infections of the Skin	408

Fungal Infections of the Skin	409
Viral Infections of the Skin	410
Virus-Induced Tumors	411
Insect Infestations	412
Dermatitis (Eczema)	412
Common Skin Tumors	415
Papulosquamous Eruptions	416
Hair Loss (Alopecia)	417
Reactive Erythemas	418
Miscellaneous Skin Disorders Seen	
in Pediatric Practice	418

16. Eye

Jennifer Lee Jung, MD	
Rebecca Sands Braverman, MD	
Introduction	420
Common Nonspecific Signs & Symptoms	420
Red Eye	420
Tearing	420
Discharge	420
Pain & Foreign Body Sensation	420
Photophobia	420
Leukocoria	421
Refractive Errors	421
Myopia (Nearsightedness)	422
Hyperopia (Farsightedness)	422
Astigmatism	422
Ophthalmic Examination	422
History	422
Visual Acuity	422
External Examination	423
Pupils	424
Alignment & Motility Evaluation	424
Ophthalmoscopic Examination	425
Ocular Trauma	426
Ocular Foreign Bodies	426
Corneal Abrasion	427
Intraocular Foreign Bodies & Perforating	
Ocular Injuries	428
Blunt Orbital Trauma	429
Lacerations	429
Burns	430
Hyphema	431
Abusive Head Trauma & Nonaccidental	
Trauma	432
Prevention of Ocular Injuries	432
Disorders of the Ocular Structures	433
Diseases of the Eyelids	433
Viral Eyelid Disease	434
Miscellaneous Eyelid Infections	435
Eyelid Ptosis	435
Horner Syndrome	436
Eyelid Tics	437

Disorders of the Nasolacrimal System	437
Nasolacrimal Duct Obstruction	437
Congenital Dacryocystocele	438
Dacryocystitis	438
Diseases of the Conjunctiva	439
Ophthalmia Neonatorum	439
Bacterial Conjunctivitis	440
Viral Conjunctivitis	440
Allergic Conjunctivitis	441
Mucocutaneous Diseases	442
Disorders of the Iris	443
Iris Coloboma	443
Aniridia	444
Albinism	444
Miscellaneous Iris Conditions	444
Claucoma	445
Uveitie	445
Aptorior Unoitic/Iridocuclitic/Iritic	445
Destarior Unaitie	440
Intermediate Liveitie	440
Disorders of the Compas	447
Cloudy Compa	448
Vinal Kanatitia	448
	448
Corneal Olcers	449
Disorders of the Lens	450
Cataracts	450
Dislocated Lenses/Ectopia Lentis	450
Disorders of the Retina	451
Retinal Hemorrhages in the Newborn	451
Retinopathy of Prematurity	451
Retinoblastoma	452

Preface

The 24th edition of *Current Diagnosis & Treatment: Pediatrics (CDTP)* features practical, up-to-date, well-referenced information on the care of children from birth through infancy, childhood, and adolescence. *CDTP* emphasizes the clinical aspects of pediatric care in the context of important underlying principles. *CDTP* provides a guide to diagnosis, understanding, and treatment of the medical problems of all pediatric patients in an easy-to-use and readable formaat.

INTENDED AUDIENCE

Like all Lange medical books, *CDTP* provides a concise yet comprehensive source of current information. Students will find *CDTP* an authoritative introduction to pediatrics and an excellent source for reference and review. *CDTP* provides excellent coverage of The Council on Medical Student Education in Pediatrics (COMSEP) curriculum used in pediatric clerkships. Residents in pediatrics (and other specialties) will appreciate the detailed descriptions of diseases as well as diagnostic and therapeutic procedures. Pediatricians, family practitioners, nurses, nurse practitioners, physician assistants, and other health care providers who work with infants, children, and adolescents will find *CDTP* a useful reference on management aspects of pediatric medicine.

COVERAGE

Forty-six chapters cover a wide range of topics, including neonatal medicine, child development and behavior, emergency and critical care medicine, and diagnosis and treatment of specific disorders according to major problems, etiologies, and organ systems. A wealth of tables and figures provides quick access to important information, such as acute and critical care procedures in the delivery room, the office, the emergency room, and the critical care unit; anti-infective agents; drug dosages; immunization schedules; differential diagnosis; and developmental disorders.

NEW TO THIS EDITION

The 24th edition of *CDTP* has been revised comprehensively by the editors and contributing authors. All chapters have been revised to reduce excessive text and condense text into tables. New references as well as up-to-date and useful websites have been added, permitting the reader to consult original material and to go beyond the confines of the textbook. As editors and practicing pediatricians, we have tried to ensure that each chapter reflects the needs and realities of day-to-day practice.

CHAPTERS WITH MAJOR REVISIONS INCLUDE:

- 4 Adolescence
- 7 Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics
- 9 Ambulatory & Office Pediatrics
- 10 Immunization
- 16 Eye
- 17 Oral Medicine & Dentistry
- 19 Respiratory Tract & Mediastinum
- 21 Gastrointestinal Tract
- 22 Liver & Pancreas
- 23 Fluid, Electrolyte, & Acid-Base Disorders & Therapy
- 25 Neurologic & Muscular Disorders
- 31 Neoplastic Disease
- 33 Immunodeficiency

PREFACE

- 36 Inborn Errors of Metabolism
- 37 Genetics & Dysmorphology
- 38 Allergic Disorders
- 41 Human Immunodeficiency Virus Infection
- 42 Infections: Bacterial & Spirochetal
- 43 Infections: Parasitic & Mycotic

CHAPTER REVISIONS

The 19 chapters that have been extensively revised, with new authors added in several cases, reflect the substantially updated material in each of their areas of pediatric medicine. Especially important are updates to the chapters on immunizations, endocrinology, neurologic and muscular disorders, and adolescence. The chapter on HIV includes current guidelines for prevention and treatment of HIV and updates information on the new antiretroviral therapies that have become available. The chapter on immunizations contains the most recently published recommendations, discusses the contraindications and precautions relevant to special populations, and includes the new vaccines licensed since the last edition of this book. Chapters on adolescence, skin, immunodeficiency, inborn errors of metabolism, and neoplastic disease are markedly updated with the latest information. All laboratory tables in Chapter 46 Pediatric Laboratory Medicine and Reference Ranges that includes reference ranges and reference intervals have been updated. All other chapters are substantially revised and references have been updated. Twenty-six new authors have contributed to these revisions.

ACKNOWLEDGMENTS

The editors would like to thank Bonnie Savone for her expert assistance in managing the flow of manuscripts and materials among the chapter authors, editors, and publishers. Her attention to detail was enormously helpful. The editors also would like to thank Tia Brayman at Children's Hospital Colorado who produced the cover photographs.

William W. Hay, Jr., MD Myron J. Levin, MD Robin R. Deterding, MD Mark J. Abzug, MD

Aurora, Colorado

Selected Highlighted Topics in the 24th Edition of CDT-P

The Adolescence chapter includes information about patient-centered care strategies and use of motivational interviewing.

The **Child Abuse & Neglect** chapter includes the use of nucleic acid amplification tests to diagnose sexually transmitted diseases in pre-pubertal children evaluated for sexual abuse.

The **Immunization** chapter includes new discussions about how HPV vaccination can prevent cancer and how a newer HPV vaccine protects against additional HPV types. There also is new discussion about how most parents in the United States choose to vaccinate their children (in 2013, < 1% of young children received no vaccines) and the problems associated with parents' concerns about vaccines and the increasing number of parents who are choosing to delay or decline vaccination for their children.

The **Poisoning** chapter includes new recommendations for evaluation and treatment for common ingestions and exposures in the pediatric population, including pharmaceuticals, household products, and designer drugs.

The Skin chapter includes the use of propranolol for infantile hemangiomas.

The Eye chapter describes how instrument-based vision screening is a novel means of detecting vision-threatening amblyogenic risk factors in preverbal, preliterate, and developmentally delayed children, and is endorsed by the American Academy of Pediatrics.

The **Oral Medicine & Dentistry** chapter includes preventive dental treatment (fluoride varnish) by physicians for high-risk populations.

The Respiratory Tract & Mediastinum chapter introduces the new cystic fibrosis drug, Orkambi.

The **Gastrointestinal Tract** chapter identifies the life-threatening impact of button batteries as startling and significant health care problem.

The Liver & Pancreas chapter identifies two new oral therapies that are available for children with chronic hepatitis B: entecavir for children 3 years or older and tenofovir for children 12 years or older.

The Hematologic Disorders chapter notes that hydroxyurea therapy is now recommended for all children with sickle cell anemia or sickle β -thalassemia.

The **Immunodeficiency** chapter describes the use of genetic testing in the evaluation of children with immunodeficiency and states of immune dysregulation.

The **Endocrine Disorders** chapter includes the use of recombinant alkaline phosphatase (asfotase alfa) for the treatment of hypophosphatasia and how it has revolutionized therapy for this disorder.

The Inborn Errors of Metabolism chapter includes updated information about diagnostic testing for a variety of disorders.

The Genetics & Dysmorphology chapter includes information on microarray testing and whole exome sequencing.

The Viral and Rickettsial chapter includes the latest information about Zika virus and dengue.

The Antimicrobial Therapy chapter includes information on antimicrobial stewardship.

And many more!

Advancing the Quality & Safety of Care

Daniel Hyman, MD

INTRODUCTION

Hippocrates' famous dictum primum non nocere 2500 years ago may have been the earliest reflection of the importance of patient safety, but the Institute of Medicine's (IOM) 1999 landmark report To Err Is Human truly galvanized the current focus on eliminating preventable harm from health care. Its most quoted statistic, that between 44,000 and 98,000 Americans die every year because of medical error, was based upon studies of hospital mortality in Colorado, Utah, and New York and extrapolated to an annual estimate for the country. The IOM followed up this report with a second publication, Crossing the Quality Chasm, in which they said, "Health care today harms too frequently, and routinely fails to deliver its potential benefits.... Between the health care we have and the care we could have lies not just a gap, but a chasm." These two reports have served as central elements in an advocacy movement that has engaged stakeholders across the continuum of our health care delivery system and changed the nature of how we think about the quality and safety of the care we provide, and receive.

In Crossing the Quality Chasm, the IOM included a simple but elegant definition of the word "Quality" as it applies to health care. They defined six domains of health care quality: (1) SAFE—free from preventable harm, (2) EFFECTIVE—optimal clinical outcomes; doing what we should do, not what we should not do according to the evidence, (3) EFFICIENT—without waste of resources—human, financial, supplies/equipment, (4) TIMELY—without unnecessary delay, (5) PATIENT/FAMILY CENTERED—according to the wishes and values of patients and their families, and (6) EQUITABLE—eliminating disparities in outcomes between patients of different race, gender, and socioeconomic status.

In the years since these two reports were published, the multiple stakeholders have been concerned about the effectiveness, safety, and cost of health care in the United States and, indeed throughout the world, have accelerated their individual and collective involvement in analyzing and improving care. In the United States, numerous governmental agencies, large employer groups, health insurance plans, consumers/ patients, health care providers, and delivery systems are among the key constituencies calling for and working toward better and safer care at lower cost. Similar efforts are occurring internationally. Indeed, the concept of the Triple Aim has been widely accepted as an organizing framework for considering the country's overall health care improvement goals.

Committee on Quality Health Care in America, Institute of Medicine: Crossing the Quality Chasm: a New Health System for the 21st Century. Washington, DC: National Academy Press, 2001.

Kohn L, Corrigan JM: To Err Is Human: Building a Safer Health System. Washington, DC: National Academy Press, 2000.

CURRENT CONTEXT

The health care industry is in a period of transformation being driven by at least four converging factors: (1) the recognition of serious gaps in the safety and quality of care we provide (and receive), (2) the unsustainable increases in the cost of care as a percent of the national economy, (3) the aging of the population, and (4) the emerging role of health care information technology as a potential tool to improve care. These are impacting health care organizations as well as individual practitioners in numerous ways that can also be traced to expectations regarding transparency and increasing accountability for results. As depicted in Figure 1-1, the Quadruple Aim (advancing the original concept of the Triple Aim) includes the simultaneous goals of achieving better care (outcomes/experience) for individual patients and families, better health status for the population, lower overall cost of care, and enhancing the experience of the health care workforce. Practitioners and trainees (and health care workers in general) must adapt to a new set of priorities that focus

CHAPTER 1

▲ **Figure 1–1.** Quadruple aim.

attention on new goals to extend our historic focus on the doctor/patient relationship and autonophysician decision making. Instead, our system's new imperatives are evidencebased medicine, advancing safety, and reducing unnecessary expense. There is recognition that we need to care for our workforce and understand their challenges if we are to achieve our patient oriented goals. Staff must be safe, both physically and psychologically, and their resiliency and stress is increasingly a focus of health care systems around the country.

The impact of health care quality improvement will increasingly influence clinical practice and the delivery of pediatric care in the future. This chapter provides a summary of some of the central elements of health care quality improvement and patient safety, and offers resources for the reader to obtain additional information and understanding about these topics.

To understand the external influences driving many of these changes, there are at least six key national organizations central to the transitions occurring:

 Center for Medicare and Medicaid Services (Department of Health and Human Services)—www.cms.gov Center for Medicare and Medicaid Services (CMS) oversees federally funded health care programs of the United States, including Medicare, Medicaid, and other related programs. CMS and the Veterans Affairs Divisions together now provide funding for more than 1 trillion of the total \$3.2 trillion the United States spends annually on health care expense. CMS is increasingly promoting payment mechanisms that withhold payment for the costs of preventable complications of care and giving incentives to providers for achieving better outcomes for their patients, primarily in its Medicare population. The agency has also enabled and advocated for greater transparency of results and makes available on its website comparative measures of performance for its Medicare population. CMS is also increasingly utilizing its standards under which hospitals and other health care provider organizations are licensed to provide care as tools to ensure greater compliance with these regulations. It has instituted a Hospital-Acquired Condition Reduction program (https://www.cms.gov/medicare/ medicare-fee-for-service-payment/acuteinpatientpps/ HAC-reduction-program.html) which targets a range of conditions, with payment reductions from Medicare based upon rates of occurrence. It is worth noting that CMS is able to generate comparative national data only for its Medicare population because it, unlike Medicaid, is a single federal program with a single financial database. Because the Medicaid program functions as 51 state/federal partnership arrangements, patient experience and costs are captured in 51 separate state-based program databases. This segmentation has limited the development of national measures for pediatric care in both inpatient and ambulatory settings. Similarly, while the reporting of HACs is uniform across the United States for Medicare patients, in the Medicaid population it varies by individual state and payment implications are both limited and state based.

- 2. National Quality Forum-www.qualityforum.org/Home National Quality Forum (NQF) is a private, not-forprofit organization whose members include consumer advocacy groups, health care providers, accrediting bodies, employers and other purchasers of care, and research organizations. Its mission is to promote improvement in the quality of American health care primarily through defining priorities for improvement, approving consensus standards and metrics for performance reporting, and through educational efforts. The NQF, for example, has endorsed a list of 29 "serious reportable events" in health care that include events related to surgical or invasive procedures, products or device failures, patient protection, care management, environmental issues, radiologic events, and potential criminal events. This list and the CMS list of HACs are both being used by insurers to reduce payment to hospitals/providers as well as to require reporting to state agencies for public review. In 2012, NQF released a set of 44 measures for the quality of pediatric care, largely representing outpatient preventive services and management of chronic conditions, and populationbased measures applicable to health plans, for example, immunization rates and frequency of well-child care.
- 3. Leapfrog—www.leapfroggroup.org

Leapfrog is a group of large employers who seek to use their purchasing power to influence the health

2

care community to achieve big "leaps" in health care safety and quality. It promotes transparency and issues public reports of how well individual hospitals meet their recommended standards, including computerized physician-order entry, ICU staffing models, and rates of hospital-acquired infections. There is some evidence that meeting these standards is associated with improved hospital quality and/or mortality outcomes.

4. Agency for Healthcare Research and Quality—www. ahrq.gov

Agency for Healthcare Research and Quality (AHRQ) is currently one of 11 agencies within the US Department of Health and Human Services, although this is one of many things subject to change with the Trump administration's 2018 budget proposal. AHRQ's primary mission has been to support health services research initiatives that seek to improve the quality of health care in the United States. Its activities extend well beyond the support of research and now include the development of measurements of quality and patient safety, reports on disparities in performance, measures of patient safety culture in organizations, and promotion of tools to improve care among others. AHRQ also convenes expert panels to assess national efforts to advance quality and patient safety and to recommend strategies to accelerate progress.

5. Specialty Society Boards

Specialty Society Boards, for example, American Board of Pediatrics (ABP). The ABP, along with other specialty certification organizations, has responded to the call for greater accountability to consumers by enhancing its maintenance of certification programs (MOC). All trainees, and an increasing proportion of active practitioners, are now subject to the requirements of the MOC program, including participation in quality improvement activities in the diplomate's clinical practice. The Board's mission is focused on assuring the public that certificate holders have been trained according to their standards and also meet continuous evaluation requirements in six areas of core competency: patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice. These are the same competencies as required of residents in training programs as certified by the Accreditation Council on Graduate Medical Education. Providers need not only to be familiar with the principles of quality improvement and patient safety, but also must demonstrate having implemented quality improvement efforts within their practice settings.

 The Joint Commission—www.jointcommission.org The Joint Commission (JC) is a private, nonprofit agency that is licensed to accredit health care provider organizations, including hospitals, nursing homes, and other health care provider entities in the United States as well as internationally. Its mission is to continuously improve the quality of care through evaluation, education, and enforcement of regulatory standards. Since 2003, JC has annually adopted a set of National Patient Safety Goals designed to help advance the safety of care provided in all health care settings. Examples include the use of two patient identifiers to reduce the risk of care being provided to an unintended patient; the use of time-outs and a universal protocol to improve surgical safety and reduce the risk of wrong site procedures; adherence to hand hygiene recommendations to reduce the risk of spreading hospital-acquired infections, to name just a few. These goals often become regulatory standards with time and widespread adoption. Failure to meet these standards can result in actions against the licensure of the health care provider, or more commonly, requires corrective action plans, measurement to demonstrate improvement, and resurveying depending upon the severity of findings. The JC publishes a monthly journal on quality and safety, available at http://store.jcrinc.com/the-joint-commission-journalon-quality-and-patient-safety/.

Finally, ongoing governmental impacts on quality and safety will be subject to modifications in the US government's anticipated repeal, replacement or changes in the Patient Protection and Affordable Care Act (PPACA) enacted by the US government in 2010. This federal health care legislation sought to provide near-universal access to health care through discounted health care exchanges that supplemented the existing, largely employer-based system. Changes in payment mechanisms for health care will continue irrespective of what happens to the PPACA, and current and future providers' practices will be economically, structurally, and functionally impacted by these emerging trends. Furthermore, changes in the funding and structure of the US health care system may ultimately also result in changes in other countries. Many countries have singlepayer systems for providing health care to their citizens and often are leaders in defining new strategies for health care improvement.

STRATEGIES & MODELS FOR QUALITY IMPROVEMENT (QI)

While there are many approaches to improving the quality of care in health care settings, the following represent three common tools for conducting clinical improvement work. The Model for Improvement (MFI) is primarily emphasized because of its ease of adoption, and because it is the foundation for most improvement efforts included in the Maintenance of Certification program of the ABP. Briefer summaries of Lean and Six-Sigma methods are also included, with listings of resources where the reader can find additional information.

"MODEL FOR IMPROVEMENT"

Widely taught and promoted by the Boston-based educational and advocacy organization the Institute for Healthcare Improvement (IHI), the MFI is grounded in three simple questions that guide the work of the improvement leader and team. The model's framework includes an Aim statement, a measurement strategy, and then the use of "rapid cycle" changes to achieve the aim. The IHI website, www.ihi.org, has an extensive resource library, and hosts an "Open School" that includes a QI/Patient safety modular curriculum for health professional students and their faculty at www.ihi.org/openschool.

AIM STATEMENT

The Aim statement answers the question, "What do we want to accomplish?" The measure question is "How will we know that a change is an improvement?" and the change component is focused on "What changes can we make that will result in improvement?" This model is represented in Figure 1–2.

Aim statements are a *written* description of what the team's improvement goal is, and also include information on who comprises the patient population and a time frame within which the improvement will be achieved. They identify a "stretch" but achievable improvement target goal, and, often, some general statement regarding how the improvement will be achieved. Aim statements are sometimes characterized using the mnemonic SMAART: Specific, Measurable, Achievable, Actionable, Relevant, and Timely. Aim statements should be unambiguous and understandable to the stakeholders, and are most likely to be achieved if they are aligned with the strategic goals of the team or organization.

For example, the following statement meets the criteria for a SMAART aim statement, "We will reduce the frequency of emergency department visits and hospitalizations

Model for Improvement

What are we trying to accomplish? How will we know that a change is an improvement? What changes can we make that will result in an improvement?

▲ Figure 1–2. Model for improvement. (Adapted with permission from Langley G, Moen R, Nolan K, et al: *The Improvement Guide: AIM Model for Improvement.* San Francisco: Jossey-Bass; 2009.)

for patients with asthma seen at E Street Pediatrics by 25% by December 31, 2017," whereas this next statement does not, "We will improve the care for patients with asthma by appropriately prescribing indicated medications and better educating families in their use."

The first example provides a specific measurable goal, a time frame, and clarity with respect to who the patients are. A 25% reduction in ED/inpatient asthma visits will require a change in the system for asthma care delivery for the entire population of children with asthma; that extent of level of improvement is a stretch, but it is much more achievable than a goal would be if it was set to "eliminate" such encounters. The second example is unclear in terms of the measure for improvement, the time frame for the goal to be met, and even the population in question. The statement provides some sense of processes that could be utilized to improve asthma care but is missing needed specificity.

MEASURES

Specific measures provide a means to assess whether or not the improvement effort is on track. Three types of measures are useful. *Outcome measures* answer questions concerning the health care impact for the patients, such as how has their health status changed? *Process measures* are related to the health care delivery system itself. They answer questions about how the system is performing. *Balancing measures* seek to identify potential unintended consequences that are related to the improvement effort being undertaken. Examples are helpful to contextualize these conceptual definitions.

Table 1–1 reflects some examples of types of measures that might be employed in an asthma QI initiative.

One might argue that adherence to a treatment plan (third process measure) is an outcome of the work of the practice/practitioner prescribing the medication. It is more consistent, however, to consider the translation of the treatment plan into action as a part of the process of care, and that the health status or outcome measure will be improved by fully improving the measured processes of care, including patient adherence to the treatment plan.

Measures are essential elements of any improvement work. It is a good idea to choose a manageable (4–6) number of measures, all of which can be obtained with limited or no extra effort, and with a mix of outcome, process, and balancing measures. Ideally, the best process measures are those that are directly linked to the outcome goal. The hypothesis in this specific example would be that assessing asthma severity and appropriately using controller medications and action plans would all contribute to reducing the number or frequency of missed school days and the need for ED/ hospital utilization.

It is important to note that measurement in the setting of an improvement project is different from measurement in a research study. Improvement projects require "just enough" data to guide the team's continuing efforts. Often, the result seen in a sequence of 10 patients is enough to tell you whether a particular system is functioning consistently or not. For example, considering the first process measure in Table 1–1, if in the last 10 patients seen with asthma, only two had their asthma severity documented, how many more charts need be checked to conclude that the system is not functioning as intended and that changes are needed? Other measures may require larger sample sizes, especially when assessing the impact of care changes on a population of patients with a particular condition. See Randolph's excellent summary for a fuller description of measurement for improvement.

CHANGES & IDEAS

Once the team's aim is established and the measures are selected, the third component of the MFI draws from industrial engineering and focuses on what changes in the system

Outcome Measures	Process Measures	Balancing Measures
Percent of children with asthma in the practice seen in the ED or hospitalized for asthma in the past 6 months	Proportion of children with an asthma severity assessment in their medical record in the past year	Average difference in the time between the last office patient's scheduled appointment time and the actual office close time
Percent of children with persistent asthma in the practice with fewer than five missed school days due to asthma in the past year	Percent of children with persistent asthma, of any severity, prescribed a controller medication at their most recent visit	Staff satisfaction with their job
	Percent of children prescribed a controller medication who report taking their medicine	
	Percent of children in a practice asthma registry provided with a complete asthma action plan in the past 12 months	

Table 1–1. Examples of types of measures used in an asthma QI initiative.

CHAPTER 1

must be made that will result in the targeted improvements. To answer the question "What changes will result in improvement?" the improvement team should incorporate "Plan-Do-Study (or check)-Act" cycles, typically referred to as PDSA cycles. The cycles include the following steps.

- *Plan*: What will we do that will likely improve the process measures linked to the outcome target goal? Who will do it? Where? When? How? How will the data be collected?
- *Do*: Implementation of the planned change(s). *TIP*! It is good to make the change cycles as small as possible, for example, trying a new process on the next five patients being seen by one provider as opposed to wide scale implementation of a new chart documentation form across an entire clinic.
- Study (or check): Once the small test of change is tried, its results are assessed. How many times did the process work as planned for the five patients included in the cycle?
- Act: Based upon the results of the study of the cycle, recommendations are made as to what the next steps ought to be to achieve the goal. At this point, the cycle then resumes and planning begins for the next cycle.

Over the course of an improvement effort, multiple tests of change might be implemented for any or all of the process measures felt to be likely to impact the outcome measures relevant to the project.

The MFI has been used by improvement teams across numerous health care settings around the world. Further information about the model and examples can be found at www.ihi.org/openschool, or in *The Improvement Guide* (Langley et al).

The IHI Open School modules are an excellent online resource for clinicians interested in learning more about the fundamentals of quality improvement and patient safety. These educational lessons are free of charge to health professional students, residents, and university faculty members, and for a modest subscription fee to other clinicians. They are also free to health care practitioners in the developing world. An excellent original resource on implementing this model in clinical practice is in Berwick's summary article from 1998.

"LEAN"

Also grounded in industrial engineering, an increasingly popular method for driving improvement efforts in health care settings is "Lean" or "Lean processing." Early thinking about Lean processes is credited to the Toyota Manufacturing Company in Japan. The crossover to health care from manufacturing is a relatively recent phenomenon, but numerous hospitals and health care delivery settings, including individual clinics, have benefited from the application of these principles to their clinical operations. Lean improvement methods focus on reducing errors and variability in repetitive steps that are part of any process. In health care, examples of repeated processes would include how patients are registered and their information obtained; how medications are ordered, compounded, distributed, and administered; how consent forms are accurately completed in a timely manner prior to surgical procedures; and how antibiotics are reliably and efficiently delivered prior to surgical procedures.

Lean is a philosophy of continuous improvement. It is grounded in recognizing that the way we do things today is merely "current state." With time, effort, focus, and longterm thinking, we can create a "future state" that is better than the status quo. It does so by focusing on identifying the value of all steps in any process and eliminating those steps that do not contribute to the value sought by the customer, or in health care, the patient/family. In doing so, improvements in outcomes, including cost and productivity, and in clinical measures of effectiveness can be realized. See Young for an early critical assessment of the incorporation of Lean into health care settings.

There are four categories that describe the essential elements of Toyota's adoption of "Lean" as a management strategy. These four categories are: (1) *philosophy* (emphasize long-term thinking over short-term gain); (2) *process* (eliminate waste through very defined approaches including an emphasis on process flow and the use of pull systems to reduce overproduction, for example); (3) *people/partners* (respect, challenge, and grow staff); and (4) *problem solving* (create a culture of continuous learning and improvement).

There are a number of hospitals that have fully integrated Lean management as a primary basis for its organizational approach to improvement. Several were featured in a "White Paper" published by the IHI in 2005.

"SIX SIGMA"

A third quality-improvement methodology also arose in the manufacturing industry. Motorola is generally credited with promoting Six Sigma as a management strategy designed to reduce the variability in its processes and thereby reducing the number of defects in its outputs. Organizations adopting Six Sigma as an improvement strategy utilize measurement-based strategies that focus on process improvement and variation reduction to eliminate defects in their work and to reduce cycle times, thereby increasing profitability and enhancing customer satisfaction. Sigma is the statistical measure of standard deviation and Motorola adopted Six Sigma as a performance indicator, promoting consistency of processes in order to have fewer than 3.4 defects per million opportunities. This performance goal has since become the common descriptor for this approach to improvement both in manufacturing and in service industries, including health care. Similar to Lean, the translation of business manufacturing strategies into health care has various challenges, but there are many processes that repeatedly occur in health care that can be routinized and made more consistent. Many health care processes fail far more frequently than 3.4 times per million opportunities. Consider pharmacy dispensing errors, medication ordering or administration errors, and patient-scheduling errors, just to name a few. These are a few of many examples of processes that could potentially benefit from the kind of rigorous analysis that is integral to the Six-Sigma approach.

In a typical Six-Sigma structured improvement project, there are five phases generally referred to as DMAIC: (1) Define (what is the problem, what is the goal?), (2) Measure (quantify the problem and improvement opportunity), (3) Analyze (use of observations and data to identify causes), (4) Improve (implementation of solutions based on data analysis), and finally, (5) Control (sustainable change).

One of the central aspects of Six Sigma as an improvement strategy is its defined focus on understanding the reasons for defects in any process. By understanding these drivers, it is then possible to revise the approach to either the manufacturing process or the service functions in order to reduce these errors and failures.

"Lean-Six Sigma" is a newer entity that draws from both methodologies in order to simplify the improvement work where possible, but retain the rigorous statistical method that is a hallmark of Six-Sigma projects. Lean focuses on where time is lost in any process and can identify opportunities to eliminate steps or reduce time. Six Sigma aims to reduce or eliminate defects in the process, thereby resulting in a higher quality product through a more efficient and lower cost process.

Regardless of the method used, improvement happens because an organization, team, or individual sets a goal to improve a current process through systematic analysis of the way things are done now, and then implementing planned changes to see how they impact the outputs or outcomes.

For additional information on Lean and Six Sigma, see www.isixsigma.com or www.asq.org/sixsigma.

PRINCIPLES OF PATIENT SAFETY (INCIDENT REPORTING, JUST CULTURE, DISCLOSURE, FMEA, RCA, RELIABILITY, CHECKLISTS)

Safe patient care avoids preventable harm; it is care that does not cause harm as it seeks to cure. The list of adverse events that are considered to be preventable is evolving. As mentioned earlier, both CMS and NQF have endorsed lists of various complications of care as being "never events" or "serious reportable events" for which providers are often now not reimbursed, and which are increasingly reportable to the public through various state transparency programs.

A national network of Children's Hospitals has been active since 2012, collaborating on a shared aim of eliminating serious harm in their now more than 110 organizations. Initially funded as a Hospital Engagement Network by the Center for Medicare and Medicaid Innovation program, Children's Hospitals Solutions for Patient Safety merges approaches to achieving reliability in evidence-based prevention practices ("bundles") with safety practices at both staff and leadership levels to reducing serious safety events (SSEs) and HACs in general. Numerous hospitals have demonstrated dramatic reductions in the occurrence rates of both HACs and SSEs with the following interventions: (1) implementation of structured processes to improve consistency of prevention processes, (2) education and reinforcement of principles of patient safety culture designed to improve communication and reduce error, and (3) effective, structured cause analyses after SSEs.

Irrespective of one's views about whether various complications are entirely preventable at the current state of science or not, these approaches reflect a changing paradigm that is impacting many aspects of health care delivery. Transparency of results is increasingly expected. Perspectives and data on how these kinds of efforts are impacting actual improvement in outcomes are mixed.

Given these trends, health care providers need to have robust systems for measuring and improving the safety of care provided to patients. The methods for improving quality reviewed earlier are frequently used to reduce harm, just as they can be used to improve effectiveness or efficiency. For example, hospitals attempting to reduce infections have successfully used these types of process improvement approaches to improve antibiotic use prior to surgical procedures or to improve hand hygiene practices. Common patient safety tools are summarized here.

Incident-reporting systems: Efforts to advance safety in any organization require a clear understanding of the kinds of harm occurring within that organization, as well as the kinds of "near-misses" that are occurring. These reporting systems can range from a simple paper reporting form to a "telephone hot-line" to a computerized database that is available to staff (and potentially patients) within the organization. Events are traditionally graded according to the severity of harm that resulted from the incident. One example is the NCC MERP Index, which grades events from A (potential to cause harm) to I (resulting in patient death). Errors that are recognized represent only a fraction of the actual errors and near-misses that are present in the system. Incident-reporting systems depend upon people recognizing the error or near-miss, being comfortable reporting it, knowing how and when to report, and then actually doing so. It is no surprise therefore that estimates for how frequently incidents that could or should be reported into incident-reporting systems range from 1.5% to 30% depending on the type of adverse or nearmiss event. "Trigger tools" (either manual chart reviews for indications of adverse events, or automated reports from electronic medical records) are increasingly being used to increase the recognition of episodes of harm in health care settings.

"Just culture": The effectiveness of incident-reporting systems is highly dependent upon the culture of the organization within which the reporting is occurring. Aviation industry safety-reporting systems are often highlighted for their successes over the past few decades in promoting reporting of aviation events that might have led to accidents. The Aviation Safety Reporting System (ASRS) prioritizes confidentiality in order to encourage reporting and protects reporters from punishment, with certain limitations when they report incidents, even if related to non-adherence to aviation regulations. Although the system is voluntary, more than 880,000 reports have been submitted and used by the Federal Aviation Administration to improve air travel safety.

In health care, the variable recognition of adverse events as well as any fear about reprisal for reporting events both work to reduce the consistent reporting of events. The concept of "just culture" has been promoted as a strategy to increase the comfort of staff members to report the occurrence of errors or nearmisses, even if they may have done something incorrectly. See the work of David Marx and the "Just Culture Community" for more information on how to evaluate error so as to support reporting and safer practices in organizations. A great deal more information about "just culture" principles is available at http://www.justculture.org. Failure modes and effects analyses (FMEA): An FMEA is a systematic methodology used to proactively identify ways in which any process might fail, and then to prioritize among strategies for reducing the risk or impact of identified potential failures. In conducting an FMEA, which all hospitals are required to do annually, a team will carefully describe and analyze each step in a particular process, consider what and how anything might go wrong, why it would happen and what the impact would be of such failures. Like Lean and Six Sigma, the FMEA has been adopted into health care from its origins in military and industrial settings. The FMEA is an effective method for identifying strategies to reduce risks in health care settings, thereby protecting patients if interventions are put into place as a result of the analysis. A tool to use in conducting an FMEA is available from the IHI (http://www. ihi.org/knowledge/Pages/Tools/FailureModesandEffects-AnalysisTool.aspx). Their site includes additional information and resources about the FMEA process.

Root-cause analyses (RCA) (postevent reviews): As contrasted with the proactive FMEA process, an RCA is a retrospective analysis of an adverse occurrence (or near-miss) that has already happened. It too is a systematic process that in this case allows a team to reach an understanding of why certain things occurred, what systems factors and human factors contributed to the occurrence, and what defects in the system might be changed in order to reduce the likelihood of recurrence. Key to an effective RCA process, and similar to the principles discussed above related to "just culture," RCAs are designed not to ask who was at fault, but rather what system reasons contributed to the event. "Why," not "who," is the essential question to be asked. The answer to the question "why did this occur" almost invariably results in a combination of factors, often illustrated by a series of pieces of Swiss cheese where the holes all line up. Taken from the writings of James Reason, the "Swiss Cheese Model" illustrates the many possible system failures that can contribute to an error, and contributes to identifying potential system changes that reduce the risk of error recurrence. Strategies for approaching retrospective RCA and the causes of human and system error are available at http://www.ncbi.nlm.nih.gov/pmc/articles/pmc1117770. The use of retrospective review processes to learn from adverse events is frequently now referred to as "Safety 1" approach to health care improvement. Increasingly, safety experts are focusing on "Safety 2," which is complementary strategy oriented to learning "when things go right," and designing systems for reliability using approaches common in the field of human factors engineering. A few selected reading materials for the interested learner are listed later.

Communication and team training: Because failures of communication are the most common identified factors in the analysis of reported serious health care events, many health care organizations have incorporated tools from other industries, particularly aviation, in order to enhance patient safety. As a result of the knowledge gained through analysis of tragic aviation accidents, the airline industry implemented methods like crew resource management training to ensure that communication among cockpit team members is effective and clear, thereby reducing risk of air accidents. Similar methods have been used to train teams in operating rooms, delivery rooms, and other team-based settings. Most of these curricula include a few common elements: introductions to be sure all team members know one another's name, promoting the likelihood of speaking up; leader clarity with team members about the expectation that all will speak up if anyone has a concern; and structured language and other tools like verbal read-back of critical information to ensure clarity in interpersonal or interdisciplinary communications. Such training also seeks to flatten the hierarchy, making it more likely that potential risks or problems will be identified and effectively addressed. Common tools used in promoting effective team communication include structured language like SBAR (Situation, Background, Assessment, and Recommendation), taken from the navy, to promote clarity of communication.

A number of resources exist in the public domain to support better teamwork and communication. One good place to start is the TeamSTEPPS program from the Agency for Healthcare Research and Quality. It can be found at http://teamstepps.ahrq.gov/.

The Newborn Infant

Danielle Smith, MD Theresa Grover, MD

INTRODUCTION

The newborn period is defined as the first 28 days of life. In practice, however, sick or very immature infants may require neonatal care for many months. There are three levels of newborn care. Level 1 refers to basic care of well newborns, neonatal resuscitation, and stabilization prior to transport. Level 2 refers to specialty neonatal care of premature infants greater than 1500 g or more than 32 weeks' gestation. Level 3 is subspecialty care of higher complexity ranging from 3A to 3C based on newborn size and gestational age. Level 4 includes availability of general surgery, cardiac surgery, and extracorporeal membrane oxygenation (ECMO). Level 4 care is often part of a perinatal center offering critical care and transport to the high-risk mother and fetus as well as the newborn infant.

THE NEONATAL HISTORY

The newborn medical history has three key components:

- 1. Maternal and paternal medical and genetic history
- 2. Maternal past obstetric history
- 3. Current antepartum and intrapartum obstetric history

The mother's medical history includes chronic medical conditions, medications taken during pregnancy, unusual dietary habits, smoking history, substance abuse history, occupational exposure to chemicals or infections of potential risk to the fetus, and any social history that might increase the risk for parenting problems and child abuse. Family illnesses and a history of congenital anomalies with genetic implications should be sought. The past obstetric history includes maternal age, gravidity, parity, blood type, and pregnancy outcomes. The current obstetric history includes the results of procedures during the current pregnancy such as ultrasound, amniocentesis, screening tests (rubella antibody, hepatitis B surface antigen, serum quadruple screen for genetic disorders, HIV [human immunodeficiency virus]), and antepartum tests of fetal well-being (eg, biophysical profiles, nonstress tests, or Doppler assessment of fetal blood flow patterns). Pregnancy-related maternal complications such as urinary tract infection, pregnancyinduced hypertension, eclampsia, gestational diabetes, vaginal bleeding, and preterm labor should be documented. Significant peripartum events include duration of ruptured membranes, maternal fever, fetal distress, meconiumstained amniotic fluid, type of delivery (vaginal or cesarean section), anesthesia and analgesia used, reason for operative or forceps delivery, infant status at birth, resuscitative measures, and Apgar scores.

ASSESSMENT OF GROWTH & GESTATIONAL AGE

It is important to know the infant's gestational age because normal behavior and possible medical problems can be predicted on this basis. The date of the last menstrual period is the best indicator of gestational age with early fetal ultrasound providing supporting information. Postnatal physical characteristics and neurologic development are also clues to gestational age. Table 2–1 lists the physical and neurologic criteria of maturity used to estimate gestational age by the Ballard method. Adding the scores assigned to each neonatal physical and neuromuscular sign yields a score corresponding to gestational age.

If the physical examination indicates a gestational age within 2 weeks of that predicted by the obstetric dates, the gestational age is as assigned by the obstetric date. Birth weight and gestational age are plotted on standard grids to determine whether the birth weight is appropriate for

Table 2–1. New Ballard score for assessment of fetal maturation of newly born infants.^a

^aSee text for a description of the clinical gestational age examination. (Reproduced with permission from Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. J Pediatr 1991 Sep;119(3):417–423.)

gestational age (AGA), small for gestational age (SGA, also known as intrauterine growth restriction [IUGR]), or large for gestational age (LGA). Birth weight for gestational age in normal neonates varies with gender, race, maternal nutrition, access to obstetric care, and environmental factors such as altitude, smoking, and drug and alcohol use. Whenever possible, standards for newborn weight and gestational age based on local or regional data should be used. Birth weight related to gestational age is a screening tool that should be supplemented by clinical data when entertaining a diagnosis of IUGR or excessive fetal growth. These data include the infant's physical examination and other factors such as parental size and the birth weight-gestational age of siblings.

An important distinction, particularly in SGA infants, is whether a growth disorder is symmetrical (weight, length, and occipitofrontal circumference [OFC] all \leq 10%) or asymmetrical (only weight \leq 10%). Asymmetrical growth restriction implies a problem late in pregnancy, such as pregnancy-induced hypertension or placental insufficiency. Symmetrical growth restriction implies an event of early pregnancy: chromosomal abnormality, drug or alcohol use, or congenital viral infections. In general, the outlook for normal growth and development is better in asymmetrically growth-restricted infants whose intrauterine brain growth has been spared.

The fact that SGA infants have fewer problems (such as respiratory distress syndrome) than AGA infants of the same birth weight, but a lower gestational age has led to the misconception that SGA infants have accelerated maturation. SGA infants, when compared with AGA infants of the same gestational age, actually have increased morbidity and mortality rates.

Knowledge of birth weight in relation to gestational age allows anticipation of some neonatal problems. LGA infants are at risk for birth trauma. LGA infants of diabetic mothers are also at risk for hypoglycemia, polycythemia,

congenital anomalies, cardiomyopathy, hyperbilirubinemia, and hypocalcemia. SGA infants are at risk for fetal distress during labor and delivery, polycythemia, hypoglycemia, and hypocalcemia.

EXAMINATION AT BIRTH

The extent of the newborn physical examination depends on the condition of the infant and the setting. Examination in the delivery room consists largely of observation plus auscultation of the chest and inspection for congenital anomalies and birth trauma. Major congenital anomalies occur in 1.5% of live births and account for 20%-25% of perinatal and neonatal deaths. Because infants are physically stressed during parturition, the delivery room examination should not be extensive. The Apgar score (Table 2-2) should be recorded at 1 and 5 minutes of age. In severely depressed infants, scores can be recorded out to 20 minutes. Although the 1- and 5-minute Apgar scores have almost no predictive value for long-term outcome, serial scores provide a useful description of the severity of perinatal depression and the response to resuscitative efforts.

Skin color is an indicator of cardiac output because of the normal high blood flow to the skin. Stress that triggers a catecholamine response redirects cardiac output away from the skin to preserve oxygen delivery to more critical organs. Cyanosis and pallor are thus two useful signs suggestive of inadequate cardiac output.

Skeletal examination at delivery serves to detect obvious congenital anomalies and to identify birth trauma, particularly in LGA infants or those born after a protracted second stage of labor where a fractured clavicle or humerus might be found.

The placenta and umbilical cord should be examined at delivery. The number of umbilical cord vessels should be determined. Normally, there are two arteries and one vein.

Fable 2–2. Infant evaluation at birth—Apgar score. ^a

^aOne minute and 5 minutes after complete birth of the infant (disregarding the cord and the placenta), the following objective signs should be observed and recorded.

^bTested after the oropharynx is clear.

Data from Apgar V, Holaday DA, James LS, et al: Evaluation of the newborn infant-second report. J Am Med Assoc 1958 Dec 13;168(15): 1985-1988.

In 1% of deliveries (5%–6% of twin deliveries), the cord has only one artery and one vein. This minor anomaly slightly increases the risk of associated defects. The placenta should be examined at delivery. Small placentas are always associated with small infants. The placental examination also includes identification of membranes and vessels (particularly in multiple gestations) as well as placental infarcts or clots (placental abruption) on the maternal side.

EXAMINATION IN THE NURSERY

The purpose of the newborn examination is to identify abnormalities or anomalies that might influence the infant's well-being and to evaluate for any acute illness or difficulty in the transition from intrauterine to extrauterine life. The examiner should have warm hands and a gentle approach. Start with observation, then auscultation of the chest, and then palpation of the abdomen. Examination of the eyes, ears, throat, and hips should be performed last, as these maneuvers are most disturbing to the infant. The heart rate should range from 120 to 160 beats/min and the respiratory rate from 30 to 60 breaths/min. Systolic blood pressure on day 1 ranges from 50 to 70 mm Hg and increases steadily during the first week of life. An irregularly irregular heart rate, usually caused by premature atrial contractions, is common, benign, and usually resolves in the first days of life.

Approximately 15%–20% of healthy newborns have one minor anomaly (a common variant that would not influence the infant's well-being, eg, a unilateral transverse palmar [simian] crease, or a single umbilical artery). Those with a minor anomaly have a 3% risk of an associated major anomaly. Approximately 0.8% of newborns have two minor anomalies, and 0.5% have three or more, with a risk of 10% and 20%, respectively, of also having a major malformation. Other common minor anomalies requiring no special investigation in healthy infants include preauricular pits, a shallow sacral dimple without other cutaneous abnormality within 2.5 cm of the anus, and three or fewer café au lait spots in a white infant or five or fewer in an African-American infant.

Skin

Observe for bruising, petechiae (common over the presenting part), meconium staining, and jaundice. Visible jaundice in the first 24 hours is never normal, and generally indicates either a hemolytic process, or a congenital hepatitis, either of which requires further evaluation. Peripheral cyanosis is commonly present when the extremities are cool or the infant is polycythemic. Generalized cyanosis merits immediate evaluation. Pallor may be caused by acute or chronic blood loss or by acidosis. In dark-skinned infants, pallor and cyanosis should be assessed in the lips, mouth, and nail beds. Plethora suggests polycythemia. Dry skin with cracking and peeling of the superficial layers is common in postterm infants. Edema may be generalized (hydrops) or localized (eg, on the dorsum of the feet in Turner syndrome). Check for birthmarks such as capillary hemangiomas and mongolian spots (bluish-black pigmentation over the back and buttocks). There are many benign skin eruptions such as milia, miliaria, erythema toxicum, and pustular melanosis that are present in the newborn period. See Chapter 15 for a more in-depth description of these conditions.

Head

Check for cephalohematoma (a swelling over one or both parietal bones that is contained within suture lines) and caput succedaneum (edema of the scalp over the presenting part that crosses suture lines). Subgaleal hemorrhages (beneath the scalp) are uncommon but can cause extensive blood loss into this large potential space, resulting in hypovolemic shock. Skull fractures may be linear or depressed and may be associated with cephalohematoma. Check for the presence and size of the fontanelles. The anterior fontanelle varies from 1 to 4 cm in any direction; the posterior fontanelle should be less than 1 cm. A third fontanelle is a bony defect along the sagittal suture in the parietal bones and may be seen in syndromes, such as trisomy 21. Sutures should be freely mobile, but are often overriding just after birth. Craniosynostosis, a prematurely fused suture causing an abnormal cranial shape, is more easily diagnosed a few days or more after birth.

Face

Unusual facies may be associated with a specific syndrome. Bruising from birth trauma (especially with face presentation) and forceps application should be identified. Face presentation may cause soft tissue swelling around the nose and mouth and significant facial distortion. Facial nerve palsy is most obvious during crying; the unaffected side of the mouth moves normally, giving an asymmetric grimace.

Eyes

Subconjunctival hemorrhages are a frequent result of birth trauma. Less commonly, a corneal tear (presenting as a clouded cornea), or a hyphema (a layering of blood in the anterior chamber of the eye) may occur. Ophthalmologic consultation is indicated in such cases. Extraocular movements should be assessed. Occasional uncoordinated eye movements are common, but persistent irregular movements are abnormal. The iris should be inspected for abnormalities such as speckling (Brushfield spots seen in trisomy 21) and colobomas. Retinal red reflexes should be present and symmetrical. Dark spots, unilateral blunted red reflex, absent reflex, or a white reflex all require ophthalmologic evaluation. Leukokoria can be caused by glaucoma (cloudy cornea), cataract, or tumor (retinoblastoma). Infants with suspected or known congenital viral infection should have a retinoscopic examination with pupils dilated to look for chorioretinitis.

Nose

Examine the nose for size and shape. In utero compression can cause deformities. Because infants younger than 1 month are obligate nose breathers, any nasal obstruction (eg, bilateral choanal atresia or stenosis) can cause respiratory distress. Unilateral choanal atresia can be diagnosed by occluding each naris, although patency is best checked by holding a cold metal surface (eg, a chilled scissor) under the nose, and observing the fog from both nares on the metal. Purulent nasal discharge at birth suggests congenital syphilis ("snuffles").

Ears

Malformed or malpositioned (low-set or posteriorly rotated) ears are often associated with other congenital anomalies. Preauricular pits and tags are common minor variants, and may be familial. Any external ear abnormality may be associated with hearing loss.

Mouth

Epithelial (Epstein) pearls are benign retention cysts along the gum margins and at the junction of the hard and soft palates. Natal teeth may be present and sometimes must be removed to prevent their aspiration. Check the integrity and shape of the palate for clefts and other abnormalities. A small mandible and retraction of the tongue with cleft palate is seen with Pierre-Robin sequence and can present as respiratory difficulty, as the tongue occludes the airway; prone positioning can be beneficial. A prominent tongue can be seen in Trisomy 21 and Beckwith-Wiedemann syndrome. Excessive oral secretions suggest esophageal atresia or a swallowing disorder.

Neck

Redundant neck skin or webbing, with a low posterior hair line, is seen in Turner syndrome. Cervical sinus tracts may be seen as remnants of branchial clefts. Check for masses: mid-line (thyroglossal duct cysts), anterior to the sternocleidomastoid (branchial cleft cysts), within the sternocleidomastoid (hematoma and torticollis), and posterior to the sternocleidomastoid (cystic hygroma).

Chest & Lungs

Check for fractured clavicles (crepitus, bruising, and tenderness). Check air entry bilaterally and the position of the mediastinum by locating the point of maximum cardiac impulse and assessment of heart tones. Decreased breath sounds with respiratory distress and a shift in the heart tones suggests pneumothorax (tension) or a space-occupying lesion (eg, diaphragmatic hernia). Pneumomediastinum causes muffled heart sounds. Expiratory grunting and decreased air entry are observed in hyaline membrane disease. Rales are not of clinical significance at this age.

Heart

Cardiac murmurs are common in the first hours and are most often benign; conversely, severe congenital heart disease in the newborn infant may be present with no murmur at all. The two most common presentations of heart disease in the newborn infant are (1) cyanosis and (2) congestive heart failure with abnormalities of pulses and perfusion. In hypoplastic left-sided heart and critical aortic stenosis, pulses are diminished at all sites. In aortic coarctation and interrupted aortic arch, pulses are diminished in the lower extremities.

Abdomen

Check for tenderness, distention, and bowel sounds. If polyhydramnios was present or excessive oral secretions are noted, pass a soft catheter into the stomach to rule out esophageal atresia. Most abdominal masses in the newborn infant are associated with kidney disorders (eg, multicystic or dysplastic, and hydronephrosis). When the abdomen is relaxed, normal kidneys may be felt but are not prominent. A markedly scaphoid abdomen plus respiratory distress suggests diaphragmatic hernia. Absence of abdominal musculature (prune belly syndrome) may occur in association with renal abnormalities. The liver and spleen are superficial in the neonate and can be felt with light palpation. A distended bladder may be seen as well as palpated above the pubic symphysis.

Genitalia & Anus

Male and female genitals show characteristics according to gestational age (see Table 2–1). In the female infant during the first few days, a whitish vaginal discharge with or without blood is normal. Check the patency and location of the anus.

Skeleton

Check for obvious anomalies such as absence of a bone, club-foot, fusion or webbing of digits, and extra digits. Examine for hip dislocation by attempting to dislocate the femur posteriorly and then abducting the legs to relocate the femur noting a clunk as the femoral head relocates. Look for extremity fractures and for palsies (especially brachial plexus injuries) and evidence of spinal deformities (eg, scoliosis, cysts, sinuses, myelomeningocele). Arthrogryposis (multiple joint contractures) results from chronic limitation of movement in utero that may result from lack of amniotic fluid or from congenital neuromuscular disease.

Neurologic Examination

Normal newborns have reflexes that facilitate survival (eg, rooting and sucking reflexes), and sensory abilities (eg, hearing and smell) that allow them to recognize their mother soon after birth. Although the retina is well developed at birth, visual acuity is poor (20/400) because of a relatively immobile lens. Acuity improves rapidly over the first 6 months, with fixation and tracking becoming well developed by 2 months.

Observe the newborn's resting tone. Normal-term newborns should exhibit flexion of the upper and lower extremities and symmetrical spontaneous movements. Extension of the extremities should result in spontaneous recoil to the flexed position. Assess the character of the cry; a highpitched cry with or without hypotonia may indicate disease of the central nervous system (CNS) such as hemorrhage or infection, a congenital neuromuscular disorder, or systemic disease. Check the following newborn reflexes:

- 1. *Sucking reflex*: The newborn sucks in response to a nipple in the mouth; observed by 14 weeks' gestation.
- 2. *Palmar grasp*: Evident with the placement of the examiner's finger in the newborn's palm; develops by 28 weeks' gestation and disappears by age 4 months.
- 3. *Moro (startle) reflex*: Hold the infant supine while supporting the head. Allow the head to drop 1–2 cm suddenly. The arms will abduct at the shoulder and extend at the elbow with spreading of the fingers. Adduction with flexion will follow. This reflex develops by 28 weeks' gestation (incomplete) and disappears by age 3 months.

Kahn O et al: Neonatal neurological examination. NeoReviews 2014;15:e316.

CARE OF THE WELL NEONATE

The primary responsibility of the level 1 nursery is care of the well neonate—promoting mother–infant bonding, establishing feeding, and teaching the basics of newborn care. Staff must monitor infants for signs and symptoms of illness, including temperature instability, change in activity, refusal to feed, pallor, cyanosis, early or excessive jaundice, tachypnea, respiratory distress, delayed (beyond 24 hours) first stool or first void, and bilious vomiting.

Several preventive measures are routine in the normal newborn nursery. Prophylactic erythromycin ointment is applied to the eyes within 1 hour of birth to prevent gonococcal ophthalmia. Vitamin K (1 mg) is given intramuscularly or subcutaneously within 4 hours of birth to prevent hemorrhagic disease of the newborn.

All infants should receive hepatitis B vaccine. Both hepatitis B vaccine and hepatitis B immune globulin (HBIG) are administered if the mother is positive for hepatitis B surface antigen (HBsAg). If maternal HBsAg status is unknown, vaccine should be given before 12 hours of age, maternal blood should be tested for HBsAg, and HBIG should be given to the neonate before 7 days of age if the test is positive.

Cord blood is collected from all infants at birth and can be used for blood typing and Coombs testing if the mother is type O or Rh-negative to help assess the risk for development of jaundice.

Bedside glucose testing should be performed in infants at risk for hypoglycemia (infants of diabetic mothers [IDMs], preterm, SGA, LGA, or stressed infants). Values below 45 mg/dL should be confirmed by laboratory blood glucose testing and treated. Hematocrit should be measured at age 3–6 hours in infants at risk for or those who have symptoms of polycythemia or anemia (see section Hematologic Disorders in the Newborn Infant).

State-sponsored newborn genetic screens (for inborn errors of metabolism such as phenylketonuria [PKU], galactosemia, sickle cell disease, hypothyroidism, congenital adrenal hyperplasia, and cystic fibrosis) are performed prior to discharge, after 24–48 hours of age if possible. In many states, a repeat test is required at 8–14 days of age because the PKU test may be falsely negative when obtained before 48 hours of age. Not all state-mandated screens include the same panel of diseases. Many states now include an expanded screen that tests for other inborn errors of metabolism such as fatty acid oxidation defects and amino or organic acid disorders. Some states also screen for severe combined immunodeficiency syndrome.

Screening for critical congenital heart disease in the newborn nursery is now a standard practice in many nurseries. The goal of screening is to identify newborn infants with structural heart disease significant enough to require intervention within the first year of life prior to symptoms developing. Newborn infants are screened by pulse-oximetry on the second day of life. Infants that screen positive are evaluated by echocardiogram prior to hospital discharge.

Infants should routinely be positioned supine to minimize the risk of sudden infant death syndrome (SIDS). Prone positioning is contraindicated unless there are compelling clinical reasons for that position. Bed sharing with adults and prone positioning are associated with increased risk of SIDS.

FEEDING THE WELL NEONATE

A neonate is ready for feeding if he or she (1) is alert and vigorous, (2) has no abdominal distention, (3) has good bowel sounds, and (4) has a normal hunger cry. These signs

usually occur within 6 hours after birth, but fetal distress or traumatic delivery may prolong this period. The healthy full-term infant should be allowed to feed every 2–5 hours on demand. The first breast-feeding should occur within 1 hour from birth if mother and baby are clinically stable. For formula-fed infants, the first feeding usually occurs by 3 hours of life. The feeding volume generally increases from 0.5 to 1 oz per feeding initially to 1.5–2 oz per feeding on day 3. By day 3, the average full-term newborn takes about 100 mL/kg/day of milk (Table 2–3).

A wide range of infant formulas satisfy the nutritional needs of most neonates. Breast milk is the standard on which formulas are based (see Chapter 11). Despite low concentrations of several vitamins and minerals in breast milk, bioavailability is high. All the necessary nutrients, vitamins, minerals, and water are provided by human milk for the first 6 months of life except vitamin K (1 mg IM is administered at birth), vitamin D (400 IU/day for all infants beginning shortly after birth), and vitamin B_{12} and zinc (if the mother is a strict vegetarian and takes no supplements). Other advantages of breast milk include (1) immunologic, antimicrobial, and anti-inflammatory factors such as immunoglobulin A (IgA) and cellular, protein, and enzymatic components that decrease the incidence of upper respiratory and gastrointestinal (GI) infections; (2) possible decreased frequency and severity of childhood eczema and asthma; (3) improved mother–infant bonding; and (4) improved neuro-developmental outcome.

Although about 70% of mothers in the United States start by breast-feeding, only 50% continue to do so at 6 months.

Baby's activity	Baby is usually wide-awake in the first hour of life. Put baby to breast within 30 min after birth.	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feedi lip smacking, and h	ing cues such aands to face.	as rooting,	Baby should appear satisfied after feedings.
Feeding routine	Baby may go into a deep sleep 2–4 h after birth.	Use chart to write Feed your baby e 8–12 times a day	e down time of eac every 1–4 h or as of	h feeding. ften as wanted—at l	east	May go one longer interval (up to 5 h between feeds) in a 24-h period.	
Breast- feeding	Baby will wake up and be alert and responsive for several more hours after initial deep sleep.	As long as the mother is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming at 10 min per side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a mir per side eve first few we Once milk s established finish the fin offering the	imum of 10–30 min ry feeding for the eks of life. upply is well allow baby to ist breast before second.	Mother's nipple tenderness is improving or is gone.
Baby's urine output		Baby must have a minimum of one wet diaper in the first 24 h.	Baby must have at least one wet diaper every 8–11 h.	You should see an increase in wet diapers (up to four to six) in 24 h.	Baby's urine should be light yellow.	Baby should have six to eight wet diapers per day of colorless or light yellow urine.	
Baby's stool		Baby may have a very dark (meconium) stool.	Baby may have a very dark second (meconium) stool.	Baby's stools should be in transition from black-green to yellow.		Baby should have three or four yellow, seedy stools a day.	The number of stools may decrease gradually after 4–6 wk.

Modified with permission from Gabrielski L: Lactation support services. Childrens Hospital Colorado, 1999.

Hospital practices that facilitate successful initiation of breast-feeding include rooming-in, nursing on demand, and avoiding unnecessary supplemental formula. Nursery staff must be trained to recognize problems associated with breast-feeding and provide help and support for mothers in the hospital. An experienced professional should observe and assist with several feedings to document good latchon. Good latch-on is important in preventing the common problems of sore nipples, unsatisfied infants, breast engorgement, poor milk supply, and hyperbilirubinemia.

EARLY DISCHARGE OF THE NEWBORN INFANT

Discharge at 24–36 hours of age is safe and appropriate for some newborns if there are no contraindications (Table 2–4) and if a follow-up visit within 48 hours is ensured. Most infants with cardiac, respiratory, or infectious disorders are identified in the first 12–24 hours of life. The exception

 Table 2–4.
 Contraindications to early newborn discharge.

Contraindications to early newborn discharge

- 1. Jaundice \leq 24 h
- 2. High risk for infection (eg, maternal chorioamnionitis); discharge allowed after 24 h with a normal transition
- 3. Known or suspected narcotic addiction or withdrawal
- 4. Physical defects requiring evaluation
- 5. Oral defects (clefts, micrognathia)

Relative contraindications to early newborn discharge (infants at high risk for feeding failure, excessive jaundice)

- 1. Prematurity or early-term infant (< 38 weeks' gestation)
- 2. Birth weight < 2700 g (6 lb)
- Infant difficult to arouse for feeding; not demanding regularly in nursery
- 4. Medical or neurologic problems that interfere with feeding (Down syndrome, hypotonia, cardiac problems)
- 5. Twins or higher multiples
- ABO blood group incompatibility or severe jaundice in previous child
- 7. Mother whose previous breast-fed infant gained weight poorly
- 8. Mother with breast surgery involving periareolar areas (if attempting to nurse)

 Table 2–5.
 Guidelines for early outpatient follow-up evaluation.

History

- Rhythmic sucking and audible swallowing for at least 10 min total per feeding?
- Infant wakes and demands to feed every 2–3 h (at least 8–10 feedings per 24 h)?
- Do breasts feel full before feedings, and softer after?
- Are there at least 6 noticeably wet diapers per 24 h?
- Are there yellow bowel movements (no longer meconium) —at least 4 per 24 h?
- Is infant still acting hungry after nursing (frequently sucks hands, rooting)?

Physical assessment

- Weight, unclothed: should not be more than 8%–10% below birth weight
- Extent and severity of jaundice
- Assessment of hydration, alertness, general well-being
- Cardiovascular examination: murmurs, brachial and femoral pulses, respirations

may be the infant for whom maternal intrapartum antibiotic prophylaxis for maternal group B streptococcal (GBS) colonization or infection was indicated. The Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) recommend that such infants be observed in hospital for at least 48 hours if their mothers received no or inadequate intrapartum antibiotic prophylaxis, or cefazolin. Hospital observation beyond 24 hours may not be necessary for well appearing full-term infants whose mothers received adequate intrapartum chemoprophylaxis and for whom ready access to medical care can be ensured if needed. Other problems, such as jaundice and breast-feeding problems, typically occur after 48 hours and can usually be dealt with on an out-patient basis.

The AAP recommends a follow-up visit within 48 hours for all newborns discharged before 72 hours of age. Infants who are small or late preterm—especially if breast-feeding are at particular risk for inadequate intake; the early visit is especially important for these infants. Suggested guidelines for the follow-up interview and physical examination are presented in Table 2–5. The optimal timing of discharge must be determined in each case based on medical, social, and financial factors.

Circumcision

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure has medical benefits, including prevention of urinary tract infections, decreased incidence of penile cancer, and decreased incidence of sexually transmitted diseases (including HIV). Most parental decisions regarding circumcision are religious and social, not medical. The risks of circumcision include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of complications is less than 1%. Local anesthesia by dorsal penile nerve block or circumferential ring block using 1% lidocaine without epinephrine, or topical anesthetic cream are safe and effective methods that should always be used. Techniques allowing visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to blind techniques (Mogen clamp) as occasional amputation of the glans occurs with the latter technique. Circumcision is contraindicated in infants with genital abnormalities (eg, hypospadias). A coagulation screen should be performed prior to the procedure in infants with a family history of serious bleeding disorders.

HEARING SCREENING

Normal hearing is critical to normal language development. Significant bilateral hearing loss is present in 1–3 per 1000 well neonates and in 2–4 per 100 neonates in the intensive care unit population. Infants should be screened for hearing loss by auditory brainstem evoked responses or evoked otoacoustic emissions as early as possible because up to 40% of hearing loss will be missed by risk analysis alone. Primary care providers and parents should be advised of the possibility of hearing loss and offered immediate referral in suspect cases. With the use of universal screening, the average age at which hearing loss is confirmed has dropped from 24–30 months to 2–3 months. If remediation is begun by 6 months, language and social development are commensurate with physical development.

COMMON PROBLEMS IN THE TERM NEWBORN

NEONATAL JAUNDICE

General Considerations

Sixty-five percent of newborns develop visible jaundice with a total serum bilirubin (TSB) level higher than 6 mg/dL during the first week of life. Bilirubin, a potent antioxidant and peroxyl scavenger, may protect the normal newborn, who is deficient in antioxidants such as vitamin E, catalase, and superoxide dismutase, from oxygen toxicity in the first days of life. Approximately 8%–10% of newborns develop excessive hyperbilirubinemia (TSB > 17 mg/dL), and 1%–2% have TSB above 20 mg/dL. Extremely high and potentially dangerous TSB levels are rare but can cause kernicterus, characterized by injury to the basal ganglia and brainstem.

Kernicterus caused by hyperbilirubinemia was common in neonates with Rh-isoimmunization until the institution of exchange transfusion for affected infants and postpartum high-titer Rho (D) immune globulin treatment to prevent sensitization of Rh-negative mothers. For several decades after the introduction of exchange transfusion and phototherapy aimed at keeping the neonate's TSB below 20 mg/dL, there were no reported cases of kernicterus in the United States. Since the early 1990s, however, there has been a reappearance of kernicterus, with more than 120 cases reported. Common factors in the recent cases are newborn discharge before 48 hours, breast-feeding, delayed measurement of TSB, unrecognized hemolysis, lack of early post discharge followup, and failure to recognize the early symptoms of bilirubin encephalopathy.

Bilirubin is produced by the breakdown of heme (iron protoporphyrin) in the reticuloendothelial system and bone marrow. Heme is cleaved by heme oxygenase to iron, which is conserved; carbon monoxide, which is exhaled; and biliverdin, which is converted to bilirubin by bilirubin reductase. This unconjugated bilirubin is bound to albumin and carried to the liver, where it is taken up by hepatocytes. In the presence of the enzyme uridyl diphosphoglucuronyl transferase (UDPGT; glucuronyl transferase), bilirubin is conjugated to one or two glucuronide molecules. Conjugated bilirubin is then excreted through the bile to the intestine. In the presence of normal gut flora, conjugated bilirubin is metabolized to stercobilins and excreted in the stool. Absence of gut flora and slow GI motility, both characteristics of the newborn, cause stasis of conjugated bilirubin in the intestinal lumen, where mucosal β -glucuronidase removes the glucuronide molecules and leaves unconjugated bilirubin to be reabsorbed (enterohepatic circulation).

Excess accumulation of bilirubin in blood depends on both the rate of bilirubin production and the rate of excretion. It is best determined by reference to an hour-specific TSB level above the 95th percentile for age in hours (Figure 2–1).

1. Physiologic Jaundice

- Visible jaundice appearing after 24 h of age.
- ▶ Total bilirubin rises by < 5 mg/dL (86 mmol/L) per day.
- Peak bilirubin occurs at 3–5 days of age, with a total bilirubin of no more than 15 mg/dL (258 mmol/L).
- Visible jaundice resolves by 1 wk in the full-term infant and by 2 wk in the preterm infant.

▲ Figure 2–1. Risk designation of full-term and near-term newborns based on their hour-specific bilirubin values. (Reproduced with permission from Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin test for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. Pediatrics 1999 Jan;103(1):6–14.)

Factors contributing to physiologic jaundice in neonates include low UDPGT activity, relatively high red cell mass, absence of intestinal flora, slow intestinal motility, and increased enterohepatic circulation of bilirubin in the first days of life. Hyperbilirubinemia outside of the ranges noted in Figure 2–1 is not physiologic and requires further evaluation.

2. Pathologic Unconjugated Hyperbilirubinemia

Pathologic unconjugated hyperbilirubinemia can be grouped into two main categories: overproduction of bilirubin or decreased conjugation of bilirubin (Table 2–6). The TSB is a reflection of the balance between these processes. Visible jaundice with a TSB greater than 5 mg/dL before 24 hours of age is most commonly a result of significant hemolysis.

A. Increased Bilirubin Production

1. Antibody-mediated hemolysis (Coombs test-positive)

A. ABO BLOOD GROUP INCOMPATIBILITY—This finding can accompany any pregnancy in a type O mother. Hemolysis is usually mild, but the severity is unpredictable because of variability in the amount of naturally occurring maternal anti-A or anti-B IgG antibodies. Although 15% of pregnancies are "setups" for ABO incompatibility (mother O, infant A or B), only 33% of infants in such cases have a positive direct Coombs test and less than 10% of these infants develop jaundice that requires therapy. Since maternal antibodies may persist for several months after birth, the newborn may become progressively more anemic over the first few weeks of life, occasionally to the point of requiring transfusion.

B. RH-ISOIMMUNIZATION—This hemolytic process is less common, more severe, and more predictable than ABO incompatibility. The severity increases with each immunized pregnancy because of an anamnestic maternal IgG antibody response. Most Rh-disease can be prevented by giving high-titer Rho (D) immune globulin to the Rh-negative woman after invasive procedures during pregnancy or after miscarriage, abortion, or delivery of an Rh-positive infant. Affected neonates are often anemic at birth, and continued hemolysis rapidly causes hyperbilirubinemia and more severe anemia. The most severe form of Rh-isoimmunization,

CHAPTER 2

 Table 2–6.
 Causes of pathologic unconjugated hyperbilirubinemia.

Overproduction of bilirubin

- 1. Hemolytic causes of increased bilirubin production (reticulocyte count elevated)
 - a. Immune-mediated: positive direct antibody (DAT, Coombs) test
 - ABO blood group incompatibility, Rh incompatibility, minor blood group antigen incompatibility
 - b. Nonimmune: negative direct antibody (DAT, Coombs) test
 - Abnormal red cell shapes: spherocytosis, elliptocytosis, pyknocytosis, stomatocytosis
 - Red cell enzyme abnormalities: glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, hexokinase deficiency, other metabolic defects
 - c. Patients with bacterial or viral sepsis
- 2. Nonhemolytic causes of increased bilirubin production (reticulocyte count normal)
 - a. Extravascular hemorrhage: cephalohematoma, extensive bruising, intracranial hemorrhage
 - b. Polycythemia
 - c. Exaggerated enterohepatic circulation of bilirubin: bowel obstruction, functional ileus
 - d. Breast-feeding-associated jaundice (inadequate intake of breast milk causing exaggerated enterohepatic circulation of bilirubin)

Decreased rate of conjugation

- 1. Crigler-Najjar syndrome (rare, severe)
 - a. Type I glucuronyl transferase deficiency, autosomal-recessive
 - b. Type II glucuronyl transferase deficiency, autosomal-dominant
- 2. Gilbert syndrome (common, milder)
- 3. Hypothyroidism

erythroblastosis fetalis, is characterized by life-threatening anemia, generalized edema, and fetal or neonatal heart failure. Without antenatal intervention, fetal or neonatal death often results. The cornerstone of antenatal management is transfusion of the fetus with Rh-negative cells, either directly into the umbilical vein or into the fetal abdominal cavity. Phototherapy is usually started in these infants upon delivery, with exchange transfusion frequently needed. Intravenous immune globulin (IVIG; 0.5–1 g/kg) given to the infant as soon as the diagnosis is made may decrease the need for exchange transfusion. Ongoing hemolysis occurs until all maternal antibodies are gone; therefore, these infants require monitoring for 2–3 months for recurrent anemia severe enough to require transfusion.

2. Nonimmune hemolysis (Coombs test-negative)

A. HEREDITARY SPHEROCYTOSIS—This condition is the most common of the red cell membrane defects and causes

hemolysis by decreasing red cell deformability. Affected infants may have hyperbilirubinemia severe enough to require exchange transfusion. Splenomegaly may be present. Diagnosis is suspected by peripheral blood smear and family history. See Chapter 30 for a more in-depth discussion.

B. G6PD DEFICIENCY-This condition is the most common red cell enzyme defect causing hemolysis, especially in infants of African, Mediterranean, or Asian descent. Onset of jaundice is often later than in isoimmune hemolytic disease, toward 1 week of age. The role of G6PD deficiency in neonatal jaundice is probably underestimated as up to 10%-13% of African Americans are G6PD-deficient. Although the disorder is X-linked, female heterozygotes are also at increased risk of hyperbilirubinemia due to X-chromosome inactivation. Their increased bilirubin production is further exaggerated by a decreased rate of bilirubin conjugation. Since G6PD enzyme activity is high in reticulocytes, neonates with a large number of reticulocytes may have falsely normal enzyme tests. A low G6PD level should always raise suspicions. Repeat testing in suspect cases with initially normal results is indicated at 2-3 months of age. Please also see Chapter 30 for more details.

3. Nonhemolytic increased bilirubin production-

Enclosed hemorrhage, such as cephalohematoma, intracranial hemorrhage, or extensive bruising in the skin, can lead to jaundice. Polycythemia leads to jaundice by increased red cell mass, with increased numbers of cells reaching senescence daily. Bowel obstruction, functional or mechanical, leads to an increased enterohepatic circulation of bilirubin.

B. Decreased Rate of Conjugation

1. UDPGT deficiency: Crigler-Najjar syndrome type I (complete deficiency, autosomal recessive) and type II (partial deficiency, autosomal dominant)—These rare conditions result from mutations in the exon or encoding region of the UDPGT gene that cause complete or nearly complete absence of enzyme activity. Both can cause severe unconjugated hyperbilirubinemia, bilirubin encephalopathy, and death if untreated. In type II, the enzyme can be induced with phenobarbital, which may lower bilirubin levels by 30%–80%. Liver transplantation is curative.

2. Gilbert syndrome—This is a common mild autosomal dominant disorder characterized by decreased hepatic UDPGT activity caused by genetic polymorphism at the promoter region of the UDPGT gene. Approximately 9% of the population is homozygous, and 42% is heterozygous for this abnormality, with a gene frequency of 0.3. Affected individuals tend to develop hyperbilirubinemia in the presence of conditions that increase bilirubin load, including G6PD deficiency. They are also more likely to have prolonged neonatal jaundice and breast-milk jaundice.

C. Hyperbilirubinemia Caused by Unknown or Multiple Factors

1. Racial differences—Asians (23%) are more likely than whites (10%–13%) or African Americans (4%) to have a peak neonatal TSB greater than 12 mg/dL (206 mmol/L). It is likely that these differences result from racial variations in prevalence of UDPGT gene polymorphisms or associated G6PD deficiency.

2. Prematurity—Premature infants often have poor enteral intake, delayed stooling, and increased enterohepatic circulation, as well as a shorter red cell life. Infants at 35–36 weeks' gestation are 13 times more likely than term infants to be readmitted for hyperbilirubinemia. Even early-term infants (37–38 weeks' gestation) are four times more likely than term neonates to have TSB greater than 13 mg/dL (224 mmol/L).

3. Breast-feeding and jaundice

A. BREAST-MILK JAUNDICE—Unconjugated hyperbilirubinemia lasting until 2–3 months of age is common in breast-fed infants. An increased prevalence of the Gilbert syndrome promoter polymorphism is likely involved. Moderate unconjugated hyperbilirubinemia for 6–12 weeks in a thriving breast-fed infant without evidence of hemolysis, hypothyroidism, or other disease strongly suggests this diagnosis.

B. BREAST-FEEDING-ASSOCIATED JAUNDICE-This common condition has also been called "lack-of-breast-milk" jaundice. Breast-fed infants have a higher incidence (9%) of unconjugated serum bilirubin levels greater than 13 mg/dL (224 mmol/L) than do formula-fed infants (2%). The pathogenesis is probably poor enteral intake and increased enterohepatic circulation. There is no apparent increase in bilirubin production as measured by carbon monoxide exhalation. Although rarely severe enough to cause bilirubin encephalopathy, nearly 100% of the infants with kernicterus reported over the past 20 years were exclusively breast-fed, and in 50%, breast-feeding was the only known risk factor. Excessive jaundice should be considered a possible sign of failure to establish an adequate milk supply, and should prompt specific inquiries. The best way to evaluate successful breast-feeding is to monitor the infant's weight, urine, and stool output (see Table 2-3). If intake is inadequate, the infant should receive supplemental formula and the mother should be instructed to nurse more frequently and to use an electric breast pump every 2 hours to enhance milk production. Consultation with a lactation specialist should be considered. Because hospital discharge of normal newborns occurs before the milk supply is established and before jaundice peaks, a follow-up visit 2 days after discharge is recommended by the AAP to evaluate adequacy of intake and degree of jaundice.

3. Bilirubin Toxicity

Unconjugated bilirubin anion is the agent of bilirubin neurotoxicity. The anion binds to the phospholipids (gangliosides) of neuronal plasma membranes causing injury, which then allows more anion to enter the neuron. Intracellular bilirubin anion binds to the membrane phospholipids of subcellular organelles, causing impaired energy metabolism and cell death. The blood-brain barrier undoubtedly has a role in protecting the infant from brain damage, but its integrity is impossible to measure clinically. The amount of albumin available to bind the unconjugated bilirubin anion and the presence of other anions that may displace bilirubin from albumin-binding sites are also important. It is unknown whether there is a fixed level of bilirubin above which brain damage always occurs. The term kernicterus describes the pathologic finding of staining of basal ganglia and brainstem nuclei, as well as the clinical syndrome of chronic brain injury due to hyperbilirubinemia. The term acute bilirubin encephalopathy describes the signs and symptoms of evolving brain injury in the newborn.

The risk of bilirubin encephalopathy is small in healthy, term neonates even at bilirubin levels of 25–30 mg/dL (430–516 mmol/L). Risk depends on the duration of hyperbilirubinemia, the concentration of serum albumin, associated illness, acidosis, and the concentrations of competing anions such as sulfisoxazole and ceftriaxone. Premature infants are at greater risk than term infants because of the greater frequency of associated illness affecting the integrity of the blood-brain barrier, reduced albumin levels, and decreased affinity of albumin-binding sites. For these reasons, the "exchange level" (the level at which bilirubin encephalopathy is thought likely to occur) in premature infants may be lower than that of a term infant.

4. Acute Bilirubin Encephalopathy

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Lethargy, poor feeding.
- ► Irritability, high-pitched cry.
- Arching of the neck (retrocollis) and trunk (opisthotonos).
- Apnea, seizures, coma (late).

Newborn infants with evolving acute bilirubin encephalopathy may be described as "sleepy and not interested in feeding." Although these symptoms are nonspecific, they are also the earliest signs of acute bilirubin encephalopathy and should trigger, in the jaundiced infant, a detailed evaluation of the birth and postnatal history, feeding and elimination history, an urgent assessment for signs of bilirubin-induced neurologic dysfunction (BIND), and a TSB and albumin measurement. Correlation between TSB level and neurotoxicity is poor. Although 65% of recently reported cases of kernicterus had TSB levels above 35 mg/dL, 15% had levels below 30 mg/dL and 8% had TSB levels below 25 mg/dL. Currently the most sensitive means of assessing neurotoxicity may be the auditory brainstem evoked response, which shows predictable, early effects of bilirubin toxicity.

5. Chronic Bilirubin Encephalopathy (Kernicterus)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Extrapyramidal movement disorder (choreoathetoid cerebral palsy).
- ► Gaze abnormality, especially limitation of upward gaze.
- Auditory disturbances (deafness, failed auditory brainstem evoked response with normal evoked otoacoustic emissions, auditory neuropathy, auditory dyssynchrony).
- ▶ Dysplasia of the enamel of the deciduous teeth.

Kernicterus is an irreversible brain injury characterized by choreoathetoid cerebral palsy and hearing impairment. Intelligence is probably normal but may be difficult to assess because of associated hearing, communication, and coordination problems. The diagnosis is clinical but is strengthened if audiologic testing shows auditory neuropathy and auditory dyssynchrony in which the otoacoustic emission test is normal but the auditory brainstem response is absent. Infants with such findings are usually deaf. Infants with milder kernicterus may have normal audiograms but abnormal auditory processing and subsequent problems with speech comprehension. Magnetic resonance imaging (MRI) scanning of the brain is nearly diagnostic if it shows abnormalities isolated to the globus pallidus, the subthalamic nuclei, or both.

Evaluation of Hyperbilirubinemia

Because most newborns are discharged at 24–48 hours of age, before physiologic jaundice peaks and before maternal milk supply is established, a predischarge TSB or a transcutaneous bilirubin measurement (TcB) is recommended to help predict which infants are at risk for severe hyperbilirubinemia. In all infants, an assessment of risk for severe hyperbilirubinemia should be performed before discharge (Table 2–7). The greater the number of risk factors, the greater the likelihood of developing severe **Table 2–7.** Factors affecting the risk of severe hyperbilirubinemia in infants 35 or more weeks' gestation (in approximate order of importance).

Major risk factors Predischarge TSB or TcB level in the high-risk zone (> 95th percentile; Figure 2–1) Jaundice observed in the first 24 h Blood group incompatibility with positive direct Coombs test, other known hemolytic disease (eg, G6PD deficiency), or elevated ETCO Gestational age 35–36 wk Previous sibling required phototherapy Cephalohematoma or significant bruising Exclusive breast-feeding, particularly if weight loss is excessive East Asian race ^a
Minor risk factors Predischarge TSB or TcB level in the high-intermediate-risk zone (75–95th percentile) Gestational age 37–38 wk Jaundice observed before discharge Previous sibling with jaundice Macrosomic infant of a diabetic mother
Decreased risk (these factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance) TSB or TcB level in the low-risk zone (Figure 2–1) Gestational age ≥ 41 wk Exclusive bottle feeding Black race ^a Discharge from hospital after 72 h

ETCO, end-tidal carbon monoxide; G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

^aRace as defined by mother's description.

hyperbilirubinemia. As recommended by the AAP, followup within 24–48 hours for all infants discharged before 72 hours of age is imperative. Visual estimation of the bilirubin level is inaccurate. TSB should be measured and interpreted based on the age of the infant in hours at the time of sampling. Term infants with a TSB level greater than the 95th percentile for age in hours have a 40% risk of developing significant hyperbilirubinemia (see Figure 2–1). Serial bilirubin levels should be obtained from a single laboratory whenever possible to make interpretation of serial measurements more meaningful. It is important to remember that these nomograms apply only to infants 36 weeks and older.

Infants with visible jaundice on the first day of life or who develop excessive jaundice require further evaluation. The minimal evaluation consists of the following:

- · Feeding and elimination history
- · Birth weight and percent weight change since birth

- Examination for sources of excessive heme breakdown
- Assessment of blood type, Coombs testing, complete blood count (CBC) with smear, serum albumin, and TSB
- G6PD test if jaundice is otherwise unexplained, and in African-American infants with severe jaundice
- Fractionated bilirubin level in infants who appear ill, those with prolonged jaundice, acholic stool, hepatosplenomegaly, or dark urine to evaluate for cholestasis

Treatment of Indirect Hyperbilirubinemia

A. Phototherapy

Phototherapy is the most common treatment for indirect hyperbilirubinemia. It is relatively noninvasive and safe. Light of wavelength 425–475 nm (blue-green spectrum) is absorbed by unconjugated bilirubin in the skin converting it to a water-soluble stereoisomer that can be excreted in bile without conjugation. Intensive phototherapy should decrease TSB by 30%–40% in the first 24 hours, most significantly in the first 4–6 hours. The infant's eyes should be

shielded to prevent retinal damage. Diarrhea, which sometimes occurs during phototherapy, can be treated if necessary by feeding a nonlactose-containing formula.

Phototherapy is started electively when the TSB is approximately 6 mg/dL (102 mmol/L) lower than the predicted exchange level for that infant (eg, at 16-19 mg/dL [272-323 mmol/L] for a full-term infant for whom exchange transfusion would be considered at a TSB of approximately 22-25 mg/dL [374-425 mmol/L]). AAP guidelines for phototherapy and exchange transfusion in infants of 35 or more weeks' gestation are shown in Figures 2-2 and 2-3. Hyperbilirubinemic infants should be fed by mouth if possible to decrease enterohepatic bilirubin circulation. Casein hydrolysate formula to supplement breast milk decreases enterohepatic circulation by inhibiting mucosal β -glucuronidase activity. IVIG (0.5–1.0 g/kg) in severe antibody-mediated hemolysis may interrupt the hemolytic process. Although phototherapy has been shown to decrease the need for exchange transfusion, its long-term benefits, if any, in infants with less severe jaundice are unknown.

- · Use total bilirubin. Do not subtract direct reacting of conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

▲ Figure 2–2. Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. These guidelines are based on limited evidence and levels shown are approximations. (Reproduced with permission from the AAP Subcommittee on Hyperbilirubinemia: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics 2004 Jul;114(1):297–316.)

CHAPTER 2

- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocolitis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 µmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
- If infant is well and 35–37 6/7 week (median risk), individualize TSB levels for exchange based on actual gestational age.

▲ Figure 2–3. Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. These guidelines represent approximations for which an exchange transfusion is indicated in infants treated with intensive phototherapy. (Reproduced with permission from the AAP Subcommittee on Hyperbilirubinemia: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics 2004 Jul;114(1):297–316.)

B. Exchange Transfusion

Although most infants with indirect hyperbilirubinemia can be treated with phototherapy, extreme indirect hyperbilirubinemia is a medical emergency. Infants should be admitted at once to a neonatal intensive care unit where exchange transfusion can be performed before irreversible neurologic damage occurs. Intensive phototherapy should be instituted immediately, during transport to the hospital if possible. As TSB nears the potentially toxic range, serum albumin should be determined. Albumin (1 g/kg) will aid in binding and removal of bilirubin during exchange transfusion, as well as afford some neuroprotection while preparing for the procedure.

Double-volume exchange transfusion (~160–200 mL/kg body weight) is most often required in infants with extreme hyperbilirubinemia secondary to Rh isoimmunization, ABO incompatibility, or hereditary spherocytosis. The procedure decreases serum bilirubin acutely by approximately 50% and removes about 80% of sensitized or abnormal red blood cells and offending antibody so that ongoing hemolysis is decreased. Exchange transfusion is also indicated in any infant with TSB above 30 mg/dL, in infants with signs of encephalopathy, or when intensive phototherapy has not lowered TSB by at least 0.5 mg/dL/h after 4 hours. The decision to perform exchange transfusion should be based on TSB, not on the indirect fraction of bilirubin.

Exchange transfusion is invasive, potentially risky, and infrequently performed. It should therefore be performed at a referral center. Mortality is 1%–5% and is greatest in the smallest, most immature, and unstable infants. Sudden death during the procedure can occur in any infant. There is a 5%–10% risk of serious complications such as necrotizing enterocolitis (NEC), infection, electrolyte disturbances, or thrombocytopenia. Isovolemic exchange (withdrawal through an arterial line with infusion through a venous line) may decrease the risk of some complications.

C. Protoporphyrins

Tin and zinc protoporphyrin or mesoporphyrin (Sn-PP, Zn-PP; Sn-MP, Zn-MP) are inhibitors of heme oxygenase, the enzyme that initiates the catabolism of heme (iron protoporphyrin). Studies are underway involving a single injection of these substances shortly after birth to prevent the formation of bilirubin. Although results are promising, these drugs are not yet approved for use in the United States.

Lauer BJ, Spector NJ: Hyperbilirubinemia in the newborn. Pediatr Rev 2011;32:341 [PMID: 21807875].

HYPOGLYCEMIA

- Blood glucose < 40 mg/dL at birth to 4 h, or < 45 mg/dL at 4–24 h of age.
- LGA, SGA, preterm, and stressed infants at risk.
- May be asymptomatic.
- Infants can present with lethargy, poor feeding, irritability, or seizures.

General Considerations

Blood glucose concentration in the fetus is approximately 15 mg/dL less than maternal glucose concentration. Glucose concentration decreases in the immediate postnatal period, to as low as 30 mg/dL in many healthy infants at 1–2 hours after birth. Concentrations below 40 mg/dL after the first feeding are considered hypoglycemic. By 3 hours, the glucose concentration in normal full-term infants stabilizes at 45 mg/dL or greater. The two groups of full-term newborn infants at highest risk for hypoglycemia are infants of diabetic mothers and growth-restricted infants.

A. Infants of Diabetic Mothers

The infant of a diabetic mother (IDM) has abundant glucose stores in the form of glycogen and fat but develops hypoglycemia because of hyperinsulinemia induced by maternal and fetal hyperglycemia. Increased energy supply to the fetus from the maternal circulation results in a macrosomic infant. The IDM is at increased risk for multiple neonatal problems including trauma during delivery, cardiomyopathy (asymmetrical septal hypertrophy) which may present with murmur, respiratory distress, or cardiac failure, and microcolon which causes symptoms of low intestinal obstruction similar to Hirschsprung disease. Other neonatal problems include hypercoagulability and polycythemia, a combination that predisposes the infant to large vein thromboses (especially the renal vein). IDMs are often somewhat immature for their gestational age and are at increased risk for surfactant deficiency, hypocalcemia, feeding difficulties, and hyperbilirubinemia.

B. Intrauterine Growth-Restricted Infants

The intrauterine growth-restricted (IUGR) infant has reduced glucose stores in the form of glycogen and body fat, and is prone to hypoglycemia. In addition, marked hyperglycemia and a transient diabetes mellitus–like syndrome occasionally develops, particularly in the very premature IUGR infant. These problems usually respond to adjustment in glucose intake, although insulin is sometimes needed transiently. Some IUGR infants have hyperinsulinemia that persists for 1 week or more.

C. Other Causes of Hypoglycemia

Hypoglycemia occurs in disorders with islet cell hyperplasia, including Beckwith-Wiedemann syndrome, nesidioblastosis, and genetic forms of hyperinsulinism. Hypoglycemia also occurs in certain inborn errors of metabolism such as glycogen storage disease and galactosemia. Endocrine causes of hypoglycemia include adrenal insufficiency and hypopituitarism, which should be suspected in the setting of hypoglycemia and micropenis. Hypoglycemia also occurs in infants with birth asphyxia, hypoxia, and bacterial or viral sepsis. Premature infants are at risk for hypoglycemia due to decreased glycogen stores.

Clinical Findings and Monitoring

The signs of hypoglycemia in the newborn infant may be nonspecific and subtle: lethargy, poor feeding, irritability, tremors, jitteriness, apnea, and seizures. Hypoglycemia due to increased insulin is the most severe and most resistant to treatment. Hypoglycemia in hyperinsulinemic states can develop within the first 30–60 minutes of life.

Blood glucose can be measured by heelstick using a bedside glucometer. All infants at risk should be screened, including IDMs, IUGR infants, premature infants, and any infant with suggestive symptoms. All low or borderline values should be confirmed by laboratory measurement of blood glucose concentration. It is important to continue surveillance of glucose concentration until the baby has been on full enteral feedings without intravenous supplementation for 24 hours, with a target of greater than 45 mg/dL before feeding. Relapse of hypoglycemia thereafter is unlikely.

Infants with hypoglycemia requiring IV glucose infusions for more than 5 days should be evaluated for less common disorders, including inborn errors of metabolism, hyperinsulinemic states, and deficiencies of counterregulatory hormones.

Treatment

Therapy is based on the provision of enteral or parenteral glucose. Treatment guidelines are shown in Table 2–8. In hyperinsulinemic states, glucose boluses should be avoided and a higher glucose infusion rate used. After initial

CHAPTER 2

 Table 2–8.
 Hypoglycemia: suggested therapeutic regimens.

Screening Test ^a	Presence of Symptoms	Action
30–40 mg/dL	No symptoms of hypoglycemia	Draw blood glucose ^b ; if the infant is alert and vigorous, feed; follow with frequent glucose monitoring.
		If the infant continues to have blood glucose < 40 mg/dL or is unable to feed, provide intravenous glucose at 6 mg/ kg/min (D ₁₀ W at 3.6 mL/kg/h).
< 40 mg/dL	Symptoms of hypoglycemia present	Draw blood glucose ^b ; provide bolus of D ₁₀ W (2 mL/kg) followed by an infusion of 6 mg/kg/min (3.6 mL/kg/h).
< 30 mg/dL	With or without symptoms of hypoglycemia	Draw blood glucose ^b ; provide bolus of D_{10} W followed by an infusion of 6 mg/kg/min.
		If IV access cannot be obtained immediately, an umbilical vein line should be used.

^aRapid bedside determination.

^bLaboratory confirmation.

correction with a bolus of 10% dextrose in water ($D_{10}W$; 2 mL/kg), glucose infusion should be increased gradually as needed from a starting rate of 6 mg/kg/min, and weaned slowly when normoglycemic. IDMs and IUGR infants with polycythemia are at greatest risk for symptomatic hypoglycemia.

Prognosis

The prognosis of hypoglycemia is good if therapy is prompt. CNS sequelae are more common in infants with hypoglycemic seizures and in neonates with persistent hyperinsulinemic hypoglycemia. Hypoglycemia may also potentiate brain injury after perinatal depression, and should be avoided.

RESPIRATORY DISTRESS IN THE TERM NEWBORN INFANT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tachypnea, respiratory rate > 60 breaths/min.
- Intercostal and sternal retractions.
- Expiratory grunting.
- Cyanosis in room air.

General Considerations

Respiratory distress is one of the most common symptom complexes of the newborn. It may result from cardiopulmonary and noncardiopulmonary causes (Table 2–9). Chest radiography, arterial blood gases, and pulse oximetry are useful in assessing the cause and severity of the distress. It is important to consider the noncardiopulmonary causes, because the natural tendency is to focus on the heart and lungs. Most of the noncardiopulmonary causes can be ruled out by the history, physical examination, and a few simple laboratory tests. The most common pulmonary causes of respiratory distress in the full-term infant are transient tachypnea, aspiration syndromes, congenital pneumonia, and pneumothorax.

A. Transient Tachypnea (Retained Fetal Lung Fluid)

Respiratory distress is typically present at birth, usually associated with a mild-to-moderate oxygen requirement $(25\%-50\% O_2)$. The infant is usually full term or late preterm, nonasphyxiated, and born following a short labor or cesarean section without labor. The pathogenesis of the disorder is related to delayed clearance of fetal lung fluid via the circulation and pulmonary lymphatics. The chest radiograph shows perihilar streaking and fluid in interlobar fissures. Resolution usually occurs within 12–24 hours. Nasal CPAP can be very helpful in the clearance of the fluid.

B. Aspiration Syndromes

Typically occurs in full-term or late preterm infants with fetal distress prior to delivery or depression at delivery. Blood or meconium may be present in the amniotic fluid. Aspiration of meconium most commonly occurs in utero as a stressed infant gasps. Delivery room management of these infants is discussed in the resuscitation section. Respiratory distress is present from birth, often accompanied by a barrel chest appearance and coarse breath sounds. Pneumonitis may cause an increasing O_2 need and may require intubation and ventilation. The chest radiograph shows coarse

asymmetric infiltrates, hyperexpansion, and, in the worst cases, lobar consolidation. In some cases, because of secondary surfactant deficiency, the radiograph shows a diffuse homogeneous infiltrate pattern. Infants who aspirate are at risk of pneumothorax because of uneven aeration with segmental overdistention and are at risk for persistent pulmonary hypertension (see section Cardiac Problems in the Newborn Infant).

C. Congenital Pneumonia

The lungs are the most common site of infection in the neonate. Infections usually ascend from the genital tract before or during labor, with the vaginal or rectal flora the most likely agents (group B streptococci and *Escherichia coli*). Infants of any gestational age, with or without a history of prolonged rupture of membranes, chorioamnionitis, or maternal antibiotic administration, may be affected. Respiratory distress may begin at birth or may be delayed for several hours. The chest radiograph may resemble that of retained lung fluid or hyaline membrane disease. Rarely, there may be a lobar infiltrate or pleural effusion. Congenital pneumonia may be complicated by acquired surfactant deficiency or systemic sepsis.

Shock, poor perfusion, absolute neutropenia (< 2000/mL), and elevated C-reactive protein provide supportive evidence for pneumonia. Gram stain of tracheal aspirate may be helpful. Because no signs or laboratory findings can confirm a diagnosis of pneumonia, all infants with respiratory distress should have a blood culture performed and should receive broad-spectrum antibiotic therapy (ampicillin, 100 mg/kg in two divided doses, and gentamicin, 4 mg/kg q24h or 2.5 mg/kg q12h) until the diagnosis of bacterial infection is eliminated.

D. Spontaneous Pneumothorax

Spontaneous pneumothorax occurs in 1% of all deliveries. Risk is increased by interventions such as positive-pressure ventilation (PPV) in the delivery room. Respiratory distress (primarily tachypnea) is present from birth and typically is not severe. Breath sounds may be decreased on the affected side; heart tones may be shifted toward the opposite side and may be distant. The chest radiograph shows pneumothorax.

Treatment usually consists of supplemental O_2 and watchful waiting. Drainage by needle thoracentesis or tube thoracostomy is occasionally required. There is a slightly increased risk of renal abnormalities associated with spontaneous pneumothorax. Thus, careful physical examination of the kidneys and monitoring of urine output are indicated. If pulmonary hypoplasia with pneumothorax is suspected, renal ultrasound is indicated.

E. Other Respiratory Tract Causes

Other respiratory tract causes of respiratory distress are rare. Bilateral choanal atresia should be suspected if there is no air movement when the infant breathes through the nose. These infants have good color and heart rate while crying at delivery but become cyanotic and bradycardiac when they resume normal nasal breathing. Other causes of upper airway obstruction usually produce some degree of stridor or poor air movement despite good respiratory effort. Pleural effusion is likely in hydropic infants. Space-occupying lesions cause a shift of the mediastinum with asymmetrical breath sounds and are apparent on chest radiographs. Many are associated with severe respiratory distress.

Treatment

Whatever the cause, neonatal respiratory distress is treated with supplemental oxygen sufficient to maintain a Pao₂ of 60-70 mm Hg and an oxygen saturation by pulse oximetry (Spo₂) of 92%–96%. Oxygen should be warmed, humidified, and delivered through an air blender. Concentration should be measured with a calibrated oxygen analyzer. An umbilical or peripheral arterial line should be considered in infants requiring more than 45% fraction of inspired oxygen (Fio₂) by 4–6 hours of life to allow frequent blood gas determinations. Noninvasive monitoring with pulse oximetry should be used.

Other supportive treatment includes IV glucose. Unless infection can be ruled out, blood cultures should be obtained, and broad-spectrum antibiotics started. Volume expansion (normal saline) can be given in infusions of 10 mL/kg over 30 minutes for low blood pressure, poor perfusion, and metabolic acidosis. Other specific testing should be done as indicated by the history and physical examination. In most cases, a chest radiograph, blood gas measurements, CBC, and blood glucose determination allow a diagnosis.

Intubation and ventilation should be undertaken if there is respiratory failure ($Pao_2 < 60 \text{ mm Hg in} > 60\% \text{ Fio}_2$. $Paco_2 > 60 \text{ mm Hg}$, or repeated apnea). Peak pressures should be adequate to produce chest wall expansion and audible breath sounds (usually 18–24 cm H₂O). Positive endexpiratory pressure (4–6 cm H₂O) should be used. Ventilation rates of 20–40 breaths/min are usually required. The goal is to maintain a Pao, of 60–70 mm Hg and a Paco, of 45–55 mm Hg.

Prognosis

Most respiratory conditions of the full-term infant are acute and resolve in the first several days. Meconium aspiration and congenital pneumonia carry a mortality rate of up to 10% and can produce significant long-term pulmonary morbidity. Mortality has been reduced by use of high-frequency oscillatory ventilation and inhaled nitric oxide for treatment of pulmonary hypertension. Only rarely is ECMO needed as rescue therapy.

Edwards MO, Kotecha SJ, Kotecha K: Respiratory distress of the term newborn infant. Paediatr Resp Rev 2013;14(1):2937 [PMID: 23347658].

HEART MURMURS

Heart murmurs are common in the first days of life and do not usually signify structural heart problems (see also Cardiac Problems in the Newborn Infant). If a murmur is present at birth, it should be considered a valvular problem until proved otherwise because the common benign transitional murmurs (eg, patent ductus arteriosus) are not audible until minutes to hours after birth.

If an infant is pink, well-perfused, and in no respiratory distress, with palpable and symmetrical pulses (right brachial pulse no stronger than the femoral pulse), the murmur is most likely transitional. Transitional murmurs are soft (grade 1-3/6), heard at the left upper to midsternal border, and generally loudest during the first 24 hours. If the murmur persists beyond 24 hours of age, blood pressure in the right arm and a leg should be determined. If there is a difference of more than 15 mm Hg (arm > leg) or if the pulses in the lower extremities are difficult to palpate, a cardiologist should evaluate the infant for coarctation of the aorta. If there is no difference, the infant can be discharged home with follow-up in 2-3 days for auscultation and evaluation for signs of congestive failure. If signs of congestive failure or cyanosis are present, the infant should be referred for evaluation without delay. If the murmur persists without these signs, the infant can be referred for elective evaluation at age 2-4 weeks.

BIRTH TRAUMA

Most birth trauma is associated with difficult delivery (eg, large fetus, abnormal presenting position, or fetal distress requiring rapid extraction). The most common injuries are soft tissue bruising, fractures (clavicle, humerus, or femur), and cervical plexus palsies. Skull fracture, intracranial hemorrhage (primarily subdural and subarachnoid), and cervical spinal cord injury can also occur.

Fractures are often diagnosed by the obstetrician, who may feel or hear a snap during delivery. Clavicular fractures may cause decreased spontaneous movement of the arm, with local tenderness and crepitus. Humeral or femoral fractures usually cause tenderness and swelling over the shaft with a diaphyseal fracture, and always cause limitation of movement. Epiphyseal fractures are harder to diagnose radiographically owing to the cartilaginous nature of the epiphysis. After 8–10 days, callus is visible on radiographs. Treatment in all cases is gentle handling, with immobilization for 8–10 days: the humerus against the chest with elbow flexed; the femur with a posterior splint from below the knee to the buttock.

Brachial plexus injuries may result from traction as the head is pulled away from the shoulder during delivery. Injury to the C5–C6 roots is most common (Erb-Duchenne palsy). The arm is limp, adducted, and internally rotated, extended, and pronated at the elbow, and flexed at the wrist (so-called waiter's tip posture). Grasp is present. If the lower nerve roots (C8–T1) are injured (Klumpke palsy), the hand is flaccid. If the entire plexus is injured, the arm and hand are flaccid, with associated sensory deficit. Early treatment

▲ Figure 2–4. Sites of extracranial bleeding in the newborn. (Reproduced with permission from Pape KE, Wigglesworth JS: Haemorrhage, ischemia, and the perinatal brain. Clinics in Developmental Medicine. Spastics International Medical Publications. William Heinemann Medical Books Limited, London, and JB Lippincott Company, Philadelphia, 1979.)

for brachial plexus injury is conservative, because function usually returns over several weeks. Referral should be made to a physical therapist so that parents can be instructed on range-of-motion exercises, splinting, and further evaluation if needed. Return of function begins in the deltoid and biceps, with recovery by 3 months in most cases.

Spinal cord injury can occur at birth, especially in difficult breech extractions with hyperextension of the neck, or in midforceps rotations when the body fails to turn with the head. Infants are flaccid, quadriplegic, and without respiratory effort at birth. Facial movements are preserved. The long-term outlook for such infants is poor.

Facial nerve palsy is sometimes associated with forceps use but more often results from in utero pressure of the baby's head against the mother's sacrum. The infant has asymmetrical mouth movements and eye closure with poor facial movement on the affected side. Most cases resolve spontaneously in a few days to weeks.

Subgaleal hemorrhage into the large potential space under the scalp (Figure 2–4) is associated with difficult vaginal deliveries and repeated attempts at vacuum extraction. It can lead to hypovolemic shock and death from blood loss and coagulopathy triggered by consumption of clotting factors. This is an emergency requiring rapid replacement of blood and clotting factors.

INFANTS OF MOTHERS WHO ABUSE DRUGS

Current studies estimate that up to 15% of women use alcohol and 5%–15% use illicit drugs during pregnancy, depending on the population studied and the methods of ascertainment. Drugs most commonly used are tobacco, alcohol, marijuana, cocaine, and methamphetamine. Because mothers may abuse many drugs and give an unreliable history of drug usage, it is difficult to pinpoint which drug is causing the morbidity seen in a newborn infant. Early hospital discharge makes recognition of these infants based on physical findings and abnormal behavior difficult. Except for alcohol, a birth defect syndrome has not been defined for any substance of abuse.

1. Cocaine & Methamphetamine

- Triad of no prenatal care, premature delivery, placental abruption.
- Possible IUGR.
- Irritability.

Cocaine and methamphetamine are often used in association with other drugs such as tobacco, alcohol, and marijuana. These stimulants can cause maternal hypertension, decreased uterine blood flow, fetal hypoxemia, uterine contractions, and placental abruption. Rates of stillbirth, placental abruption, symmetric IUGR, and preterm delivery are increased in users. In the high-risk setting of no prenatal care, placental abruption, and preterm labor, urine toxicology screens should be performed on the mother and infant; consent from the mother for testing her urine may be required. Meconium or an umbilical cord sample should be sent for drug screening as it enhances diagnosis by indicating cumulative drug exposure from the first trimester forward. Although no specific malformation complex or withdrawal syndrome is described for cocaine and methamphetamine abuse, infants may show irritability, tremors, increased stress response, and poor state regulation.

Children of mothers who use methamphetamines are at particularly high risk for neglect and abuse. Social services

CHAPTER 2

evaluation is especially important to assess the home environment for these risks. The risk of SIDS is three to seven times higher in infants of users than in those of nonusers (0.5%–1% of exposed infants). The risk may be lessened by environmental interventions such as avoidance of tobacco smoke and supine infant positioning.

2. Opioids

- CNS—irritability, hyperactivity, hypertonicity, incessant high-pitched cry, tremors, seizures.
- GI—vomiting, diarrhea, weight loss, poor feeding, incessant hunger, excessive salivation.
- Metabolic and respiratory—nasal stuffiness, sneezing, yawning, sweating, hyperthermia.
- Often IUGR.

Clinical Findings

The withdrawal signs seen in infants born to narcoticaddicted mothers, whether heroin, prescription narcotics, or methadone, are similar. These symptoms include problems with feeding and sleep, fever, increased tone, tremors, and seizures, and are referred to as neonatal abstinence syndrome (NAS). The symptoms in infants born to methadonemaintained mothers may be delayed in onset, more severe, and more prolonged than those seen with heroin addiction. Symptoms usually begin within 1–3 days of life. The clinical picture is typical enough to suggest a diagnosis even if a maternal history of narcotic abuse has not been obtained. Confirmation should be made with maternal and newborn toxicology screening.

Treatment

If opioid abuse or withdrawal is suspected, the infant is not a candidate for early discharge. A serial scoring system should be used, to objectively diagnose NAS and quantify the severity of symptoms. Supportive treatment includes swaddling the infant and providing a quiet, dimly lit environment, minimizing procedures, and disturbing the infant as little as possible. Specific treatment should be used when the infant has severe symptoms or excessive weight loss. No single drug has been identified as optimally effective. Oral morphine (0.1–0.5 mg/kg/dose q6–12h) or methadone (0.05–0.1 mg/kg/dose q6–12h) are the most commonly used first-line agents for NAS. Phenobarbital (5 mg/kg/dose daily) may be used for increased irritability, particularly in patients who were exposed to multiple drugs. Treatment can be tapered over several days to 2 weeks, as tolerated. It is also important to review maternal tests for HIV, hepatitis B, and hepatitis C, as all are common in intravenous drug users.

Prognosis

These infants often have chronic neurobehavioral handicaps; however, it is difficult to distinguish the effects of in utero drug exposure from those of the environment. Infants of opioid abusers have a four- to fivefold increased risk of SIDS.

3. Alcohol

Alcohol is the only recreational drug of abuse that is clearly teratogenic, and prenatal exposure to alcohol is the most common preventable cause of mental retardation. Prevalence estimates of fetal alcohol syndrome (FAS) in the United States range from 0.5 to 2 per 1000 live births with up to 1 in 100 having lesser effects (fetal alcohol spectrum disorders). The effects of alcohol on the fetus and newborn are determined by the degree and timing of ethanol exposure and by the maternal, fetal, and placental metabolism of ethanol, which is likely genetically determined. Although there is no clear evidence that minimal amounts of alcohol are harmful, there is no established safe dose. Fetal growth and development are adversely affected if drinking continues throughout the pregnancy, and infants can occasionally experience withdrawal similar to that associated with maternal opioid abuse. Clinical features of FAS that may be observed in the newborn period are listed in Table 2-10. This diagnosis is usually easier to recognize in older infants and children.

4. Tobacco Smoking

The fetus is exposed to nicotine concentrations that are 15% higher than in maternal blood. Smoking has a negative effect on fetal growth rate. The more the mother smokes,

Table 2–10. Features observed in fetal alcohol syndrome in the newborn.

Craniofacial Short palpebral fissures Thin vermillion of upper lip Flattened philtrum
Growth Prenatal and postnatal growth deficiency (small for gestational age, failure to thrive)
Central nervous system Microcephaly Partial or complete agenesis of the corpus callosum Optic nerve hypoplasia

Hypotonia, poor feeding

the greater the degree of IUGR. There is a twofold increase in low birth weight even in light smokers (< 10 cigarettes per day). Infants exposed to nicotine prenatally are also at increased risk for preterm labor and SIDS. Smoking during pregnancy has been associated with irritability, hypertonicity, hyperexcitability, and tremors in the newborn.

5. Marijuana

Marijuana is the most frequently used illegal drug, and now that it is legal in certain states, there is concern for increased use among pregnant women. It does not appear to be teratogenic, and although a mild abstinence-type syndrome has been described, infants exposed to marijuana in utero rarely require treatment. Some long-term neurodevelopmental problems, particularly increased impulsivity and hyperactivity and problems in abstract and visual reasoning, have been noted.

6. Other Drugs

Other drugs with potential effects on the newborn fall in two categories. First are drugs to which the fetus is exposed because of therapy for maternal conditions. The human placenta is relatively permeable, particularly to lipophilic solutes. If possible, maternal drug therapy should be postponed until after the first trimester to avoid teratogenic effects. Drugs with potential fetal toxicity include antineoplastics, antithyroid agents, warfarin, lithium, and angiotensin-converting enzyme inhibitors (eg, captopril and enalapril). Anticonvulsants, especially high-dose or multiple drug therapy, may be associated with craniofacial abnormalities. The use of selective serotonin reuptake inhibitors, benzodiazepines, and antipsychotic medications appears to be generally safe, and risk should be balanced against the risk of untreated psychiatric conditions in the mother. However, up to 33% of infants exposed to SSRI medications in utero experience signs of NAS during the first days of life. Paroxetine seems to have the greatest propensity to cause abstinence symptoms. Phenobarbital may be used for severe irritability.

In the second category are drugs transmitted to the infant in breast milk. Most drugs taken by the mother achieve some concentration in breast milk, although they usually do not present a problem to the infant. If the drug is one that could have adverse effects on the infant, timing breast-feeding to coincide with trough concentrations in the mother may be useful.

MULTIPLE BIRTHS

- Monochorial twins
 - · Always monozygous (identical twins) and same sex.
 - · Can be diamniotic or monoamniotic.
 - Risk for twin-to-twin transfusion and higher risk of congenital anomalies, neurodevelopmental problems, and cerebral palsy.
- Dichorial twins
 - Either dizygous (fraternal twins) or monozygous (identical twins); same sex or different sex.
 - Can have growth restriction due to abnormal placental implantation.
 - Not at risk for twin transfusion syndrome; less risk for anomalies and neurodevelopmental problems than monochorial twins.

Historically, twinning occurred at a rate of 1 in 80 pregnancies (1.25%). The incidence of twinning and higher-order multiple births in the United States has increased because of assisted reproductive technologies. In 2014, twins occurred in 3.4% of live births in the United States, a greater than 70% increase since 1980.

A distinction should be made between dizygous (fraternal) and monozygous (identical) twins. Race, maternal parity, and maternal age affect the incidence of dizygous, but not monozygous, twinning. Drugs used to induce ovulation, such as clomiphene citrate and gonadotropins, increase the incidence of dizygotic or polyzygotic twinning. Monozygous twinning also seems to be more common after assisted reproduction. The incidence of malformations is also increased in identical twins and may affect only one of the twins. If a defect is found in one twin, the other should be examined carefully for lesser degrees of the same defect.

Early transvaginal ultrasound and examination of the placenta after birth can help establish the type of twinning. Two amnionic membranes and two chorionic membranes are found in all dizygous twins and in one-third of monozygous twins even when the placental disks appear to be fused into one. A single chorionic membrane always indicates monozygous twins. The rare monochorial, monoamniotic situation (1% of twins) is especially dangerous, with a high risk of antenatal cord entanglement and death of one or both twins. Close fetal surveillance is indicated, and preterm delivery is often elected.

McQueen K, Murphy-Oikonen J: Neonatal abstinence syndrome. NEJM 2016;375:2468 [PMID: 28002715].

Complications of Multiple Births

A. Intrauterine Growth Restriction

There is some degree of IUGR in most multiple pregnancies, especially after 32 weeks, although it is usually not clinically significant with two exceptions. First, in monochorial twin pregnancy an arteriovenous shunt may develop between the twins (twin-twin transfusion syndrome). The twin on the venous side (recipient) becomes plethoric and larger than the smaller anemic twin (donor), who may ultimately die or be severely growth restricted. The occurrence of polyhydramnios in the larger twin and severe oligohydramnios in the smaller may be the first sign of this problem. Second, discordance in size (birth weights that are significantly different) can also occur when separate placentas are present if one placenta develops poorly, because of a poor implantation site. In this instance, no fetal exchange of blood takes place but the growth rates of the two infants are different.

B. Preterm Delivery

Length of gestation tends to be inversely related to the number of fetuses. The mean age at delivery for singletons is 38.8 weeks, for twins 35.3 weeks, for triplets 32.2 weeks, and for quadruplets 29.9 weeks. The prematurity rate in multiple gestations is 5–10 times that of singletons, with 50% of twins and 90% of triplets born before 37 weeks. There is an increased incidence of cerebral palsy in multiple births, more so with monochorial than dichorial infants. Prematurity is the main cause of increased mortality and morbidity in twins, although in the case of monochorial twins, intravascular exchange through placental anastomoses, particularly after the death of one twin, also increases the risk substantially.

C. Obstetric Complications

Polyhydramnios, pregnancy-induced hypertension, premature rupture of membranes, abnormal fetal presentations, and prolapsed umbilical cord occur more frequently in women with multiple fetuses. Multiple pregnancies should always be identified prenatally with ultrasound examinations; doing so allows the obstetrician and pediatrician or neonatologist to plan management jointly. Because neonatal complications are usually related to prematurity, prolongation of pregnancy significantly reduces neonatal morbidity.

NEONATAL INTENSIVE CARE

PERINATAL RESUSCITATION

Perinatal resuscitation refers to the steps taken by the obstetrician to support the infant during labor and delivery and the resuscitative steps taken by the pediatrician after delivery. Intrapartum support includes maintaining maternal blood pressure, maternal oxygen therapy, positioning the mother to improve placental perfusion, readjusting oxytocin infusions or administering a tocolytic if appropriate, minimizing trauma to the infant, obtaining all necessary cord blood samples, and completing an examination of the placenta. The pediatrician or neonatologist focuses on temperature support, initiation and maintenance of effective ventilation, maintenance of perfusion and hydration, and glucose regulation.

A number of conditions associated with pregnancy, labor, and delivery place the infant at risk for birth asphyxia: (1) maternal diseases such as diabetes, pregnancy-induced hypertension, heart and renal disease, and collagen-vascular disease; (2) fetal conditions such as prematurity, multiple births, growth restriction, and fetal anomalies; and (3) labor and delivery conditions, including fetal distress with or without meconium in the amniotic fluid, and administration of anesthetics and opioid analgesics.

Physiology of Birth Asphyxia

Birth asphyxia can be the result of (1) acute interruption of umbilical blood flow (eg, prolapsed cord with cord compression), (2) premature placental separation, (3) maternal hypotension or hypoxia, (4) chronic placental insufficiency, and (5) failure to perform resuscitation properly.

The neonatal response to asphyxia follows a predictable pattern (Figure 2–5). The initial response to hypoxia is an increase in respiratory rate and a rise in heart rate and blood pressure. Respirations then cease (primary apnea) as heart rate and blood pressure begin to fall. The initial period of apnea lasts 30–60 seconds. Gasping respirations (3–6/min) then begin, while heart rate and blood pressure gradually decline. Secondary or terminal apnea then ensues, with further decline in heart rate and blood pressure. The longer the duration of secondary apnea, the greater is the risk for hypoxic organ injury. A cardinal feature of the defense against hypoxia is the underperfusion of certain tissue beds (eg, skin, muscle, kidneys, and GI tract), which allows maintenance of perfusion to core organs (ie, heart, brain, and adrenals).

Response to resuscitation also follows a predictable pattern. During the period of primary apnea, almost any physical stimulus causes the infant to initiate respirations. Infants in secondary apnea require PPV. The first sign of recovery is an increase in heart rate, followed by an increase in blood pressure with improved perfusion. The time required for rhythmic, spontaneous respirations to occur is related to the duration of the secondary apnea. As a rough rule, for each minute past the last gasp, 2 minutes of positive pressure ventilation (PPV) is required before gasping begins and 4 minutes is required to reach rhythmic breathing. Not until sometime later do spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management

When asphyxia is anticipated, a resuscitation team of at least two persons should be present: one to manage the airway and one to monitor the heartbeat and provide assistance. The necessary equipment and drugs are listed in Table 2–11.

A. Steps in the Resuscitative Process

- 1. Dry the infant well and place him or her under a radiant heat source. Do not allow the infant to become hyperthermic.
- 2. Position the infant to open the airway. Gently suction the mouth, then the nose.
- 3. Quickly assess the infant's condition. The best criteria are the infant's respiratory effort (apneic, gasping, or regular) and heart rate (> 100 or < 100 beats/min).

Table 2–11. Equipment for neonatal resuscitation.

Clinical Needs	Equipment
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servo control heating, temperature probe, gallon size food- grade plastic bag or plastic wrap and an exothermic blanket (preterm)
Airway management	Suction: bulb suction, mechanical suction with sterile catheters (6Fr, 8Fr, 10Fr), meconium aspirator
	Ventilation: manual infant resuscitation bag connected to manometer or with a pressure- release valve, or T-piece resuscitator, capable of delivering 100% oxygen; appropriate masks for term and preterm infants, oral airways, stethoscope, oxygen blender, pulse oximeter
	Intubation: neonatal laryngoscope with No. 0 and No. 1 blades; endotracheal tubes (2.5, 3.0, 3.5 mm outer diameter with stylet): extra bulbs and batteries for laryngoscope; scissors, adhesive tape, gloves, end-tidal CO ₂ detection device
Gastric decompression	Nasogastric tube: 8Fr with 20-mL syringe
Administration of drugs and volume replacement	Sterile umbilical catheterization tray, umbilical catheters (3.5Fr and 5Fr), normal saline, drug box ^a with appropriate neonatal vials and dilutions, sterile syringes, needles, and alcohol sponges
Transport	Warmed transport isolette with oxygen source

^aEpinephrine 1:10,000; 10% dextrose.

Modified with permission from Gabbe SG et al: Obstetrics: Normal and Problem Pregnancies. Philadelphia: Churchill Livingstone, 2007.

A depressed heart rate—indicative of hypoxic myocardial depression—is the single most reliable indicator of the need for resuscitation.

- 4. Infants who are breathing and have heart rates more than 100 beats/min usually require no further intervention other than supplemental oxygen if persistently cyanotic. Infants with heart rates less than 100 beats/min and apnea or irregular respiratory efforts should be stimulated gently. The infant's back should be rubbed and/or heels flicked.
- 5. If the infant fails to respond to tactile stimulation within a few seconds, begin bag and mask ventilation, using a soft mask that seals well around the mouth and nose.

CHAPTER 2

For the initial inflations, pressures up to $30-40 \text{ cm H}_2\text{O}$ may be necessary to overcome surface-active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest accompanied by an improvement in heart rate, perfusion, and color. After the first few breaths, lower the peak pressure to 15–20 cm H₂O. The chest movement should resemble that of an easy breath rather than a deep sigh. The rate of bagging should be 40–60 breaths/min. An oximeter probe should be placed on the infant's right hand.

6. Most neonates can be resuscitated effectively with a bag and mask. If the infant does not respond to bag and mask ventilation, reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and the oropharynx, and try ventilating with the mouth open. An increase in peak pressure should also be attempted, but if the infant does not respond within 30 seconds, intubation is appropriate. Failure to respond to intubation and ventilation can result from (1) mechanical difficulties (Table 2-12), (2) profound asphyxia with myocardial depression, and (3) inadequate circulating blood volume. Quickly rule out the mechanical causes listed in Table 2-12. Check to ensure that the endotracheal tube passes through the vocal cords. A CO₂ detector placed between the endotracheal tube and the bag can be helpful as a rapid confirmation of proper tube position in the airway. Occlusion of the tube should be suspected when there is resistance to bagging and no chest wall movement. Very few neonates (~0.1%) require either cardiac compressions or drugs during resuscitation. Almost all newborns respond to ventilation if done effectively. All

	Table 2–12.	Mechanical	causes of failed	resuscitation.
--	-------------	------------	------------------	----------------

Cause	Examples
Equipment failure	Malfunctioning bag, oxygen not connected or running
Endotracheal tube malposition	Esophagus, right main stem bronchus
Occluded endotracheal tube	
Insufficient inflation pressure to expand lungs	
Space-occupying lesions in the thorax	Pneumothorax, pleural effusions, diaphragmatic hernia
Pulmonary hypoplasia	Extreme prematurity, oligohydramnios

Reproduced with permission from Gabbe SG et al: *Obstetrics: Normal and Problem Pregnancies.* Philadelphia: Churchill Livingstone, 2007.

resuscitations in term infants should begin using room air. Oxygen concentration can be increased using an oxygen blender during PPV. It is not expected for the preductal (right hand) oxygen saturation to reach 90% until 10 minutes of age. The use of 100% oxygen may increase the risk of postresuscitative oxidative injury without any improvement in efficacy.

- 7. If mechanical causes are ruled out and the heart rate remains less than 60 beats/min after intubation and effective PPV for 30 seconds, cardiac compressions should be initiated. Chest compressions should be synchronized with ventilation at a 3:1 ratio (90 compressions and 30 breaths/min).
- If drugs are needed, the drug and dose of choice is epinephrine 1:10,000 solution (0.1–0.3 mL/kg) given via an umbilical venous line. If volume loss is suspected, 10 mL/kg of normal saline should be administered through an umbilical vein line.

B. Continued Resuscitative Measures

The appropriateness of continued resuscitative efforts should be reevaluated in infants who do not respond to initial measures. In current practice, resuscitative efforts are made even in apparent stillbirths (ie, infants whose Apgar score at 1 minute is 0–1). Modern resuscitative techniques have led to improved survival in such infants, with 60% of survivors showing normal development. Although it is clear that resuscitation of these infants should be performed, subsequent continued support depends on the response to resuscitation. If the Apgar score does not improve markedly in the first 10 minutes of life, the mortality rate and the incidence of severe developmental handicaps among survivors are high.

C. Special Considerations

1. Delayed cord clamping—Current recommendations for neonatal resuscitation include that cord clamping should be delayed for at least 30 to 60 seconds for most vigorous term and preterm newborns. In cases where placental circulation is compromised (placental abruption, umbilical cord compression or avulsion) the umbilical cord should be clamped immediately and the initial steps of resuscitation begun.

2. Preterm infants

A. Minimizing heat loss improves survival. Prewarmed towels should be available. The environmental temperature of the delivery suite should be raised to more than 25° C (especially for infants weighing < 1500 g). An occlusive skin cover such as a gallon-sized food-grade plastic bag with an opening to slip over the infant's head and an exothermic blanket should be used to minimize heat loss in the extremely low-birth-weight (< 1000 g) infant.

B. The lungs of preterm infants are especially prone to injury from PPV due to volutrauma. For this reason, if possible, the infant's respiratory efforts should be supported with nasal continuous positive airway pressure (CPAP) rather than PPV. If PPV is needed, a T-piece resuscitation device should be used to allow precise and consistent regulation of pressure delivery. Resuscitation in the preterm should begin with a blended oxygen concentration of 21%–30% with titration to achieve target oxygen saturations.

c. In the infant of extremely low gestational age (< 26 weeks), immediate intubation for administration of surfactant should be considered.

D. Volume expanders should be infused slowly to minimize rapid swings in blood pressure, especially important in the ELBW infant.

3. Narcotic depression—In the case of opioid administration to the mother within 4 hours of delivery, institute resuscitation as described earlier. When the baby is stable with good heart rate, color, and perfusion, but still has poor respiratory effort, a trial of naloxone (0.1 mg/kg IV) may be indicated. Naloxone should not be administered in place of PPV. Naloxone should not be used in the infant of an opioid-addicted mother because it will precipitate withdrawal. Respiratory depression may recur over the next hours, requiring close observation of the newborn.

4. Meconium-stained amniotic fluid—Resuscitation of the infant should proceed with the same initial steps as an infant born without meconium-stained amniotic fluid.

5. Universal precautions—In the delivery suite, universal precautions should always be observed.

Treatment of the Asphyxiated Infant

Asphyxia is manifested by multiorgan dysfunction, seizures, neonatal encephalopathy, and metabolic acidemia. The infant with significant perinatal hypoxia and ischemia is at risk for dysfunction of multiple end organs (Table 2–13). The organ of greatest concern is the brain.

The features of neonatal encephalopathy are decreased level of consciousness, poor tone, decreased spontaneous movement, periodic breathing or apnea, and seizures. Brainstem signs (oculomotor and pupillary disturbances, absent gag reflex) may also be present. The severity and duration of clinical signs correlate with the severity of the insult. Other evaluations helpful in assessing severity in the full-term infant include electroencephalogram (EEG) and MRI which, particularly with diffusion-weighted imaging, is useful in the early evaluation of infants with perinatal asphyxia. A markedly abnormal EEG with voltage suppression and slowing evolving into a burst-suppression pattern is associated with severe clinical symptoms. MRI may show perfusion defects and areas of ischemic injury on diffusion-weighted imaging.

Table 2–13. Signs and symptoms caused by asphyxia.

Neonatal encephalopathy, seizures
Respiratory distress due to aspiration or secondary surfactant
deficiency, pulmonary hemorrhage
Persistent pulmonary hypertension
Hypotension due to myocardial dysfunction
Transient tricuspid valve insufficiency
Anuria or oliguria due to acute tubular necrosis
Feeding intolerance; necrotizing enterocolitis
Elevated aminotransferases due to liver injury
Adrenal insufficiency due to hemorrhage
Disseminated intravascular coagulation
Hypocalcemia
Hypoglycemia
Persistent metabolic acidemia
Hyperkalemia

Management is directed at supportive care and treatment of specific abnormalities. Fluids should be restricted initially to 60-80 mL/kg/day; oxygenation should be maintained with mechanical ventilation if necessary; blood pressure should be supported with judicious volume expansion (if hypovolemic) and pressors; and glucose should be in the normal range of 45-100 mg/dL. Hypocalcemia, coagulation abnormalities, and metabolic acidemia should be corrected and seizures treated with IV phenobarbital (20 mg/kg as loading dose, with total initial 24-hour dosing up to 40 mg/kg). Hypothermia, either selective head cooling or whole body cooling, initiated within 6 hours of birth, has been shown to improve outcome at 24 months and 6-7 year follow-up of infants with moderate neurologic symptoms and an abnormal amplitude-integrated EEG. Efficacy has not been proved in the most severe cases of neonatal encephalopathy.

Birth Asphyxia: Long-Term Outcome

Fetal heart rate tracings, cord pH, and 1-minute Apgar scores are imprecise predictors of long-term outcome. Apgar scores of 0–3 at 5 minutes in full-term infants are associated with an increased risk of death in the first year of life and an 8% risk of cerebral palsy among survivors. The risks of mortality and morbidity increase with more prolonged depression of the Apgar score. The single best predictor of outcome is the severity of clinical neonatal encephalopathy (severe symptomatology including coma carries a 75% chance of death and a 100% rate of neurologic sequelae among survivors). The major sequela of neonatal encephalopathy is cerebral palsy with or without mental retardation and epilepsy. Other prognostic features are prolonged seizures refractory to therapy, markedly abnormal EEG, and MRI scan with evidence of major ischemic injury.

THE PRETERM INFANT

Premature infants comprise the majority of high-risk newborns. The preterm infant faces a variety of physiologic handicaps:

- 1. The ability to coordinate sucking, swallowing, and breathing is not achieved until 34–36 weeks' gestation. Therefore, enteral feedings must be provided by gavage.
- Lack of body fat stores causes decreased ability to maintain body temperature, and may predispose to hypoglycemia.
- Pulmonary immaturity-surfactant deficiency is associated with structural immaturity in infants younger than 26 weeks' gestation. This condition is exacerbated by the combination of noncompliant lungs and an extremely compliant chest wall, causing inefficient respiratory mechanics.
- 4. Immature respiratory control leads to apnea and bradycardia.
- 5. Persistent patency of the ductus arteriosus compromises pulmonary gas exchange because of overperfusion and edema of the lungs.
- Immature cerebral vasculature and structure predisposes to subependymal and intraventricular hemorrhage, and periventricular leukomalacia (PVL).
- 7. Impaired substrate absorption by the GI tract compromises nutritional management.
- Immature renal function (including both filtration and tubular functions) complicates fluid and electrolyte management.
- 9. Increased susceptibility to infection.
- Immaturity of metabolic processes predisposes to hypoglycemia and hypocalcemia.

1. Delivery Room Care

See section Perinatal Resuscitation.

2. Care in the Nursery

A. Thermoregulation

Maintaining stable body temperature is a function of heat production and conservation balanced against heat loss. Heat production in response to cold stress occurs through voluntary muscle activity, involuntary muscle activity (shivering), and thermogenesis not caused by shivering. Newborns produce heat mainly through the last of these three mechanisms. This metabolic heat production depends on the quantity of brown fat, which is very limited in the preterm infant. In addition to decreased heat production in preterm infants, heat loss is accelerated because of a high ratio of surface area to body mass, reduced insulation by subcutaneous tissue, and water loss through the immature skin.

The thermal environment of the preterm neonate must be regulated carefully. The infant can be kept warm in an isolette, in which the air is heated and convective heat loss is minimized. The infant can also be kept warm on an open bed with a radiant heat source. Ideally, the infant should be kept in a neutral thermal environment. The neutral thermal environment allows the infant to maintain a stable core body temperature with a minimum of metabolic heat production through oxygen consumption. The neutral thermal environment depends on the infant's size, gestational age, and postnatal age. The neutral thermal environment (for either isolette or radiant warmer care) can be obtained by maintaining an abdominal skin temperature of 36.5°C. Generally, when infants reach 1700–1800 g, they are able to maintain temperature while bundled in an open crib.

B. Monitoring the High-Risk Infant

At a minimum, equipment to monitor heart rate, respirations, and blood pressure should be available. Oxygen saturation is assessed continuously using pulse oximetry, correlated with arterial oxygen tension (Pao_2) as needed. Transcutaneous Po_2 and Pco_2 can also be used to assess oxygenation and ventilation in sicker infants. Arterial blood gases, electrolytes, glucose, calcium, bilirubin, and other chemistries must be measured on small volumes of blood. Early in the care of a sick preterm infant, the most efficient way to sample blood for tests as well as to provide fluids and monitor blood pressure is through an umbilical arterial line. Once the infant is stable and the need for frequent blood samples is reduced (usually 4–7 days), the umbilical line should be removed. All indwelling lines are associated with morbidity from thrombosis, infection, and bleeding.

C. Fluid and Electrolyte Therapy

Fluid requirements in preterm infants are a function of (1) insensible losses (skin and respiratory tract), (2) urine output, (3) stool output (< 5% of total), and (4) other losses, such as nasogastric losses. In most circumstances, the fluid requirement is determined largely by insensible losses plus urine losses. The major contribution to insensible water loss is evaporative skin loss. The rate of water loss is a function of gestational age (body weight, skin thickness, and maturity), environment (losses are greater under a radiant warmer than in an isolette), and the use of phototherapy. Respiratory

losses are minimal when humidified oxygen is used. The renal contribution to water requirement is influenced by the limited ability of the preterm neonate either to concentrate the urine and conserve water, or to excrete a water load.

Electrolyte requirements are minimal for the first 24–48 hours until there is significant urinary excretion. Basal requirements thereafter are as follows: sodium, 3 mEq/kg/day; potassium, 2 mEq/kg/day; chloride, 2–3 mEq/kg/day; and bicarbonate, 2–3 mEq/kg/day. In the infant younger than 30 weeks' gestation, sodium and bicarbonate losses in the urine are often elevated, thereby increasing the infant's requirements.

Initial fluid management after birth varies with the infant's size and gestation. Infants of more than 1200 g should start at 80–100 mL/kg/day of D_{10} W. Those weighing less should start at 100–120 mL/kg/day of either D_{10} W or D_5 W (infants < 800 g and born before 26 weeks' gestation often become hyperglycemic on D_{10} W at these infusion rates). The most critical issue in fluid management is monitoring. Monitoring body weight, urine output, fluid and electrolyte intake, serum and urine electrolytes, and glucose allows fairly precise determination of the infant's water, glucose, and electrolyte needs. Parenteral nutrition should be started early, preferably on the first day, and continued until an adequate enteral intake is achieved.

D. Nutritional Support

The average caloric requirement for the growing premature infant is 120 kcal/kg/day. Desired weight gain is 15–20 g/kg/ day for infants younger than 35 weeks, and 15 g/kg/day for

those older than 35 weeks; linear and head circumference growth should average 1 cm/wk. Infants initially require IV glucose infusion to maintain blood glucose concentration in the range of 60-100 mg/dL. Infusions of 5-7 mg/kg/min (~80-100 mL/kg/day of D₁₀W) are usually needed. Aggressive nutritional support in the very low-birth-weight infant should be started as soon as possible after birth, with parenteral alimentation solutions containing 3-4 g/kg/day of amino acids (Table 2-14). Small-volume trophic feeds with breast milk or 20 kcal/oz premature formula should be started by gavage at 10% or less of the infant's nutritional work intake as soon as possible, generally within the first few days after birth. After several days of trophic feeds the infant can be slowly advanced to full caloric needs over 5-7 days. Even extremely small feedings can enhance intestinal readiness to accept larger feeding volumes. Intermittent bolus feedings are preferred because these appear to stimulate the release of gut-related hormones and may accelerate maturation of the GI tract, although in the extremely lowbirth-weight infant (< 1000 g) or the postsurgical neonate, continuous-drip feeds are sometimes better tolerated.

In general, long-term nutritional support for infants of very low birth weight consists either of breast milk supplemented to increase protein, caloric density, and mineral content, or infant formulas modified for preterm infants. In these formulas, protein concentrations and caloric concentrations are relatively high. In addition, premature formulas contain some medium-chain triglycerides—which do not require bile for absorption—as an energy source. Increased calcium and phosphorus are provided to enhance bone mineralization. The infant should gradually be offered

	Volume (mL/kg/day)	Carbohydrate (g/dL)	Protein (g/kg)	Lipid (g/kg)	Calories (kcal/kg)			
Peripheral: short-term (7–10 day)								
Starting solution	100–150	D ₁₀ W	3	1	56-84			
Target solution	150	D _{12.5} W	3–4	3	80–110			
Central: long-term (> 10 day)								
Starting solution	100–150	D ₁₀ W	3	1	56-84			
Target solution	130	D _{12.5} -D ₁₅ W	3–4	3	80–110			

Table 2-	-14	Use of	narenteral	alimentation	solutions
I able 2		036 01	Darenterar	annientation	SOLUCIOUS

Notes

1. Advance dextrose in central hyperalimentation as tolerated per day as needed to achieve appropriate weight gain, as long as blood glucose remains normal, keeping glucose as 40%–60% of total calories administered.

- 2. Advance lipids by 0.5–1.0 g/kg/day as long as triglycerides are normal. Use 20% concentration.
- 3. Total water should be 100-150 mL/kg/day, depending on the child's fluid needs.

Monitoring

- 1. Blood glucose two or three times a day when changing dextrose concentration, then daily.
- 2. Electrolytes daily, then twice a week when the child is receiving a stable solution.
- 3. Every 1–2 wk: blood urea nitrogen and serum creatinine; total protein and serum albumin; serum calcium, phosphate, magnesium, direct bilirubin, and CBC with platelet counts.
- 4. Triglyceride level after 24 h at 2 g/kg/day and 24 h at 3 g/kg/day, then every other week.

feedings of higher caloric density after a substantial volume (100–120 mL/kg/day) of 20 kcal/oz breast milk or formula is tolerated. Success of feedings is assessed by timely passage of feeds out of the stomach without emesis or large residual volumes, an abdominal examination free of distention, and a normal stool pattern.

When the preterm infant approaches term, the nutritional source for the bottle-fed infant can be changed to a transitional formula (22 kcal/oz) until age 6–9 months. Additional iron supplementation (2–4 mg/kg/day) is recommended for premature infants, beginning at 2 weeks to 2 months of age, depending on gestational age and number of previous transfusions. Infants who are treated with erythropoietin (epoetin alfa) for anemia of prematurity require a higher dosage of 4–6 mg/kg/day. Iron overload is a possibility in multiply transfused sick preterm infants; such infants should be evaluated with serum ferritin levels prior to beginning iron supplementation.

3. Apnea in the Preterm Infant

- Respiratory pause of sufficient duration to result in cyanosis or bradycardia.
- Most common in infants born before 34 weeks' gestation; onset before 2 weeks of age.
- Methylxanthines (eg, caffeine) provide effective treatment.

General Considerations

Apnea is defined as a respiratory pause lasting more than 20 seconds—or any pause accompanied by cyanosis and bradycardia. Shorter respiratory pauses associated with cyanosis or bradycardia also qualify as significant apnea, whereas periodic breathing, which is common in full-term and preterm infants, is defined as regularly recurring ventilatory cycles interrupted by short pauses *not* associated with bradycardia or color change. By definition, apnea of prematurity is not associated with a predisposing factor, and is a diagnosis

Table 2–15. Causes of apnea in the preterm infant.

Temperature instability—both cold and heat stress

Posthemorrhagic hydrocephalus
Seizures
Drugs (eg, morphine)
Apnea of prematurity

of exclusion. A variety of processes may precipitate apnea (Table 2–15) and should be considered before a diagnosis of apnea of prematurity is established.

Apnea of prematurity is the most frequent cause of apnea. Most apnea of prematurity is mixed apnea characterized by a centrally (brainstem) mediated respiratory pause preceded or followed by airway obstruction. Less common is pure central or pure obstructive apnea. Apnea of prematurity is the result of immaturity of both the central respiratory regulatory centers and protective mechanisms that aid in maintaining airway patency.

Clinical Findings

Onset is typically during the first 2 weeks of life. The frequency of spells gradually increases with time. Pathologic apnea should be suspected if spells are sudden in onset, unusually frequent, or very severe. Apnea at birth or on the first day of life is unusual but can occur in the nonventilated preterm infant. In the full-term or late preterm infant, presentation at birth suggests neuromuscular abnormalities of an acute (asphyxia, birth trauma, or infection) or chronic (eg, congenital hypotonia or structural CNS lesion) nature.

All infants—regardless of the severity and frequency of apnea—require a minimum screening evaluation, including a general assessment of well-being (eg, tolerance of feedings, stable temperature, normal physical examination), a check of the association of spells with feeding, measurement of Pao₂ or Sao₂, blood glucose, hematocrit, and a review of the drug history. Infants with severe apnea of sudden onset require more extensive evaluation for primary causes, especially infection.

Treatment

Any underlying cause should be treated. If the apnea is due simply to prematurity, symptomatic treatment is dictated by the frequency and severity of apneic spells. Spells frequent enough to interfere with other aspects of care (eg, feeding), or severe enough to cause cyanosis or bradycardia necessitating significant intervention or bag and mask ventilation require treatment. Caffeine citrate (20 mg/kg as loading dose and then 5-10 mg/kg/day) is the drug of choice. Side effects of caffeine are generally mild, and include tachycardia and occasional feeding intolerance. Target drug level, if monitored, is usually 10-20 mcg/mL. Nasal continuous positive airway pressure (CPAP), by treating the obstructive component of apnea, is effective in some infants. Intubation and ventilation can eliminate apneic spells but carry the risks associated with endotracheal intubation. Although many preterm infants are treated medically for possible refluxassociated apnea, there is little evidence to support this intervention. If suspected, a trial of continuous drip gastric or transpyloric feedings can be helpful as a diagnostic and therapeutic intervention.

Prognosis

In most premature infants, apneic and bradycardiac spells cease by 34–36 weeks postmenstrual age. Spells that require intervention cease prior to self-resolving episodes. In infants born at less than 28 weeks' gestation, episodes may continue past term. Apneic and bradycardiac episodes in the nursery are not predictors of later SIDS, although the incidence of SIDS is slightly increased in preterm infants. Thus, home monitoring in infants who experienced apnea in the nursery is rarely indicated.

4. Hyaline Membrane Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tachypnea, cyanosis, and expiratory grunting.
- Poor air movement despite increased work of breathing.
- Chest radiograph showing hypoexpansion and air bronchograms.

General Considerations

The most common cause of respiratory distress in the preterm infant is hyaline membrane disease. The incidence increases from 5% of infants born at 35–36 weeks' gestation to more than 50% of infants born at 26–28 weeks' gestation. This condition is caused by a deficiency of surfactant

▲ Figure 2–6. Pressure–volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. (Reproduced with permission from Fanaroff AA, Martin RJ: *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 6th ed. Mosby; 1997.)

production as well as surfactant inactivation by protein leak into airspaces. Surfactant decreases surface tension in the alveolus during expiration, allowing the alveolus to remain partly expanded and maintain a functional residual capacity. The absence or inactivation of surfactant results in poor lung compliance and atelectasis. The infant must expend a great deal of effort to expand the lungs with each breath, and respiratory failure ensues (Figure 2–6).

Clinical Findings

Infants with hyaline membrane disease show all the clinical signs of respiratory distress. On auscultation, air movement is diminished despite vigorous respiratory effort. The chest radiograph demonstrates diffuse bilateral atelectasis, causing a ground-glass appearance. Major airways are highlighted by the atelectatic air sacs, creating air bronchograms. In the unintubated child, doming of the diaphragm and hypoinflation occur.

Treatment

Supplemental oxygen, nasal CPAP, early intubation for surfactant administration and ventilation, and placement of umbilical artery and vein lines are the initial interventions required. A ventilator that can deliver breaths synchronized with the infant's respiratory efforts (synchronized intermittent mandatory ventilation) and accurately deliver a preset tidal volume (5–6 mL/kg) should be used. Alternatively, pressure limited ventilation with measurement of exhaled tidal volumes can be used. High-frequency ventilators are available for rescue of infants doing poorly on conventional ventilation.
Surfactant replacement is used both in the delivery room as prophylaxis for infants born before 27 weeks' gestation and with established hyaline membrane disease as rescue, preferably within 2-4 hours of birth. Surfactant therapy decreases both the mortality rate in preterm infants and air leak complications of the disease. During the acute course, ventilator settings and oxygen requirements are significantly lower in surfactant-treated infants than in controls. The dose of the bovine-derived beractant (Survanta) is 4 mL/kg, the calf lung surfactant extract (Infasurf) is 3 mL/kg, and the porcinederived poractant (Curosurf) is 1.25-2.5 mL/kg, given intratracheally. Repeat dosing is indicated in infants who remain on the ventilator in more than 30%-40% oxygen. A total of two to three doses given 8-12 hours apart may be administered. As the disease evolves, proteins that inhibit surfactant function leak into the air spaces, making surfactant replacement less effective. In stable infants, a trial of nasal CPAP at 5-6 cm H₂O pressure can be attempted prior to intubation and surfactant administration. For those who require mechanical ventilation, extubation to nasal CPAP should be done as early as possible to minimize lung injury and evolution of chronic lung disease. Nasal intermittent positive-pressure ventilation (NIPPV) is another modality that may be attempted for ventilatory support of the VLBW infant, with potential for less morbidity. Antenatal administration of corticosteroids to the mother is an important strategy to accelerate lung maturation. Infants whose mothers were given corticosteroids more than 24 hours prior to preterm birth are less likely to have respiratory distress syndrome and have a lower mortality rate.

5. Chronic Lung Disease in the Premature Infant

General Considerations

Chronic lung disease, defined as respiratory symptoms, oxygen requirement, and chest radiograph abnormalities at 36 weeks postconception, occurs in about 20% of preterm infants ventilated for surfactant deficiency. The incidence is higher at lower gestational ages and in infants exposed to chorioamnionitis prior to birth. The development of chronic lung disease is a function of lung immaturity at birth, inflammation, and exposure to high oxygen concentrations and ventilator volutrauma. Surfactant-replacement therapy or early nasal CPAP has diminished the severity of chronic lung disease. The mortality rate from chronic lung disease is very low, but there is still significant morbidity secondary to reactive airway symptoms and hospital readmissions during the first 2 years of life for intercurrent respiratory infection.

Treatment

Long-term supplemental oxygen, mechanical ventilation, and nasal CPAP are the primary therapies for chronic lung disease of the premature infant. Diuretics (furosemide,

1-2 mg/kg/day, or hydrochlorothiazide-spironolactone, 1-2 mg/kg/day), inhaled β_2 -adrenergics, inhaled corticosteroids (fluticasone or budesonide), and systemic corticosteroids (dexamethasone [0.2 mg/kg/day], prednisone [1-2 mg/kg/day], or hydrocortisone [4-5 mg/kg/day]) are used as adjunctive therapy. The use of systemic corticosteroids remains controversial. Although a decrease in lung inflammation can aid infants in weaning from ventilator support, there are data associating dexamethasone use in the first week of life with an increased incidence of cerebral palsy. This risk must be balanced against the higher risk of neurodevelopmental handicap in infants with severe chronic lung disease. There is likely a point in the course of these infants at which the benefit of using systemic corticosteroids for the shortest amount of time at the lowest dose possible outweighs the risk of continued mechanical ventilation. After hospital discharge, some of these infants will require oxygen at home. This can be monitored by pulse oximetry with a target Sao, of 94%-96%. Some will continue to manifest pulmonary symptomatology into adolescence.

6. Patent Ductus Arteriosus

- Hyperdynamic precordium.
- Widened pulse pressure.
- ► Hypotension.
- Presence of a systolic heart murmur in many cases.

General Considerations

Clinically significant patent ductus arteriosus usually presents on days 3–7 as the respiratory distress from hyaline membrane disease is improving. Presentation can be on days 1 or 2, especially in infants born before 28 weeks' gestation and in those who have received surfactant-replacement therapy. The signs include a hyperdynamic precordium, increased peripheral pulses, and a widened pulse pressure with or without a systolic machinery type heart murmur. Early presentations are sometimes manifested by systemic hypotension without a murmur or hyperdynamic circulation. These signs are often accompanied by an increased need for respiratory support and metabolic acidemia. The presence of patent ductus arteriosus is confirmed by echocardiography.

Treatment

Treatment of patent ductus arteriosus is by medical or surgical ligation. A clinically significant ductus can be closed with indomethacin (0.2 mg/kg IV q12h for three doses) in about two-thirds of cases. If the ductus reopens or fails to close completely, a second course of drug may be used or surgical ligation can be considered if the infant remains symptomatic. In addition, in the extremely low-birth-weight infant (< 1000 g) who is at very high risk of developing a symptomatic ductus, a prophylactic strategy of indomethacin (0.1 mg/kg q24h for 3-5 days) beginning on the first day of life may be used, with the possible additional benefit of decreasing the incidence of severe IVH, although there is no evidence of an effect on mortality or neurodevelopment. The most common side effect of indomethacin is transient oliguria, which can be managed by fluid restriction until urine output improves. Indomethacin should not be used if the infant is hyperkalemic, if the creatinine is higher than 2 mg/dL, or if the platelet count is less than 50,000/mL. There is an increased incidence of intestinal perforation if indomethacin is used concomitantly with hydrocortisone in extremely low-birth-weight infants (9% vs 2% for either drug alone). Ibuprofen lysine can be used as an alternative to indomethacin given every 24 hours as an initial dose of 10 mg/kg and then 5 mg/kg for two doses. Oliguria is less severe and less frequent than with indomethacin.

Sallmon H, Koehne P, Hansmann G: Recent advances in the treatment of preterm newborn infants with patent ductus arteriosus. Clin Perinatol 2016;43(3):113 [PMID: 26876125].

7. Necrotizing Enterocolitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Feeding intolerance with gastric residuals or vomiting.
- Bloody stools.
- Abdominal distention and tenderness.
- Pneumatosis intestinalis on abdominal radiograph.

General Considerations

NEC is the most common acquired GI emergency in the newborn. It is most common in preterm infants, with an incidence of 10% in infants less than 1500 g. In full-term

infants, it occurs in association with polycythemia, congenital heart disease, and birth asphyxia. The pathogenesis of NEC is multifactorial. Ischemia, immaturity, microbial dysbiosis (proliferation of pathogenic bacteria with less colonization with beneficial or commensal bacteria), and genetics are all thought to play a role. In up to 20% of affected infants, the only risk factor is prematurity. IUGR infants with a history of absent or reversed end-diastolic flow in the umbilical artery prior to delivery have abnormalities of splanchnic flow after delivery and have an increased risk of NEC.

Clinical Findings

The most common presenting sign is abdominal distention. Other signs are vomiting, increased gastric residuals, hemepositive stools, abdominal tenderness, temperature instability, increased apnea and bradycardia, decreased urine output, and poor perfusion. There may be an increased white blood cell count with an increased band count or, as the disease progresses, absolute neutropenia. Thrombocytopenia often occurs along with stress-induced hyperglycemia and metabolic acidosis. Diagnosis is confirmed by the presence of pneumatosis intestinalis (air in the bowel wall) or biliary tract air on a plain abdominal radiograph. There is a spectrum of disease, and milder cases may exhibit only distention of bowel loops with bowel wall edema.

Treatment

A. Medical Treatment

NEC is managed by making the infant NPO, nasogastric decompression of the gut, maintenance of oxygenation, mechanical ventilation if necessary, and IV fluids to replace third-space GI losses. Enough fluid should be given to restore good urine output. Other measures include broad-spectrum antibiotics (usually ampicillin, a third-generation cephalosporin or an aminoglycoside, and possibly additional anaerobic coverage), close monitoring of vital signs, and serial physical examinations and laboratory studies (blood gases, white blood cell count, platelet count, and radiographs). Although there are no proven strategies to prevent NEC, use of trophic feedings, breast milk, and cautious advancement of feeds, as well as probiotic agents, may provide some protection.

B. Surgical Treatment

Indications for surgery are evidence of perforation (free air present on a left lateral decubitus or cross-table lateral film), a fixed dilated loop of bowel on serial radiographs, abdominal wall cellulitis, or deterioration despite maximal medical support. All of these signs are indicative of necrotic bowel. In the operating room, necrotic bowel is removed and ostomies are created, although occasionally a primary end-to-end anastomosis may be performed. In extremely low-birth-weight infants, the initial surgical management may simply be the placement of peritoneal drains. Reanastomosis in infants with ostomies is performed after the disease resolves and the infant is bigger (usually > 2 kg and after 4–6 weeks).

Course & Prognosis

Infants treated medically or surgically should not be refed until the disease is resolved (normal abdominal examination and resolution of pneumatosis), usually after 7–10 days. Nutritional support during this time should be provided by total parenteral nutrition.

Death occurs in 10% of cases. Surgery is needed in less than 25% of cases. Long-term prognosis is determined by the amount of intestine lost. Infants with short bowel require long-term support with IV nutrition (see Chapter 21). Late strictures—about 3–6 weeks after initial diagnosis—occur in 8% of patients whether treated medically or surgically, and generally require operative management. Infants with surgically managed NEC have an increased risk of poor neurodevelopmental outcome.

Neu J, Walker A: Necrotizing enterocolitis. N Engl J Med 2011;364:255 [PMID: 21247316].

8. Anemia in the Premature Infant

General Considerations

In the premature infant, the hemoglobin concentration reaches its nadir at about 8–12 weeks and is 2–3 g/dL lower than that of the full-term infant. The lower nadir in premature infants appears to be the result of decreased erythropoietin response to the low red cell mass. Symptoms of anemia include poor feeding, lethargy, increased heart rate, poor weight gain, and perhaps periodic breathing.

Treatment

Transfusion is not indicated in an asymptomatic infant simply because of a low hematocrit. Most infants become symptomatic if the hematocrit drops below 20%. Infants on ventilators and supplemental oxygen are usually maintained with hematocrits above 25%–30%. Alternatively, infants can be treated with erythropoietin (350 U/kg/day for 7–10 days for hematocrits < 28%). The therapeutic goal is to minimize blood draws and use conservative guidelines for transfusion. Delayed cord clamping 1–2 minutes after birth, if possible, can significantly decrease the need for future transfusion. Use of erythropoietin may increase the rate and severity of retinopathy of prematurity, and should be used judiciously.

Hensch LA, Indrikovs AJ, Shattuck KE. Transfusion in extremely low-birth-weight premature neonates: current practice trends, risks, and early interventions to decrease the need for transfusion. NeoReviews 2015;16:e287.

9. Intraventricular Hemorrhage

- Large bleeds cause hypotension, metabolic acidosis, and altered neurologic status; smaller bleeds can be asymptomatic.
- Routine cranial ultrasound scanning is essential for diagnosis in infants born before 32 weeks' gestation.

General Considerations

Periventricular-intraventricular hemorrhage occurs almost exclusively in premature infants. The incidence is 15%-25% in infants born before 31 weeks' gestation and weighing less than 1500 g. The highest incidence occurs in infants of the lowest gestational age (< 26 weeks). Bleeding most commonly occurs in the subependymal germinal matrix (a region of undifferentiated cells adjacent to or lining the lateral ventricles). Bleeding can extend into the ventricular cavity. The proposed pathogenesis of bleeding is presented in Figure 2-7. The critical event is ischemia with reperfusion injury to the capillaries in the germinal matrix in the immediate perinatal period, in the face of immature cerebral pressure autoregulation. The actual amount of bleeding is also influenced by a variety of factors that affect the pressure gradient across the injured capillary wall, such as venous congestion. This pathogenetic scheme applies also to intraparenchymal bleeding (venous infarction in a region rendered ischemic) and to PVL (ischemic white matter injury in a water-shed region of arterial supply). CNS complications in preterm infants are more frequent in infants exposed to intrauterine and postnatal infection, implying also the involvement of inflammatory mediators in the pathogenesis of brain injury.

Clinical Findings

Up to 50% of hemorrhages occur before 24 hours of age, and virtually all occur by the fourth day. The clinical syndrome ranges from rapid deterioration (coma, hypoventilation, decerebrate posturing, fixed pupils, bulging anterior fontanelle, hypotension, acidosis, or acute drop in hematocrit) to a more gradual deterioration with more subtle neurologic changes, to absence of any specific physiologic or neurologic signs.

The diagnosis can be confirmed by real-time ultrasound scan. Routine scanning should be done at 10–14 days in all infants born before 29 weeks' gestation. Hemorrhages are graded as follows: grade I, germinal matrix hemorrhage only; grade II, intraventricular bleeding without ventricular enlargement; grade III, intraventricular bleeding with ventricular enlargement; or grade IV, any intraparenchymal

▲ Figure 2–7. Pathogenesis of periventricular and intraventricular hemorrhage.

bleeding. The amount of bleeding is minor (grade I or II) in 75% of infants who bleed and major in the remainder. Follow-up ultrasound examinations are scheduled based on the results of the initial scan. Infants with no bleeding or germinal matrix hemorrhage require only a single follow-up scan at age 4-6 weeks to look for PVL. An infant with blood in the ventricular system is at risk for posthemorrhagic ventriculomegaly. This is usually the result of impaired absorption of cerebrospinal fluid (CSF) but can also occur secondary to obstructive phenomena. An initial follow-up scan should be done 1-2 weeks after the first scan. Infants with intraventricular bleeding and ventricular enlargement should be followed every 7-10 days until ventricular enlargement stabilizes or decreases. Infants born at 29-32 weeks' gestational age need only a single late scan done at 4-6 weeks of age to look for PVL or ventriculomegaly.

Treatment

During acute hemorrhage, supportive treatment (restoration of volume and hematocrit, oxygenation, and ventilation) should be provided to avoid further cerebral ischemia. Progressive posthemorrhagic hydrocephalus is treated initially with a subgaleal shunt. When the infant is large enough, this can be converted to a ventriculoperitoneal shunt.

Although the incidence and severity of intracranial bleeding in premature infants have decreased, strategies to prevent this complication are still needed. Maternal antenatal corticosteroids appear to decrease the risk of intracranial bleeding, and phenobarbital may have a role in the mother who has not been prepared with steroids and is delivering before 28 weeks' gestation. Magnesium sulfate administered to the mother appears to reduce the rate of cerebral palsy, although not the rate of IVH per se. The route of delivery may be important as infants delivered by cesarean section have a decreased rate of intracranial bleed. Postnatal strategies are less effective. Early indomethacin administration may have some benefit in minimizing bleeding, especially in males, with unclear influence on long-term outcome.

Prognosis

No deaths occur as a result of grades I and II hemorrhages. Grades III and IV hemorrhages carry a mortality rate of 10%–20%. Posthemorrhagic ventricular enlargement is rarely seen with grade I hemorrhages but is seen in 54%–87% of grades II–IV hemorrhages. Very few of these infants will require a ventriculoperitoneal shunt. Long-term neurologic sequelae are seen slightly more frequently in infants with grades I and II hemorrhages than in preterm infants without bleeding. In infants with grades III and IV hemorrhages, severe sequelae occur in 20%–25% of cases, mild sequelae in 35% of cases, but no sequelae in 40% of cases. Severe PVL, large parenchymal bleeds, especially if bilateral, and progressive hydrocephalus increase the risk of neurologic sequelae. It is important to note that extremely low-birth-weight

43

infants without major ultrasound findings also remain at increased risk for both cerebral palsy and cognitive delays. Recent reports using quantitative MRI scans demonstrate that subtle gray and white matter findings not seen with ultrasound are prevalent in preterm survivors and are predictive of neurodevelopmental handicap. This is especially true in infants born weighing less than 1000 g and before 28 weeks' gestation.

Bass WT: Periventricular leukomalacia. NeoReviews 2011;12:e76. Whitelaw A: Core concepts: intraventricular hemorrhage. NeoReviews 2011;12:e94.

10. Retinopathy of Prematurity

- Risk of severe retinopathy is greatest in the most immature infants.
- Diagnosis depends on screening eye examinations in at-risk preterm infants.
- Examination evaluates stage of abnormal retinal vascular development, extent of retinal detachment, and distribution and amount of retina involved.

Retinopathy of prematurity occurs only in the incompletely vascularized premature retina. The incidence of retinopathy in infants weighing less than 1250 g is 66%, but only 6% have retinopathy severe enough to warrant intervention. The incidence is highest in infants of the lowest gestational age. The condition appears to be triggered by an initial injury to the developing retinal vessels and low levels of insulin-like growth factor-1. After the initial injury, normal vessel development may follow or abnormal vascularization may occur due to excessive vascular endothelial growth factor (VEGF), with ridge formation on the retina. Lability in oxygen levels with periods of hypoxia/hyperoxia likely potentiates this progression. The frequency of retinopathy progressing to the need for treatment can be diminished by careful monitoring of the infant's oxygen saturation levels. The process can regress at this point or may continue, with growth of fibrovascular tissue into the vitreous associated with inflammation, scarring, and retinal folds or detachment. The disease is graded by stages of abnormal vascular development and retinal detachment (I–V), by the zone of the eye involved (1–3, with zone 1 being the posterior region around the macula), and by the amount of the retina involved, in "clock hours" (eg, a detachment in the upper, outer quadrant of the left eye would be defined as affecting the left retina from 12 to 3 o'clock).

Initial eye examination should be performed at 31 weeks' postmenstrual age or at 4 weeks of age, whichever is earlier, in infants born at 30 weeks' gestation or less, as well as in infants up to 32 weeks' gestation with an unstable clinical course. Follow-up occurs at 1- to 3-week intervals, depending on the findings, until the retina is fully vascularized. Laser therapy is used in infants with progressive disease at risk for retinal detachment. Although this treatment does not always prevent retinal detachment, it reduces the incidence of poor outcomes based on visual acuity and retinal anatomy. A new form of therapy is intravitreal bevacizumab, an anti-VEGF monoclonal antibody, which may prove to be superior to laser therapy for severe Zone I and II retinopathy of prematurity.

11. Discharge & Follow-up of the Premature Infant

A. Hospital Discharge

Criteria for discharge of the premature infant include maintaining normal temperature in an open crib, adequate oral intake, acceptable weight gain, and absence of apnea and bradycardia spells requiring intervention. Infants going home on supplemental oxygen should not desaturate below 80% in room air or should demonstrate the ability to arouse in response to hypoxia. Factors such as support for the mother at home and the stability of the family situation play a role in the timing of discharge. Home nursing visits and early physician follow-up can be used to hasten discharge. Additionally, the AAP recommends that preterm infants have a period of observation in an infant car seat, preferably their own, before hospital discharge, with careful positioning to mimic optimal restraint as would occur in the car, to see that they do not have obstructive apnea or desaturation for periods up to 90-120 minutes.

B. Follow-up

With advances in obstetric and maternal care, survival of infants born after 28 weeks' gestation or weighing as little as 1000 g at birth is now better than 90%. Seventy to 80% survive at 26–27 weeks' gestation and birth weights of 800–1000 g. Survival at gestational age 25 weeks and birth weight 700–800 g is 50%–70%, with a considerable drop-off below this level.

These high rates of survival come with some morbidity. Major neurologic sequelae, including cerebral palsy, cognitive delay, and hydrocephalus, occur in 10%–25% of survivors of birth weight less than 1500 g. The rate of these sequelae tends to be higher in infants with lower birth weights. Infants with birth weights less than 1000 g also have an increased rate of lesser disabilities, including learning, behavioral, and psychiatric problems. Risk factors for neurologic sequelae include seizures, grade III or IV intracranial hemorrhage, PVL, ventricular dilation, white matter abnormalities on term-equivalent MRI examinations, severe IUGR, poor early head growth, need for mechanical ventilation, chronic lung disease, NEC, and low socioeconomic class. Maternal fever and chorioamnionitis are associated with an increased risk of cerebral palsy. Other morbidities include chronic lung disease and reactive airway disease, resulting in increased severity of respiratory infections and hospital readmissions in the first 2 years; retinopathy of prematurity with associated loss of visual acuity and strabismus; hearing loss; and growth failure. All of these issues require close multidisciplinary outpatient follow-up. Infants with residual lung disease are candidates for monthly palivizumab (Synagis) injections during their first winter after hospital discharge to prevent infection with respiratory syncytial virus. Routine immunizations should be given at the appropriate chronologic age and should not be agecorrected for prematurity.

THE LATE PRETERM INFANT

The rate of preterm births in the United States has increased by more than 30% in the past 30 years, so that preterm infants now comprise 12.8% of all births. Late preterm births, those from 34 0/7 to 36 6/7 weeks' gestation (Figure 2–8), have increased the most, and now account for over 70% of all preterm births. While births less than 34 weeks' gestation have increased by 10% since 1990, late preterm births have increased by 25%. This is in part due to changes in obstetric practice with an increase in inductions of labor (up from 9.5% in 1990 to 22.5% today), and an increase in cesarean sections (currently > 30% of all births), as well as a rise in multiple births and an increasing demand for cesarean section "at maternal request."

Compared with term infants, late preterm infants have higher prevalence of acute neonatal problems including respiratory distress, temperature instability, hypoglycemia, kernicterus, apnea, seizures, feeding problems, and rehospitalization after hospital discharge. The respiratory issues are caused by delayed clearance of lung fluid or surfactant deficiency, or both, and can progress to respiratory failure requiring mechanical ventilation, persistent pulmonary hypertension, and even ECMO support. Feeding issues are caused by immature coordination of suck and swallow, which can interfere with bottle feeding and cause failure to establish successful breast-feeding, putting the infant at risk for excessive weight loss and dehydration. These infants are nearly five times as likely as full-term infants to require either supplemental IV fluids, or gavage feedings. Related both to feeding issues and immaturity, late preterm infants have at least four times the risk of developing a bilirubin level above 20 mg/dL when compared with infants born after 40 completed weeks. As a consequence, late preterm gestation is a major risk factor for excessive hyperbilirubinemia and kernicterus. Rehospitalizations due to jaundice, proven or suspected infection, feeding difficulties, and failure to thrive are much more common than in term infants. Longterm development may also be adversely affected, with some large population-based studies showing a higher incidence of cerebral palsy, developmental delay, and behavioral and emotional disturbances compared with term infants.

Late preterm infants, even if similar in size to their term counterparts, should be considered preterm rather than near term, and require closer in-hospital monitoring after birth for complications. Although they may feed reasonably well for the first day or two, they often fail to increase feeding volume and become sleepier and less interested in feeding as they lose weight and become jaundiced, especially if younger than 36 weeks. Discharge of these newborns should be delayed until they have demonstrated reliable and appropriately increasing intake despite the expected weight loss and jaundice, and absence of other issues such as hypothermia, hypoglycemia, or apnea. If nursing, use of a breast pump to ensure adequate emptying of the breast and milk supply should also be instituted, along with supplementation of the infant's breast-feeding with expressed milk by bottle or gavage. It is better to ensure adequate feeding and mature behaviors for an extra day or two in the hospital than to have a readmission for "lethargy and poor feeding, possible sepsis" after premature discharge. Following nursery discharge, close outpatient follow-up is indicated, generally within 48-72 hours, to ensure continued adequate intake and weight gain.

Engle WA: Infants born late preterm: definition, physiologic and metabolic immaturity, and outcomes. NeoReviews 2009;10:e280.

CARDIAC PROBLEMS IN THE NEWBORN INFANT

STRUCTURAL HEART DISEASE

1. Cyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cyanosis, initially without associated respiratory distress.
- ► Failure to increase Pao, with supplemental oxygen.
- Chest radiograph with decreased lung markings suggests right heart obstruction, while increased lung markings suggest transposition or pulmonary venous obstruction.

General Considerations

The causes of cyanotic heart disease in the newborn are transposition of the great vessels, total anomalous pulmonary venous return, truncus arteriosus (some types), tricuspid atresia, and pulmonary atresia or critical pulmonary stenosis. Many are diagnosed antenatally by ultrasound.

Clinical Findings

Infants with these disorders present with early cyanosis. The hallmark of many of these lesions is cyanosis without associated respiratory distress. In most of these infants, tachypnea develops over time either because of increased pulmonary blood flow or secondary to metabolic acidemia from progressive hypoxemia. Diagnostic aids include comparing the blood gas or oxygen saturation in room air to that in 100% Fio₂. Failure of Pao₂ or Sao₂ to increase suggests cyanotic heart disease. Note: A Pao,, if feasible, is the preferred measure. Saturation in the newborn may be misleadingly high despite pathologically low Pao2 due to the left-shifted oxyhemoglobin dissociation curve seen with fetal hemoglobin. Other useful aids are chest radiography, electrocardiography, and echocardiography. Routine pulse oximetry screening in the first day of life is recommended for all infants, to detect subtle reductions in Sao, that may be the only initial sign of critical congenital heart disease.

Transposition of the great vessels is the most common form of cyanotic heart disease presenting in the newborn.

Examination may reveal a systolic murmur and single S₂. Chest radiograph shows cardiomegaly and a narrow mediastinum with normal or increased lung markings. There is little change in Pao₂ or Sao₂ with supplemental oxygen. Total anomalous pulmonary venous return, in which venous return is obstructed, presents early with severe cyanosis and respiratory failure because of severe pulmonary edema. The chest radiograph typically shows a small to normal heart size with marked pulmonary edema. Infants with rightsided heart obstruction (pulmonary and tricuspid atresia, critical pulmonary stenosis, and some forms of truncus arteriosus) have decreased lung markings on chest radiographs and, depending on the severity of hypoxia, may develop metabolic acidemia. Those lesions with an underdeveloped right-sided heart will have left-sided predominance on electrocardiography. Although tetralogy of Fallot is the most common form of cyanotic heart disease, the obstruction at the pulmonary valve is often not severe enough to result in cyanosis in the newborn. In all cases, diagnosis can be confirmed by echocardiography.

2. Acyanotic Presentations

- Most newborns with symptomatic acyanotic heart disease have left-sided outflow obstruction.
- Differentially diminished pulses (coarctation) or decreased pulses throughout (aortic atresia).
- Metabolic acidemia.
- Chest radiograph showing large heart and pulmonary edema.

General Considerations

Newborn infants who present with serious acyanotic heart disease usually have congestive heart failure secondary to left-sided outflow tract obstruction. Infants with left-to-right shunt lesions (eg, ventricular septal defect) may have murmurs in the newborn period, but clinical symptoms do not occur until pulmonary vascular resistance drops enough to cause significant shunting and subsequent congestive heart failure (usually at 3–4 weeks of age).

Clinical Findings

Infants with left-sided outflow obstruction generally do well in the first days of life until the ductus arteriosus—the source of all or some of the systemic flow—narrows. Tachypnea, tachycardia, congestive heart failure, and metabolic acidosis develop. On examination, these infants have abnormalities of the pulses. In aortic atresia (hypoplastic left-sided heart syndrome) and stenosis, all peripheral pulses are diminished, whereas in aortic coarctation, differential pulses (diminished or absent in the lower extremities) are evident, and Spo_2 and blood pressure may be lower in the legs than in the right upper extremity. Chest radiographic films in these infants show a large heart and pulmonary edema. Diagnosis is confirmed with echocardiography.

3. Treatment of Cyanotic & Acyanotic Lesions

Early stabilization includes supportive therapy as needed (eg, IV glucose, oxygen, ventilation for respiratory failure, and pressor support). Specific therapy includes infusions of prostaglandin E₁ (0.0125-0.025 mcg/kg/min) to maintain ductal patency. In some cyanotic lesions (eg, pulmonary atresia, tricuspid atresia, and critical pulmonary stenosis) in which lung blood flow is ductus-dependent, this improves pulmonary blood flow and Pao, by allowing shunting through the ductus to the pulmonary artery. In left-sided outflow tract obstruction, systemic blood flow is ductus-dependent; prostaglandins improve systemic perfusion and acidosis. Further specific management-including palliative surgical and cardiac catheterization procedures—is discussed in Chapter 20. Neurodevelopmental outcome with congenital heart disease depends on the lesion, associated defects and syndromes, severity of neonatal presentation, and complications related to palliative and corrective surgery.

PERSISTENT PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Onset of symptoms on day 1 of life.
- Hypoxia with poor response to high concentrations of inspired oxygen.
- Right-to-left shunts through the foramen ovale, ductus arteriosus, or both.
- Most often associated with parenchymal lung disease.

General Considerations

Persistent pulmonary hypertension of the newborn (PPHN) results when the normal decrease in pulmonary vascular resistance after birth does not occur. Most affected infants are full term or postterm, and many have experienced perinatal asphyxia. Other clinical associations include meconium aspiration syndrome, hyaline membrane disease, perinatal depression, neonatal sepsis, chronic intrauterine hypoxia, and pulmonary hypoplasia.

There are three underlying pathophysiologic mechanisms of PPHN: (1) vasoconstriction due to perinatal hypoxia related to an acute event such as sepsis or asphyxia; (2) prenatal increase in pulmonary vascular smooth muscle development, often associated with meconium aspiration syndrome; and (3) decreased cross-sectional area of the pulmonary vascular bed associated with lung hypoplasia (eg, diaphragmatic hernia).

Clinical Findings

Clinically, the syndrome is characterized by onset on the first day of life, usually from birth. Respiratory distress is prominent, and Pao₂ is usually poorly responsive to high concentrations of inspired oxygen. Many infants have associated myocardial depression with systemic hypotension. Echocardiography reveals right-to-left shunting at the level of the ductus arteriosus or foramen ovale, or both. The chest radiograph may show lung infiltrates related to associated pulmonary pathology (eg, meconium aspiration or hyaline membrane disease). If the majority of right-to-left shunting is at the ductal level, pre- and postductal differences in Pao₂ and Sao₂ will be observed.

Treatment

Therapy for PPHN involves treatment of associated multiorgan dysfunction. Specific therapy is aimed at both increasing systemic arterial pressure and decreasing pulmonary arterial pressure to reverse the right-to-left shunting through fetal pathways. First-line therapy includes oxygen and ventilation (to reduce pulmonary vascular resistance) and crystalloid infusions (10-30 mL/kg) to improve systemic pressure. Ideally, systolic pressure should be greater than 50-60 mm Hg. With compromised cardiac function, systemic pressors can be used as second-line therapy (eg, dopamine, 5-20 mcg/kg/min; epinephrine 0.05-0.3 mcg/kg/min; or both). Metabolic acidemia should be corrected because acidemia exacerbates pulmonary vasoconstriction. Pulmonary vasodilation can be enhanced using inhaled nitric oxide, at doses of 5-20 ppm. High-frequency oscillatory ventilation has proved effective in many of these infants, particularly those with severe associated lung disease, by improving lung expansion and recruitment. In cases in which conventional therapy is failing (poor oxygenation despite maximum support), ECMO is used. The lungs are essentially at rest during ECMO, and with resolution of pulmonary hypertension infants are weaned from ECMO back to ventilator therapy. Approximately 10%-15% of survivors of PPHN have significant neurologic sequelae, with cerebral palsy or cognitive delays. Other sequelae such as chronic lung disease, sensorineural hearing loss, and feeding problems have also been reported.

ARRHYTHMIAS

Irregularly irregular heart rates, commonly associated with premature atrial contractions and less commonly with premature ventricular contractions, are common in the first days of life in well newborns. These arrhythmias are typically benign. Clinically significant bradyarrhythmias are seen in association with congenital heart block. Heart block can be seen in an otherwise structurally normal heart (associated with maternal lupus) or with structural cardiac abnormalities. In the absence of fetal hydrops, the bradyarrhythmia is often well tolerated. Cardiac pacing may be required if there are symptoms of inadequate cardiac output.

Tachyarrhythmias can be either wide complex (ventricular tachycardia) or narrow complex (supraventricular tachycardia) on ECG. Supraventricular tachycardia is the most common neonatal tachyarrhythmia and may be a sign of structural heart disease, myocarditis, left atrial enlargement, and aberrant conduction pathways, or may be an isolated event. Acute treatment is ice to the face to induce a vagal response, and if unsuccessful, IV adenosine (50 mcg/kg). If there is no response, the dose can be increased every 2 minutes by 50 mcg/kg to a maximum dose of 250 mcg/kg. Long-term prophylactic antiarrhythmic therapy is generally indicated; cardiology consultation is suggested. Cardioversion is rarely needed for supraventricular tachycardia but is needed acutely for hemodynamically unstable ventricular tachycardia.

GASTROINTESTINAL & ABDOMINAL SURGICAL CONDITIONS IN THE NEWBORN INFANT

ESOPHAGEAL ATRESIA & TRACHEOESOPHAGEAL FISTULA

- Polyhydramnios (see also Chapter 21).
- Excessive drooling and secretions; choking with attempted feeding.
- Unable to pass an orogastric tube to the stomach.

General Considerations

Esophageal atresia is characterized by a blind esophageal pouch with or without a fistulous connection between the proximal or distal esophagus and the trachea. In 85% of infants, the fistula is between the distal esophagus and the airway. Polyhydramnios is common because of high GI obstruction. Incidence is approximately 1 in 3000 births.

Clinical Findings

Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis is confirmed with chest radiograph after careful placement of a nasogastric (NG) tube to the point at which resistance is met. The tube will be seen radiographically in the blind pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the bowel. In esophageal atresia without tracheoesophageal fistula, no gas is seen in the bowel.

Treatment

The NG tube in the proximal pouch should be placed on low intermittent suction to drain secretions and prevent aspiration. The head of the bed should be elevated to prevent reflux of gastric contents through the distal fistula into the lungs. IV glucose and fluids should be provided and oxygen administered as needed. Definitive treatment is surgical, and the technique used depends on the distance between the segments of esophagus. If the distance is short, the fistula can be ligated and the ends of the esophagus anastomosed. If the ends of the esophagus cannot be brought together, the initial surgery is fistula ligation and a feeding gastrostomy. Echocardiography should be performed prior to surgery to rule out a right-sided aortic arch (for which a left-sided thoracotomy would be preferred).

Prognosis

Prognosis is determined primarily by the presence or absence of associated anomalies, particularly cardiac, and low birth weight. Mortality is highest when the infant is less than 2000 g and has a serious associated cardiac defect. Vertebral, anal, cardiac, renal, and limb anomalies may be observed (VACTERL association). Evaluation for associated anomalies should be initiated early.

Kunisaki SM, Foker JE: Surgical advances in the fetus and neonate: esophageal atresia. Clin Perinatol 2012;39(2):349361 [PMID: 22682384].

INTESTINAL OBSTRUCTION

- Infants with high intestinal obstruction present soon after birth with emesis.
- Bilious emesis suggests intestinal malrotation with midgut volvulus until proved otherwise.
- Low intestinal obstruction is characterized by abdominal distention and late onset of emesis, often with delayed or absent stooling.

General Considerations

Intestinal obstruction is the most common surgical emergency seen in neonates. A history of polyhydramnios is common, and the fluid, if bile-stained, can easily be confused with thin meconium staining. The higher the location of the obstruction in the intestine, the earlier the infant will develop vomiting and the less prominent the abdominal distention will be. Lower intestinal obstruction presents with abdominal distention and later onset of emesis. Most obstructions are bowel atresias, often caused by an ischemic event during development. Approximately 30% of cases of duodenal atresia are associated with Down syndrome. Meconium ileus is a distal small bowel obstruction caused by viscous meconium produced in utero and may be the presenting symptom of cystic fibrosis. Hirschsprung disease is caused by a failure of neuronal migration to the myenteric plexus of the distal bowel. The distal bowel lacks ganglion cells, causing a lack of peristalsis in that region with a functional obstruction.

Malrotation with midgut volvulus is a surgical emergency that appears in the first days to weeks as bilious vomiting without distention or tenderness. If malrotation is not treated promptly, torsion of the intestine around the superior mesenteric artery will lead to necrosis of the entire small bowel. For this reason, bilious vomiting in the neonate always demands immediate attention and evaluation.

Clinical Findings

Diagnosis of intestinal obstructions depends on plain abdominal radiographs with either upper GI series (high obstruction suspected) or contrast enema (lower obstruction apparent) to define the area of obstruction. Table 2–16 summarizes the findings expected.

Infants with meconium ileus are presumed to have cystic fibrosis, although infants with pancolonic Hirschsprung disease, colon pseudo-obstruction syndrome, or colonic dysgenesis or atresia may also present with meconium impacted in the distal ileum. Definitive testing for cystic fibrosis by the sweat chloride test or genetic testing should be performed. Intestinal perforation in utero results in meconium peritonitis with residual intra-abdominal calcifications. Many perforations are completely healed at birth.

Site of Obstruction	Clinical Findings	Plain Radiographs	Contrast Study
Duodenal atresia	Down syndrome (30%–50%); early vomiting, sometimes bilious	"Double bubble" (dilated stomach and proximal duodenum, no air distal)	Not needed
Malrotation and volvulus	Bilious vomiting with onset anytime in the first few weeks	Dilated stomach and proximal duodenum; paucity of air distally (may be normal gas pattern)	UGI shows displaced duodenojejunal junction with "corkscrew" deformity of twisted bowel
Jejunoileal atresia, meconium ileus	Bilious gastric contents > 25 mL at birth; progressive distention and bilious vomiting	Multiple dilated loops of bowel; intra- abdominal calcifications if in utero perforation occurred (meconium peritonitis)	Barium or osmotic contrast enema shows microcolon; contrast refluxed into distal ileum may demonstrate and relieve meconium obstruction (successful in about 50% of cases)
Meconium plug syndrome; Hirschsprung disease	Distention, delayed stooling (> 24 h)	Diffuse bowel distention	Barium or osmotic contrast enema outlines and relieves plug; may show transition zone in Hirschsprung disease; delayed emptying (> 24 h) suggests Hirschsprung disease

Table 2–16. Intestinal obstruction.

UGI, upper gastrointestinal contrast study.

If the infant has no signs of obstruction or ongoing perforation, no immediate evaluation is needed. Low intestinal obstruction may present with delayed stooling (> 24 hours in term infants is abnormal) with mild distention. Radiographic findings of gaseous distention should prompt contrast enema to diagnose (and treat) meconium plug syndrome. If no plug is found, the diagnosis may be small left colon syndrome (occurring in IDMs) or Hirschsprung disease. Rectal biopsy is required to clarify these two diagnoses. Imperforate anus is generally apparent on physical examination, although a rectovaginal fistula with a mildly abnormal-appearing anus can occasionally be confused with normal. High imperforate anus in males may be associated with rectourethral or rectovesical fistula, with meconium "pearls" seen along the median raphe of the scrotum, and meconium being passed via the urethra.

Treatment

OG suction to decompress the bowel, IV glucose, fluid and electrolyte replacement, and respiratory support as necessary should be instituted. Antibiotics are usually indicated in the setting of bowel distention due to risk of bacterial translocation. The definitive treatment for these conditions (with the exception of meconium plug syndrome, small left colon syndrome, and some cases of meconium ileus) is surgical.

Prognosis

Up to 10% of infants with meconium plug syndrome are subsequently found to have cystic fibrosis or Hirschsprung disease. For this reason, it is appropriate to obtain a sweat chloride test and rectal biopsy in all of these infants before discharge, especially the infant with meconium plug syndrome who is still symptomatic after contrast enema.

In duodenal atresia associated with Down syndrome, the prognosis depends on associated anomalies (eg, heart defects) and the severity of prestenotic duodenal dilation and subsequent duodenal dysmotility. Otherwise, these conditions usually carry an excellent prognosis after surgical repair.

Juang D, Snyder C: Neonatal bowel obstruction. Surg Clin N Am 2012;92(3):685711 [PMID: 22595716].

ABDOMINAL WALL DEFECTS

1. Omphalocele

Omphalocele is a membrane-covered herniation of abdominal contents into the base of the umbilical cord; the incidence is 2 per 10,000 live births. Over 50% of cases have either an abnormal karyotype or an associated syndrome. The sac may contain liver and spleen as well as intestine. Prognosis varies with the size of the lesion, the presence of pulmonary hypoplasia and respiratory insufficiency, and the presence of associated abnormalities.

At delivery, the omphalocele is covered with a sterile dressing soaked with warm saline to prevent fluid loss. NG decompression is performed, and IV fluids, glucose, and antibiotics are given. If the contents of the omphalocele will fit into the abdomen and can be covered with skin, muscle, or both, primary surgical closure is done. If not, staged closure is performed, with placement of a Gore-Tex patch over the exposed contents, and gradual coverage of the patch by skin over days to weeks. A large ventral hernia is left, which is repaired in the future.

2. Gastroschisis

In gastroschisis, the uncovered intestine extrudes through a small abdominal wall defect to the right of the umbilical cord. There is no membrane or sac and no liver or spleen outside the abdomen. Gastroschisis is associated with intestinal atresia in approximately 10%-20% of infants, and with IUGR. The evisceration is thought to be related to abnormal involution of the right umbilical vein or a vascular accident involving the omphalomesenteric artery, although the exact cause is unknown. The prevalence of gastroschisis has been increasing worldwide over the past 20 years, from 0.03% to 0.1%. Environmental factors, including use of illicit drugs such as methamphetamine and cocaine, and cyclooxygenase inhibitors such as aspirin and ibuprofen taken during pregnancy, may be involved. Young maternal age is also strongly linked to the occurrence of gastroschisis.

Therapy initially involves placing the bowel or the lower half of the infant into a Silastic bowel bag to decrease fluid and electrolyte losses as well as to conserve heat. IV fluids, antibiotics, and low intermittent gastric suction are required. The infant is placed right side down to preserve bowel perfusion. Subsequent therapy involves replacement of the bowel into the abdominal cavity. This is done as a single primary procedure if the amount of bowel to be replaced is small. If the amount of bowel is large or if the bowel is much dilated, staged closure with placement of a Silastic silo and gradual reduction of the bowel into the underdeveloped abdominal cavity over several days is preferred. Perioperatively, thirdspace fluid losses may be extensive; fluid and electrolyte therapy, therefore, must be monitored carefully. Bowel motility may be slow to return if the bowel was dilated, thickened, matted together, and covered with a fibrinous "peel" at delivery. Prolonged intravenous nutrition is often required, but long-term outcome is very good.

Lakshminarayanan B, Lakhoo K: Abdominal wall defects. Early Hum Dev 2014;90(12):917920 [PMID: 25448781].

DIAPHRAGMATIC HERNIA

- Respiratory distress from birth.
- Poor breath sounds; flat or scaphoid abdomen.
- Bowel loops seen in the chest with mediastinal shift to opposite side on chest radiograph.

This congenital malformation consists of herniation of abdominal organs into the hemithorax (usually left-sided) through a posterolateral defect in the diaphragm. The incidence overall is 1 in 2500 births. It is usually diagnosed antenatally by ultrasound, and, if so, delivery should occur at a perinatal center. If undiagnosed, it should be suspected in any infant with severe respiratory distress, poor breath sounds, and a scaphoid abdomen. The rapidity and severity of presentation depend on several factors: the degree of pulmonary hypoplasia resulting from lung compression by the intrathoracic abdominal contents in utero; degree of associated pulmonary hypertension; and associated anomalies, especially chromosomal abnormalities and congenital cardiac defects. Affected infants are prone to development of pneumothorax during attempts at ventilation of the hypoplastic lungs.

Treatment includes intubation, mechanical ventilation, and decompression of the GI tract with an orogastric (OG) tube. An IV infusion of glucose and fluid should be started. Chest radiograph confirms the diagnosis. Surgery to reduce the abdominal contents from the thorax and close the diaphragmatic defect is delayed until after the infant is stabilized and pulmonary hypertension and compliance have improved, usually after 24-48 hours. Both pre- and postoperatively, pulmonary hypertension may require therapy with high-frequency oscillatory ventilation, inhaled nitric oxide, pressors, or ECMO. The survival rate for infants with this condition is improving, and now approaches 70%. Use of a gentle ventilation style and permissive hypercarbia is recommended to avoid barotrauma and further lung injury. Many of these infants have ongoing problems with pulmonary hypertension and severe gastroesophageal reflux, and are at risk for neurodevelopmental problems, behavior problems, hearing loss, and poor growth.

GASTROINTESTINAL BLEEDING

Upper Gastrointestinal Bleeding

Upper GI bleeding sometimes occurs in the newborn nursery but is rarely severe. Old blood ("coffee-grounds" material) in the stomach of the newborn may be either swallowed maternal blood or infant blood from gastritis or stress ulcer. Bright red blood from the stomach is most likely from acute bleeding due to gastritis or iatrogenic from trauma related to a nasogastric tube. Treatment generally consists of gastric lavage to obtain a sample for Apt testing or blood typing to determine if it is mother's or baby's blood, and antacid medication. If the volume of bleeding is large, intensive monitoring, fluid and blood replacement, and endoscopy are indicated. Coagulation studies should also be sent, and vitamin K administration confirmed or repeated.

Lower Gastrointestinal Bleeding

Rectal bleeding in the newborn is less common than upper GI bleeding and is associated with infections (eg, *Salmonella* acquired from the mother perinatally), milk protein intolerance (blood streaks with diarrhea), or, in ill infants, NEC. An abdominal radiograph should be obtained to rule out pneumatosis intestinalis or other abnormalities in gas pattern suggesting inflammation, infection, or obstruction. If the radiograph is negative and the examination is benign, a protein hydrolysate or elemental formula should be tried. The nursing mother should be instructed to avoid all cow milk protein products in her diet. If the amount of rectal bleeding is large or persistent, endoscopy may be needed.

Boyle JT: Gastrointestinal bleeding in infants and children. Pediatr Rev 2008;29:39 [PMID: 18245300].

GASTROESOPHAGEAL REFLUX

Physiologic regurgitation is common in infants. Reflux is pathologic and should be treated when it results in failure to thrive owing to excessive regurgitation, poor intake due to dysphagia, or chronic respiratory symptoms of wheezing and recurrent pneumonias suggestive of aspiration. Diagnosis is clinical, with confirmation by pH probe or impedance study. Barium radiography is helpful to rule out anatomic abnormalities causing delayed gastric emptying but is not diagnostic of pathologic reflux.

Most antireflux therapies have not been studied systematically in infants, especially in premature infants, and there is little correlation between clinical symptoms and documented gastroesophageal reflux events when studied. Treatment modalities have included thickened feeds for those with frequent regurgitation and poor weight gain, and positioning in a prone or left side down position for 1 hour after a feeding, although this may increase risk for SIDS. Gastric acid suppressants such as ranitidine (2 mg/kg bid) or lansoprazole (1.5 mg/kg/day) can also be used, especially if there is associated irritability; however, these may be associated with an increased incidence of NEC and invasive infections in the young and/or premature infant. Prokinetic agents such as erythromycin or metoclopramide are of little benefit and have significant side effects. Because most infants improve by 12–15 months of age, surgery is reserved for the most severe cases.

Rosen R: Gastroesophageal reflux in infants: more than just a pHenomenon. JAMA Pediatr 2014;168(1):8389 [PMID: 24276411]

INFECTIONS IN THE NEWBORN INFANT

There are three major routes of perinatal infection: (1) blood-borne transplacental infection of the fetus (eg, cyto-megalovirus [CMV], rubella, and syphilis); (2) ascending infection with disruption of the barrier provided by the amniotic membranes (eg, bacterial infections after 12–18 hours of ruptured membranes); and (3) infection on passage through an infected birth canal or exposure to infected blood at delivery (eg, herpes simplex, hepatitis B, HIV, and bacterial infections).

Susceptibility of the newborn infant to infection is related to immaturity of the immune system at birth. This feature applies particularly to the preterm neonate. Passive protection against some organisms is provided by transfer of IgG across the placenta, particularly during the third trimester of pregnancy. Preterm infants, especially those born before 30 weeks' gestation, do not have the full amount of passively acquired antibody.

BACTERIAL INFECTIONS

1. Bacterial Sepsis

- Most infants with early-onset sepsis present at < 24 hours of age.
- Respiratory distress is the most common presenting symptom.
- Hypotension, acidemia, and neutropenia are associated clinical findings.
- The presentation of late-onset sepsis is more subtle.

General Considerations

The incidence of early-onset (< 3 days) neonatal bacterial infection is 1-2 in 1000 live births. If rupture of the membranes occurs more than 24 hours prior to delivery, the infection rate increases to 1 in 100 live births. If early rupture of membranes with chorioamnionitis occurs, the infection

rate increases further to 1 in 10 live births. Regardless of membrane rupture, infection rates are five times higher in preterm than in full-term infants.

Clinical Findings

Early-onset bacterial infections appear most commonly on day 1 of life, the majority by 12 hours of age. Respiratory distress due to pneumonia is the most common presenting sign. Other features include unexplained low Apgar scores without fetal distress, poor perfusion, and hypotension. Late-onset bacterial infection (> 3 days of age) presents in a more subtle manner, with poor feeding, lethargy, hypotonia, temperature instability, altered perfusion, new or increased oxygen requirement, and apnea. Late-onset bacterial sepsis is more often associated with meningitis or other localized infections.

Low total white count, absolute neutropenia (< 1000/mL), and elevated ratio of immature to mature neutrophils all suggest neonatal bacterial infection. Thrombocytopenia is another common feature. Other laboratory signs are hypoglycemia or hyperglycemia, unexplained metabolic acidosis, and elevated C-reactive protein and procalcitonin. In earlyonset bacterial infection, pneumonia is often present; chest radiography shows infiltrates, but these infiltrates cannot be distinguished from those resulting from other causes of neonatal lung disease. Presence of a pleural effusion makes a diagnosis of pneumonia more likely. Definitive diagnosis is made by positive cultures from blood, CSF, or other body fluids.

Early-onset infection is most often caused by group B β -hemolytic streptococci (GBS) and gram-negative enteric pathogens (most commonly *E coli*). Other organisms to consider are nontypeable *Haemophilus influenzae*, *Enterococcus*, *Staphylococcus aureus*, other streptococci, and *Listeria monocytogenes*. Late-onset sepsis is caused by coagulase-negative staphylococci (most common in infants with indwelling central venous lines), *S aureus*, GBS, *Enterococcus*, and gram-negative organisms, in addition to *Candida* species (see section Fungal Sepsis).

Treatment

A high index of suspicion is important in diagnosis and treatment of neonatal infection. Infants with risk factors (rupture of membranes > 18 hours, maternal chorioamnionitis, prematurity) need to be carefully observed for signs of infection. Evaluation with a CBC and differential, blood and CSF cultures are indicated in infants with clinical signs of early sepsis. Early-onset sepsis is usually caused by GBS or gram-negative enteric organisms; broadspectrum coverage, therefore, should include ampicillin (100–150 mg/kg/day divided every 12 hours) plus an aminoglycoside (3–4 mg/kg/dose every 24 hours based on gestational age at birth) or third-generation cephalosporin

(cefotaxime 100 mg/kg/day divided every 12 hours). Lateonset infections can also be caused by the same organisms, but coverage may need to be expanded to include staphylococci. In particular, the preterm infant with an indwelling catheter is at risk for infection with coagulase-negative staphylococci, for which vancomycin (10-15 mg/kg every 8-24 hours based on gestational and postnatal age) is the drug of choice. Initial broad-spectrum coverage should also include a third-generation cephalosporin (cefotaxime or ceftazidime, if Pseudomonas aeruginosa is strongly suspected) or an aminoglycoside. To prevent the development of vancomycin-resistant organisms, vancomycin should be stopped as soon as cultures and sensitivities indicate that it is not needed. The evaluation for late-onset symptoms should include cultures of blood, urine, and CSF. The duration of treatment for proven sepsis is 10-14 days of IV antibiotics. In sick infants, the essentials of good supportive therapy should be provided: IV glucose and nutritional support, volume expansion and pressors as needed, and oxygen and ventilator support.

Prevention

Prevention of early-onset neonatal GBS infection has been achieved with intrapartum administration of penicillin given more than 4 hours prior to delivery, with overall rates of infection now at 0.3–0.4 cases per 1000 live births. The current guideline (Figure 2–9) is to perform a vaginal and rectal GBS culture at 35–37 weeks' gestation in all pregnant women. Prophylaxis with penicillin or ampicillin is given to GBS-positive women, to those who had GBS bacteriuria during the current pregnancy, to those who had a previous infant with invasive GBS disease, and to those who have unknown GBS status at delivery with risk factors for infection. Figure 2–10 presents an algorithm for secondary prevention of early-onset GBS infections in newborns.

2. Meningitis

Any newborn with bacterial sepsis is at risk for meningitis. The incidence is low in infants presenting in the first day of life, and higher in infants with later-onset infection. The workup for any newborn with possible signs of CNS infection should include a lumbar puncture because blood cultures can be negative in neonates with meningitis. The presence of seizures should increase the suspicion for meningitis. Diagnosis is suggested by a CSF protein level higher than 150 mg/dL, glucose less than 30 mg/dL, leukocytes of more than 20/µL, and a positive Gram stain. The diagnosis is confirmed by culture. The most common organisms are GBS and gram-negative enteric bacteria. Although sepsis can be treated with antibiotics for 10-14 days, meningitis requires 14-21 days. Gram-negative infections, in particular, are difficult to eradicate, and may relapse. The mortality rate of neonatal meningitis is approximately 10%, with significant neurologic morbidity present in one-third of the survivors.

3. Pneumonia

The respiratory system can be infected in utero, on passage through the birth canal, or postnatally. Early-onset neonatal

Intrapartum GBS prophylaxis indicated In	Intrapartum GBS prophylaxis not indicated	
Previous infant with invasive GBS disease	 Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy) 	
GBS bacteriuria during any trimester of the current pregnancy1	 GBS bacteriuria during previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy) 	
 Positive GBS vaginal-rectal screening culture in late gestation² during current pregnancy¹ 	 Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors 	
 Unknown GBS status at the onset of lab or (culture not done, incomplete, or results unknown) and any of the following: Delivery at < 37 weeks' cestation 	 Cesarean delivery performed before onset of labor on a woman wit intact amniotic membranes, regardless of GBS colonization status gestational age 	
- Amniotic membrane rupture ≥ 18 hours	gootalional ago	

Abbreviation: GBS, group B streptococcal; NAAT, nucleic acid amplification test

¹Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with interact amniotic membranes.

²Optimal timing for prenatal GBS screening as at 35–37 weeks' gestation.

- Intrapartum NATT⁴ positive for GBS

³If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis. ⁴NAAT testing for GBS is optional and might not be available in all settings, if intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at \leq 37 weeks' gestation, amniotic membrane rupture at \geq 18 hours, or temperature \geq 100.4°F [\geq 38.0°C]) is present, then intrapartum antibiotic prophylaxis is indicated.

▲ Figure 2–9. Indications for intrapartum antimicrobial prophylaxis to prevent early-onset group B streptococcal (GBS) disease using a universal prenatal culture screening strategy at 35–37 weeks' gestation for all pregnant women. (Reproduced with permission from Verani JR, McGee L, Schrag SJ, et al: Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. MMWR Recomm Rep 2010 Nov 19;59(RR-10):1–36.)

CHAPTER 2

Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (*if* respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).

[†]Antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.

SConsultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific. ILimited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).

**See Figure 2–13 for indications for intrapartum GBS prophylaxis.

^{††}If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.

\$ If \ge 37 weeks' gestation, observation may occur at home after 24 hours if other

discharge criteria have been met, access to medical care is readily available,

and a person who is able to comply fully with instructions for home observation will be present.

If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.

¹¹Some experts recommend a CBC with differential and platelets at age 6–12 hours.

▲ Figure 2–10. Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns. (Reproduced with permission from Verani JR, McGee L, Schrag SJ, et al: Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. MMWR Recomm Rep 2010 Nov 19;59(RR-10):1–36.)

infection is usually associated with pneumonia. Pneumonia should also be suspected in older neonates with a recent onset of tachypnea, retractions, and cyanosis. In infants already receiving respiratory support, an increase in the requirement for oxygen or ventilator support, perhaps with a change in the character of tracheal secretions, may indicate pneumonia. Not only common bacteria but also viruses (CMV, respiratory syncytial virus, adenovirus, influenza, herpes simplex, parainfluenza) and *Chlamydia* can cause pneumonia. In infants with preexisting respiratory disease, intercurrent pulmonary infections contribute to the development of chronic lung disease.

4. Urinary Tract Infection

Infection of the urine is uncommon in the first days of life. Urinary tract infection in the newborn can occur in association with genitourinary anomalies and is usually caused by gram-negative enteric pathogens, or *Enterococcus*. Urine should always be evaluated as part of the workup for later-onset infection. Culture should be obtained either by suprapubic aspiration or bladder catheterization. Antibiotic IV therapy is continued for 3–5 days if the blood culture is negative and clinical signs resolve quickly, and then completed with oral medications. Evaluation for genitourinary anomalies with an ultrasound examination and a voiding cystourethrogram should be done in most cases.

5. Omphalitis

A normal umbilical cord stump atrophies and separates at the skin level. A small amount of purulent material at the base of the cord is common and can be minimized by keeping the cord open to air and dry. The cord can become colonized with streptococci, staphylococci, or gram-negative organisms that can cause local infection. Infections are more common in cords manipulated for venous or arterial lines. Omphalitis is diagnosed when redness and edema develop in the soft tissues around the stump. Local and systemic cultures should be obtained. Treatment is with broad-spectrum IV antibiotics (usually nafcillin at 50-75 mg/kg/day divided every 8-12 hours) or vancomycin, a third-generation cephalosporin, and anaerobic coverage with metronidazole (15 mg/kg/day divided every 12 hours) as the infection may be polymicrobial. Complications are determined by the degree of infection of the cord vessels and include septic thrombophlebitis, hepatic abscess, necrotizing fasciitis, and portal vein thrombosis. Surgical consultation should be obtained because of the potential for necrotizing fasciitis.

6. Conjunctivitis

Neisseria gonorrhoeae may colonize an infant during passage through an infected birth canal. Gonococcal ophthalmitis presents at 3–7 days with copious purulent conjunctivitis. The diagnosis can be suspected when gram-negative intracellular diplococci are seen on a Gram-stained smear and confirmed by culture. Treatment for nondisseminated disease is with IV or IM ceftriaxone, 25–50 mg/kg (not to exceed 125 mg) given once. For disseminated disease (sepsis, arthritis, or meningitis) cefotaxime for 7–10 days is preferred. Prophylaxis at birth is with 0.5% erythromycin ointment. Infants born to mothers with known gonococcal disease should also receive a single dose of ceftriaxone. If significant hyperbilirubinemia is present, cefotaxime is preferred.

Chlamydia trachomatis is another important cause of conjunctivitis, appearing at 5 days to several weeks of age

with conjunctival congestion, edema, and minimal discharge. The organism is acquired at birth after passage through an infected birth canal. Acquisition occurs in 50% of infants born to infected women, with a 25%–50% risk of conjunctivitis. Prevalence in pregnancy is over 10% in some populations. Diagnosis is by isolation of the organism or by rapid antigen detection tests. Treatment is with oral erythromycin (30 mg/kg/day in divided doses q8–12h) for 14 days. Topical treatment alone will not eradicate nasopharyngeal carriage, leaving the infant at risk for the development of pneumonitis.

FUNGAL SEPSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Risk factors include low birth weight, indwelling central lines, and multiple antibiotic exposures.
- Colonization with Candida species is common; systemic infection occurs in 5%–7% of infants.
- Presents with often subtle clinical deterioration, thrombocytopenia, and hyperglycemia.

With the survival of smaller, sicker infants, infection with *Candida* species has become more common. Infants of extremely low birth weight with central lines who have had repeated exposures to broad-spectrum antibiotics are at highest risk. For infants of birth weight less than 1500 g, colonization rates of 27%–64% have been demonstrated. Many of these infants develop cutaneous lesions, with the GI tract as the initial site of colonization. A much smaller percentage develops systemic disease. Infection is more common in the smallest and least mature infants; up to 20% in infants 24 weeks' gestation, and 7% overall in those less than 1000 g.

Clinical features of fungal sepsis can be indistinguishable from those of late-onset bacterial sepsis but are often more subtle. Thrombocytopenia or hyperglycemia may be the earliest and only signs. Deep organ involvement (renal, eye, or endocarditis) is commonly associated with systemic candidiasis. Treatment is with intravenous fluconazole (12 mg/kg loading dose followed by 6 mg/kg daily) or an amphotericin B lipid complex (5 mg/kg given daily). Prophylaxis for those infants at highest risk, for example, with central venous lines and receiving parenteral nutrition, is recommended. Prophylaxis with fluconazole diminishes intestinal colonization with yeast and decreases the frequency of systemic disease, with an overall reduction in invasive candidal disease of 83%, from 9% to 1.6%, without significant adverse effects, or resistance to fluconazole. Nystatin prophylaxis may also be effective but has been less rigorously tested.

CONGENITAL INFECTIONS

- Can be acquired in utero, perinatally, and postnatally.
- Can be asymptomatic in the newborn period.
- Clinical symptom complexes include IUGR, chorioretinitis, cataracts, cholestatic jaundice, thrombocytopenia, skin rash, and brain calcifications.
- Diagnosis can be confirmed using polymerase chain reaction (PCR) testing, antigen and antibody studies, and culture.

1. Cytomegalovirus Infection

Cytomegalovirus (CMV) is the most common virus transmitted in utero, affecting approximately 1% of all newborns (see also Chapter 40). Symptomatic disease in the newborn period occurs in 10% of these congenitally infected infants, with a spectrum of findings including hepatosplenomegaly, petechiae and "blueberry muffin" spots, growth restriction, microcephaly, direct hyperbilirubinemia, thrombocytopenia, intracranial calcifications, and chorioretinitis. More than half of these infants will develop long-term sequelae, including sensorineural deafness in 20%-30%. Sensorineural hearing loss is common even in asymptomatic infants, leading to deafness in another 10%-15%. Transmission of CMV can occur during either primary or reactivated maternal infection; the risk of symptomatic neonatal disease is highest when the mother acquires a primary infection in the first half of pregnancy. Diagnosis in the neonate should be confirmed by culture of the virus from urine. Rapid diagnosis is possible with polymerase chain reaction (PCR) testing of urine or saliva. Diagnosis can also be confirmed in utero from an amniocentesis specimen. Oral valganciclovir therapy for 6 months is recommended for neonates with symptomatic congenital infection, particularly infections affecting the central nervous system, to prevent progression of hearing loss and neuronal damage. Infection can also be acquired around the time of delivery, and postnatally through blood transfusion or ingestion of CMV-infected

breast milk. These infections generally cause no symptoms or sequelae although hepatitis, pneumonia, and neurologic illness may occur in compromised seronegative premature infants. Transfusion risk can be minimized by using frozen, washed red blood cells; leukodepleted blood; or CMV antibody-negative donors.

2. Rubella

Congenital rubella infection occurs as a result of maternal rubella infection during pregnancy (see also Chapter 40). The risk of fetal infection and congenital defects is as high as 80%-85% in mothers infected during the first trimester, but after 12 weeks' gestation, the risk of congenital malformation decreases markedly. Features of congenital rubella syndrome include microcephaly and encephalitis; cardiac defects (patent ductus arteriosus and pulmonary arterial stenosis and arterial hypoplasia); cataracts, retinopathy, and microphthalmia; growth restriction, hepatosplenomegaly, thrombocytopenia, and purpura; and deafness. Affected infants can be asymptomatic at birth but develop clinical sequelae during the first year of life as the viral infection is persistent due to an inadequate immune response. The diagnosis should be suspected in cases of a characteristic clinical illness in the mother (rash, adenopathy, and arthritis) confirmed by an increase in serum rubella-specific IgM or culture of pharyngeal secretions in the infant. Congenital rubella is now rare in industrialized countries because of widespread immunization but is still possible due to the prevalence of unimmunized individuals in the population and widespread travel.

3. Varicella

Congenital varicella syndrome is rare (1%–2% after maternal varicella infection acquired during the first 20 weeks of pregnancy) and may include limb hypoplasia, cutaneous scars, microcephaly, cortical atrophy, chorioretinitis, and cataracts. Perinatal exposure (5 days before to 2 days after delivery) can cause severe to fatal disseminated varicella in the infant. If maternal varicella infection develops within this perinatal risk period, the newborn should receive varicellazoster immune globulin or IVIG. If this has not been done, subsequent illness can be treated with IV acyclovir.

Hospitalized premature infants of at least 28 weeks' gestation whose mothers have no history of chickenpox—and all infants younger than 28 weeks' gestational age—should receive varicella immune globulin following any postnatal exposure.

4. Toxoplasmosis

Toxoplasmosis is caused by the protozoan *Toxoplasma* gondii (see also Chapter 43). Maternal infection occurs in 0.1%–0.5% of pregnancies and is usually asymptomatic; it is

and learning disabilities within months to years. The sources of infection include exposure to cat feces and ingestion of raw or undercooked meat. Although the risk of transmission increases to 90% near term, fetal damage is most likely to occur when maternal infection occurs in the second to sixth month of gestation.

Clinical findings may include growth restriction, chorioretinitis, seizures, jaundice, hydrocephalus, microcephaly, intracranial calcifications, hepatosplenomegaly, adenopathy, cataracts, maculopapular rash, thrombocytopenia, and pneumonia. The serologic diagnosis is based on a positive toxoplasma-specific IgA, IgE, or IgM in the first 6 months of life, a rise in serial IgG levels compared to the mother's, or a persistent IgG beyond 12 months. Infants with suspected infection should have eye and auditory examinations and a computed tomographic (CT) scan of the brain. Organism isolation from placenta or cord blood and PCR tests on amniotic fluid or CSF are also available for diagnosis.

Spiramycin (an investigational drug in the United States) treatment of primary maternal infection is used to try to reduce transmission to the fetus. Neonatal treatment using pyrimethamine and sulfadiazine with folinic acid can improve long-term outcome.

5. Parvovirus B19 Infection

Parvovirus B19 is a small, nonenveloped, single-stranded DNA virus that causes erythema infectiosum (fifth disease) in children, with a peak incidence at ages 6–7 years. Transmission to the mother is primarily by respiratory secretions. The virus replicates initially in erythroid progenitor cells and induces cell-cycle arrest, resulting in severe anemia, myocarditis, nonimmune hydrops, or fetal death in approximately 3%–6% of fetuses infected during pregnancy. Resolution of the hydrops may occur in utero, either spontaneously or after fetal transfusion. Mothers who have been exposed may have specific serologic testing, and serial ultrasound, Doppler examinations, and percutaneous umbilical cord blood sampling of the fetus to assess for anemia. If the fetus survives, the long-term outcome is good with no late effects from the infection.

6. Congenital Syphilis

Active primary and secondary maternal syphilis leads to transplacental passage of *Treponema pallidum* to the fetus in nearly 100% of affected pregnancies while latent maternal infection leads to transplacental infection of the fetus in 40% of cases, and late maternal infection in 10% (see also Chapter 42). Fetal infection is rare before 18 weeks' gestation. Fetal infection can result in stillbirth or prematurity.

Findings of early congenital syphilis (presentation before age 2 years) include mucocutaneous lesions, lymphadenopathy, hepatosplenomegaly, bony changes, and hydrops, although newborn infants are often asymptomatic. Late manifestations (after 2 years of age) in untreated infants involve the central nervous system, bones and joints, teeth, eyes, and skin. An infant should be evaluated for congenital syphilis if he or she has proven or probable congenital syphilis, defined as a suggestive examination, serum quantitative nontreponemal titer more than fourfold the mother's, or positive darkfield or fluorescent antibody test of body fluids, or birth to a mother with positive nontreponemal tests confirmed by a positive treponemal test but without documented adequate treatment (parenteral penicillin G), including the expected fourfold decrease in nontreponemal antibody titer. Infants of mothers treated less than 1 month before delivery also require evaluation. Evaluation should include physical examination, a quantitative nontreponemal serologic test for syphilis, CBC, CSF examination for cell count and protein, Venereal Disease Research Laboratory testing, and long bone radiographs. Treatment in most cases is aqueous penicillin G (50,000 U/kg every 12 hours) or procaine penicillin G (50,000 U/kg IM daily) for 10 days.

7. Congenital Zika Infection

The Zika virus is a mosquito-borne virus that generally causes a mild and self-limited infection. Congenital Zika syndrome is a recently described constellation of congenital anomalies including microcephaly, intracranial calcifications or other brain abnormalities or ocular anomalies associated with maternal Zika infection during pregnancy. The exact risk of complications to the fetus because of congenital infection is unknown, with estimates ranging from a 1% to 13% risk of microcephaly following first-trimester infection. The CDC's current recommendation is to test for Zika infection in infants born to mothers with laboratory evidence of Zika infection during pregnancy and infants who have clinical features of congenital Zika infection and maternal history suggestive of exposure to Zika (travel to areas with high prevalence of infection). Testing should be done directly on the infant's blood (not cord blood) within 2 days of birth, if possible. Both molecular (blood PCR) and immunologic (IgM) testing is recommended. There is no treatment for congenital Zika infection.

PERINATALLY ACQUIRED INFECTIONS

1. Herpes Simplex

Herpes simplex virus infection is usually acquired at birth during transit through an infected birth canal (see also Chapter 40). The mother may have either primary or reactivated secondary infection. Primary maternal infection, because of the high titer of organisms and the absence of antibodies, poses the greatest risk to the infant. The risk of neonatal infection with vaginal delivery in this setting is 25%-50%. Seventy-five percent of mothers with primary herpes at the time of delivery are asymptomatic. The risk to an infant born to a mother with recurrent herpes simplex is much lower (< 1%). Time of presentation of localized (skin, eye, or mouth) or disseminated disease (pneumonia, shock, or hepatitis) in the infant is usually 5-14 days of age. CNS disease presents later, at 14-28 days with lethargy, fever, and seizures. In rare cases, presentation is as early as day 1 of life, suggesting in utero infection. In about 45% of patients, localized skin, eye, and mouth disease is the first indication of infection. Another 30% present with CNS disease, whereas the remaining 25% have disseminated or multiorgan disease indistinguishable from bacterial sepsis. Herpes infection should be considered in neonates with sepsis syndrome, negative bacteriologic culture results, and liver dysfunction or coagulopathy. Herpes simplex virus also should be considered as a causative agent in neonates with fever, irritability, and abnormal CSF findings, especially in the presence of seizures. PCR testing of vesicles, blood, or CSF is diagnostic but may be falsely negative in the CSF early in the course. If a blood or CSF PCR performed shortly after the onset of symptoms is negative, it should be repeated if herpes simplex virus disease is considered a strong possibility.

Acyclovir (60 mg/kg/day divided q8h) is the drug of choice for neonatal herpes infection. Localized disease is treated for 14 days, and a 21-day course is used for disseminated or CNS disease. Prompt initiation of therapy improves survival of neonates with CNS and disseminated disease and prevents the spread of localized disease. Prevention is possible by delivery by cesarean section within 6 hours after rupture of the membranes in the presence of known infection. Given the low incidence of infection in the newborn from recurrent maternal infection, cesarean delivery is not indicated for asymptomatic mothers with a history of recurrent herpes. Cesarean deliveries are performed in mothers with active lesions (either primary or recurrent) at the time of delivery. Infants born to mothers with a history of herpes simplex virus infection but no active lesions can be observed closely after birth, and do not need to be isolated. In infants born to mothers with active lesions-regardless of the route of delivery-cultures of the eye, oropharynx, nasopharynx, and rectum should be performed 24 hours after delivery, and the infant should be in contact isolation. If the infant is

colonized (positive cultures) or if symptoms consistent with herpes infection develop, treatment with acyclovir should be started. In cases of primary maternal genital infection at the time of vaginal delivery, infant specimens should be obtained and the infant treated with IV acyclovir for 10 days. The major problem facing perinatologists is the high percentage of asymptomatic primary maternal infection. In these cases, infection in the neonate is not currently preventable. Cultures should be obtained and acyclovir started, pending the results of those cultures, in any infant who presents at the right age with symptoms consistent with neonatal herpes.

The prognosis is good for localized skin and mucosal disease that does not progress, although skin recurrences are common. The mortality rate for disseminated herpes is high (approximately 30%), with significant morbidity among survivors of both disseminated (20%) and CNS (80%) infections despite treatment. Cutaneous recurrences are common in all types, and examination of the CSF should be considered with skin recurrences. Infants with herpes encephalitis should receive long-term oral acyclovir for 6 months after completion of intravenous treatment.

2. Hepatitis B & C

Infants become infected with hepatitis B at the time of birth; intrauterine transmission is rare. Clinical illness is rare in the neonatal period, but infants born to positive mothers are at risk of becoming chronic hepatitis B surface antigen (HBsAg) carriers and developing chronic active hepatitis, and even hepatocellular carcinoma. The presence of HBsAg should be determined in all pregnant women. If the result is positive, the infant should receive hepatitis B immune globulin (HBIG) and hepatitis B vaccine as soon as possible after birth, followed by two subsequent vaccine doses at 1 and 6 months of age. If HBsAg has not been tested prior to birth in a mother at risk, the test should be run after delivery and hepatitis B vaccine given within 12 hours after birth. If the mother is subsequently found to be positive, HBIG should be given as soon as possible (preferably within 48 hours, but not later than 1 week after birth). Subsequent vaccine doses should be given at 1 and 6 months of age. In premature infants born to HBsAg-positive mothers, vaccine and HBIG should be given at birth, but a three-vaccine hepatitis B series should be given beginning at 1 month of age.

Perinatal transmission of hepatitis C occurs in about 5% of infants born to mothers who carry the virus; maternal coinfection with HIV increases the risk of transmission. Serum antibody to hepatitis C and hepatitis C RNA have been detected in colostrum, but the risk of hepatitis C transmission is similar in breast-fed and bottle-fed infants. Up to 12 months of age, the only reliable screen for hepatitis C infection is PCR. After that time, the presence of hepatitis C antibodies in the infant strongly suggests that infection has occurred.

3. Enterovirus Infection

Enterovirus infections occur most frequently in the late summer and early fall. Infection is usually acquired in the perinatal period. There is often a history of maternal fever, diarrhea, and/or rash in the week prior to delivery. The illness appears in the infant in the first 2 weeks of life and is most commonly characterized by fever, lethargy, irritability, diarrhea, and/or rash. More severe forms occasionally occur, especially if infection occurs before 1 week of age, including meningoencephalitis, myocarditis, hepatitis, pneumonia, shock, and disseminated intravascular coagulation. Diagnosis is best confirmed by PCR.

Treatment is supportive care. The prognosis is good in most cases, except those with severe hepatitis, myocarditis, or disseminated disease, which carry high mortality rates.

4. HIV Infection

HIV can be acquired in utero or at the time of delivery, or can be transmitted postpartum via breast milk (see also Chapter 41). Testing for HIV should be performed in all pregnant women. Without treatment, transmission of virus occurs in 13%-39% of births to infected mothers, mostly at the time of delivery. The combination of maternal zidovudine treatment during pregnancy and of the infant for the first 6 weeks of life, elective cesarean delivery, and avoidance of breastfeeding can lower transmission to 1%-2%. Current guidelines for antiretroviral drugs in pregnant HIV-infected women are similar to those for nonpregnant patients (eg, highly active antiretroviral combination therapy). In cases of unknown HIV status at presentation in labor, rapid HIV testing should be offered, and, if positive, intrapartum maternal treatment and postpartum neonatal treatment should be offered. The risk of transmission is increased in mothers with advanced disease, high viral loads, low CD4 counts, and intrapartum events such as chorioamnionitis and prolonged membrane rupture that increase exposure of the fetus to maternal blood.

Newborns with congenitally acquired HIV are usually asymptomatic. Infants of HIV-infected women should be tested by HIV DNA PCR at less than 48 hours, at 2 weeks, at 1–2 months, and at 2–4 months. If an infant aged 4 months has a negative PCR result, infection can be reasonably excluded. HIV-positive mothers should be counseled not to breast-feed their infants if safe feeding alternatives are available.

HEMATOLOGIC DISORDERS IN THE NEWBORN INFANT

BLEEDING DISORDERS

Bleeding in the newborn infant may result from inherited clotting deficiencies (eg, factor VIII deficiency) or acquired disorders—hemorrhagic disease of the newborn (vitamin K deficiency), disseminated intravascular coagulation, liver failure, and isolated thrombocytopenia.

1. Vitamin K Deficiency Bleeding of the Newborn

- Frequently exclusively breast fed, otherwise clinically well infant.
- Bleeding from mucous membranes, GI tract, skin, or internal (intracranial).
- Prolonged prothrombin time (PT), relatively normal partial thromboplastin time (PTT), normal fibrinogen and platelet count.

Bleeding is caused by the deficiency of the vitamin K-dependent clotting factors (II, VII, IX, and X). Bleeding occurs in 0.25%-1.7% of newborns who do not receive vitamin K prophylaxis after birth, generally in the first 5 days to 2 weeks in an otherwise well infant. There is an increased risk in infants of mothers receiving therapy with anticonvulsants that interfere with vitamin K metabolism. Early vitamin K deficiency bleeding (0-2 weeks) can be prevented by either parenteral or oral vitamin K administration, whereas late disease (onset 2 weeks to 6 months) is most effectively prevented by administering parenteral vitamin K. Sites of ecchymoses and surface bleeding include the GI tract, umbilical cord, circumcision site, and nose, although devastating intracranial hemorrhage can occur. Bleeding from vitamin K deficiency is more likely to occur in exclusively breast-fed infants because of very low amounts of vitamin K in breast milk and slower and more restricted intestinal bacterial colonization. Differential diagnosis includes disseminated intravascular coagulation and hepatic failure. Coagulation studies reveal a prolonged prothrombin (PT) with normal partial thromboplastin time (PTT) and fibrinogen level.

Treatment consists of 1 mg of vitamin K SC or IV. IM injections should be avoided in infants who are actively bleeding. Such infants may also require factor replacement in addition to vitamin K administration.

2. Thrombocytopenia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Generalized petechiae; oozing at cord or puncture sites.
- Thrombocytopenia, often marked (platelets < 10,000– 20,000/mL).
- In an otherwise well infant, suspect isoimmune thrombocytopenia.
- In a sick or asphyxiated infant, suspect disseminated intravascular coagulation.

Infants with thrombocytopenia have generalized petechiae and platelet counts less than 150,000/mL (usually < 50,000/mL; may be < 10,000/mL). Neonatal thrombocytopenia can be isolated in a seemingly well infant or may occur in association with a deficiency of other clotting factors in a sick infant. The differential diagnosis for thrombocytopenia is presented in Table 2–17. Treatment of neonatal thrombocytopenia is transfusion of platelets (10 mL/kg of platelets increases the platelet count by ~70,000/mL). Indications for transfusion in the full-term infant are clinical bleeding or a total platelet count less than 10,000–20,000/mL. In the preterm infant at risk for intraventricular hemorrhage, transfusion is indicated for counts less than 40,000–50,000/mL.

Isoimmune (alloimmune) thrombocytopenia is analogous to Rh-isoimmunization, with a human platelet antigen [HPA]-1a (in 80%)- or HPA-5b (in 15%)-negative mother and an HPA-1a- or HPA-5b-positive fetus. Transplacental passage of IgG antibody leads to platelet destruction. If platelet transfusion is required for acute bleeding, washed maternal platelets may be the most readily available antigen-negative platelet source, because 98% of the general population will also be HPA-1a- or HPA-5b-positive. Treatment with IVIG infusion, 1 g/kg/day for 2-3 days, until the platelet count has doubled or is over 50,000/mL, is potentially beneficial. Twenty to thirty percent of infants with isoimmune thrombocytopenia will experience intracranial hemorrhage, half of them before birth. Antenatal therapy of the mother with IVIG with or without steroids may reduce this risk.

Infants born to mothers with idiopathic thrombocytopenic purpura are at low risk for serious hemorrhage despite the thrombocytopenia, and treatment is usually unnecessary. If bleeding does occur, IVIG can be used in addition to platelet transfusion. **Table 2–17.** Differential diagnosis of neonatal thrombocytopenia.

Disorder	Clinical Tips	
Immune Passively acquired antibody; idiopathic thrombocyto- penic purpura, systemic lupus erythematosus, drug-induced Isoimmune sensitization to HPA-1a antigen	Proper history, maternal thrombocytopenia No rise in platelet count from random donor platelet transfusion. Positive antiplatelet antibodies in baby's serum, sustained rise in platelets by transfusion of mother's platelets	
Infections Bacterial infections Congenital viral infections	Sick infants with other signs consistent with infection	
Syndromes Absent radii Fanconi anemia	Congenital anomalies, associated pancytopenia	
Disseminated intravascular coagulation (DIC)	Sick infants, abnormalities of clotting factors	
Giant hemangioma		
Thrombosis	Hyperviscous infants, vascular catheters	
High-risk infant with respiratory distress syndrome, pulmonary hypertension, etc	Isolated decrease in platelets is not uncommon in sick infants even in the absence of DIC (localized trapping)	

DIC, disseminated intravascular coagulation; HPA, human platelet antigen.

ANEMIA

- ► Hematocrit < 40% at term birth.
- Acute blood loss—signs of hypovolemia, normal reticulocyte count.
- Chronic blood loss—pallor without hypovolemia, elevated reticulocyte count.
- Hemolytic anemia—accompanied by excessive hyperbilirubinemia.

60

The newborn infant with anemia from acute blood loss presents with signs of hypovolemia (tachycardia, poor perfusion, and hypotension), with an initially normal hematocrit that falls after volume replacement. Anemia from chronic blood loss is evidenced by pallor without signs of hypovolemia, with an initially low hematocrit and reticulocytosis.

Anemia can be caused by hemorrhage, hemolysis, or failure to produce red blood cells. Anemia occurring in the first 24–48 hours of life is the result of hemorrhage or hemolysis. Hemorrhage can occur in utero (fetoplacental, fetomaternal, or twin-to-twin), perinatally (cord rupture, placenta previa, placental abruption, or incision through the placenta at cesarean section), or internally (intracranial hemorrhage, cephalohematoma, or ruptured liver or spleen). Hemolysis is caused by blood group incompatibilities, enzyme or membrane abnormalities, infection, and disseminated intravascular coagulation, and is accompanied by significant hyperbilirubinemia.

Initial evaluation should include a review of the perinatal history, assessment of the infant's volume status, and a complete physical examination. A Kleihauer-Betke test for fetal cells in the mother's circulation should be done. A CBC, blood smear, reticulocyte count, and direct and indirect Coombs tests should be performed. This simple evaluation should suggest a diagnosis in most infants. Most infants tolerate anemia quite well due to the increased oxygen availability in the extrauterine environment; however, treatment with erythropoietin or transfusion might be needed if the infant develops signs of cardiopulmonary compromise. Additionally, if blood loss is the cause of the anemia, early supplementation with iron will be needed. It is important to remember that hemolysis related to blood group incompatibility can continue for weeks after birth. Serial hematocrits should be followed, because late transfusion may be needed.

POLYCYTHEMIA

- ▶ Hematocrit > 65% (venous) at term.
- Plethora, tachypnea, retractions.
- ► Hypoglycemia, irritability, lethargy, poor feeding.

Polycythemia in the newborn is manifested by plethora, cyanosis, respiratory distress with tachypnea and oxygen need, hypoglycemia, poor feeding, emesis, irritability, and lethargy. Hyperbilirubinemia is expected. The consequence of polycythemia is hyperviscosity with decreased perfusion of the capillary beds. Clinical symptomatology can affect several organ systems (Table 2–18). Deep vein or artery

Central nervous system	Irritability, jitteriness, seizures, lethargy
Cardiopulmonary	Respiratory distress secondary to congestive heart failure, or persistent pulmonary hypertension
Gastrointestinal	Vomiting, heme-positive stools, distention, necrotizing enterocolitis
Renal	Decreased urinary output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

Table 2–18. Organ-related symptoms of hyperviscosity.

thrombosis is a severe complication. Screening can be done by measuring a capillary (heel stick) hematocrit. If the value is greater than 68%, a peripheral venous hematocrit should be measured. Values greater than 65% should be considered consistent with hyperviscosity.

Elevated hematocrits occur in 2%–5% of live births. Delayed cord clamping is the most common cause of benign neonatal polycythemia. Although 50% of polycythemic infants are AGA, the prevalence of polycythemia is greater in the SGA and LGA populations. Other causes of increased hematocrit include (1) twin-twin transfusion, (2) maternalfetal transfusion, and (3) chronic intrauterine hypoxia (SGA infants, and LGA infants of diabetic mothers).

Treatment should be considered for symptomatic infants. Treatment for asymptomatic infants based strictly on hematocrit is not indicated as there is no proven long-term benefit for neurodevelopmental outcome. Treatment for symptomatic infants is isovolemic partial exchange transfusion with normal saline, effectively decreasing the hematocrit. The amount to exchange (in milliliters) is calculated using the following formula:

> Number of milliliters to exchange = (PVH - DH)/PVH $\times BV(mL/kg) \times Wt (kg)$

where PVH is the peripheral venous hematocrit, DH is the desired hematocrit, BV is the blood volume in mL/kg, and Wt is the weight in kilograms.

Blood is withdrawn at a steady rate from an umbilical venous line while the replacement solution is infused at the same rate through a peripheral IV line over 15–30 minutes. The desired hematocrit value is 50%–55%; the assumed blood volume is 80 mL/kg.

RENAL DISORDERS IN THE NEWBORN INFANT

Renal function and the speed of maturation after birth depend on postmenstrual age (see also Chapter 24). The glomerular filtration rate is 20 mL/min/1.73 m² in full-term neonates and 10–13 mL/min/1.73 m² in infants born at 28–30 weeks' gestation. Creatinine can be used as a clinical marker of glomerular filtration rate. Values in the first month of life are shown in Table 2–19. Creatinine at birth reflects the maternal level and should decrease slowly over the first 3–4 weeks. An increasing serum creatinine is never normal.

The ability to concentrate urine and retain sodium also depends on gestational age. Infants born before 28–30 weeks' gestation are compromised in this respect and can easily become dehydrated and hyponatremic. Preterm infants also have an increased bicarbonate excretion and a low tubular maximum for glucose (~120 mg/dL).

RENAL FAILURE

- Clinical setting—birth depression, hypovolemia, hypotension, shock.
- Low or delayed urine output (< 1 mL/kg/h).</p>
- Rising serum creatinine; hyperkalemia; metabolic acidosis; fluid overload.

Renal failure is most commonly seen in the setting of birth asphyxia, hypovolemia, or shock from any cause. The normal rate of urine flow is 1–3 mL/kg/h. After a hypoxic or ischemic insult, acute tubular necrosis may ensue. Typically, 2–3 days of anuria or oliguria is associated with hematuria, proteinuria, and a rise in serum creatinine. The period of anuria or oliguria is followed by a period of polyuria and

then gradual recovery. During the polyuric phase, excessive urine sodium and bicarbonate losses may be seen.

The initial management is restoration of the infant's volume status. Thereafter, restriction of fluids to insensible water loss (40-60 mL/kg/day) without added electrolytes, plus milliliter-for-milliliter urine replacement, should be instituted. Serum and urine electrolytes and body weights should be followed frequently. These measures should be continued through the polyuric phase. Finally, many of these infants experience fluid overload and should be allowed to lose enough water through urination to return to birth weight. Hyperkalemia, which may become life-threatening, may occur in this situation despite the lack of added IV potassium. If the serum potassium reaches 7 mEq/L, therapy should be started with glucose and insulin infusion. Nebulized albuterol, IV Lasix, and binding resins per rectum may also be used to quickly decrease serum potassium levels. Calcium chloride (20 mg/kg bolus) and correction of metabolic acidosis with bicarbonate are also helpful in the acute management of arrhythmias resulting from hyperkalemia.

Peritoneal dialysis is occasionally needed for the management of neonatal acute renal failure and for removal of waste products and excess fluid. Hemodialysis, although possible, is difficult due to the small blood volume of the infant and problems with vascular access. Although most acute renal failure in the newborn resolves, ischemic injury severe enough to result in acute cortical necrosis and chronic renal failure can occur. Such infants are also at risk of developing hypertension.

URINARY TRACT ANOMALIES

Abdominal masses in the newborn are most frequently caused by renal enlargement. Most common is a multicystic or dysplastic kidney; congenital hydronephrosis is second in frequency. Chromosomal abnormalities and syndromes with multiple anomalies frequently include renal abnormalities. An ultrasound examination is the first step in diagnosis. In pregnancies complicated by oligohydramnios, renal agenesis or bladder outlet obstruction secondary to posterior urethral valves should be considered.

Only bilateral disease or disease in a solitary kidney is associated with oligohydramnios, significant morbidity, and death. Such infants will generally also have pulmonary hypoplasia, and present with pulmonary rather than renal insufficiency.

Ultrasonography identifies many infants with renal anomalies (most often hydronephrosis) prior to birth. Postnatal evaluation of infants with hydronephrosis should include renal ultrasound and a voiding cystourethrogram at about 1 week of age, depending on the severity of the antenatal findings. Earlier postnatal ultrasound might underestimate the severity of the hydronephrosis due to low glomerular filtration rates in the first days of life, although cases in which oligohydramnios or severe renal abnormality are suspected will be accurately diagnosed even on the first day of life. Voiding cystourethrogram is indicated to determine the severity of vesicoureteral reflux in the setting of significant hydronephrosis.

RENAL VEIN THROMBOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of IDM, birth depression, dehydration.
- Hematuria, oliguria.
- Thrombocytopenia, polycythemia.
- Renal enlargement on examination.

Renal vein thrombosis occurs most often in dehydrated polycythemic newborns. At particular risk is the IDM with polycythemia. If fetal distress is superimposed on polycythemia and dehydration, prompt reduction in blood viscosity is indicated. Thrombosis is unilateral in 70%, usually begins in intrarenal venules, and can extend into larger veins and the vena cava. Hematuria, oliguria, thrombocytopenia, and possibly an enlarged kidney raise suspicion for this diagnosis. With bilateral renal vein thrombosis, anuria ensues. Diagnosis can be confirmed with an ultrasound examination that includes Doppler flow studies of the kidneys. Treatment involves correcting the predisposing condition; systemic heparinization or the use of thrombolytics for this condition is controversial. Prognosis for a full recovery is uncertain. Many infants will develop significant atrophy of the affected kidney, and some develop systemic hypertension. All require careful follow-up.

Mistry K: Renal and urologic diseases of the newborn: neonatal acute kidney injury. Curr Pediatr Rev 2014;10(2):8891 [PMID: 25088261]

NEUROLOGIC PROBLEMS IN THE NEWBORN INFANT

SEIZURES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Usual onset at 12–48 hours.
- Seizure types include subtle (characterized by variable findings), tonic, and multifocal clonic.
- Most common causes include hypoxic-ischemic encephalopathy, intracranial bleeds, and infection.

Newborns rarely have well-organized tonic-clonic seizures because of their incomplete cortical organization and a preponderance of inhibitory synapses. The most common type of seizure is characterized by a constellation of findings, including horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking and other oralbuccal movements; swimming or bicycling movements; and desaturation and apneic spells. Strictly tonic or multifocal clonic episodes are also seen.

Clinical Findings

The differential diagnosis of neonatal seizures is presented in Table 2–20. Most neonatal seizures occur between 12 and 48 hours of age. Later-onset seizures suggest meningitis, benign familial seizures, or hypocalcemia. Information regarding antenatal drug use, the presence of birth asphyxia or trauma, and family history (regarding

Table 2–20. Differential diagnosis of neonatal seizures.

Diagnosis	Comment
Hypoxic-ischemic encephalopathy	Most common cause (60%), onset in first 24 h
Intracranial hemorrhage	Up to 15% of cases, periventricular/ intraventricular hemorrhage, subdural or subarachnoid bleeding, stroke
Infection	12% of cases
Hypoglycemia	Small for gestational age, IDM
Hypocalcemia, hypomagnesemia	Infant of low birth weight, IDM
Hyponatremia	Rare, seen with SIADH
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine dependency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
No cause found	10% of cases
Benign familial neonatal seizures	

IDM, infant of a diabetic mother; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

CHAPTER 2

inherited disorders) should be obtained. Physical examination focuses on neurologic features, other signs of drug withdrawal, concurrent signs of infection, dysmorphic features, and intrauterine growth. Screening workup should include blood glucose, ionized calcium, and electrolytes in all cases. Further workup depends on diagnoses suggested by the history and physical examination. In most cases, a lumbar puncture should be done. Hemorrhages, perinatal stroke, and structural disease of the CNS can be addressed with brain imaging (ultrasound, CT, MRI). Metabolic workup should be pursued when appropriate. EEG should be done; the presence of spike discharges must be noted and the background wave pattern evaluated. Correlation between EEG changes and clinical seizure activity is sometimes absent making a prolonged EEG with video monitoring a useful tool.

Treatment

Adequate ventilation and perfusion should be ensured. Hypoglycemia should be treated immediately with a 2-mL/kg infusion of $D_{10}W$ followed by IV glucose infusion. Other treatments such as calcium or magnesium infusion and antibiotics are indicated to treat hypocalcemia, hypomagnesemia, and suspected infection. Electrolyte abnormalities should be corrected. Phenobarbital (20 mg/kg IV) should be administered to stop seizures. Supplemental doses of 5 mg/kg can be used if seizures persist, up to a total of 40 mg/kg. If seizures persist, therapy with fosphenytoin or levetiracetam may be indicated. For refractory seizures, a trial of pyridoxine is indicated.

Prognosis

Outcome is related to the underlying cause of the seizure. The outcomes for hypoxic-ischemic encephalopathy and intraventricular hemorrhage have been discussed earlier in this chapter. In these settings, seizures that are difficult to control carry a poor prognosis for normal development. Seizures resulting from hypoglycemia, infection of the CNS, some inborn errors of metabolism, and developmental defects also have a high rate of poor outcome. Seizures caused by hypocalcemia or isolated subarachnoid hemorrhage generally resolve without sequelae.

Hypotonia

One should be alert to the diagnosis of congenital hypotonia when a mother has polyhydramnios and a history of poor fetal movement. The newborn may present with poor respiratory effort and birth asphyxia. For a discussion of causes and evaluation, see Chapter 25.

INTRACRANIAL HEMORRHAGE

1. Primary Subarachnoid Hemorrhage

Primary subarachnoid hemorrhage is the most common type of neonatal intracranial hemorrhage. In the full-term infant, it can be related to trauma of delivery, whereas subarachnoid hemorrhage in the preterm infant can be seen in association with germinal matrix hemorrhage. Clinically, these hemorrhages can be asymptomatic or can present with seizures and irritability on day 2, or rarely, a massive hemorrhage with a rapid downhill course. The seizures associated with subarachnoid hemorrhage are very characteristic—usually brief, with a normal examination interictally. Diagnosis can be suspected on lumbar puncture and confirmed with CT scan or MRI. Long-term follow-up is uniformly good.

2. Subdural Hemorrhage

Subdural hemorrhage is related to birth trauma; the bleeding is caused by tears in the veins that bridge the subdural space. Most commonly, subdural bleeding is from ruptured superficial cerebral veins, with blood over the cerebral convexities. These hemorrhages can be asymptomatic or may cause seizures, with onset on days 2–3 of life, vomiting, irritability, and lethargy. Associated findings include retinal hemorrhages and a full fontanelle. The diagnosis is confirmed by CT scan or MRI.

Specific treatment entailing needle drainage of the subdural space is rarely necessary. Most infants survive; 75% are normal on follow-up.

3. Neonatal Stroke

Focal cerebral ischemic injury can occur in the context of intraventricular hemorrhage in the premature infant and hypoxic-ischemic encephalopathy. Neonatal stroke has also been described in the context of underlying disorders of thrombolysis, maternal drug use (cocaine), a history of infertility, preeclampsia, prolonged membrane rupture, and chorioamnionitis. In some cases, the origin is unclear. The injury often occurs antenatally. The most common clinical presentation of an isolated cerebral infarct is with seizures, and diagnosis can be confirmed acutely with diffusion-weighted MRI scan. The most frequently described distribution is that of the middle cerebral artery.

Treatment is directed at controlling seizures. Use of anticoagulants and thrombolytics is controversial. Long-term outcome is variable, ranging from near normal to hemiplegias and cognitive deficits.

- van der aA NE et al: Neonatal stroke: a review of the current evidence on epidemiology, pathogenesis, diagnostics, and therapeutic options. Acta Paediatr 2014;103(4):356364 [PMID: 24428836].

METABOLIC DISORDERS IN THE NEWBORN INFANT

HYPERGLYCEMIA

Hyperglycemia may develop in preterm infants, particularly those of extremely low birth weight who are also SGA. Glucose concentrations may exceed 200–250 mg/dL, particularly in the first few days of life. This transient diabetes-like syndrome usually lasts approximately 1 week.

Management may include simply reducing glucose intake while continuing to supply IV amino acids to prevent protein catabolism with resultant gluconeogenesis and worsened hyperglycemia. Intravenous insulin infusions may be needed in infants who remain hyperglycemic despite glucose infusion rates of less than 5–6 mg/kg/min, but caution should be used as hypoglycemia is a frequent complication.

HYPOCALCEMIA

- Irritability, jitteriness, seizures (see also Chapter 34).
- Normal blood glucose.
- Possible dysmorphic features, congenital heart disease (DiGeorge syndrome).

Calcium concentration in the immediate newborn period decreases in all infants. The concentration in fetal plasma is higher than that of the neonate or adult. Hypocalcemia is usually defined as a total serum concentration less than 7 mg/dL (equivalent to a calcium activity of 3.5 mEq/L), although the physiologically active fraction, ionized calcium, should be measured whenever possible, and is usually normal even when total calcium is as low as 6–7 mg/dL. An ionized

calcium level above 0.9 mmol/L (1.8 mEq/L; 3.6 mg/dL) is not likely to be detrimental.

Clinical Findings

The clinical signs of hypocalcemia and hypocalcemic tetany include a high-pitched cry, jitteriness, tremulousness, and seizures.

Hypocalcemia tends to occur at two different times in the neonatal period. Early-onset hypocalcemia occurs in the first 2 days of life and has been associated with prematurity, maternal diabetes, asphyxia, and rarely, maternal hypoparathyroidism. Late-onset hypocalcemia occurs at approximately 7–10 days and is observed in infants receiving modified cow's milk rather than infant formula (high phosphorus intake), in infants with hypoparathyroidism (DiGeorge syndrome, 22q11 deletion), or in infants born to mothers with severe vitamin D deficiency. Hypomagnesemia should be sought and treated in cases of hypocalcemia that are resistant to treatment.

Treatment

A. Oral Calcium Therapy

The oral administration of calcium salts, often along with vitamin D, is the preferred method of treatment for chronic forms of hypocalcemia resulting from hypoparathyroidism. (See Chapter 34.)

B. Intravenous Calcium Therapy

IV calcium therapy is usually needed for infants with symptomatic hypocalcemia or an ionized calcium level below 0.9 mmol/L. A number of precautions must be observed when calcium is given intravenously. The infusion must be given slowly so that there is no sudden increase in calcium concentration of blood entering the right atrium, which could cause severe bradycardia and even cardiac arrest. Furthermore, the infusion must be observed carefully, because an IV infiltrate containing calcium can cause full-thickness skin necrosis requiring grafting. For these reasons, IV calcium therapy should be given judiciously and through a central venous line if possible. IV administration of 10% calcium gluconate is usually given as a bolus of 100-200 mg/kg (1-2 mL/kg) over approximately 10-20 minutes, followed by a continuous infusion (0.5-1 g/kg/day) over 1-2 days, if central venous access is available. Ten percent calcium chloride (20 mg/kg or 0.2 mL/kg per dose) may result in a larger increment in ionized calcium and greater improvement in mean arterial blood pressure in sick hypocalcemic infants and thus may have a role in the newborn. Note: Calcium salts cannot be added to IV solutions that contain sodium bicarbonate because they precipitate as calcium carbonate.

Prognosis

The prognosis is good for neonatal seizures entirely caused by hypocalcemia that is promptly treated.

INBORN ERRORS OF METABOLISM

- Altered level of consciousness (poor feeding, lethargy, seizures) in a previously well-appearing infant (see also Chapter 36).
- Tachypnea without hypoxemia or distress.
- Hypoglycemia, respiratory alkalosis, metabolic acidosis.
- Recurrent "sepsis" without proven infection.

Each individual inborn error of metabolism is rare, but collectively they have an incidence of 1 in 1000 live births. Expanded newborn genetic screening undoubtedly aids in the diagnosis of these disorders; however, many infants will present prior to these results being available. These diagnoses should be entertained when infants who were initially well present with sepsis-like syndromes, recurrent hypoglycemia, neurologic syndromes (seizures or altered levels of consciousness), or unexplained acidosis (suggestive of organic acidemias).

In the immediate neonatal period, urea cycle disorders present as an altered level of consciousness (coma) secondary to hyperammonemia. A clinical clue that supports this diagnosis is hyperventilation with primary respiratory alkalosis, along with low blood urea nitrogen. The other major diagnostic category to consider consists of infants with severe and unremitting acidemia secondary to organic acidemias.

QUALITY ASSESSMENT & IMPROVEMENT IN THE NEWBORN NURSERY & NICU

Quality improvement initiatives are critical for NICUs to provide the best care possible for patients. This involves recognition that there is a gap between care as it is and care as it could and should be. Clinical units either individually or as part of a consortium need to identify goals for improvement and carry out changes using a plan-do-study-act (PDSA) approach to rapid cycle improvements in care. This involves planning and enacting a change, studying and analyzing the data collected during the change and then acting to assess what changes are to be made for the next PDSA cycle. Individual units can benchmark their care through participation in multicenter databases such as the Vermont Oxford Network or Children's Hospitals Neonatal Consortium, in which many NICUs submit data. These data can form the framework for strategies to improve performance in areas in a unit that are below network standards. Examples of possible initiatives include lowering the incidence of central line-associated bacteremia, decreasing the incidence of ventilator-associated pneumonia or structured feeding protocols to decrease the incidence of necrotizing enterocolitis.

Garber SJ, Puopolo KM: Prevention of central line-associated bloodstream infections among infants in the neonatal intensive care unit. NeoReviews 2015;16:e211.

Child Development & Behavior

Edward Goldson, MD Ann Reynolds, MD

INTRODUCTION

This chapter provides an overview of typical development, identifies developmental variations, and discusses several developmental disorders. The chapter does not cover typical development in the newborn period or adolescence (see Chapters 2 and 4, respectively). It addresses behavioral variations that reflect the spectrum of normal development, along with developmental and behavioral disorders and their treatment. The developmental principle of ongoing change and maturation is integral to the daily practice of pediatrics. It is the basic science of pediatrics. For example, we recognize that a 3-month-old infant is very different from a 3-year-old toddler or a 13-year-old adolescent, not only with respect to what the child can do but also in terms of the kinds of illness he or she might have. From the perspective of the general pediatrician, all these areas should be viewed in the context of a "medical home." The medical home is defined as the setting that provides consistent, continuous, culturally competent, comprehensive, and sensitive care to children and their families. It is a setting that advocates for all children, whether they are typical or have developmental challenges or disabilities. By incorporating the principles of child development—the concept that children are constantly changing-the medical home is the optimum setting to understand and enhance typical development and to address variations, delays, and deviations as they may occur in the life trajectory of the child and the family.

NORMAL DEVELOPMENT

Typical children follow a trajectory of increasing physical size (http://www.cdc.gov/growthcharts/clinical_charts.htm) and increasing complexity of function. The first 5 years of life are a period of extraordinary physical growth and increasing complexity of function. The child triples his or

her birth weight within the first year and achieves two-thirds of his or her adult brain size by age $2\frac{1}{2}-3$ years of age. The child progresses from a totally dependent infant at birth to a mobile, verbal person who is able to express his or her needs and desires by age 2–3 years. In the ensuing 3 years the child further develops the capacity to interact with peers and adults, achieves considerable verbal and physical prowess, and becomes ready to enter the academic world of learning and socialization.

It is critical for the clinician to identify disturbances in development during these early years because there may be windows of time or sensitive periods when appropriate interventions may be instituted to effectively address developmental challenges.

THE FIRST 2 YEARS

From a motor perspective, children develop in a cephalocaudal direction. They can lift their heads with good control at 3 months, sit independently at 6 months, crawl at 9 months, walk at 1 year, and run by 18 months. The child learning to walk has a wide-based gait at first. Next, he or she walks with legs closer together, the arms move medially, a heeltoe gait develops, and the arms swing symmetrically by 18–24 months.

Clinicians often focus on gross motor development, but an appreciation of fine motor development and dexterity, particularly the grasp, can be instructive not only in monitoring normal development but also in identifying deviations in development. The grasp begins as a raking motion involving the ulnar aspect of the hand at age 3–4 months. The thumb is added to this motion at about age 5 months as the focus of the movement shifts to the radial side of the hand. The thumb opposes the fingers for picking up objects just before age 7 months, and the neat pincer grasp emerges at about age 9 months. Most young children have symmetrical movements. Children should not have a significant hand preference before 1 year of age and typically develop handedness between 18 and 30 months.

Language is a critical area to consider as well. Communication is important from birth (Figure 3–1, see Table 3–2), particularly the nonverbal, reciprocal interactions between infant and caregiver. By age 2 months, these interactions begin to include melodic vowel sounds called *cooing* and reciprocal vocal play between parent and child. Babbling, which adds consonants to vowels, begins by age 6–10 months, and the repetition of sounds such as "da-dadada" is facilitated by the child's increasing oral muscular control. Babbling reaches a peak at age 12 months. The child then moves into a stage of having needs met by using individual words to represent objects or actions. It is common at this age for children to express wants and needs by pointing to objects or using other gestures. Children usually have 5–10 comprehensible words by 12–18 months; by age 2 years they are putting 2–3 words into phrases, 50% of which their caregivers can understand (Tables 3–1 and 3–2; see Figure 3–1). The acquisition of expressive vocabulary varies greatly between 12 and 24 months of age. As a group, males and children who are bilingual tend to develop expressive language more slowly during that time. It is important to note, however, that for each individual, milestones should still fall within the expected range. Gender and exposure to two languages should never be used as an excuse for failing to refer a child who has significant delay in the acquisition of speech and language for further evaluation. It is also

▲ Figure 3–1. Early Language Milestone Scale-2. (Reproduced with permission from Coplan J: Early Language Milestone Scale, 2nd edition. Austin: Pro Ed; 1993.)

Table 3–1. Developmental charts.

1–2 mo

Activities to be observed:

Holds head erect and lifts head. Turns from side to back. Regards faces and follows objects through visual field. Drops toys. Becomes alert in response to voice.

Activities related by parent:

Recognizes parents. Engages in vocalizations. Smiles spontaneously.

3–5 mo

Activities to be observed:

Grasps cube—first ulnar then later thumb opposition. Reaches for and brings objects to mouth. Makes "raspberry" sound. Sits with support.

Activities related by parent:

Laughs. Anticipates food on sight. Turns from back to side.

6–8 mo

Activities to be observed:

Sits alone for a short period. Reaches with 1 hand. First scoops up a pellet; then grasps it using thumb opposition. Imitates "bye-bye." Passes object from hand to hand in midline. Babbles.

Activities related by parent:

Rolls from back to stomach. Is inhibited by the word *no*.

9–11 mo

Activities to be observed:

Stands alone.

Imitates pat-a-cake and peek-a-boo.

Uses thumb and index finger to pick up pellet.

Activities related by parent:

Walks by supporting self on furniture. Follows 1-step verbal commands, eg, "Come here," "Give it to me."

1у

Activities to be observed:

Walks independently. Says "mama" and "dada" with meaning. Can use a neat pincer grasp to pick up a pellet. Releases cube into cup after demonstration. Gives toys on request. Tries to build a tower of 2 cubes.

Activities related by parent:

Points to desired objects. Says 1 or 2 other words.

18 mo

Activities to be observed:

- Builds tower of 3–4 cubes. Throws ball. Seats self in chair. Dumps pellet from bottle. Activities related by parent: Walks up and down stairs with help. Says 4–20 words. Understands a 2-step command. Carries and hugs doll.
 - Feeds self.

24 mo

Activities to be observed:

Speaks short phrases, 2 words or more. Kicks ball on request. Builds tower of 6–7 cubes. Points to named objects or pictures. Jumps off floor with both feet. Stands on either foot alone. Uses pronouns. Activities related by parent: Verbalizes toilet needs. Pulls on simple garment. Turns pages of book singly. Plays with domestic mimicry.

30 mo

Activities to be observed: Walks backward. Begins to hop on 1 foot. Uses prepositions. Copies a crude circle. Points to objects described by use. Refers to self as I. Holds crayon in fist. Activities related by parent: Helps put things away. Carries on a conversation.

3 у

Activities to be observed: Holds crayon with fingers. Builds tower of 9–10 cubes. Imitates 3-cube bridge. Copies circle. Gives first and last name. Activities related by parent: Rides tricycle using pedals. Dresses with supervision.

CHAPTER 3

3–4 у

Activities to be observed:

Climbs stairs with alternating feet.

Begins to button and unbutton.

"What do you like to do that's fun?" (Answers using plurals, personal pronouns, and verbs.)

Responds to command to place toy in, on, or under table.

Draws a circle when asked to draw a person.

Knows own sex. ("Are you a boy or a girl?")

Gives full name.

Copies a circle already drawn. ("Can you make one like this?") Activities related by parent:

Feeds self at mealtime.

Takes off shoes and jacket.

4–5 y

Activities to be observed:

Runs and turns without losing balance.

May stand on 1 leg for at least 10 seconds.

Buttons clothes and laces shoes. (Does not tie.)

- Counts to 4 by rote. "Give me 2 sticks." (Able to do so from pile of 4 tongue depressors.)
- Draws a person. (Head, 2 appendages, and possibly 2 eyes. No torso yet.)

Knows the days of the week. ("What day comes after Tuesday?") Gives appropriate answers to: "What must you do if you are sleepy? Hungry? Cold?" Copies + in imitation.

Activities related by parent:

Self-care at toilet. (May need help with wiping.) Plays outside for at least 30 minutes. Dresses self except for tying.

5–6 у

Activities to be observed:

Can catch ball.

Skips smoothly.

Copies a + already drawn.

Tells age.

Concept of 10 (eg, counts 10 tongue depressors). May recite to higher number by rote.

Knows right and left hand.

Draws recognizable person with at least 8 details.

Can describe favorite television program in some detail.

Activities related by parent:

Does simple chores at home (eg, taking out garbage, drying silverware).

Goes to school unattended or meets school bus.

Good motor ability but little awareness of dangers.

6–7 у

Acti	viti	es	to	be	observed:	
	-			-		

Copies a Δ .

Defines words by use. ("What is an orange?" "To eat.") Knows if morning or afternoon. Draws a person with 12 details. Reads several 1-syllable printed words. (My, dog, see, boy.)

7–8 y

Activities to be observed:

Counts by 2s and 5s. Ties shoes. Copies a ◊.

Knows what day of the week it is. (Not date or year.)

No evidence of sound substitution in speech (eg, fr for thr).

Draws a man with 16 details.

Reads paragraph #1 Durrell:

Reading:

Muff is a little yellow kitten. She drinks milk. She sleeps on a chair. She does not like to get wet.

Corresponding arithmetic:

7	6	6	8
+4	+7	4	-3

Adds and subtracts 1-digit numbers.

8–9 y

Activities to be observed:

Defines words better than by use. ("What is an orange?" "A fruit.") Can give an appropriate answer to the following:

"What is the thing for you to do if ...

- -you've broken something that belongs to someone else?"
- —a playmate hits you without meaning to do so?" Reads paragraph #2 Durrell:

Readina:

A little black dog ran away from home. He played with two big dogs. They ran away from him. It began to rain. He went under a tree. He wanted to go home, but he did not know the way. He saw a boy he knew. The boy took him home.

Corresponding arithmetic:

	67		
67	16	14	- 84
+4	+27	-8	- 30

Is learning borrowing and carrying processes in addition and subtraction.

9–10 y

Activities to be observed: Knows the month, day, and year. Names the months in order. (15 s, 1 error.) Makes a sentence with these 3 words in it: (1 or 2. Can use words

orally in proper context.)

1. work ... money ... men

2. boy ... river ... ball

Reads paragraph #3 Durrell:

Reading:

Six boys put up a tent by the side of a river. They took things to eat with them. When the sun went down, they went into the tent to sleep. In the night, a cow came and began to eat grass around the tent. The boys were afraid. They thought it was a bear.

Should comprehend and answer the question: "What was the cow doing?"

Corresponding arithmetic:

5204	23	837
-530	<u>×3</u>	<u>×7</u>

Learning simple multiplication.

Table 3-1. Developmental charts. (Continued)		
10–12 y Activities to be observed: Should read and comprehend paragraph #5 Durrell: Reading: In 1807, Robert Fulton took the first long trip in a steamboat. He went one hundred and fifty miles up the Hudson River. The boat went five miles an hour. This was faster than a	Reading: Golf originated in Holland as a game played on ice. The game in its present form first appeared in Scotland. It became unusually popular and kings found it so enjoyable that it was known as "the royal game." important to note that most children are not truly bilingual. Most children have one primary language, and any other languages are secondary.

Receptive language usually develops more rapidly than expressive language. Word comprehension begins to increase at age 9 months, and by age 13 months the child's receptive vocabulary may be as large as 20–100 words. After age 18 months, expressive and receptive vocabularies increase dramatically, and by the end of the second year there is typically a quantum leap in language development. The child begins to put together words and phrases, and begins to use language to represent a new world, the symbolic world. Children begin to put verbs into phrases and focus much of their language on describing their new abilities, for example, "I go out." They begin to incorporate prepositions, such as "I" and "you" into speech and ask "why?" and "what?" questions more frequently. They also begin to appreciate time factors and to understand and use this concept in their speech.

The Early Language Milestone Scale-2 is a simple tool for assessing early language development in the pediatric office setting. Another frequently used screening tool for the ambulatory setting is Ages and Stages.

ambulatory setting is Ages and Stages. One may memorize the developmental milestones that characterize the trajectory of the typical child; however, these milestones become more meaningful and clinically useful if placed in empirical and theoretical contexts. The first 2 years of life have been described as the sensorimotor period, during which infants learn with increasing sophistication how to link sensory input from the environment with a motor response. Infants build on primitive reflex patterns of behavior (termed *schemata*; sucking is an example) and constantly incorporate or assimilate new experiences. The schemata evolve over time as infants accommodate new experiences and as new levels of cognitive ability unfold in an orderly sequence. This period of behavioral development follows the neurologic development of neural networks through dendritic branching and pruning (apoptosis).

In the first year of life, the infant's perception of reality revolves around itself and what it can see or touch. The infant follows the trajectory of an object through the field of vision, but before age 6 months the object ceases to exist once it leaves the infant's field of vision. At age 9–12 months, the infant gradually develops the concept of object permanence, or the realization that objects exist even when not seen. The development of object permanence correlates with enhanced frontal activity appearing on the electroencephalogram (EEG). The concept attaches first to the image of the mother or primary caregiver because of his or her emotional importance and is a critical part of attachment behavior (discussed later). In the second year, children extend their ability to manipulate objects by using instruments, first by imitation and later by trial and error.

Age	Speech	Language	Articulation
1 mo	Throaty sounds		Vowels: \ah \uh \ee\
2 mo	Vowel sounds ("eh"), coos		
2½ mo	Squeals		
3 mo	Babbles, initial vowels		
4 mo	Guttural sounds ("ah," "go")		Consonants: m, p, b
5 mo			Vowels: \o \u\
7 mo	Imitates speech sounds		
8 mo			Syllables: da, ba, ka
10 mo		"Dada" or "mama" nonspecifically	Approximates names: baba/bottle
12 mo	Jargon begins (own language)	1 word other than "mama" or "dada"	Understandable: 2–3 words
13 mo		3 words	
16 mo		6 words	Consonants: t, d, w, n, h
18–24 mo		2-word phrases	Understandable 2-word phrases
24–30 mo		3-word phrases	Understandable 3-word phrases
2 у	Vowels uttered correctly	Approximately 270 words; uses pronouns	Approximately 270 words; uses phrases
3 у	Some degree of hesitancy and uncertainty common	Approximately 900 words; intelligible 4-word phrases	Approximately 900 words; intelligible 4-word
4 y		Approximately 1540 words; intelligible 5-word phrases or sentences	Approximately 1540 words; intelligible 5-word phrases
б у		Approximately 2560 words; intelligible 6- or 7-word sentences	Approximately 2560 words; intelligible 6- or 7-word sentences
7–8 у	Adult proficiency		

Table 3-2. Normal speech and language development.

Data from Berry MF: Language Disorders of Children. Appleton-Century-Crofts; 1969; and from Bzoch K, League R: Receptive Expressive Emergent Language Scale. University Park Press; 1970.

In the first year of life, there is a bidirectional attachment process called *bonding*. The parents learn to be aware of and to interpret the infant's cues, which reflect its needs. A more sensitive emotional interaction process develops that can be seen in the mirroring of facial expressions by the primary caregiver and infant and in their mutual engagement in cycles of attention and inattention, which further develop into social play. Basic trust versus mistrust is another way of describing the reciprocal interaction that characterizes this stage. Turn-taking games, which occur between ages 3 and 6 months, are a pleasure for both the parents and the infant and are an extension of mirroring behavior. They also represent an early form of imitative behavior, which is important in later social and cognitive development. More sophisticated games, such as peek-a-boo, occur at approximately age 9 months. The infant's thrill at the reappearance of the face that vanished momentarily demonstrates the emerging understanding of object permanence. Age 8–9 months is also a critical time in the attachment process because this is when separation anxiety and stranger anxiety become marked. The infant at this stage is able to appreciate discrepant events that do not match previously known schemata. These new events cause uncertainty and subsequently fear and anxiety. The infant must be able to retrieve previous schemata and incorporate new information over an extended time. These abilities are developed by age 8 months and give rise to the fears that may subsequently develop: stranger anxiety and separation anxiety. In stranger anxiety, the infant analyzes the face of a stranger, detects the mismatch with previous schemata or what is familiar, and responds with fear or anxiety, leading to crying. In separation anxiety, the child perceives the difference between the primary caregiver's presence and his or her absence by remembering the schema of the caregiver's presence. Perceiving the inconsistency, the

/3

child first becomes uncertain and then anxious and fearful. This begins at age 8 months, reaches a peak at 15 months, and disappears by the end of 2 years in a relatively orderly progression as central nervous system (CNS) maturation facilitates the development of new skills. A parent can put the child's understanding of object permanence to good use by placing a picture of the mother (or father) near the child or by leaving an object (eg, her sweater) where the child can see it during her absence. A visual substitute for the parent's presence may comfort the child.

Once the child can walk independently, he or she can move away from the parent and explore the environment. Although the child uses the parent as "home base," returning frequently for reassurance, he or she has now taken a major step toward independence. This is the beginning of mastery over the environment and an emerging sense of self. The "terrible twos" and the frequent self-asserting use of "no" are the child's attempt to develop a better idea of what is or might be under his or her control. The child is starting to assert his or her autonomy. As children develop a sense of self, they begin to understand the feelings of others and develop empathy. They hug another child who is in perceived distress or become concerned when one is hurt. They begin to understand how another child feels when he or she is harmed, and this realization helps them to inhibit their own aggressive behavior. Children also begin to understand right and wrong and parental expectations. They recognize that they have done something "bad" and may signify that awareness by saying "uhoh" or with other expressions of distress. They also take pleasure in their accomplishments and become more aware of their bodies.

Also, developing at this age is the important behavior of play. Play is the child's means of learning. Play is a very complex process whose purpose can include the practice and rehearsal of roles, skills, and relationships; a means of revisiting the past; a means of actively mastering a range of experiences; and a way to integrate the child's life experiences. It involves emotional development (affect regulation and gender identification and roles), cognitive development (nonverbal and verbal function and executive functioning and creativity), and social/motor development (motor coordination, frustration tolerance, and social interactions such as turn taking). Of interest is that play has a developmental progression. The typical 6- to 12-month-old engages in the game of peek-a-boo, which is a form of social interaction. During the next year or so, although children engage in increasingly complex social interactions and imitation, their play is primarily solitary. However, they do begin to engage in symbolic play such as by drinking from a toy cup and then by giving a doll a drink from a toy cup. By age 2-3 years children begin to engage in parallel play (engaging in behaviors that are imitative). This form of play gradually evolves into more interactive or collaborative play by age 3-4 years and is also more thematic in nature. There are of course wide

variations in the development of play, reflecting cultural, educational, and socioeconomic variables. Nevertheless, the development of play does follow a sequence that can be assessed and can be very informative in the evaluation of the child.

Brain maturation sets the stage for toilet training. After age 18 months, toddlers have the sensory capacity for awareness of a full rectum or bladder and are physically able to control bowel and urinary tract sphincters. They also take great pleasure in their accomplishments, particularly in appropriate elimination, if it is reinforced positively. Children must be given some control over when elimination occurs. If parents impose severe restrictions, the achievement of this developmental milestone can become a battle between parent and child. The development of bowel control encompasses a more generalized theme of socialized behavior.

AGES 2-4 YEARS

The 2- to 4-year-old stage begins when language has facilitated the creation of mental images in the symbolic sense. The child begins to manipulate the symbolic world; sorts out reality from fantasy imperfectly; and may be terrified of dreams, wishes, and foolish threats. Most of the child's perception of the world is interpreted in reference to his or her needs or influence. Cause-effect relationships are confused with temporal ones or interpreted with respect to themselves. For example, children may focus their understanding of divorce on themselves ("My father left because I was bad" or "My mother left because she didn't love me"). Illness and the need for medical care are also commonly misinterpreted at this age. The child may make a mental connection between a sibling's illness and a recent argument, a negative comment, or a wish for the sibling to be ill. The child may experience significant guilt unless the parents are aware of these misperceptions and take time to deal with them.

At this age, children also endow inanimate objects with human feelings. They also assume that humans cause or create all natural events. For instance, when asked why the sun sets, they may say, "The sun goes to his house" or "It is pushed down by someone else." Magical thinking blossoms between ages 3 and 5 years as symbolic thinking incorporates more elaborate fantasy. Fantasy facilitates development of role playing and emotional growth. Children test new experiences in fantasy, both in their imagination and in play. In their play, children often create magical stories and novel situations that reflect issues with which they are dealing, such as aggression, relationships, fears, and control. Children often invent imaginary friends at this time, and nightmares or fears of monsters are common. At this stage, other children become important in facilitating play, such as in a preschool group. Play gradually becomes more cooperative; shared fantasy leads to game playing.

EARLY SCHOOL YEARS: AGES 5–7 YEARS

Attendance at kindergarten at age 5 years marks an acceleration in the separation-individuation theme initiated in the preschool years. The child is ready to relate to peers in a more interactive manner. The brain has reached 90% of its adult weight. Sensorimotor coordination abilities are maturing and facilitating pencil-and-paper tasks and sports, both part of the school experience. Cognitive abilities are still at the preoperational stage, and children focus on one variable in a problem at a time. However, most children have mastered conservation of length by age 5½ years, conservation of mass and weight by 6½ years, and conservation of volume by 8 years.

By first grade, there is more pressure on the child to master academic tasks—recognizing numbers, letters, and words and learning to write. Concrete operations typically begin after age 6 years, when the child is able to perform mental operations concerning concrete objects that involve manipulation of more than one variable. The child is able to order, number, and classify because these activities are related to concrete objects in the environment and because these activities are stressed in early schooling. Magical thinking diminishes greatly at this time, and the reality of cause-effect relationships is better understood. Fantasy and imagination are still strong and are reflected in themes of play.

MIDDLE CHILDHOOD: AGES 7–11 YEARS

From 7 to 11 years of age, children devote most of their energies to school and peer group interactions. For the 7-year-old child, the major developmental tasks are achievement in school and acceptance by peers. Academic expectations intensify, become more abstract, and require the child to concentrate on, attend to, and process increasingly complex auditory and visual information. Children with significant learning disabilities or problems with attention, organization, and impulsivity may have difficulty with academic tasks and subsequently may receive negative reinforcement from teachers, peers, and even parents. Such children may develop a poor self-image manifested as behavioral difficulties. The pediatrician must evaluate potential learning disabilities in any child who is not developing adequately at this stage or who presents with emotional or behavioral problems. The developmental status of school-aged children is not documented as easily as that of younger children because of the complexity of the milestones. In the school-aged child, the quality of the response, the attentional abilities, and the child's emotional approach to the task can make a dramatic difference in success at school. The clinician must consider all of these aspects in the differential diagnosis of learning disabilities and behavioral disorders.

BEHAVIORAL & DEVELOPMENTAL VARIATIONS

Variations in children's behavior reflect a blend of intrinsic biological characteristics and the environments with which the children interact. Often identified as complaints by parents, such normal variations in behavior are a reflection of each child's unique, individual biologic and temperament traits and the parents' responses. There are no cures for these behaviors, but management strategies are available that can enhance the parents' understanding of the child and the child's relationship to the environment. These strategies also facilitate the parents' care of the growing infant and child.

The last section of this chapter discusses developmental disorders of cognitive and social competence. Diagnosis and management of these conditions requires a comprehensive and often multidisciplinary approach. The health care provider can play a major role in diagnosis, coordinating the child's evaluation, interpreting the results to the family, and in providing reassurance and support.

NORMALITY & TEMPERAMENT

The physician confronted by a disturbance in physiologic function rarely has doubts about what is atypical. Variations in temperament and behavior are not as straightforward. Labeling such variations as disorders implies that a disease entity exists.

The behaviors described in this section are viewed as part of a continuum of responses by the child to a variety of internal and external experiences. Temperament, for example, is a genetically influenced behavioral disposition that is stable over time. It sometimes is thought of as being the "how" of behavior as distinguished from the "why" (motivation) and the "what" (ability). Temperament is an independent psychological attribute that is expressed as a response to an external stimulus. The influence of temperament is bidirectional: The effect of a particular experience will be influenced by the child's temperament, and the child's temperament will influence the responses of others in the child's environment. Temperament is the style with which the child interacts with the environment.

The perceptions and expectations of parents must be considered when a child's behavior is evaluated. A child whom one parent might describe as hyperactive might not be characterized as such by the other parent. This truism can be expanded to include all the dimensions of temperament. Thus, the concept of "goodness of fit" comes into play. For example, if the parents want and expect their child to be predictable but that is not the child's behavioral style, the parents may perceive the child as being bad or having a behavioral disorder rather than as having a developmental variation. An appreciation of this phenomenon is important because the physician may be able to enhance the parents' understanding of the child and influence their responses to the child's behavior. When there is goodness of fit, there will be more harmony and a greater potential for healthy development not only of the child but also of the family. When goodness of fit is not present, tension and stress can result in parental anger, disappointment, frustration, and conflict with the child.

All models of temperament seek to identify intrinsic behavioral characteristics that lead the child to respond to the world in particular ways. One child may be highly emotional and another less so (ie, calmer) in response to a variety of experiences, stressful or pleasant. The clinician must recognize that each child brings some intrinsic, biologically based traits to its environment and that such characteristics are neither good nor bad, right nor wrong, normal nor abnormal; they are simply part of the child. Thus, as one looks at variations in development, one should abandon the illness model and consider this construct as an aid to understanding the nature of the child's behavior and its influence on the parent-child relationship.

ENURESIS & ENCOPRESIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A child who does not achieve urine and bowel continence by 5–6 years of age and generally has no underlying pathology to which the incontinence can be attributed.
- The child does not respond to a full bladder or rectum.
- The child is constipated and/or is withholding stools.

Enuresis and encopresis are common childhood problems encountered in the pediatric and family practitioner's office. Bedwetting is particularly common with about 20% of children in the first grade occasionally wetting the bed and 4% wetting the bed two or more times a week. Enuresis is more common in boys than in girls. In a recent large US study, the prevalence of enuresis among boys 7 and 9 years was 9% and 7%, respectively, and among girls at those ages, 6% and 3%, respectively. The data on constipation and encopresis seem less clear with about 1%-3% of children experiencing this problem, but with anywhere from 0.3% to 29% of children worldwide experiencing constipation. Overall, encopresis/constipation accounts for 3% of referrals to pediatricians' offices. What is more striking, however, is that constipation and enuresis often co-occur; in such a case the constipation needs to be dealt with before the enuresis can be addressed.

ENURESIS

Enuresis is defined as repeated urination into the clothing during the day and into the bed at night by a child who is chronologically and developmentally older than 5 years; this pattern of urination must occur at least twice a week for 3 months. Enuresis has been categorized by the International Children's Continence Society as monosymptomatic or non-monosymptomatic. Monosymptomatic enuresis is uncomplicated nocturnal enuresis (NE; must never have been dry at night for over 6 months with no daytime accidents); it is a reflection of a maturational disorder and there is no underlying organic problem. Complicated or nonmonosymptomatic enuresis often involves NE and daytime incontinence and often reflects an underlying disorder. The evaluation of both forms needs to take into consideration both the medical and psychological implications of these conditions.

Monosymptomatic enuresis reflects a delay in achieving nighttime continence and reflects a delay in the

maturation of the urologic and neurologic systems. Both micturition and anorectal evacuation are dependent on neural connections and communications between the frontal lobes, locus ceruleus, mid pons, sacral voiding center, and the bladder and rectum. With respect to enuresis, most children are continent at night within 2 years of achieving daytime control. However, 15.5% of 7.5-year-old children wet the bed but only about 2.5% meet the criteria for enuresis. With each year of age the frequency of bedwetting decreases: by 15 years only about 1%–2% of children continue to wet. This occurs more commonly among boys than girls.

The causes for NE are varied and probably interact with one another. Genetic factors are strongly implicated, as enuresis tends to run in families. Many children with NE have a higher threshold for arousal and do not awake to the sensation of a full bladder. NE also can be a result of overproduction of urine from decreased production of desmopressin or a resistance to antidiuretic hormone. In such cases, the bladder has decreased functional capacity and empties before it is filled.

The evaluation of a child with NE involves a complete history and physical examination to rule out any anatomical abnormalities, underlying pathology, or the presence of constipation. In addition, every child with NE should undergo a urinalysis including a specific gravity. A urine culture should be obtained, especially in girls.

Treatment involves education and the avoidance of being judgmental and shaming the child. Most children feel ashamed and the goal of treatment is to help the child establish continence and maintain his or her self-esteem. A variety of behavioral strategies have been employed such as limiting liquids before sleep and awakening the child at night so that he/she can go to the toilet. Central to this simple strategy is consistency on the parents' part and the need for the child to be completely awake. If this simple approach is unsuccessful, the use of bedwetting alarms is suggested. Every time the alarm goes off, the child should go to the toilet and void. Therapy needs to be continued for at least 3 months and used every night. Critical to the success of therapy is that parents need to be active participants and get up with the child, as many children will just turn off the alarm and go back to sleep. The alarm system, which is a form of cognitive behavioral therapy, has been found to cure two-thirds of affected children and should be highly recommended to affected children and their parents as a safe, effective treatment for NE. The most common cause of failure of this intervention is that the child doesn't awaken or the parents do not wake the child.

While behavioral strategies should be the first line of treatment, when these fail one may need to turn to medications. Desmopressin acetate (DDAVP), an antidiuretic hormone analogue, has been used successfully. DDAVP decreases urine production. Imipramine, a tricyclic antidepressant, also has been used successfully to control NE, although the mechanism of action is not understood. However, potential adverse side effects, including the risk of death with an overdose, suggest that imipramine should be used only as a last resort. Unfortunately, when such medications are stopped, there is a very high relapse rate.

Daytime incontinence or non-monosymptomatic enuresis is more complicated than NE. Daytime continence is achieved by 70% of children by 3 years of age and by 90% of children by 6 years. When this is not the case, one needs to consider underlying pathology, including cystitis, diabetes insipidus, diabetes mellitus, seizure disorders, neurogenic bladder, anatomical abnormalities of the urinary tract system such as urethral obstruction, constipation, and psychological stress and child maltreatment. A complete history and physical examination must be obtained, along with a diary that includes daily records of voiding and fecal elimination. Treatment must be directed at the underlying pathology and often requires the input of pediatric subspecialists. Following diagnosis, family support and education are essential.

ENCOPRESIS

Constipation (see Chapter 21) is defined by two or more of the following events for 2 months: (1) fewer than three bowel movements per week; (2) more than one episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large that it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation.

Encopresis is described in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) as the repeated passage of stool into inappropriate places (such as in the underpants) by child who is chronologically or developmentally older than 4 years. It occurs each month for at least 3 months and is not attributable to the physiologic effects of a substance or another medical condition except to the mechanism involving constipation. Behavioral scientists often divide encopresis into (1) retentive encopresis, (2) continuous encopresis, and (3) discontinuous encopresis. In rare instances children have severe toilet phobia and so do not defecate into the toilet. It is critical to note that more than 90% of the cases of encopresis result from constipation. Thus, in the evaluation of a child with encopresis, one must rule out underlying pathology associated with constipation (see Chapter 21) while at the same time addressing functional and behavioral issues. Conditions associated with constipation include metabolic disorders such as hypothyroidism, neurologic disorders such as cerebral palsy or tethered cord, and anatomical abnormalities of the anus. In addition, children who have been continent can also develop encopresis as a response to stress or child maltreatment.

ficult to COMMON

The prevalence of encopresis is somewhat difficult to precisely ascertain as it is a subject often kept secret by the family and the child. However, some authors report that 1%–3% of children ages 4–11 years of age suffer from encopresis. The highest prevalence is between 5 and 6 years of age.

A complete history and meticulous physical examination must be performed, including a rectal examination, particularly looking for abnormalities around the anus and spine. An abdominal radiograph can be helpful in determining the degree of constipation, the appearance of the bowel, and whether there is obstruction. Assuming no gastrointestinal abnormalities, initial intervention starts with treatment of constipation. Subsequently education, support, and guidance around evacuation are essential, including behavioral strategies such as having the child sit on the toilet after meals to stimulate the gastrocolic reflex. It is most important to avoid punishing the child and making him or her feel guilty and ashamed. Helping the child to clean himself and his clothing in a nonjudgmental, nonpunitive manner is far more productive approach than criticism and reproach. At the same time, if there is an underlying psychiatric disorder such as depression, the child should be treated for the mental health problem along with the treatment of the constipation.

When medical management of constipation is indicated, oral medication or an enema for "bowel cleanout" followed by oral medications should be used. Such treatment can be monitored by abdominal radiographs to be sure that the colon is clean. A bowel regimen needs to be established with the goal of the child achieving continence and defecating in the toilet bowl on a regular basis. The child should be encouraged to have a daily bowel movement, and the use of fiber, some laxatives, and even mineral oil can be helpful. Consultation with a gastroenterologist should be considered in more refractory cases.

COMMON DEVELOPMENTAL CONCERNS

COLIC

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

An otherwise healthy infant aged 2–3 months seems to be in pain, cries for > 3 hours a day, for > 3 days a week, for > 3 weeks ("rule of threes").

Infant colic is characterized by severe and paroxysmal crying that occurs mainly in the late afternoon. The infant's knees are drawn up and its fists are clenched, flatus is expelled, the facies has a pained appearance, and there is minimal response to attempts at soothing. Studies in the United States have shown that among middle-class infants, crying occupies about 2 hours per day at 2 weeks of age, about 3 hours per day by 6 weeks, and gradually decreases to about 1 hour per day by 3 months. The word "colic" is derived from Greek kolikos ("pertaining to the colon"). Although colic has traditionally been attributed to gastrointestinal disturbances, this has never been proven. Others have suggested that colic reflects a disturbance in the infant's sleep-wake cycling or an infant state regulation disorder. In any case, colic is a behavioral sign or symptom that begins in the first few weeks of life and peaks at age 2-3 months. In about 30%-40% of cases, colic continues into the fourth and fifth months.

A colicky infant is healthy and well fed but cries for more than 3 hours a day, for more than 3 days a week, and for more than 3 weeks-commonly referred to as the "rule of threes." The important word in this definition is "healthy." Thus, before the diagnosis of colic can be made, the pediatrician must rule out diseases that might cause crying. With the exception of the few infants who respond to elimination of cow's milk from its own or the mother's diet, there has been little firm evidence of an association of colic with allergic disorders. Gastroesophageal reflux is often suspected as a cause of colicky crying in young infants. Undetected corneal abrasion, urinary tract infection, and unrecognized traumatic injuries, including child abuse, must be among the physical causes of crying considered in evaluating these infants. Some attempts have been made to eliminate gas with simethicone and to slow gut motility with dicyclomine. Simethicone has not been shown to ameliorate colic. Dicyclomine has been associated with apnea in infants and is contraindicated.

This then leaves characteristics intrinsic to the child (ie, temperament) and parental caretaking patterns as contributing to colic. Behavioral states have three features: (1) They

CHAPTER 3

are self-organizing-that is, they are maintained until it is necessary to shift to another one; (2) they are stable over several minutes; and (3) the same stimulus elicits a state-specific response that is different from other states. The behavioral states are (among others) a crying state, a quiet alert state, an active alert state, a transitional state, and a state of deep sleep. The states of importance with respect to colic are the crying state and the transitional state. During transition from one state to another, infant behavior may be more easily influenced. Once an infant is in a stable state (eg, crying), it becomes more difficult to bring about a change (eg, to soothe). How these transitions are accomplished is probably influenced by the infant's temperament and neurologic maturity. Some infants move from one state to another easily and can be diverted easily; other infants sustain a particular state and are resistant to change.

Another factor to be considered in evaluating the colicky infant is the feeding and handling behavior of the caregiver. Colic is a behavioral phenomenon that involves interaction between the infant and the caregiver. Different caregivers perceive and respond to crying behavior differently. If the caregiver perceives the crying infant as being spoiled and demanding and is not sensitive to or knowledgeable about the infant's cues and rhythms-or is hurried and "rough" with the infant-the infant's ability to organize and soothe him- or herself or respond to the caregiver's attempts at soothing may be compromised. Alternatively, if the temperament of an infant with colic is understood and the rhythms and cues deciphered, crying can be anticipated and the caregiver can intervene before the behavior becomes "organized" in the crying state and more difficult to extinguish.

Management

- 1. Parents need to be educated about the developmental characteristics of crying behavior and made aware that crying increases normally into the second month and abates by the third to fourth month.
- 2. Parents need reassurance, based on a complete history and physical examination, that the infant is not sick. A discussion of the differential/potential causes and why they have been ruled out can be helpful. Although these behaviors are stressful, they are normal variants and are usually self-limited. This discussion can be facilitated by having the parent keep a diary of crying and weight gain. If there is a diurnal pattern and adequate weight gain, an underlying disease process is less likely to be present. It is important to relieve parental anxiety.
- 3. For parents to effectively soothe and comfort the infant, they need to understand the infant's cues. The pediatrician (or nurse) can help by observing the infant's behavior and devising interventions aimed at calming

both the infant and the parents. One should encourage a quiet environment without excessive handling. Rhythmic stimulation such as gentle swinging or rocking, soft music, drives in the car, or walks in the stroller may be helpful, especially if the parents are able to anticipate the onset of crying. Another approach is to change the feeding habits so that the infant is not rushed, has ample opportunity to burp, adaptive nipple if bottle fed, and, if necessary, can be fed more frequently so as to decrease gastric distention if that seems to be contributing to the problem.

- 4. Medications such as phenobarbital elixir and dicyclomine should not be used because of the risk of adverse reactions and overdosage. A trial of ranitidine hydrochloride or other proton pump inhibitor might be of help if proven gastroesophageal reflux is contributing to the child's discomfort.
- 5. For colic that is refractory to behavioral management, a trial of changing the feedings and eliminating cow's milk from the formula or from the mother's diet if she is nursing may be indicated. The use of whey hydrolysate formulas for formula-fed infants has been suggested. There is conflicting evidence regarding the use of probiotics to treat infant colic.
- 6. There is no conclusive evidence for complementary and alternative interventions to treat colic. While herbal remedies have been suggested, there are no well-designed studies supporting herbal therapies in the treatment of colic. Furthermore, herbal remedies have potential for toxicity and neurologic impairment, compounded by lack of knowledge of appropriate dosing in children. The same holds true for the use of chiropractic interventions and reflexology; there are no well-designed studies to support the use of these interventions, and the risks of adverse events outweigh the possible benefits. However, there are several studies suggesting probiotics—*Lactobacillus reuteri*—may be helpful in the management of colic in breast fed babies but not in bottle fed infants.

FEEDING DISORDERS IN INFANTS & YOUNG CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Inadequate or disordered intake of food due to any of the following conditions:
 - Poor oral-motor coordination.
 - Fatigue resulting from a chronic disease.
 - · Lack of appetite.
 - · Behavioral issues relating to parent-child interaction.
 - Pain associated with feeding.

Children have feeding problems for various reasons, including oral-motor dysfunction (gagging, trouble with chewing, and/or swallowing, aspiration), cardiopulmonary disorders leading to fatigue, gastrointestinal disturbances causing pain, social, or emotional issues, and problems with regulation. The common denominator, however, is food refusal. Infants and young children may refuse to eat if they find eating painful or frightening. They may have had unpleasant experiences (emotional or physiologic) associated with eating, they may be depressed, or they may be engaged in a developmental conflict with the caregiver that is being played out in the arena of feeding. The infant may refuse to eat if the rhythm of the feeding experience with the caregiver is not harmonious. The child who has had an esophageal atresia repair and has a stricture may find eating uncomfortable. The very young infant with severe oral candidiasis may refuse to eat because of pain. The child who has had a choking experience associated with feeding may be terrified to eat (oral-motor dysfunction or aspiration). The child who is forced to eat by a maltreating parent or an overzealous caregiver may refuse feeds. Children who have required nasogastric feedings or who have required periods of fasting and intravenous nutrition in the first 1-2 months of life are more likely to display food refusal behavior upon introduction of oral feedings.

Depression in children may be expressed through food refusal. Food refusal may develop when the infant's cues around feeding are not interpreted correctly by the parent. The infant who needs to burp more frequently or who needs time between bites but instead is rushed will often passively refuse to eat. Some will be more active refusers, turning their heads away to avoid the feeder, spitting out food, or pushing away food.

The normal developmental and interactive feeding stages through which the child normally progresses are establishment of homeostasis (0–2 months), attachment

(2-6 months), and separation and individuation (6 months to 3 years). During the first stage, feeding can be accomplished most easily when the parent allows the infant to determine the timing, amount, pacing, and preference of food intake. During the attachment phase, allowing the infant to control the feeding permits the parent to engage the infant in a positive manner. This paves the way for the separation and individuation phase. When a disturbance occurs in the parent-child relationship at any of these developmental levels, difficulty in feeding may ensue, with both the parent and the child contributing to the dysfunctional interaction. One of the most striking manifestations of food refusal occurs during the stage of separation and individuation. Conflict may arise if the parent seeks to dominate the child by intrusive and controlling feeding behavior at the same time the child is striving to achieve autonomy. The scenario then observed is of the parent forcing food on the child while the child refuses to eat. This often leads to extreme parental frustration and anger, and the child may be inadequately nourished and developmentally and emotionally thwarted.

When the pediatrician is attempting to sort out the factors contributing to food refusal, it is essential first to obtain a complete history, including a social history. This should include information concerning the parents' perception of the child's behavior and their expectations of the child. Second, a complete physical examination should be performed, with emphasis on oral-motor behavior and other clues suggesting neurologic, anatomic, or physiologic abnormalities that could make feeding difficult. The child's emotional state and developmental level must be determined. This is particularly important if there is concern about depression or a history of developmental delays. If evidence of oral-motor difficulty is suspected, evaluation by an occupational therapist or speech pathologist is warranted. Third, the feeding interaction needs to be observed live, if possible. Finally, the physician needs to help the parents understand that infants and children may have different styles of eating and different food preferences, and may refuse foods they do not like. This is not necessarily abnormal but may reflect differences in temperament and variations in the child's way of processing olfactory, gustatory, and tactile stimuli.

Management

The goal of intervention is to identify factors contributing to the disturbance and to work to overcome them. The parents may be encouraged to view the child's behavior differently and try not to impose their expectations and desires. Alternatively, the child's behavior may need to be modified so that the parents can provide adequate nurturing.

When the chief complaint is failure to gain weight, a different approach is required. The differential diagnosis should include not only food refusal but also medical disorders

CHAPTER 3

and maltreatment. The most common reason for failure to gain weight is inadequate caloric intake. Excessive weight loss may be due to vomiting or diarrhea, to malabsorption, or to a combination of these factors. In this situation more extensive diagnostic evaluation may be needed. Laboratory studies may include a complete blood count; erythrocyte sedimentation rate; urinalysis and urine culture; blood urea nitrogen; serum electrolytes and creatinine; and stool examination for fat, occult blood, and ova and parasites. Some practitioners also include liver and thyroid profiles. Occasionally an assessment of swallowing function or evaluation for the presence of gastroesophageal reflux may be indicated. Because of the complexity of the problem, a team approach to the diagnosis and treatment of failure to thrive, or poor weight gain, may be most appropriate. The team should include a physician, nurse, social worker, and dietitian. Occupational and physical therapists, developmentalists, and psychologists may be required.

The goals of treatment of the child with poor weight gain are to establish a consistent pattern of weight gain and to establish better family functioning if that is identified with the poor weight gain. Guidelines to accomplishing these goals include the following: (1) Establish a comprehensive diagnosis that considers all factors contributing to poor weight gain; (2) monitor the feeding interaction and ensure appropriate weight gain; (3) monitor the developmental progress of the child and the changes in the family dynamics that facilitate optimal weight gain and psychosocial development; and (4) provide support to the family as they seek to help the child.

SLEEP DISORDERS

- Children aged < 12 years:</p>
 - Difficulty initiating or maintaining sleep that is viewed as a problem by the child or caregiver.
 - Bedtime resistance or need for caregiver intervention to initiate sleep or to go back to sleep.

- May be characterized by its severity, chronicity, frequency, and associated impairment in daytime function in the child or family.
- May be due to a primary sleep disorder or occur in association with other sleep, medical, or psychiatric disorders.
- Adolescents—difficulty initiating or maintaining sleep, or early morning awakening, or nonrestorative sleep, or a combination of these problems.

Sleep problems impact quality of life and are considered a public health problem. Poor sleep in children is associated with maladaptive daytime behaviors, poorer developmental outcome, greater parental stress, obesity, insulin resistance, alterations in sympathetic tone, and immune dysfunction. Sleep is a complex physiologic process influenced by intrinsic biologic properties, temperament, cultural norms and expectations, and environmental conditions. Between 20% and 40% of children experience sleep disturbances at some point in the first 4 years of life. The percentage decreases to 10%-12% in school-aged children. The most common sleep disorder encountered by pediatricians is insomnia, or difficulty with initiating and maintaining sleep. Parasomnias refer to abnormalities of arousal, partial arousal, and transitions between stages of sleep. Other sleep disorders include sleep-disordered breathing (covered in greater depth in Chapter 19), restless legs syndrome (RLS)/periodic limb movement disorder (PLMD, narcolepsy, and circadian rhythm disturbances. Narcolepsy, benign neonatal sleep myoclonus, and nocturnal frontal lobe epilepsy will be covered in Chapter 25. DSM-5 no longer differentiates between primary and secondary insomnia in an effort to acknowledge the importance of managing sleep issues no matter what the perceived cause, and to recognize the bidirectional and interactive effects between sleep issues and coexisting conditions.

Sleep is controlled by two mechanisms. One is homeostatic drive, which is the increase in pressure to fall asleep over the course of the day. The second is the circadian rhythm, which is the drive to be alert. This drive for alertness increases over the course of the morning, dips in the early afternoon, and then rises again to the highest levels several hours before bedtime. This increase in alertness, which occurs several hours prior to bedtime, is often called the "forbidden zone," because it may be more difficult to fall asleep during that time. There also are two different biologic clocks. The first is a circadian rhythm-daily sleep-wake cycle. The second is an ultradian rhythm that occurs several times per night-the stages of sleep. Sleep stages cycle every 50-60 minutes in infants to every 90 minutes in adolescents. The daily circadian clock is longer than 24 hours. Environmental cues entrain the sleep-wake cycle into a 24-hour cycle. The cues include light-dark, ambient temperature, core body temperature, noise, social interaction, hunger, pain, and hormone production. Without the ability to perceive these cues (ie, blindness), a child might have difficulty entraining a 24-hour sleep-wake cycle.

Two major sleep stages have been identified clinically and with the use of polysomnography: rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. In REM sleep, muscle tone is relaxed, the sleeper may twitch and grimace, and the eyes move erratically beneath closed lids. REM sleep occurs throughout the night but is increased during the latter half of the night. NREM sleep is divided into four stages. In the process of falling asleep, the individual enters stage 1, light sleep, characterized by reduced body movements, slow eye rolling, and sometimes opening and closing of the eyelids. Stage 2 sleep is characterized by slowing of eye movements, slowing of respirations and heart rate, and relaxation of the muscles. Most mature individuals spend about half of their sleep time in this stage. Stages 3 and 4 (also called delta or slow-wave sleep) are the deepest NREM sleep stages, during which the body is relaxed, breathing is slow and shallow, and the heart rate is slow. The deepest NREM sleep occurs during the first 1-3 hours after going to sleep. Most parasomnias occur early in the night during deep NREM sleep. Dreams and nightmares that occur later in the night occur during REM sleep.

Sleep is clearly a developmental phenomenon. Infants are not born with a sleep-wake cycle. REM sleep is more common than NREM sleep in newborns and decreases by 3-6 months of age. Sleep patterns slowly mature throughout infancy, childhood, and adolescence until they become adult like. Newborns sleep 10-19 hours per day in 2- to 5-hour blocks. Over the first year of life, the infant slowly consolidates sleep at night into a 9- to 12-hour block and naps gradually decrease to one per day by about 12 months. Most children stop napping between 3 and 5 years of age. In 2015, the National Sleep Foundation published recommendations for the total number of hours of sleep per day in different age groups: 1- to 2-year-olds—11-14 hours per day; 3- to 5-yearolds—10-13 hours per day; 6- to 13-year-olds—9-11 hours per day. Adolescents need 9-91/2 hours per night but often only get 7-7¼ hours per night. This is complicated by an approximate 1- to 3-hour sleep phase delay in adolescence that is due to physiologic changes in hormonal regulation of the circadian system. Often, adolescents are not tired until 2 hours after their typical bedtime but still must get up at the same time in the morning. Some school districts have implemented later start times for high school students because of this phenomenon.

PARASOMNIAS

Parasomnias include both NREM arousal disorders such as confusional arousals, night terrors, sleeptalking (somniloquy), and sleepwalking (somnambulism), and REM-associated sleep abnormalities which are beyond the scope of this chapter.

Night Terrors and Sleepwalking

Night terrors commonly occur within 2 hours after falling asleep, during the deepest stage of NREM sleep, and are often associated with sleepwalking. They occur in about 3% of children and most cases occur between ages 3 and 8 years. During a night terror, the child may sit up in bed screaming, thrashing about, and exhibiting rapid breathing, tachycardia, and sweating. The child is often incoherent and unresponsive to comforting. The episode may last up to 1/2 hour, after which the child goes back to sleep and has no memory of the event the next day. Management of night terrors consists of reassurance of the parents plus measures to avoid stress, irregular sleep schedule, or sleep deprivation, which prolongs deep sleep when night terrors occur. Scheduled awakening (awakening the child 30-45 minutes before the time the night terrors usually occur) has been used in children with nightly or frequent night terrors, but there is little evidence that this is effective.

Sleepwalking also occurs during slow-wave/deep sleep and is common between 4 and 8 years of age. It is often associated with other complex behaviors during sleep. It is typically benign except that injuries can occur while the child is walking around. Steps should be taken to ensure that the environment is free of obstacles and that doors to the outside are locked. Parents may also wish to put a bell on their child's door to alert them that the child is out of bed. As with night terrors, steps should be taken to avoid stress and sleep deprivation. Scheduled awakenings may also be used if the child sleep walks frequently and at a predictable time.

Nightmares

Nightmares are frightening dreams that occur during REM sleep, typically followed by awakening, which usually occurs in the latter part of the night. The peak occurrence is between ages 3 and 5 years, with an incidence between 25% and 50%. A child who awakens during these episodes is usually alert. He or she can often describe the frightening images, recall the dream, and talk about it during the day. The child seeks and will respond positively to parental reassurance. The child will often have difficulty going back to sleep and will want to stay with their parents. Nightmares are usually self-limited and need little treatment. They can be associated with stress, trauma, anxiety, sleep deprivation that can cause a rebound in REM sleep, and medications that increase REM sleep.

INSOMNIA

Insomnia includes difficulty initiating sleep and nighttime awakenings. Although parasomnias are frightening, insomnia is frustrating. It can result in daytime fatigue for both the

CHAPTER 3

parents and the child, parental discord about management, and family disruption.

Several factors contribute to these disturbances. The quantity and timing of feeds in the first year of life will influence nighttime awakening. Most infants beyond age 6 months can go through the night without being fed. Thus, under normal circumstances, night waking for feeds is probably a learned behavior and is a function of the child's arousal and the parents' response to that arousal.

Bedtime habits can influence settling in for the night as well as nighttime awakening. If the child learns that going to sleep is associated with pleasant parental behavior such as rocking, singing, reading, or nursing, going back to sleep after nighttime arousal without these pleasant parental attentions may be difficult. This is called a sleep-onset association disorder and usually is the reason for night waking. Every time that the child gets to the light sleep portion of the sleep-wake cycle, he or she may wake up. This is usually brief and not remembered the next morning, but for the child who does not have strategies for getting to sleep independently, getting back to sleep may require the same interventions needed to get to sleep initially. Most of these interventions require a parent. Night waking occurs in 40%–60% of infants and young children.

Parents need to set limits for the child while acknowledging the child's individual biologic rhythms. They should resist the child's attempts to put off bedtime or to engage them during nighttime awakenings. The goal is to establish clear bedtime rituals, to put the child to bed while still awake, and to create a dark, quiet, secure bedtime environment.

The child's temperament is another factor contributing to sleep. It has been reported that children with low sensory thresholds and less rhythmicity (regulatory disorder) are more prone to night waking. Night waking often starts at about 9 months as separation anxiety is beginning. Parents should receive anticipatory guidance prior to that time so that they know to reassure their child without making the interaction prolonged or pleasurable. Finally, psychosocial stressors and changes in routine can play a role in night waking.

Insomnia is common in children with complex medical conditions and neurologic, developmental, and psychiatric disorders.

SLEEP-DISORDERED BREATHING

Sleep-disordered breathing or obstructive sleep apnea is characterized by obstructed breathing during sleep accompanied by loud snoring, chest retractions, morning headaches, dry mouth, and daytime sleepiness. Obstructive sleep apnea occurs in 1%–3% of preschoolers. It has its highest peak in childhood between the ages of 2 and 6 years. It has been associated with daytime behavioral disorders, including attention-deficit/hyperactivity disorder (ADHD). (See Chapter 19.)

RESTLESS LEGS SYNDROME & PERIODIC LIMB MOVEMENT DISORDER

Restless legs syndrome (RLS) and periodic limb movement disorder (PLMD) are common disorders in adults and frequently occur together. The frequency of these disorders in children is about 2%. RLS is associated with an uncomfortable sensation in the lower extremities that occurs at night when trying to fall asleep, is relieved by movement, and is sometimes described by children as "creepy-crawly" or "itchy bones." PLMD is stereotyped, repetitive limb movements often associated with a partial arousal or awakening. These disorders have been associated with iron deficiency. A diagnosis of RLS is generally made by history and a diagnosis of PLMD can be made with a sleep study. Caffeine, nicotine, antidepressants, and other drugs have been associated with RLS and PLMD. The medical evaluation includes obtaining a serum ferritin and C-reactive protein (CRP) level as ferritin can be falsely elevated during inflammation. If the CRP is normal and the ferritin is less than 30-50 ng/mL, treatment with ferrous sulfate should be considered. Medications have been studied for treatment of RLS and PLMD in adults but not in children.

Management of Sleep Disorders

The BEARS is a mnemonic that has been recommended for screening for sleep problems in primary care: Bedtime resistance, Excessive daytime sleepiness, Awakening during the night, Regularity and duration of sleep, Sleep-disordered breathing. Screening for the quality and quantity of sleep at every well-child visit has been recommended by Honaker and Meltzer (2016) due to the impact of sleep problems and evidence that parents will not necessarily bring up sleep issues or be aware of what constitutes poor sleep. Once a problem with sleep is identified, a complete medical and psychosocial history should be obtained, and a physical examination performed. A detailed sleep history and diary should be completed, and both parents should contribute. Assessment for allergies, lateral neck films, and polysomnography may be indicated to complete the evaluation, especially if sleep-disordered breathing is suspected. It is important to consider disorders such as gastroesophageal reflux, which may cause discomfort or pain when recumbent. Dental pain or eczema may cause nighttime awakening. It is also important to make sure that any medications that the child is taking do not interfere with sleep.

The key to treatment of children who have difficulty going to sleep or who awaken during the night and disturb others is for the physician and parents to understand normal sleep patterns, daytime and nighttime habits that promote sleep, responses that inadvertently reinforce undesirable sleep behavior, and the child's individual temperament traits. The ABCs of SLEEPING were developed by Allen et al (2016) as a mnemonic for typical recommendations offered to improve sleep: Age-appropriate Bedtimes and wake times with Consistency, Schedules and routines, Location (quiet, dark, cool environment), Exercise and diet, no Electronics in the bedroom or before bed, Positivity (positive home environment), Independence when falling asleep, Needs of child met during the day, equals Great sleep. Good sleep hygiene includes discontinuing any activities that are stimulating in the hour before bedtime. It is also important to dim lights and avoid blue light during the "wind down" time. Television and video games are particularly stimulating. Apps are available to decrease blue light and increase red/orange light at night on computers, phones, and tablets. Exposure to light and physical activity during the day are helpful and it is important to ask about caffeine ingestion. Many recommendations for improving sleep in pediatric patients have limited evidence base. Allen et al reviewed available literature and found moderate to strong evidence to support an association between the following recommendations and good sleep: age-appropriate and consistent nap, bed, and wake times; bedtime by 9 PM; regular schedule; limiting access to electronics during and after bedtime by removing them from the bedroom; need to learn to fall asleep independently; establishing a positive living environment; and supporting emotional needs during the day. The literature does not support limiting exercise in the 1-4 hours prior to bedtime. Other interventions had insufficient, limited, or equivocal evidence. Further study is needed to establish evidence-based practices.

Sleep hygiene education and cognitive behavioral therapy for insomnia are considered first-line treatments for pediatric insomnia.

There is little evidence regarding pharmacologic management of sleep disorders in children. While the role for melatonin in children with typical development is unclear, there is mounting evidence that it can be effective in children with visual impairments, developmental disabilities, and autism spectrum disorders (ASDs). Medications such as clonidine are often used for sleep disorders, especially in children with ADHD and ASD, but there are little data to support its use.

The Pediatric Sleep Medicine Update in Pediatric Clinics of North America from June 2011 is a good resource for more in-depth information.

TEMPER TANTRUMS & BREATH-HOLDING SPELLS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Behavioral responses to stress, frustration, and loss of control.
- Tantrum—child may throw him- or herself on the ground, kick, scream, or strike out at others.
- Breath-holding spell—child engages in a prolonged expiration that is reflexive and may become pale or cyanotic.
- Rule out underlying organic disease in children with breath-holding spells (eg, CNS abnormalities, Rett syndrome, seizures).

1. Temper Tantrums

Temper tantrums are common between ages 12 months and 4 years, occurring about once a week in 50%–80% of children in this age group. The child may throw him- or herself down, kick and scream, strike out at people or objects in the room, and hold his or her breath. These behaviors may

be considered normal as the young child seeks to achieve autonomy and mastery over the environment. They are often a reflection of immaturity as the child strives to accomplish age-appropriate developmental tasks and meets with difficulty because of inadequate motor and language skills, impulsiveness, or parental restrictions. In the home, these behaviors may be annoying. In public, they are embarrassing.

Some children tolerate frustration well, are able to persevere at tasks, and cope easily with difficulties; others have a much greater problem dealing with experiences beyond their developmental level. Parents can minimize tantrums by understanding the child's temperament and what he or she is trying to communicate. Parents must also be committed to supporting the child's drive to master his or her feelings.

Management

Appropriate intervention can provide an opportunity for enhancing the child's growth. The tantrum is a loss of control on the child's part that may be a frightening event and a blow to the child's self-image. The parents and the physician need to view these behaviors within the child's developmental context rather than from a negative, adversarial, angry perspective.

Several suggestions can be offered to parents and physicians to help manage tantrums:

- 1. Minimize the need to say "no" by "child-proofing" the environment so that fewer restrictions need to be enforced.
- Use distraction when frustration increases; direct the child to other, less frustrating activities; and reward the positive response.
- 3. Present options within the child's capabilities so that he or she can achieve mastery and autonomy.
- 4. Fight only those battles that need to be won and avoid those that arouse unnecessary conflict.
- 5. Do not abandon the preschool child when a tantrum occurs. Stay nearby during the episode without intruding. A small child may need to be restrained. An older child can be asked to go to his or her room. Threats serve no purpose and should not be used.
- 6. Do not use negative terms when the tantrum is occurring. Instead, point out that the child is out of control and give praise when he or she regains control.
- 7. Never let a child hurt him- or herself or others.
- 8. Do not "hold a grudge" after the tantrum is over, but do not grant the child's demands that led to the tantrum.
- Seek to maintain an environment that provides positive reinforcement for desired behavior. Do not overreact to undesired behavior, but set reasonable limits and provide responsible direction for the child.

10. Approximately 5%–20% of young children have severe temper tantrums that are frequent and disruptive. Such tantrums may result from a disturbance in the parent-child interaction, poor parenting skills, lack of limit setting, and permissiveness. They may be part of a larger behavioral or developmental disorder or may emerge under adverse socioeconomic conditions, in circumstances of maternal depression and family dysfunction, or when the child is in poor health. Referral to a psychologist or psychiatrist is appropriate while the pediatrician continues to support and work with the family.

2. Breath-Holding Spells

Whereas temper tantrums can be frustrating to parents, breath-holding spells can be terrifying. The name for this behavior may be a misnomer in that it connotes prolonged inspiration. In fact, breath-holding occurs during expiration and is reflexive-not volitional-in nature. It is a paroxysmal event occurring in 0.1%-5% of healthy children from age 6 months to 6 years. The spells usually start during the first year of life, often in response to anger or a mild injury. The child is provoked or surprised, starts to crybriefly or for a considerable time-and then falls silent in the expiratory phase of respiration. This is followed by a color change. Spells have been described as either pallid (acyanotic) or cyanotic, with the latter usually associated with anger and the former with an injury such as a fall. The spell may resolve spontaneously, or the child may lose consciousness. In severe cases, the child may become limp and progress to opisthotonos, body jerks, and urinary incontinence. Only rarely does a spell proceed to asystole or a seizure.

Management

For the child with frequent spells, underlying disorders such as seizures, orthostatic hypotension, obstructive sleep apnea, abnormalities of the CNS, tumors, familial dysautonomia, and Rett syndrome need to be considered. An association exists among breath-holding spells, pica, and iron-deficiency anemia. These conditions can be ruled out on the basis of the history, physical examination, and laboratory studies. Once it has been determined that the child is healthy, the focus of treatment is behavioral. Parents should be taught to handle the spells in a matter-of-fact manner and monitor the child for any untoward events. The reality is that parents cannot completely protect the child from upsetting and frustrating experiences and probably should not try to do so. Just as in temper tantrums, parents need to help the child control his or her responses to frustration. Parents need to be careful not to be too permissive and submit to the child's every whim for fear the child might have a spell.

If loss of consciousness occurs, the child should be placed on his or her side to protect against head injury and aspiration. Maintaining a patent oral airway is essential, but cardiopulmonary resuscitation should be avoided. There are no prophylactic medications. Atropine, 0.01 mg/kg given subcutaneously, has been used with some benefit in spells accompanied by bradycardia or asystole.

WELL-CHILD SURVEILLANCE & SCREENING

The American Academy of Pediatrics (AAP) recently published guidelines for surveillance and screening at well-child visits. Surveillance is a procedure for recognizing children at risk for a developmental disorder and involves asking parents if they have concerns about their child's development. The PEDS (Pediatric Evaluation of Developmental Status) can be used for this purpose. Screening involves use of a standardized tool to clarify identified risk. An evaluation would be done by a specialist and would involve a more definitive evaluation of a child's development.

Surveillance should occur at all well-child visits. Screening of development should occur at 9, 18, and 30 months. Because a 30-month visit is not part of the standard wellchild visit schedule and may not be reimbursed, screening may occur at 24 months instead. It is also recommended that autism-specific screening should occur at the 18-month visit. Although an autism-specific screen was only recommended at the 18-month visit in the AAP guidelines, the Autism Workgroup of the AAP separately recommended a second autism-specific screen at 24-30 months in order to pick up children missed at the 18-month screen. Because the average age of regression in children with autism is 16-20 months, some children may be missed by a single screen at 18 months. In 2016, the US Preventative Services Task Force Recommendation Statement for screening for autism in young children for whom no concerns had been raised concluded that there was insufficient evidence to recommend for or against screening. They commented on the lack of evidence but did not suggest that screening should not occur. Clinicians should keep in mind that if they are administering a screen because they are concerned and the child passes the screen, they should still schedule an early follow-up visit to ensure that appropriate progress has been made and that there are no further concerns.

Implementation of screening requires planning for timing of screening administration during office visits, defining the process for referral, and designing handouts prior to beginning screening. Screening is done to optimize the child's development. However, it also demonstrates to the parent the interest their care provider has not only for the child's physical well-being but also for the child's developmental and psychosocial well-being. Parents of children who receive a developmental assessment express greater satisfaction with their care provider.

The Child Health and Development Interactive System (CHADIS) is an online system that allows parents and teachers to complete screening questionnaires online prior to the visit. It supports billing for 96110 screening assessments and complex visits, and provides quality assurance documentation.

DEVELOPMENTAL DISORDERS

Developmental disorders include abnormalities in one or more aspects of development, such as verbal, motor, visualspatial, attention, and social abilities. Problems with development are often noted by parents when a child does not meet typical motor and language milestones. Developmental disorders may also include difficulties with behavior or attention. ADHD is the most common neurodevelopmental disorder. ADHD occurs in 2%–10% of school-aged children and may occur in combination with a variety of other learning or developmental issues. Mild developmental disorders are often not noted until the child is of school age.

Many biological and psychosocial factors influence a child's performance on developmental tests. In the assessment of the child, it is important to document adverse psychosocial factors, such as neglect or poverty, which can negatively influence developmental progress. Many of the biological factors that influence development are genetic.

The diagnostic criteria for developmental disorders are found in the DSM-5. The term *mental retardation* has been replaced by *intellectual disability* (ID). The diagnostic criteria for ASDs changed dramatically in DSM-5 with some changes in the criteria for ADHD. There are also subtle changes to communication disorders, specific learning disorder, and motor disorders. These can be found at the following website: www.psychchiatry.org/practice/dsm/dsm5.

Evaluation

The neurodevelopmental evaluation must focus on (1) defining the child's level of developmental abilities in a variety of domains, including language, motor, visual-spatial, attention, and social abilities; (2) attempting to determine the etiology of the child's developmental delays; and (3) planning a treatment program. These objectives are ideally achieved by a multidisciplinary team that may include a physician, a psychologist, a speech or language therapist, an occupational therapist, and an educational specialist. This type of evaluation is ideal but not always readily available.

Medical & Neurodevelopmental Examination

The medical history should include the pregnancy, labor, and delivery to identify conditions that might compromise the child's CNS function. The physician must ask the child's parents about prenatal exposures to toxins, medications, alcohol, drugs, smoking, and infections; maternal chronic illness; complications of pregnancy or delivery; and neonatal course. Problems such as poor weight gain, chronic illnesses, hospitalizations, and maltreatment can interfere with typical development. Major illnesses or hospitalizations should be discussed. Any CNS problems, such as trauma, infection, or encephalitis, should be documented. The presence of metabolic diseases and exposure to environmental toxins such as lead should be determined. Chronic diseases such as chronic otitis media, hyper- or hypothyroidism, and chronic renal failure can impact typical development. The presence of motor or vocal tics, seizures, gastrointestinal, or sleep disturbances should be documented. In addition, parents should be questioned about any motor, cognitive, or behavioral regression.

The physician should review and document the child's developmental milestones. The physician should also review temperament, difficulties with sleep or feeding, tantrums, poor attention, impulsivity, hyperactivity, anxiety/fears, and aggression. When asking questions about problematic behaviors, it is important to have the parent describe the behavior including frequency and duration. It is also important to try to determine triggers of the behavior and consequences or potential reinforcers of the behavior (ABC—antecedent/ behavior/consequence).

A detailed history of school-related events should be recorded, including previous special education support, evaluations through the school, history of repeating grades, difficulties with specific academic areas, problems with peers, and the teacher's impressions of the child's difficulties, particularly related to problems with attention, impulsivity, or hyperactivity. Input from teachers can be invaluable and should be sought prior to the evaluation.

An important aspect of the medical history is a detailed family history of emotional or behavioral problems, learning disabilities, ID, or psychiatric disorders. Parental learning strengths and weaknesses, temperament difficulties, or attentional problems may be passed on to the child. For instance, dyslexia is often inherited.

The neurodevelopmental examination should include a careful assessment of dysmorphic features such as epicanthal folds, palpebral fissure size, shape and length of the philtrum, low-set or posteriorly rotated ears, prominent ear pinnae, unusual dermatoglyphics (eg, a single transverse palmar crease), hyperextensibility of the joints, syndactyly, clinodactyly, or other anomalies. A detailed physical and neurologic examination needs to be carried out with an emphasis on both soft and hard neurologic findings. Soft signs can include motor incoordination, which can be related to handwriting problems and academic delays in written language or drawing. Visual-motor coordination abilities can be assessed by having the child write, copy shapes and designs, or draw a person.

The child's growth parameters, including height, weight, and head circumference, need to be assessed. Normal hearing and visual acuity should be documented or evaluated. Cranial nerve abnormalities and oral-motor coordination problems need to be noted. The examiner should watch closely for motor or vocal tics. Both fine and gross motor abilities should be assessed. Tandem gait, ability to balance on one foot, and coordinating a skip should be evaluated based on age. Tremors can be noted when watching a child stack blocks or draw.

The developmental aspects of the examination can include an assessment of auditory processing and perceptual ability with simple tasks, such as two- to fivefold directions, assessing right and left directionality, memory for a series of spoken words or digit span, and comprehension of a graded paragraph. In assessing expressive language abilities, the examiner should look for difficulties with word retrieval, formulation, articulation, and adequacy of vocabulary. Visual-perceptual abilities can be assessed by simple visual memory tasks, puzzles, or object assembly, and evaluating the child's ability to decode words or organize math problems. Visual-motor integration and coordination can be assessed again with handwriting, design copying, and drawing a person. Throughout the assessment, the clinician should pay special attention to the child's ability to focus attention and concentrate, and to other aspects of behavior or affect, such as evidence of depression or anxiety.

Additional questionnaires and checklists—such as the Child Behavior Checklist by Achenbach; ADHD scales such as the Conners' Parent/Teacher Rating Scale; Vanderbilt ADHD Diagnostic Parent/Teacher Rating Scales; and the Swanson, Nolan, and Pelham Questionnaire-IV—can be used to help with this assessment.

Referral of family to community resources is critical, as is a medical home (described earlier in this chapter).

ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

ADHD is a common neurodevelopmental disorder that may affect about 7%-8% of children and 2.5% of adults. It is associated with a triad of symptoms: impulsivity, inattention, and hyperactivity. DSM-5 describes three ADHD subtypes: hyperactive-impulsive, inattentive, and combined. To be classified according to one or another of these subtypes, the child must exhibit six or more of the symptoms listed in Table 3-3. DSM-5 include the same 18 symptoms, 2 symptom domains, and require 6 symptoms from each domain for children younger than 17. DSM-5 includes the following changes: Criteria will address symptoms across the lifespan, symptoms causing the impairment will need to be present prior to age 12 instead of age 7, and some symptoms will need to be present across more than one setting. Overall there are significant challenges in academic functioning and social interactions. A diagnosis will be allowed in children with ASD, and symptom thresholds will be lower in adolescents 17 and older and in adults (only five symptoms required from each category).

The majority of children with ADHD have a combined type with symptoms of inattention as well as hyperactivity and impulsivity. Girls have a higher prevalence of the inattentive subtype; boys have a higher prevalence of the hyperactive subtype. Although symptoms begin in early childhood, they can diminish between ages 10 and 25 years. Hyperactivity declines more quickly, and impulsivity and inattentiveness often persist into adolescence and adulthood. ADHD may be combined with other psychiatric conditions, such as mood disorder in approximately 20% of patients, conduct disorders in 20%, and oppositional defiant disorder in up to 40%. Up to 25% of children with ADHD seen in a referral clinic have tics or Tourette syndrome. Conversely, well over 50% of individuals with Tourette syndrome also have ADHD.

ADHD has a substantial genetic component. Several candidate genes have been identified but only explain a small part of the variance, although there is strong evidence that ADHD is a disorder involving multiple genes. ADHD is also associated with a variety of genetic disorders including fragile X syndrome, Williams syndrome, Angelman syndrome, XXY syndrome (Klinefelter syndrome), and Turner syndrome. Fetal alcohol syndrome (FAS) is also strongly associated with ADHD. CNS trauma, CNS infections, prematurity, and a difficult neonatal course with brain injury can also be associated with later ADHD. Metabolic problems such as hyperthyroidism can sometimes cause ADHD. These organic causes of ADHD should be considered in the evaluation of any child presenting with attentional problems, hyperactivity, or impulsivity. Particularly inattention can occur with obstructive sleep apnea. However, in the majority of children who have ADHD, the cause remains unknown.

Management

The treatment of ADHD varies depending on the complexity of the individual case, including comorbid disorders such as anxiety, sleep disorders, and learning disabilities. It is important to educate the family regarding the symptoms of ADHD and to clarify that it is a neurologic disorder which makes the symptoms difficult for the child to control. Despite that, behavior modification techniques usually help these children and should include structure with consistency in daily routine, positive reinforcement whenever possible, and time-out for negative behaviors. A variety of educational interventions can be helpful, including preferential seating in the classroom, a system of consistent positive behavior reinforcement, consistent structure, the repetition of information when needed, and the use of instruction that incorporates both visual and auditory modalities. Many children with ADHD have significant social difficulties, and social skills training can be helpful. Individual counseling is beneficial in alleviating poor self-esteem, oppositional behavior, and conduct problems.

Stimulant medications (methylphenidate, dextroamphetamine, mixed amphetamine, and lisdexamfetamine) are available in short- and long-acting preparations and in tablet, capsule, liquid, and dermal patch forms. Alternative medications for the treatment of ADHD include extendedrelease clonidine or guanfacine, which are α_2 -adrenergic presynaptic agonists. Atomoxetine, which is a norepinephrine reuptake inhibitor, has also been used as a second-line medication or as an adjunct treatment with the stimulants It should be noted that the stimulants are rapidly acting while

CHAPTER 3

Table 3–3. Attention-deficit/hyperactivity disorder.

Diagnostic Criteria

- A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):
 - 1. Inattention: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities.

Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age \geq 17), at least five symptoms are required.

- a. Often fails to pay close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, work is inaccurate).
- b. Often has difficulty sustaining attention in tasks or play activities (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading).
- c. Often does not seem to listen when spoken to directly (eg, mind seems elsewhere, even in the absence of any obvious distraction).
- d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (eg, starts tasks but quickly loses focus and is easily sidetracked).
- e. Often has difficulty organizing tasks and activities (eg, difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
- f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
- g. Often loses things necessary for tasks or activities (eg, school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
- h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
- i. Is often forgetful in daily activities (eg, doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
- 2. Hyperactivity and impulsivity: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities: Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age ≥ 17), at least five symptoms are required.
 - a. Often fidgets with or taps hands or feet or squirms in seat.
 - b. Often leaves seat in situations when remaining seated is expected (eg, leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
 - c. Often runs about or climbs in situations where it is inappropriate. (Note: In adolescents or adults, may be limited to feeling restless.)
 - d. Often unable to play or engage in leisure activities quietly.
 - e. Is often "on the go," acting as if "driven by a motor" (eg, is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
 - f. Often talks excessively.
 - g. Often blurts out an answer before a question has been completed (eg, completes people's sentences; cannot wait for turn in conversation).
 - h. Often has difficulty waiting his or her turn (eg, while waiting in line).
 - i. Often interrupts or intrudes on others (eg, butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (eg, at home, school, or work; with friends or relatives; in other activities).
- D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (eg, mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

atomoxetine takes more time for there to be an effect (ie, 2–4 weeks). It is most important that no matter what medication is used, the diagnosis is correct and the correct dosage is prescribed. A recent study has demonstrated that one of the major factors contributing to treatment failure is inadequate dosing or the failure to recognize the presence of comorbid conditions such as learning disability, anxiety disorders, and depression.

88

Seventy to 90% of children with normal intellectual abilities respond well to stimulant medications. Stimulants enhance both dopamine and norepinephrine neurotransmission, which seems to improve impulse control, attention, and hyperactivity. The main side effects of methylphenidate and dextroamphetamine include appetite suppression and resulting weight loss, as well as sleep disturbances. Atomoxetine is a selective inhibitor of the presynaptic norepinephrine transporter, which increases norepinephrine and dopamine, and has a similar side-effect profile to the stimulants as well as side effects associated with antidepressants. Some individuals experience increased anxiety, particularly with higher doses of stimulant medications. Children with autism and developmental disabilities may be at increased risk for side effects with stimulants. Stimulants may exacerbate psychotic symptoms. They may also exacerbate motor tics in 30% of patients, but in 10% motor tics may be improved.

Cardiovascular effects of stimulant medications have undergone significant scrutiny over the past several years and do not appear to increase the risk of sudden death over the risk in the general population, especially in children without any underlying risk. Prior to beginning a stimulant medication, it is recommended that clinicians obtain any history of syncope, palpitations, chest pain, and family history of sudden death prior to age 30 that may predispose a child to sudden death. Stimulant products and atomoxetine should generally not be used in patients with serious heart problems or in those for whom an increase in BP or HR would be problematic. Consultation with the child's cardiologist would be indicated prior to making a decision about stimulant use. The US Food and Drug Administration (FDA) includes this statement in the labeling of stimulants: "sudden death has been reported in association with CNS stimulant treatment at usual doses in children and adolescents with structural cardiac abnormalities or other serious heart problems." The FDA has recommended that patients treated with ADHD medications should be monitored for changes in HR or BP.

AUTISM SPECTRUM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Two core features:

- Persistent deficits in social communication and social interaction across multiple contexts.
- Restricted, repetitive patterns of behavior, interests, or activities.

Autism spectrum disorder (ASD) is a neurologic disorder characterized by (1) persistent deficits in social communication and social interaction across multiple contexts and (2) restricted, repetitive patterns of behavior, interests, or activities. Autism was grouped under the pervasive developmental disorders in the DSM-IV with Asperger disorder, pervasive developmental disorder not otherwise specified, childhood disintegrative disorder (CDD), and Rett syndrome. DSM-5 combines autism, PDD, and Asperger syndrome into ASDs. Table 3-4 lists the DSM-5 criteria for diagnosis of an ASD. DSM-IV stipulated that the typical features or signs should be present prior to 3 years of age. DSM-5 now uses a caveat that the typical features or signs may not be present until social demands become greater and may be difficult to recognize in an individual who has learned compensatory strategies. As with any disorder, the typical features or signs must cause "clinically significant impairment" in function. As ASD and ID may be diagnosed in the same individual, social communication function should be impaired in comparison to the individual's "general developmental level." Severity is now specified as level I: "requiring support," level II: "requiring substantial support," and level III: "requiring very substantial support."

ASDs are relatively common, occurring in approximately 1 in 68 children based on surveillance data from the CDC in 2012. Males are overrepresented by about 4.5:1. About 32% of children with ASD also have an ID, and the prevalence of ID is higher in girls (37%) than in boys (31%). An etiology can be found in 6%–15% of children with ASD, or up to 30%–40% who have had a "thorough clinical genetics evaluation" or have "complex autism" the term used for children with co-occurring microcephaly, seizures, dysmorphic features, or major congenital anomalies. This percentage may increase as newer techniques such as whole-exome sequencing become more widely used. There is a strong familial component.

Table 3-4. Autism spectrum disorder.

Diagnostic Criteria

- A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
 - 1. Deficits in social-emotional reciprocity, ranging, eg, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
 - 2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, eg, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.

3. Deficits in developing, maintaining, and understanding relationships, ranging, eg, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

- B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
 - 1. Stereotyped or repetitive motor movements, use of objects, or speech (eg, simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
 - 2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (eg, extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
 - 3. Highly restricted, fixated interests that are abnormal in intensity or focus (eg, strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
 - 4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (eg, apparent indifference to pain/ temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

- C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Modified from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition. (Copyright ©2013). American Psychiatric Association. All rights reserved.

Parents of one child with autism of unknown etiology have a 7%-23% chance of having a second child with autism. The prevalence is higher if the second child is male or the affected child is female. The concordance rate among monozygotic twins is high but not absolute, and there is an increased incidence of speech, language, reading, attention, and affective disorders in family members of children with autism. The genetics of ASD are complex and inheritance patterns appear to be multifactorial. ASD is a heterogeneous disorder for which single gene disorders are not commonly found. As many as 800 susceptibility genes have been identified. These genes often have variable penetrance and expression, as well as "pleiotropy" (one genotype associated with different disorders such as one copy number variant associated with ASD, seizures, or schizophrenia). In addition epigenetics, gene-gene interactions, and gene-environment interactions may also play a role.

Evaluation & Management

Children with ASD are often not diagnosed until age 3–4 years, when their disturbances in reciprocal social interaction and

communication become more apparent. However, impairments in communication and behavior can often be recognized in the first 12-18 months of life. The most common early characteristics are a consistent failure to orient to one's name, regard people directly, use gestures, and to develop speech. Even if one of these skills is present, it is often diminished in frequency, inconsistent, or fleeting. Sharing affect or enjoyment is an important precursor to social interaction. By 16-18 months a child should have "joint attention," which occurs when two people attend to the same thing at the same time. This is usually accomplished by shifting eye gaze, pointing, or saying "look." Toddlers should regularly point to get needs met ("I want that") and to show ("look at that") by 1 year of age. By 18 months a toddler should be able to follow a point, imitate others, and engage in functional play (using toys in the way that they are intended to be used, such as rolling a car, throwing a ball, or feeding a baby doll). Restricted interests and repetitive behaviors sometimes do not emerge until after age 2, but usually are present before age 2.

There is mounting evidence that a diagnosis of ASD can be made reliably by age 2 years and is stable over time.

Because there is evidence that early intervention is particularly important for children with ASD, great interest has arisen in developing a screening instrument that can be used in very young children. The Modified Checklist for Autism in Toddlers—Revised with Follow up (M-CHAT-R/F) is designed for children 16–30 months of age. It is a parent report measure with 20 yes/no questions. There are clinician-administered follow-up questions for those who screen positive. Just under 50% of children who screen positive initially (M-CHAT-R/F score \geq 3) and after follow-up (M-CHAT-R/F score \geq 2) will go on to be diagnosed with an ASD; however, 95% will have some type of developmental concern. Fewer children screen positive on the initial parent completed screen with the revised version of the M-CHAT. It can be downloaded at https://m-chat.org/about.php.

An autism-specific screen is recommended at 18 and 24–30 months. The second screen is recommended because some of the symptoms may be more obvious in an older child and because about 30% of children with ASD experience a regression or plateau in skills between 12 and 24 months. Screening at 18 months could miss many of these children.

When behaviors raising concern for ASD are noted, the primary care provider should complete a thorough history and examination as discussed in the previous section on developmental disorders and the child should be referred to a team of specialists experienced in the assessment of ASD. At the same time, the child should also be referred to a local early intervention program and to a speech and language pathologist to begin therapy as soon as possible. If the diagnostic features are clearly present, a primary care provider may make a diagnosis of ASD to start autism-specific treatments as soon as possible. All children with ASD should have a formal audiology evaluation. A chromosomal microarray (CMA) and a DNA for fragile X syndrome should be considered first-tier tests in children with ASD. Second-tier tests are beyond the scope of this chapter (see the American College of Medical Genetics and Genomics practice guidelines (2013) or the review article by Yin and Schaaf (2017) for a more detailed discussion). Metabolic screening, lead level, and thyroid studies may also be done if indicated by findings in the history and physical examination. Although more evidence is needed, routine screening for metabolic disorders has been suggested including screening for mitochondrial disorders if there is evidence of an abnormal neurologic examination or lactic acidosis. An evaluation by a clinical geneticist should be offered to every family. A Wood lamp examination for tuberous sclerosis is also recommended. Neuroimaging is not routinely indicated even in the presence of mild/relative macrocephaly because children with autism often have relatively large heads. Neuroimaging should be done if microcephaly or focal neurologic signs are noted.

Approximately 30% of children with ASD demonstrate a plateau or loss of skills (usually only language and/or social skills) between 12 and 24 months of age. This regression/

plateau in skills has been documented in prospective longitudinal studies of infant siblings of children with ASD who go on to be diagnosed with ASD. The loss is often gradual. It can co-occur with atypical development and can be fluctuating. It usually occurs before the child attains a vocabulary of 10 words. If a child presents with regression, he or she should be referred to a child neurologist. An overnight EEG should be considered when there is a history of regression to rule out electrical status epilepticus in sleep. Metabolic testing and a magnetic resonance imaging (MRI) of the brain should also be considered when there is a history of regression.

Early, intensive behavioral intervention for children with ASD is essential. The National Research Council reviewed the available literature in 2001 and recommended entry into treatment as soon as autism is suspected; 25 hours of intervention per week; parent training and involvement in treatment; ongoing assessment, program evaluation, and programmatic adjustment as needed; and intervention that focuses on communication, social interaction, and play skills that can be generalized in a naturalistic setting. Functional use of language leads to better behavioral and medical outcomes. Early detection and early intervention have a positive impact on children with ASDs. The National Research Council states: "A substantial subset of children with autistic spectrum disorders are able to make marked progress during the period that they receive intensive early intervention, and nearly all children with autistic spectrum disorders appear to show some benefit. Children with ASD who begin treatment before age $3-3\frac{1}{2}$ years make the greatest gains with intervention." Naturalistic training models for children with ASD implemented before age 3 result in 90% of children attaining functional use of language compared to 20% who begin intervention after age 5. The Early Start Denver Model (ESDM) is one model for early intervention. In a recent study, 48 children 18-30 months of age were randomly assigned to ESDM for 20 h/wk for 2 years or community intervention. The group that received ESDM improved by a mean of 17.6 standard points on developmental testing (Mullen) versus 7.0 points in the control group. Standard scores for adaptive function were maintained in the ESDM group and decreased in the control group. There are many models for this type of intervention and much variability in what is available in different areas of the country. Families should be encouraged to find a model that best suits the needs of the child and the family.

The primary care provider provides a medical home for children with ASD. This requires coordination of care. One role of the primary care provider is to ensure that medical concerns such as sleep disorders, seizures, or gastrointestinal symptoms are addressed. Any worsening of behavior in a child with autism may be secondary to unrecognized medical issues such as pain from a dental abscess or esophagitis. Practice pathways for primary care providers for management of multiple co-occurring conditions in children with ASD 92

have been developed through the Autism Speaks-Autism Treatment Network. A practice pathway for the identification, evaluation, and management of insomnia in children with ASDs has been developed. The pathway stresses the importance of screening for sleep issues in children with ASD and interviewing around comorbid medical conditions that may impact sleep. Individualizing behavior strategies/ sleep hygiene for the child with ASD is also very important. In addition, psychiatric comorbidities such as anxiety and ADHD are common in children with ASD and should be addressed by the PCP or a specialist. Psychopharmacologic management may be needed to address issues with attention, hyperactivity, anxiety, irritability, aggression, and other behaviors that have a significant impact on daily function. Multiple recent reviews of psychopharmacologic treatments are available. A clinical practice pathway for evaluation and medication choice for ADHD symptoms in children with ASD has also been developed. Children with ASD are less likely to respond to stimulants than children with typical development and are more likely to have side effects. Smaller doses and nonstimulants such as guanfacine should be considered especially in children younger than 5 years, children with IQ less than 50-70, severe anxiety, unstable mood, or low weight/poor appetite. A practice pathway for the management of irritability and problem behavior (aggression toward property, self, or others) in children with ASD was published in 2016. The pathway includes evaluation for conditions that may contribute to irritability and problem behavior: medical (sleep problems, medication side effects, and management of pain or discomfort associated with gastrointestinal, dental, or other medical conditions); impairment in ability to communicate; psychiatric (anxiety, depression); environmental stressors (psychosocial, inadequate educational and behavioral supports, change in routine); and unintentional reinforcement (attention, task avoidance, removal from overwhelming sensory stimuli, or tangible reward such as giving a snack to calm the child). A functional behavioral assessment is helpful to determine the antecedent and consequence of the behavior. Reinforcing positive behavior, providing supports in the environment to assist with tolerance of triggers, providing replacement behaviors for negative behaviors, and avoiding reinforcement are strategies to improve behavior. Risperidone and aripiprazole are the only medications that have an FDA indication for treatment of irritability and aggression in children with ASD. The practice pathway recommended consideration of clonidine and N-acetylcysteine prior to atypical antipsychotics when there were no significant safety concerns necessitating urgent use of the medication that is most likely to improve behavior. These medications have limited evidence for safety and efficacy but appear to have fewer longterm side effects. Anxiety is common in children with ASD with approximately 40% having at least one anxiety disorder. Anxiety can be difficult to diagnose in children with ASD due to difficulty with communication and insight/recognition of feelings and due to some overlap with symptoms of ASD. Anxiety in children with ASD can present with irritability/externalizing behaviors and with dysregulation or symptoms that mimic ADHD. A recent review of diagnosis and management of anxiety in children with ASD recommended using feedback from multiple sources such as the child, parent, clinician, therapists, and school personnel when evaluating for the presence of an anxiety disorder. Randomized controlled trials (RCT) for treating anxiety in children with ASD show moderate efficacy with cognitive behavioral therapy. There have been no RCTs for medications to treat anxiety in children with ASD. Selective serotonin reuptake inhibitors (SSRI) may be used but clinicians should start with low doses and increase slowly while monitoring for behavioral activation. Alpha agonists and propranolol can sometimes be helpful as well. Many complementary and alternative (CAM) treatments for autism have been proposed. As many as 33% of families use special diets and 54% of families use supplements for their child with ASD based on data from the Interactive Autism Network. Most have limited evidence regarding safety and efficacy. The review of CAM prepared by the AAP Task Force on Complementary and Alternative Medicine and the Provisional Section on Complementary, Holistic, and Integrative Medicine is particularly valuable.

INTELLECTUAL DISABILITY

The field of developmental disabilities has been evolving and redefining the constructs of disability and using new terms to reflect that evolution. The term *mental retardation* is considered pejorative, demeaning, and dehumanizing; therefore, the term *intellectual disability* (ID) is used. DSM-5 uses the diagnosis *intellectual disability* (intellectual developmental disorder) and emphasizes the need for evaluation of adaptive function in addition to cognitive testing (IQ). The term *disability* is used by professionals and advocacy groups.

Recently, a rethinking of the construct of disability has emerged that shifts the focus from limitations in intellectual functioning and adaptive capability (a person-centered trait) to a human phenomenon with its source in biologic or social factors and contexts. The current view is a social-ecological conception of disability that articulates the role of disease or disorder leading to impairments in structure and function, limitations in activities, and restriction in participation in personal and environmental interactions. The term *intellectual disability*, which is consistent with this broader view, is increasingly being used and reflects an appreciation of the humanness and potential of the individual. The diagnostic criteria currently remain the same; however, the construct and context has changed.

Having noted this, it is important to acknowledge that significant delays in the development of language, motor skills, attention, abstract reasoning, visual-spatial skills, and academic or vocational achievements are associated with ID. Deficits on standardized testing in cognitive and adaptive functioning greater than two standard deviations below the mean for the population are considered to fall in the range of ID. The most common way of reporting the results of these tests is by using an intelligence quotient. The intelligence quotient is a statistically derived number reflecting the ratio of age-appropriate cognitive function and the child's actual level of cognitive function. A number of accepted standardized measurement tools, such as the Wechsler Intelligence Scale for Children, fifth edition, can be used to assess these capacities. To receive a diagnosis of ID, a child must not only have an intelligence quotient of less than 70 but must also demonstrate adaptive skills more than two standard deviations below the mean. Adaptive function refers to the child's ability to function in his or her environment and can be measured by a parent or teacher interview using an instrument such as the Vineland Adaptive Behavior Scales. Cognitive function tends to predict academic success and adaptive function tends to predict level of independence in daily living skills. Levels of severity are based on adaptive function which determines the level of supports needed.

Global Developmental Delay (GDD) is the diagnosis used for children with significant delays in at least two developmental domains (cognitive, speech and language, gross and fine motor, social, and daily living skills). This diagnosis is typically used in children younger than 5 years due to poor predictive validity of cognitive testing prior to age 5–6 years. The diagnosis of GDD is also used in children older than 5 who cannot adequately participate in standardized testing.

The prevalence of ID is approximately 1%–3% in the general population and may vary by age. Mild levels of ID are more common and more likely to have a sociocultural cause than are more severe levels. Poverty, deprivation, or a lack of exposure to a stimulating environment can contribute to developmental delays and poor performance on standardized tests.

Evaluation

Children who present with developmental delays should be evaluated by a team of professionals as described at the beginning of this section. For children $0-3\frac{1}{2}$ years of age, the Bayley Scales of Infant Development, third edition, is a well-standardized developmental test. For children older than 3 years, standardized cognitive testing—such as the Wechsler Preschool and Primary Scale of Intelligence, fourth edition; the Wechsler Intelligence Scale for Children, fifth edition; the Stanford-Binet V; or the Differential Abilities Scale, second edition—should be administered to assess cognitive function over a broad range of abilities, including verbal and nonverbal scales. For the nonverbal patient, a scale such as the Leiter, third edition, will assess skills that do not involve language. A full psychological evaluation in school-aged children should include an emotional assessment if psychiatric or emotional problems are suspected. Such problems are common in children with developmental delays or ID.

The evaluation of a child with ID or GDD should include a complete medical and family history; as well as a physical examination, including head circumference, neurologic examination, dysmorphology examination, and skin examination for neurocutaneous stigmata. Clinicians should also screen for co-occurring conditions such as sleep problems, feeding problems, obesity, gastrointestinal disorders, and behavioral and psychiatric conditions. Families should be offered a genetics evaluation. Expert consensus recommends fragile X molecular genetic testing and CMA as the initial workup for ID/GDD unless the child's phenotype suggests more targeted testing, as in the case of Down or Williams syndrome. If there is a family history of multiple miscarriages suggesting a possible balanced translocation, a karyotype is recommended in addition to CMA. In children with ID/GDD, CMA will be positive about 6%-10% of the time and Fragile X testing will be positive in about 2%-3%. Families should be counseled about the possibility of CMA finding a copy number variation of unknown clinical relevance or one with clinical relevance unrelated to ID/GDD. A child with an abnormal result should receive genetic counseling from a medical geneticist or certified genetic counselor. Second-tier testing may include nonsyndromic X-linked ID genes and high-density X-CMA in males, and MECP2 deletion, duplication, and sequencing in females. Whole-exome sequencing may also be considered in patients for whom there is a high index of suspicion that a cytogenetic etiology exists but whose workup has been negative. An audiology evaluation should be completed, even if a child passed a hearing evaluation at birth. An ophthalmology examination should also be considered. An EEG should be considered if there are any concerns for seizures or a regression in skills.

Neuroimaging should be considered in patients with microcephaly, macrocephaly, seizures, loss of psychomotor skills, or specific neurologic signs such as spasticity, dystonia, ataxia, or abnormal reflexes. A lead level should be considered in children who frequently put toys or other nonfood items in their mouth. Thyroid function studies should be carried out in any patient who exhibits clinical features associated with hypothyroidism.

Screening for Inborn Errors of Metabolism (IEM) has a relatively low yield (0%-5%) in children who present with developmental delay or ID. Most patients with IEM will be identified by newborn screening or present with specific indications for more focused testing, such as failure to thrive, recurrent unexplained illnesses, plateauing or loss of developmental skills, coarse facial features, cataracts, recurrent coma, abnormal sexual differentiation, arachnodactyly, hepatosplenomegaly, deafness, structural hair abnormalities, muscle tone changes, and skin abnormalities. However, treatable forms of IEMs may present later or without regression or plateau. There are currently 89 "treatable" types of IEM. Treatments may target improvement in symptoms, slowing progression of the disease, or providing support during an illness. While controversy over cost-benefit of screening for rare diseases exists, van Karnebeek et al proposed a two-tiered approach to screening for treatable IEM, which is based on "availability, affordability, yield, and invasiveness." Tier 1 tests/"nontargeted screening tests" include blood tests for lactate, ammonia, plasma amino acids, total homocysteine, acylcarnitine profile, copper, ceruloplasmin; and urine tests for organic acids, purines and pyrimidines, creatine metabolism, oligosaccharides, and glycosaminoglycans. Testing for 7- and 8-dehydrocholesterol to screen for Smith-Lemli Opitz syndrome and screening for congenital disorders of glycosylation may also be included in first-tier testing. Second-tier testing usually comprises tests that are the only tests for one disease or are more invasive such as tests of cerebrospinal fluid. AAP guidelines for tier 1 tests are somewhat different and include blood tests for plasma amino acids, total homocysteine, acylcarnitine profile; and urine tests for organic acids, purines and pyrimidines, creatine metabolism, oligosaccharides, and mucopolysaccharides. An app has been developed, which is helpful for identifying appropriate tests for treatable etiologies of ID/GDD.

Serial follow-up of patients is important as the physical and behavioral phenotype changes over time and diagnostic testing improves with time. Although cytogenetic testing may have been negative 10 years earlier, advances in high-resolution techniques may now reveal an abnormality that was not identified previously. A stepwise approach to diagnostic testing may also be more cost-effective, so that the test most likely to be positive is done first.

Management

Once a diagnosis of ID is made, treatment should include a combination of individual therapies, such as speech and language therapy, occupational therapy or physical therapy, special education support, behavioral therapy or counseling, and medical intervention, which may include psychopharmacology. To illustrate how these interventions work together, two disorders are described in detail in the next section.

SPECIFIC FORMS OF INTELLECTUAL DISABILITY & ASSOCIATED TREATMENT ISSUES

1. Fragile X Syndrome

The most common inherited cause of intellectual disability (ID) is fragile X syndrome, which is caused by a trinucleotide expansion within the fragile X mental retardation I (FMR1) gene (see Chapter 37). The full mutation is associated with methylation of the gene, which turns off transcription, resulting in a deficiency in the FMR1 protein. This protein regulates the metabotropic glutamate receptor 5. Fragile X syndrome includes a broad range of symptoms. Children with fragile X syndrome often present with developmental delays, social anxiety, hyperactivity, and difficult behavior in early childhood. Most males will have ID with symptoms such as gaze aversion, perseverative language, hand biting, and significant hypersensitivity to environmental stimuli. About 20% of males with fragile X syndrome meet criteria for an ASD. Girls are usually less affected by the syndrome because they have a second X chromosome that produces FMR1 protein. Approximately 30% of girls with the full mutation have cognitive deficits and a greater proportion have ADHD, anxiety, and shyness. Prominent ears; long, thin face; prominent jaw and forehead; joint hyperextensibility; and macroorchidism (in boys) are common; however, approximately 30% of children with fragile X syndrome may not have these features. The diagnosis should be suspected in any child with behavioral problems and developmental delays. As boys move into puberty, macroorchidism becomes more obvious, and facial features can become more elongated. Medical conditions commonly associated with fragile X syndrome include seizures, strabismus, otitis media, gastroesophageal reflux, mitral valve prolapse, and hip dislocation.

Management

A variety of therapies are helpful for individuals with fragile X syndrome. Speech and language therapy can decrease oral hypersensitivity, improve articulation, enhance verbal output and comprehension, and stimulate abstract reasoning skills. Because approximately 10% of boys with the syndrome will be nonverbal at age 5 years, the use of augmentative communication techniques may be helpful. Occupational therapy can be helpful in providing techniques for calming hyperarousal to stimuli and in improving the child's fine and gross motor coordination and motor planning. If the behavioral problems are severe, it can be helpful to involve a behavioral psychologist who emphasizes positive reinforcement, time-outs, consistency in routine, and the use of both auditory and visual modalities, such as a picture schedule, to help with transitions and new situations.

Psychopharmacology can also be useful to treat ADHD, aggression, anxiety, or severe mood instability. Clonidine or guanfacine may be helpful in low doses to treat hyperarousal, tantrums, or hyperactivity. Stimulant medications such as methylphenidate and dextroamphetamine are usually beneficial by age 5 years and occasionally earlier. Relatively low doses are used because irritability is often a problem with higher doses.

Anxiety may also be a significant problem and the use of a selective serotonin reuptake inhibitor (SSRI) is often helpful. SSRIs may also decrease aggression or moodiness, although in approximately 25% of cases, an increase in agitation or activation may occur. Aggression may become a significant problem in childhood or adolescence for individuals with fragile X syndrome. In addition to behavioral management, medication may be needed. Clonidine, guanfacine, or an SSRI may decrease aggression, and sometimes an atypical antipsychotic may be needed.

Clinical trials have begun in adults and children with fragile X syndrome to evaluate targeted treatments such as metabotropic glutamate receptor 5 antagonists and γ -aminobutyric acid (GABA) agonists. These medications have shown promising results in mouse models of fragile X syndrome.

An important component of management is genetic counseling. Parents should meet with a genetic counselor after the diagnosis of fragile X syndrome is made because there is a high risk that other family members are carriers or may be affected by the syndrome. A detailed family history is essential. Female carriers have a 50% risk of having a child with the fragile X mutation. Male carriers are at risk for developing FXTAS, a neurodegenerative disorder, as they age.

It is also helpful to refer a newly diagnosed family to a parent support group. Educational materials and parent support information may be obtained on the National Fragile X Foundation website. Fragile X Research Foundation: http://www.fraxa.org.

2. Fetal Alcohol Spectrum Disorders

Alcohol exposure in utero is associated with a broad spectrum of developmental problems, ranging from learning disabilities to severe ID. Fetal alcohol spectrum disorders (FASD) is an umbrella term describing the range of effects that can occur in an individual exposed to alcohol prenatally. The prevalence of FASD is about 1%-5%. Thus, physicians should always ask about alcohol (and other drug) intake during pregnancy. This is particularly true when evaluating a child presenting with developmental delays. The exact amount of alcohol consumption that leads to teratogenesis remains unclear. Thus, it is best to say that to avoid an FASD, abstention from all alcoholic drinks during pregnancy is essential. Features associated with FASD include facial anomalies, including short palpebral fissures (≤ 10th percentile), thin upper lip, and smooth philtrum (lip/philtrum guide is available for some races/ethniciites);

Table 3-5. Fetal alcohol spectrum disorders (FASD).

poor prenatal or postnatal growth (height or weight \leq 10th percentile); CNS abnormalities including poor brain growth (head circumference \leq 10th percentile), morphogenesis, or neurophysiology (recurrent nonfebrile seizures with no other known etiology); neurobehavioral impairment; and major congenital cardiac, skeletal, renal, ocular, or auditory malformations or dysplasias.

New clinical consensus guidelines for the diagnosis or FASD were published in 2016 by Hoyme et al (Table 3-5). The new guidelines include definitions for prenatal alcohol exposure and neurobehavioral dysfunction, an updated definition of alcohol related birth defects, a dysmorphology rating system, a lip/philtrum guide for North American white population, and an increase in cutoffs for head circumference, growth, and palpebral fissure percentile cutoffs from less than 3% to 10% or less in an effort to increase sensitivity for identifying children with FASD. The guidelines give criteria for Documented Prenatal Alcohol Exposure: six or more drinks per week for 2 weeks or more during the pregnancy; three or more drinks per occasion on two or more occasions during the pregnancy; documented social or legal problems related to alcohol; documented intoxication; positive alcohol-exposure biomarker during pregnancy or at birth such as fatty acid ethyl esters, phosphatidylethanol, or ethyl glucuronide; or increased prenatal risk on a validated screening tool. This does not mean that alcohol use during pregnancy in amounts lower than that guidelines recommend is safe. AAP's position is that no amount of alcohol during pregnancy is considered safe. The guidelines also

FASD Diagnoses	Clinical Features Required	Confirmed Prenatal Exposure
Fetal alcohol syndrome	 At least 2 of 3 specified facial anomalies^a Poor prenatal or postnatal growth^b At least 1 CNS abnormality^c Neurobehavioral impairment 	±
Partial fetal alcohol syndrome (with known exposure)	 At least 2 of 3 specified facial anomalies^a Neurobehavioral impairment 	+
Partial fetal alcohol syndrome (without known exposure)	 At least 2 of 3 specified facial anomalies^a Growth deficiency or CNS abnormality^{b,c} Neurobehavioral impairment 	-
Alcohol-related neurodevelopmental disorder	Neurobehavioral impairment (cannot be made before 3 years of age)	+
Alcohol-related birth defects	One major congenital malformation ^d	+

^aFacial anomalies: short palpebral fissures (≤ 10th percentile), thin upper lip, and smooth philtrum (lip/philtrum guide is available for some races/ethniciites).

^bPoor prenatal or postnatal growth (height or weight \leq 10th percentile).

^cCentral nervous system (CNS) abnormalities: poor brain growth (head circumference \leq 10th percentile), morphogenesis, or neurophysiology (recurrent nonfebrile seizures with no other known etiology).

^dMajor congenital anomalies, malformations, or dysplasias: cardiac, skeletal, renal, ocular, or auditory.

recommend that a multidisciplinary team make the diagnosis and that other disorders be considered or ruled out. Disorders with overlapping features include Cornelia deLange, 22q11.2 deletion syndrome, 15q duplication syndrome, Noonan syndrome, Dubowitz syndrome, and exposure to other teratogens such as valproic acid. The dysmorphology rating system was developed to aid in this process. The DSM-5 also added the diagnosis Neurobehavioral Disorder With Prenatal Alcohol Exposure (ND-PAE) while stipulating that more study is indicated.

Management

Individuals with FASD typically have significant difficulty with complex cognitive tasks and executive function (planning, conceptual set shifting, affective set shifting, response inhibition, and fluency). They process information slowly. They may do well with simple tasks but have difficulty with more complex tasks. They have difficulty with attention and short-term memory. They are also at risk for social difficulties and mood disorders. Functional classroom assessments can be a very helpful part of a complete evaluation. Structure is very important for individuals with FASD. Types of structure that may be helpful are visual structure (color code each content area), environmental structure (keep work area uncluttered, avoid decorations), and task structure (clear beginning, middle, and end). Psychopharmacologic intervention may be needed to address issues such as attention and mood.

Adolescence

Amy E. Sass, MD, MPH Molly J. Richards, MD

INTRODUCTION

Adolescence is a period of rapid physical, emotional, cognitive, and social development. Generally, adolescence begins at age 11–12 years and ends between ages 18 and 21. Most teenagers complete puberty by age 16–18 years; in Western society; however, for educational and cultural reasons, the adolescent period is prolonged to allow for further psychosocial development before the individual assumes adult status. The developmental passage from childhood to adulthood includes the following steps: (1) completing puberty and somatic growth; (2) developing socially, emotionally, and cognitively, and moving from concrete to abstract thinking; (3) establishing an independent identity and separating from the family; and (4) preparing for a career or vocation.

EPIDEMIOLOGY

Adolescents (ages 10–19) and young adults (ages 20–24) make up 21% of the population of the United States. Adolescence is typically a healthy time of life but several important public health and social problems can greatly affect morbidity and mortality during these years. Environmental factors are critical in challenging or supporting an adolescent's health. The positive development of young people facilitates their adoption of healthy behaviors. The behavioral patterns established during the developmental periods of adolescence help determine young people's current health status and their risk for developing chronic diseases in adulthood.

MORTALITY DATA

In 2014, there were 9,586 deaths among adolescents aged 15–19 years, representing a rate of 45.5 per 100,000. Cultural and environmental rather than organic factors

pose the greatest threats to life. The three leading causes of death in adolescents aged 15–19 years were unintentional injury (41%), suicide (18%), and homicide (15%) (Figure 4–1). The primary cause of unintentional injury death was motor vehicle crashes (56.8%), followed by poisoning (29.5%), which includes prescription drug overdoses. Since 2000, deaths from opioid overdose have increased by over twofold among 15–24 year olds. Homicide deaths were predominantly attributable to firearms (86.6%), and firearms were also a leading mechanism of suicide death (44.8%). The mortality rate of adolescent males aged 15–19 was more than twice that of females (63.3 vs 26.8 per 100,000, respectively), largely due to higher rates of unintentional injury, homicide, and suicide death among males.

The rate of adolescent mortality has declined by 12% since 2000. This decline may be largely attributable to decreases in unintentional injury. Motor vehicle crashes, the leading cause of death among teenagers in the United States, account for more than one-quarter of deaths in this age group. Death rates from motor vehicle accidents have decreased from 26.9/100,000 in 2000 to 11.9/100,000 in 2014.

The most concerning aspect about recent mortality data is the rise in suicide rates. Although the absolute increase has been relatively modest, the mortality rate from suicide in adolescents 15–19 years has risen steadily: 7.5/100,000 in 2010 to 8.7/100,000 in 2014. 2013 was the first year in which suicide overtook homicide as the second leading cause of death in adolescents.

MORBIDITY DATA

Demographic and economic changes in the American family have had a profound effect on children and adolescents. In 2013, more than 16.5 million children younger than 18 years lived in households with incomes below 100% of

▲ Figure 4–1. Leading causes of death (Ages 15–24 years in 2014).

the U.S. Census Bureau's poverty threshold, representing 22.3% of all children in the United States and an increase from 20.7% in 2009. Poverty affects many aspects of a child's life, including living conditions, nutrition, and access to health care. Significant racial and ethnic disparities also exist with nearly 50% of non-Hispanic American Indian/Alaska Native children, 38.8% of non-Hispanic Black children, and 34.3% of Hispanic children living in households with incomes below 100% of the poverty, compared to 12.8% of non-Hispanic white children. Single-parent families are particularly vulnerable to poverty. In 2013, 44.7% of children living in a mother-headed household experienced poverty, as did 21.3% of children living in a father-headed household, compared with 13.2% of children living in two-parent families.

The major causes of morbidity during adolescence are psychosocial and often correlate with poverty: unintended pregnancy, sexually transmitted infection (STI), substance abuse, smoking, dropping out of school, depression, running away from home, physical violence, and juvenile delinquency. High-risk behavior in one area is frequently associated with problems in another (Figure 4–2). For example, teenagers who live in a dysfunctional family (eg, alcoholism, physical, or sexual abuse) are much more likely to be depressed than other teenagers. A depressed teenager is at greater risk for drug and alcohol abuse, academic failure, inappropriate sexual activity, STIs, pregnancy, and suicide.

Early identification of the teenager at risk for these problems is important in preventing immediate complications and future associated morbidities.

PROVIDING A MEDICAL HOME FOR ADOLESCENTS

The American Academy of Pediatrics (AAP) developed the primary care medical home (PCMH) as a model of delivering primary care that is accessible, continuous, comprehensive, family-centered, coordinated, compassionate, and culturally effective to every child and adolescent. In addition, a PCMH for pediatric and adolescent patients is a family-centered partnership within a community-based system that provides uninterrupted care with appropriate payment to support and sustain optimal health outcomes. PCMHs address preventative, acute, and chronic care from birth through transition to adulthood. Adolescent and young adults enrolled in CHAPTER 4

▲ Figure 4–2. Interrelation of high-risk adolescent behavior.

PCMHs are more likely to receive multiple preventive services including immunizations, screening for sexually transmitted infections, and contraception. Unfortunately, adolescents and young adults are the most likely age group to be uninsured and have the lowest rates of primary care use of any age group. Furthermore, health care coverage is disproportionately lacking by minority youth. Adolescents, therefore, frequently receive care within a variety of delivery systems with varying access to comprehensive care or specialty care and from a variety of providers with varied levels of training in adolescent care. They are also often seen in pediatric clinics that may not be geared toward teens, making them feel less comfortable and leading them not to access care or to access care in urgent care or emergency room settings. On the other hand, adolescents respond positively to settings and services that communicate sensitivity to their age and progressing autonomy. Age and developmentally appropriate health information pamphlets and educational materials about adolescent health and wellness issues are appreciated by patients and their families.

Medical Home Initiatives for Children With Special Needs Project Advisory Committee. The Medical Home. Pediatr 2002;110(1) [PMID: 12093969].

RELATING TO THE ADOLESCENT PATIENT

Adolescence is one of the physically healthiest periods in life. The challenge of caring for most adolescents lies not in managing complex organic disease, but in accommodating the cognitive, emotional, and psychosocial changes that influence health behavior. The provider's initial approach to the adolescent may determine the success or failure of the visit. Although providers may have biases, they must learn to put them aside. Adolescents may initially present as closed off, angry, sullen or frustrated but this is often a result of feeling afraid, intimidated or judged. They may be acutely aware of being distrusted, disliked or not listened to as that may have been their experience in other medical settings. The primary care provider should behave simply and honestly, without an authoritarian or excessively professional manner. Because the self-esteem of many young adolescents is fragile, the provider must be careful not to overpower and intimidate the patient. To establish a comfortable and trusting relationship, the provider should

Garcia-Huidobro D et al: Effect of patient-centered medical home on preventive services for adolescents and young adults. Pediatr 2016; 137(6): PMID: 27244851.

Heron M: Deaths: leading causes for 2014. Natl Vital Stat Rep 2016;65(5) [PMID: 27376998].

strive to present the image of an ordinary person who has special training and skills.

Establishing rapport with an adolescent may not happen during the first visit but is easier to accomplish if the following tips are kept in mind:

- Remember that the adolescent is your primary patient. Introduce yourself to the adolescent first and address your questions to him/her. This can be a significant change for adolescents and their families from a pediatrics model, where the parent/guardian does most of the talking. It is an important transition and may be initially difficult for both the adolescent and family.
- 2. Show genuine interest in the adolescent, as a person and as a patient, and point out positive accomplishments. Despite adolescents' reputation as "sullen," they are often very eager to talk about their interests and respond well when the many positive things in their lives are emphasized (instead of focusing on only negative aspects of their behaviors).
- 3. Treat adolescent concerns seriously and take time to listen. Providers often get frustrated with teenagers' complaints of pain (vague and overstated). Adolescents' reports of severe pain may be an attempt to be taken seriously rather than indicating that they are critically ill. Take time listening to adolescents and explain your findings. Many teens just want to be reassured that they are "normal" or that they do not have a serious illness. They may have specific concerns (eg, about an STI or cancer) that they will not disclose unless you ask. Taking time to discuss their concerns and to give reassurance when appropriate often prevents unnecessary testing and multiple repeat visits (especially to emergency rooms).
- 4. Use a developmentally oriented approach. While it is important to cover areas of sexuality, family, peer group, and drug use, the clinician should keep in mind the developmental stage of the adolescent. For example, it would not be appropriate to ask a 12-year-old prepubertal male the same questions in the same manner as for an 18-year-old fully mature male.

Because the onset and termination of puberty vary from child to child, chronologic age may be a poor indicator of physical, physiologic, and emotional maturity. In communicating with an adolescent, the provider must be sensitive to the adolescent's developmental level. Recognizing that outward appearance and chronologic age may not be an accurate reflection of cognitive development.

THE STRUCTURE OF THE VISIT

The Interview

The first few minutes may determine the entire outcome of the interview. Starting the interview with neutral, nonpersonal questions can help the adolescent feel more comfortable and defuse anxiety. Having the adolescent and parent/guardian complete a paper or electronic health history questionnaire prior to the start of the appointment is useful to identify health concerns and collect past medical and surgical historical data, medication use and medication allergies, family history of medical and psychiatric problems, and a review of systems (Figure 4-3). The questionnaire should also contain social history questions that assess healthy behaviors as well as risk behaviors that could be detrimental to health. Adolescents often report health concerns and report behaviors on a questionnaire that they may not articulate verbally. Ideally, the adolescent should complete his/her questionnaire privately without the parent/guardian seeing the responses, particularly about confidential risk behaviors.

Confidentiality

Confidentiality protection is an essential component of health care for adolescents. Assurance of confidential care is needed for adolescents to access health care services. It is also an important part of the provider–patient relationship. Adolescents are more likely to disclose sensitive information, have positive perceptions of care, feel more actively involved in their own healthcare, and return for future care if physicians assure confidentiality. Despite the importance of confidentiality, many teens do not identify their primary care physician as a source of confidential care.

Families remain crucial to supporting teens' health and psychosocial development. They offer vital information about the home environment, school, medical and family history and a myriad of other issues that adolescents may not know or may not offer. Beginning in early adolescence, providers should routinely spend at least part of each visit alone with each patient to convey to the young patients and their parents that this is a standard part of adolescent health care and begins the slow transition process into adulthood (independent provider-patient relationships). It is important to discuss with teens and their parents the importance of confidentiality, but that confidentiality does not extend to life-threatening concerns. Although parents hold complex views regarding adolescent confidentiality, studies have shown that parents usually support the idea that adolescents should have the opportunity to openly communicate with their provider alone. At the age of 18 years it is appropriate to ask adolescents whether or not they want parents involved in their medical visits.

It is important to remind adolescents that sensitive issues are discussed because they are important for health. At the beginning of the interview, it is useful to say, "I am going to ask you some personal questions. This is not because I am trying to pry into your personal business, but because these questions are important to your health. Revised 04/21/2015

I want to assure you that what we talk about is confidential, just between the two of us, except in certain circumstances. If you tell me that you are hurting yourself or someone else is hurting you or if you intend to hurt someone else, we will have to share this information with your parents (or guardians)."

Berlan ED, Bravender T: Confidentiality, consent and caring for the adolescent patient. Curr Opin Pediatr 2009;21:450–456.
SAM Position Statement. Confidential health care for adolescents: position paper of the society for adolescent medicine. J Adolesc Health 2004;35:160–167.

The HEADSS Assessment

Health care providers who see adolescents must be able and willing to take a developmentally appropriate psychosocial history. The HEADSS (Home, Education/ employment, Activities, Drugs, Sexuality, and Suicide/ depression) assessment acronym is useful for organizing this history (Table 4–1). Ideally the sensitive aspects of the history should be obtained with the adolescent alone. Providers may need to be flexible with history taking to allow for this to happen after the parent/guardian leaves the examination room.

Table 4–1. HEADSS assessment.

	Questions	Reasons
Home and environment	Where do you live, and who lives there with you? How do you get along with your parents, siblings? Is there anything you would like to change about your family?	Home life has an important impact on an adolescent's ability to succeed. It is important to know whether they live in a safe and supportive environment.
Education and employment	Are you in school? What are you good at in school? What do you like about school? What is hard for you? What grades do you get? How much school did you miss last year? Why? Have you ever been suspended or expelled? Why? How do you get along with your teachers/peers? Have you been involved with bullying? What are your future plans/goals?	School is likely the primary social activity in the adolescent's life. Problems in school, academically or socially, can be an indicator of other issues (medical and/or psychosocial). Future goals and plans can be important motivators in high-risk behavior change.
Activities	Tell me about your relationships with friends? What do you (or your friends) do for fun? Are you involved in any extracurricular activities or activities in your community? Do you have a job? How many hours a week do you work? Do you play sports or exercise? What activities do you do and how often? How many hours of screen time do you have per day?	Disengagement and withdrawal can be a sign of other problems.
Drugs	Many young people experiment with marijuana, drugs, smoking cigarettes, or drinking alcohol. Have you or your friends ever tried them? What did you try? How often do you use these things? Do you ever operate a vehicle under the influence of drugs or alcohol or ride with an impaired driver?	Positive answers can lead to more in-depth evaluation of use (see Chapter 5).
Sexuality/ Relationships	Are you in a romantic relationship or have you been in one in the past? Tell me about your partner. Do you feel you have a healthy relationship? How do you define a healthy relationship? Have you (or your friends) had sex? How do you feel about it?	It is important to normalize sexual feelings even in the absence of sexual activity. Teens not having sex can still have conversations about sexuality, including masturbation. It is also important to avoid assumptions about patients' sexual orientation and to be nonjudgmental about sexual practices.
Suicide/depression	Have you had long periods of time where you felt down, depressed, or irritable? Have you ever thought about death, dying or suicide?	Psychosocial history should reveal indicators of depression.

HEADSS, Home, Education/employment, Activities, Drugs, Sexuality, and Suicide/depression.

Asking About Abuse and Violence

Using a generalizing scenario to discuss these difficult topics can be helpful; that is, "Some of my patients have told me that their parents may get very angry and hit them. Does anything like this happen in your family?" Questions also should be asked about dating violence and sexual abuse/assault; that is, "Have you ever been pressured or forced to have sex when you didn't want to?" It is also important to ask teens about their personal history of being a victim and/or perpetrator of violence, that is, fighting, arrests, and involvement with law enforcement, gang involvement, use of weapons and firearms, violence issues among peers, and the presence and security of weapons/firearms in the home, as these factors may place the adolescent at a higher risk of unintentional injury and death.

Physical Examination

A complete physical examination should be conducted at adolescent annual health supervision visits (Table 4–2). During early adolescence, teenagers may be shy and modest. The examiner should address this concern directly, because

Table 4–2. Physical examination of adolescents.

- A complete physical examination is included as part of every health supervision visit. The following examination components are especially important in the adolescent patient:
- Vital Signs: Measure and plot height and weight on CDC clinical growth charts (http://www.cdc.gov/growthcharts/clinical_charts .htm). Calculate and plot BMI on CDC clinical growth charts. Measure BP and evaluate elevated BP by age and height percentiles to determine the degree of hypertension per the National Heart, Lung, and Blood Institute BP tables for children and adolescents (http://www.nhlbi.nih.gov/files/docs/guidelines/child_ tbl http://www.nhlbi.nih.gov/files/docs/guidelines/child_tbl.pdf).
- Skin: Inspect for acne, acanthosis nigricans, atypical nevi, tattoos, piercings, and signs of abuse or self-inflicted injury.
- Spine: Examine back for scoliosis with Adam's forward bend test (also assess for leg length discrepancy).

Breast

- Female: Assess SMR. Conduct clinical breast examination for breast disorders if there is a reported concern
- Male: Examine breasts if inspection shows breast hypertrophy and gynecomastia vs other breast pathology is suspected.

Genitalia

- Female: Perform visual inspection of external genitalia to assess SMR, anatomic and skin abnormalities and signs of STIs (warts, vesicles, pathologic vaginal discharge).
- Male: Perform visual inspection for circumcision status, SMR, and signs of STIs (warts, vesicles, penile discharge).
- Examine testicles for abnormalities (hydroceles, hernias, varicoceles, or masses).

BMI, body mass index (height [cm]/weight [kg²]), BP, blood pressure; CDC, Centers for Disease Control and Prevention; SMR, sexual maturity rating; STI, sexually transmitted infection. it can be allayed by acknowledging the uneasiness verbally and by explaining the purpose of the examination. For example, "Many boys that I see who are your age are embarrassed to have their penis and testes examined. This is an important part of the examination for a couple of reasons. First, I want to make sure that there aren't any physical problems, and second, it helps me determine if your development is proceeding normally." This also introduces the subject of sexual development for discussion. Chaperones may be needed for parts of the physical examination (breast, genitals) when the patient is of a different sex than the provider or there are sensitive issues, for example, past history of sexual abuse. Adolescents should also be asked whether they prefer if their parent/guardian is in the room during the physical examination. Attempts should be made to keep the examination as discrete as possible by keeping any parts of the body that are not being examined covered by a sheet, gown, or clothing.

A pictorial chart of sexual development is useful for showing the patient how development is proceeding and what changes to expect. Figure 4–4 shows the relationship between height, penis and testes development, and pubic hair growth in the male, and Figure 4–5 shows the relationship between height, breast development, menstruation, and pubic hair growth in the female. Although teenagers may not admit that they are interested in this subject, they are usually attentive when it is raised. It can be helpful for them to know that puberty progresses in a predictable order, but that the rate of progression is variable. This discussion is particularly useful in counseling teenagers who lag behind their peers in physical development.

GUIDELINES FOR ADOLESCENT PREVENTIVE SERVICES

ADOLESCENT SCREENING

The American Medical Association Guidelines for Adolescent Preventive Services (GAPS) and the American Academy of Pediatrics' Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents cover health screening and guidance, immunization, and health care delivery. The goals of these guidelines are to (1) deter adolescents from participating in behaviors that jeopardize health; (2) detect physical, emotional, and behavioral problems early and intervene promptly; (3) reinforce and encourage behaviors that promote healthful living; and (4) provide immunization against infectious diseases. The guidelines recommend that adolescents between ages 11 and 21 years have annual routine health visits. Health services should be developmentally appropriate and culturally sensitive. Confidentiality between patient and provider should be ensured. Table 4-3 lists the current adolescent screening guidelines from the American Academy of Pediatrics, the U.S. Department of Health and Human Services and the Centers for Disease Control.

PROMOTING HEALTHY BEHAVIORS

Motivational Interviewing

The majority of adolescent morbidity and mortality is preventable and is related to unhealthy behaviors. The role of a pediatric provider in adolescent visits is to screen for unhealthy behaviors and promote healthy behaviors. Practitioners may report feeling frustrated with adolescents because they are resistant to change or "do not want help". Primary care in adolescents has historically been delivered as "anticipatory guidance" in a lecture-based format. This model may not be very effective, especially in adolescence. In contrast, motivational interviewing (MI) has been shown to effectively change several health behaviors in adolescents. These includes tobacco use, substance use, and control in type I diabetes.

MI is a counseling style that guides patients toward behavior change by helping to resolve ambivalence. Adolescents may know that certain behaviors are bad for them (smoking, drug use, unprotected sex, binge eating) but also have reasons they do not want to change (enjoy the "high", use with peers, etc.) and/or are not confident in their ability to change. MI promotes collaboration between provider and patient, with the patient ultimately deciding what goals he/she would like to achieve and how to achieve them (Table 4–4).

MI starts with a provider's assessing a patient's motivation and readiness for change. Some providers do this by asking a patient to indicate on a scale from 0 to 10 how important it is for him/her to change, how ready he/she is to start making a change, and how confident he/she is in his/ her ability to make a change. If a patient says he/she feels

108

▲ **Figure 4–5.** Adolescent female sexual maturation and growth.

it is 5/10 important, the provider can then ask why it is so important? Why is it not a 3 or a 4? This provides the patient with the opportunity to tell the provider why it is important to change, rather than telling the provider convincing reasons why it is not important to make changes. This is called "change talk" and is a hallmark of MI. The provider can then ask what it would take to make the number higher. The provider should avoid asking the adolescent why it is *not* important, as that will put the patient in the position of indicating reasons he/she cannot or does not want to change.

Other components of MI are to "roll with resistance" and resist the "righting reflex." Providers often seek to fix problems or challenge patients' stated barriers, causing patients to come up with new reasons they cannot make changes. If the provider is the only one arguing in favor of change, patients and families can become even more entrenched in not changing. They begin arguing against the provider and effectively convincing themselves of reasons that they cannot change. Instead of progressing into this conflictual stance, the provider should focus on the patient's own individual goals and reflect on the patient's challenges.

The guiding principles of MI are to express empathy toward patients and meet them where they are in the process of change, as many patients are ambivalent. The process of MI seeks to progress through stages of change (precontemplative, contemplative, preparation, action), but with the understanding that the provider cannot force a patient into a stage he/she is not ready for. Instead of imposing goals and being disappointed or frustrated when these goals are not accomplished, a patient needs to make his/her own goals if motivated to do so, even if the goals seem insignificant to the provider. It is acceptable to take time to work through this process as long as there is no acute danger. In situations of medical or psychiatric instability, MI is not an appropriate tool.

Developing discrepancies is another MI strategy. This can be done by asking a patient about his/her goals for health and the future and how he/she feels these goals align with
 Table 4–3.
 Adolescent Screening Guidelines.

	ААР	USPSTF	CDC
Cancer			
Cervical cancer	Per USPSTF guidelines.	Start cytology screening at age 21 y and screen every 3 y if cytology normal.	Screen women age 21–29 y every 3 y with cytology. Women with HIV should be screened within 1 y of sexual activity or initial HIV diagnosis using conventional or liquid- based cytology; testing should be repeated 6 mo later.
Testicular cancer	AAP Bright Futures recommends testicular examination for hernia, varicocele or epididymitis.	Screening with physician examination or self examination is not recommended.	
Cardiovascular (CV)			
Blood pressure	Check annually.	Current evidence is insufficient to assess the balance of benefits and harms of screening for primary hypertension in asymptomatic children and adolescents to prevent subsequent cardiovascular disease in childhood or adulthood.	
Lipid levels	 Based on integrated guidelines for CV Health and Risk Reduction in Children and Adolescents https:// www.nhlbi.nih.gov/health-pro/guidelines/current/ cardiovascular-health-pediatric-guidelines 9–11 y: Universal lipid screen with nonfasting non-HDL cholesterol or fasting lipid profile. 12–17 y: Obtain fasting lipid profile if FH newly positive, parent with dyslipidemia, any other risk factors or high-risk condition. 18–21 y: Measuring nonfasting non-HDL cholesterol or fasting lipid profile in all once. 	Current evidence is insufficient to assess the balance of benefits and harms of screening for lipid disorders in children and adolescents 20 y or younger.	
General Health			
Obesity	Screen BMI annually.	Screen children aged 6 y and older for obesity and refer as appropriate for comprehensive, intensive behavioral intervention to promote improvement in weight status.	
Diabetes	Children \geq 10 y and older with 2 or more risk factors (RF) should be screened every 2 y. RFs include: BMI > 85 percentile, FH of T2 DM, high-risk ethnic group, signs of insulin resistance (dyslipidemia, hypertension, polycystic ovarian syndrome and acanthosis nigricans).		
Scoliosis	Females at age 10 and 12 y. Males once at age 13 or 14 y.	Recommends against the routine screening of asymptomatic adolescents for idiopathic scoliosis.	

(Continued)

	AAP	USPSTF	CDC
Anemia	Assess annually for risk factors (diet low in iron rich foods, history of iron deficiency anemia, excessive menstrual bleeding). Screen those with risk factors with HgB or HCT at minimum.		Screen all nonpregnant women every 5–10 y, starting in adolescence.
Behavioral Health			
Depression	Screen youth ≥ 12 y using the PHQ2 or other tools available in the GLAD-PC toolkit: http://www. glad-pc.org/	Screen adolescents aged 12–18 y for major depressive disorder. Screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up.	
Substance use	Screen youth ≥ 11 y with CRAFFT screening tool: http://www.ceasar-boston.org/CRAFFT/index.php	Current evidence is insufficient to assess the balance of benefits and harms of primary care–based behavioral interventions to prevent or reduce illicit drug or nonmedical pharmaceutical use in children and adolescents. This recommendation applies to children and adolescents who have not already been diagnosed with a substance use disorder.	
Tobacco use	Screen youth ≥ 11 y.	Clinicians should provide interventions, including education or brief counseling, to prevent initiation of tobacco use among school-aged children and adolescents.	
Sexually Transmitted [Diseases		
Chlamydia Trachomatis	Per CDC.	Screen sexually active females. Repeat screening if sexual history reveals new or persistent risk factors since the last negative test result.	Screen all sexually active women < 25 y annually. Retest \ge 3 mo after treatment.
Nesseria Gonorrhoeae	Per CDC.	Screen sexually active females. Repeat screening if sexual history reveals new or persistent risk factors since the last negative test result.	Screen all sexually active women < 25 y annually. Retest approximately 3 mo after treatment. Screen at least annually for sexually active MSM at sites of contact (urethra, rectum, pharynx) regardless of condom use. Screen every 3–6 mo if increased risk.

Table 4–3. Adolescent Screening Guidelines. (Cont

(Continued)
Table 4–3. Adolescent Scr	ening Guidelines. (Continued)
---------------------------	-------------------------------

	ААР	USPSTF	CDC
Herpes Simplex virus	Per CDC.	Routine serologic screening not recommended.	Consider HSV serology in men and women coming for STD evaluation especially if they have multiple sexual partners. Consider HSV serology in MSM if infection status unknown and history of previously undiagnosed genital infection.
Human immuno- deficiency virus	Adolescents should be screened for HIV according to USPSTF recommendations once between the ages of 15 and 18 y, making every effort to preserve confidentiality of the adolescent.	Screen adolescents older than 15 y at least once. Repeat screening or screen younger adolescents if risk factors for infection present.*	Screen all adolescents who seek evaluation and treatment for STD. Screen sexually active MSM at least annually if HIV status is unknown or negative and the patient or his sex partner(s) have had more than one sex partner since most recent HIV test.
Syphilis		Screen for syphilis infection in people who are at increased risk for infection (MSM, persons living with HIV, history of incarceration, history of commercial sex work).	Screen sexually active MSM at least annually and every 3–6 mo if at increased risk of infection.*

AAP, American Academy of Pediatrics; BMI, body mass index; CDC, Centers for Disease Control; FH, family history; HCT, hematocrit; HDL, high-density lipoprotein; HgB, hemoglobin; MSM, men who have sex with men; T2 DM, type 2 diabetes mellitus; USPSTF, US Preventive Services Task Force.

*history of sexually transmitted diseases (STDs), multiple sex partners, inconsistent condom use, sex work, illicit drug use, patients seeking care in high prevalence settings (eg, clinics located in higher prevalence geography [prevalence \geq 1%], STD clinics, correctional facilities, homeless shelters, tuberculosis clinics, clinics serving MSM, adolescent clinics with high STD rates).

current health and/or behaviors (eg, failing school and wanting to go to medical school). Supporting self-efficacy and using the patient's and his/her family's own resources and solutions to break down barriers to change are important, as they will bring longer lasting change. Most essential is for the provider to listen reflectively, avoid confrontation, and roll with resistance. It can be frustrating to see patients putting their health at risk but it is important, when appropriate, to meet patients where they are in their readiness to change. This allows them to find their internal motivations, encourages autonomy, and establishes collaboration between patients and providers in achieving healthy and attainable goals.

TRANSITION TO ADULT CARE

It is important for health care providers to have a transition process for transitioning primary care and subspecialty medical care of adolescents to adult providers. This process should incorporate education, guidance and step-wise planning. Patients should be actively involved in this process to maximize their self efficacy. Even older adolescents and young adults need assistance from providers and their families as they enter the adult health care system.

The American Academy of Pediatrics' Clinical Report, "Supporting the Health Care Transition From Adolescence to Adulthood in the Medical Home" describes three key components of transition: provider readiness, family readiness, and youth readiness.

 Provider readiness refers to practice policies that allow for a smooth transition. Policies addressing transition should be discussed with patients and families early and

Barnes AJ, Gold MA: Promoting healthy behaviors in pediatrics. Pediatr Rev Sep 2012, 33:9.

Brief Counseling for Marijuana Dependence—A Manual for Treating Adults http://www.integration.samhsa.gov/clinicalpractice/sbirt/brief_counseling_for_marijuana_dependence.pdf. Accessed date: March 27, 2017

Table 4-4. Motivational interviewing skills.

Skill	Description			
Evoke motivations and commit	Evoke motivations and commitment to change			
Ask open-ended questions	Tell me about, Describe for me, Tell me more			
Explore patients' reason for change	"Have you ever tried to quit? Why did you try to quit? Do you see yourself smoking marijuana in 5 y? Why not?			
Evoke change talk and reflect it back	"What are the good things about smoking marijuana? What are the not-so-good things about smoking marijuana?" When you look at this list of pros and cons, what do you think?"			
Use readiness and confidence "rulers"	"On a scale from 0 to 10 where 10 is the most and 0 is the least, where would you say you are now?"			
Affirm and accept	Affirmations are statements that provide positive feedback about goal-oriented behaviors or personal characteristics or strengths, reinforcing autonomy and self-efficacy. <i>"I can see that you are upset about being here, but I'd like to tell you that I am impressed that you chose to come here anyway."</i>			
Listen reflectively	Reflective listening shows that you are listening and understanding. Patient: "I know it really upsets my parents but it just isn't that big a deal." Provider: "You don't think it's such a big deal but you know that your parents are really worried about you and it sounds like you feel badly about that."			
Express empathy	"You've worked hard on this problem and it's frustrating you that it's not much better yet."			
Develop discrepancies	"You do not want to quit marijuana because most of your friends smoke and you think it helps you relax, and, at the same time, you know it makes your parents angry and you want to play football and are worried it will get you in trouble with your coach."			
Roll with resistance	Accept patients' statements of resistance rather than confronting them directly: Patient: "Most of the people I know get high. Why do we even have to talk about it?" Provider: "It's hard to figure out why we have to talk about it when it is all around you. Kind of makes you wonder how you could be the only one who is having problems with pot."			
Avoid righting reflex	Avoid the desire to fix things, direct persuasion, and confrontation.			
Support self-efficacy	Increase patient perception about his/her skills, resources and abilities that the patient may access to achieve desired goals. "You say you quit before so you may have good ideas about how to do it again. Tell me what they are."			
Encourage autonomy	Convey that responsibility for making change resides with the patient or parent who must decide if, how, and when change will occur.			
Encourage self-direction	Patient: "I know I made a mistake, but the hoops that they are making me jump through are getting ridiculous." Provider: "You don't like what others are asking you to do, but so far you are choosing to follow-through with what they are asking. It takes a lot of fortitude to do that. Tell me what motivates you."			

regularly and patients should be assessed for transition readiness (often with use of checklists).

- Family readiness: The medical home must understand and address family needs during transition, as the process of transition can be complex and emotional. This includes education and communication with families about the transition process and differences between pediatric and adult models of care.
- Patient readiness: The patient must be the driver in the transition process. It is important to empower and to

encourage youth to assume increasing responsibility for their own health care. Documenting patient readiness and steps needed to achieve a successful transition are important in this process (eg, ability to schedules one's own medical appointments, obtain medications, know medications and doses, etc.).

The final step of transition occurs when the provider implements an adult care model or the patient transfers to an adult medical home provider. Direct communication between pediatric and adult providers is essential for a smooth transition, especially in the case of patients with special needs.

American Academy of Pediatrics, American Academy of Family Physicians, and American College of Physicians, Transitions Clinical Report Authoring Group: Supporting the health care transition from adolescence to adulthood in the medical home. Pediatr 2011;128;182;

http://www.gottransition.org/

GROWTH & DEVELOPMENT

PUBERTY

Pubertal growth and physical development are a result of activation of the hypothalamic-pituitary-gonadal axis in late childhood. Before puberty, pituitary and gonadal hormone levels are low. It is estimated that at least 50% of pubertal timing is determined by genetics and ethnicity is one such factor. Nutrition and general health can also affect the pubertal process. At onset of puberty, the inhibition of gonadotropinreleasing hormone in the hypothalamus is removed, allowing pulsatile production and release of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). In early to middle adolescence, pulse frequency and amplitude of LH and FSH secretion increase, stimulating the gonads to produce estrogen or testosterone. In females, FSH stimulates ovarian maturation, granulosa cell function, and estradiol secretion. LH is important in ovulation and also is involved in corpus luteum formation and progesterone secretion. Initially, estradiol inhibits the release of LH and FSH. Eventually, estradiol becomes stimulatory, and the secretion of LH and FSH becomes cyclic. Estradiol levels progressively increase, resulting in maturation of the female genital tract and breast development.

In males, LH stimulates the interstitial cells of the testes to produce testosterone. FSH stimulates the production of spermatocytes in the presence of testosterone. The testes also produce inhibin, a Sertoli cell protein that inhibits the secretion of FSH. During puberty, circulating testosterone levels increase more than 20-fold. Levels of testosterone correlate with the physical stages of puberty and the degree of skeletal maturation.

PHYSICAL GROWTH

A teenager's weight almost doubles in adolescence, and height increases by 15%–20%. During puberty, major organs double in size, except for lymphoid tissue, which decreases in mass. Before puberty, there is little difference in the muscular strength of boys and girls. The muscle mass and muscle strength both increase during puberty, with maximal strength lagging behind the increase in mass by many months. Boys attain greater strength and mass, and strength continues to increase into late puberty. Although motor coordination lags behind growth in stature and musculature, it continues to improve as strength increases.

The pubertal growth spurt begins nearly 2 years earlier in girls than in boys. Girls reach peak height velocity between ages 11½ and 12 years, and boys between ages 13½ and 14 years. Linear growth at peak velocity is 9.5 cm/y \pm 1.5 cm in boys and 8.3 cm/y \pm 1.2 cm in girls. Pubertal growth lasts about 2–4 years and continues longer in boys than in girls. By age 11 years in girls and age 12 years in boys, 83%–89% of ultimate height is attained. An additional 18–23 cm in females and 25–30 cm in males is achieved during late pubertal growth. Following menarche, height rarely increases more than 5–7.5 cm.

In boys, the lean body mass increases from 80% to 85% to approximately 90% at maturity. Muscle mass doubles between 10 and 17 years. By contrast, in girls, the lean body mass decreases from approximately 80% of body weight in early puberty to approximately 75% at maturity.

SEXUAL MATURATION

Sexual maturity rating (SMR) is useful for categorizing genital development. SMR staging includes age ranges of normal development and specific descriptions for each stage of pubic hair growth, penis, and testis development in boys, and breast maturation in girls. Figures 4–4 and 4–5 show this chronologic development. SMR 1 is prepuberty and SMR 5 is adult maturity. In SMR 2 the pubic hair is sparse, fine, nonpigmented, and downy; in SMR 3, the hair becomes pigmented and curly and increases in amount; and in SMR 4, the hair is adult in texture but limited in area. The appearance of pubic hair precedes axillary hair by more than 1 year. Male genital development begins with SMR 2 during which the testes become larger and the scrotal skin reddens and coarsens. In SMR 3, the penis lengthens; and in SMR 4, the penis enlarges in overall size and the scrotal skin becomes pigmented.

Female breast development follows a predictable sequence. Small, raised breast buds appear in SMR 2. In SMR 3, the breast and areolar tissue generally enlarge and become elevated. The areola and nipple form a separate mound from the breast in SMR 4, and in SMR 5 the areola assumes the same contour as the breast.

There is great variability in the timing and onset of puberty and growth, and psychosocial development does not always parallel physical changes. Chronologic age, therefore, may be a poor indicator of physiologic and psychosocial development. Skeletal maturation correlates well with growth and pubertal development.

Teenagers began entering puberty earlier in the last century because of better nutrition and socioeconomic conditions. In the United States, the average age at menarche is 12.53 years, but varies by race and ethnicity; 12.57 for non-Hispanic whites; 12.09 years in non-Hispanic blacks, and 12.09 for

ADOLESCENCE

Mexican American girls. Among girls reaching menarche, the average weight is 48 kg, and the average height is 158.5 cm. Menarche may be delayed until age 16 years or may begin as early as age 10. Although the first measurable sign of puberty in girls is the beginning of the height spurt, the first conspicuous sign is usually the development of breast buds between 8 and 11 years. Although breast development usually precedes the growth of pubic hair, the sequence may be reversed. A common concern for girls at this time is whether the breasts will be of the right size and shape, especially because initial breast growth is often asymmetrical. The growth spurt starts at about age 9 years in girls and peaks at age 111/2 years, usually at SMR 3-4 breast development and SMR 3 pubic hair development. The spurt usually ends by age 14 years. Girls who mature early will reach peak height velocity sooner and attain their final height earlier. Girls who mature late will attain a greater final height because of the longer period of growth before the growth spurt ends. Final height is related to skeletal age at onset of puberty as well as genetic factors. The height spurt correlates more closely with breast developmental stages than with pubic hair stages.

The first sign of puberty in the male, usually between ages 10 and 12 years, is scrotal and testicular growth. Pubic hair usually appears early in puberty but may do so any time between ages 10 and 15 years. The penis begins to grow significantly a year or so after the onset of testicular and pubic hair development, usually between ages 10 and 13¹/₂ years. The first ejaculation usually occurs about 1 year after initiation of testicular growth, but its timing is highly variable. About 90% of boys have this experience between ages 11 and 15 years. Gynecomastia, a hard nodule under the nipple, occurs in a majority of boys, with a peak incidence between ages 14 and 15 years. Gynecomastia usually disappears within 6 months to 2 years. The height spurt begins at age 11 years but increases rapidly between ages 12 and 13 years, with the peak height velocity reached at age 131/2 years. The period of pubertal development lasts much longer in boys and may not be completed until age 18 years. The height velocity is higher in males (8-11 cm/y) than in females (6.5-9.5 cm/y). The development of axillary hair, deepening of the voice, and the development of chest hair in boys usually occur in mid-puberty, about 2 years after onset of growth of pubic hair. Facial and body hair begin to increase at age 16-17 years.

PSYCHOSOCIAL DEVELOPMENT

Adolescence is a period of progressive individuation and separation from the family. Adolescents must learn who they are, decide what they want to do, and identify their personal strengths and weaknesses. Because of the rapidity of physical, emotional, cognitive, and social growth during adolescence, it is useful to divide psychological development into three phases (Table 4–5). Early adolescence is roughly from 10 to 13 years of age; middle adolescence is from 14 to 16 years; and late adolescence is from 17 years and later.

Early Adolescence

Early adolescence is characterized by rapid growth and development of secondary sex characteristics. Body image, self-concept, and self-esteem fluctuate dramatically. Concerns about how personal growth and development deviate from that of peers may be great, especially in boys with short stature or girls with delayed breast development or delayed menarche. Although there is a certain curiosity about sexuality, young adolescents generally feel more comfortable with members of the same sex. Peer relationships become increasingly important. Young teenagers still think concretely and cannot easily conceptualize about the future. They may have vague and unrealistic professional goals, such as becoming a movie star or professional athlete.

Middle Adolescence

During middle adolescence, as rapid pubertal development subsides, teenagers become more comfortable with their new bodies. Intense emotions and wide swings in mood are typical. Although some teenagers go through this experience relatively peacefully, others struggle. Cognitively, the middle adolescent moves from concrete thinking to formal operations and abstract thinking. With this new mental power comes a sense of omnipotence and a belief that the world can be changed by merely thinking about it. Sexually active teenagers may believe they do not need to worry about using contraception because they can't get pregnant ("it won't happen to me"). With the onset of abstract thinking, teenagers begin to see themselves as others see them and may become extremely self-centered. Because they are establishing their own identities, relationships with peers and others are narcissistic. Experimenting with different self-images is common. As sexuality increases in importance, adolescents may begin dating and experimenting with sex. Peers determine the standards for identification, behavior, activities, and clothing and provide emotional support, intimacy, empathy, and the sharing of guilt and anxiety during the struggle for autonomy. The struggle for independence and autonomy is often a stressful period for both teenagers and parents.

Table 4–5. Stages of adolescent development.

Stages of Adolescence	Cognitive Development	Social-Emotional Development
Early adolescence: ~10–13 y	 Growing capacity for abstract thought Interested in present, limited thought to future Intellectual interests expand Deeper moral thinking 	 Struggle with sense of identity Worries about being normal, feels awkward about self and body Realize parents aren't perfect; increased conflict with parents Desire for independence Tendency to return to "childish" behavior especially when stressed Moodiness Rule and limit testing Greater interest in privacy
Middle adolescence: ~14–16 y	 Continued growth of capacity for abstract thought Greater capacity for setting goals Interest in moral reasoning Thinking about meaning of life 	 Intense self-involvement Continued adjustment to changing body and worries about being normal Distance from parents, drive for independence Peers gain importance Feelings of love and passion
Late adolescence: ~ ≥17 y	 Ability to think ideas through Ability to delay gratification Examination of inner experiences Increased concern for future Continued interest in moral reasoning 	 Firmer sense of identity Increased emotional stability Increased concern for others Increased independence and self-reliance Peer relationships remain important Development of more serious relationships

Data from American Academy of Child and Adolescent's Facts for Families (2008).

Late Adolescence

During late adolescence, the young person generally becomes less self-centered and more caring of others. Social relationships shift from the peer group to the individual. Dating becomes much more intimate. By 10th grade, 40.9% of adolescents (41.9% of males and 39.6% of females) have had sexual intercourse, and by 12th grade, this has increased to 62.3% (59.6% of males and 65% of females). Abstract thinking allows older adolescents to think more realistically about their plans for the future. This is a period of idealism; older adolescents have rigid concepts of what is right or wrong.

Sexual Orientation

In addition to rapid physical changes during puberty, adolescence is also characterized by emotional and sexual changes during which sexual discovery, exploration, and experimentation are part of the process of incorporating sexuality into one's identity. Sexual orientation has been referred to as "an individual's pattern of physical and emotional arousal toward other persons." Typically, sexual orientation emerges before or early in adolescence. Gender identity is knowledge of one's self as being male or female and gender expression is the outward expression of being male or female. Awareness of gender identity happens in early childhood, and by age 3 years, children can identify themselves as a boy or a girl and, by age 4 years, gender identity is stable. It is not uncommon for younger children to experience and display gender role confusion. For some children, conflict can develop with awareness that he/she actually identifies with traits of the opposite gender (vs lacking interest in what society defines as typical gender-specific activities). Conflict about gender can lead to dysphoria and dislike about the parts of themselves that are different from the gender that they identify with. Many children will resolve their dysphoria by the time they complete adolescence and others who continue to feel dysphoria may seek treatment to transition to the opposite gender.

Individuals who self-identify as heterosexuals are attracted to people of the opposite gender; homosexual individuals self-identify as being attracted to people of the same gender, and bisexual adolescents report attraction to both genders. Generally, self-identified homosexual people are referred to as "gay" if male and "lesbian" if female. Sexuality and identity formation are dynamic processes and adolescents who struggle with their sexual attractions are referred to as "questioning." Sexuality is inherently more complex than these simple definitions; for example, many self-identified heterosexual youth report having sex with same-gendered partners. Many young people also resist definitions and terminology regarding their sexuality. Overall, adolescents who self-identify as lesbian, gay, bisexual, transgender, and/or questioning (LGBTQ) comprise a sexual minority population.

Heterosexism is the societal expectation that heterosexuality is the norm and that LGBTQ youth are "abnormal." Some LGBT youth may feel that it is necessary to hide their sexuality from family and friends and this nondisclosure can be ultimately damaging to a developing self-image. Parents' and other family members' reactions to a young person "coming out" or declaring his/or her self-identified sexuality vary, and parental rejection of sexual minority youth is unfortunately common.

Although many LGBTQ youth are resilient, they are a vulnerable population and experience many health disparities that providers need to be aware of. Population studies and public health data demonstrate that sexual minority youth are at increased risk of tobacco and substance abuse; being victims of violence including bullying, physical and sexual abuse; increased rates of STI and HIV acquisition; school avoidance and failure; depression and suicide; homelessness; and other crises. As part of providing culturally effective care to reduce health disparities experienced by sexual minority youth, providers should use gender-neutral terms to encourage adolescents to discuss any questions they have about their sexual orientation or sexual behaviors. Providers will optimize opportunities to learn about youths' behaviors by creating an accepting environment and providing nonjudgmental and confidential care. For transgender youth, providers should affirm their feelings of gender dysphoria and provide referrals to qualified mental health and medical professionals for more information about transition. Providers can also be sources of support for parents and family members of sexual minority youth. Organizations such as Parents, Families and Friends of Lesbians and Gays (www.pflag.org) or Gay Family Support (www.gayfamilysupport.com) can provide valuable resources. Nonprofit organizations such as the United Way and local adult LGBTQ and sexual health advocacy organizations are additional resources for sexual minority youth and their families.

ADOLESCENT GYNECOLOGY & REPRODUCTIVE HEALTH

BREAST EXAMINATION

The breast examination should be part of the routine physical examination in girls as soon as breast budding occurs. The preadolescent will thus accept breast examination as a routine part of health care, and the procedure can serve as an opportunity to offer reassurance and education. The breast examination begins with inspection of the breasts for symmetry and SMR stage. Asymmetrical breast development is common in young adolescents, and is generally transient, although 25% of women may continue to have asymmetry as adults. Organic causes of breast asymmetry include unilateral breast hypoplasia, amastia, absence of the pectoralis major muscle, and unilateral juvenile hypertrophy, in which there is rapid overgrowth of breast tissue usually immediately after thelarche.

The breast examination is performed with the patient supine and the ipsilateral arm placed behind the head. Using flat finger pads, the examiner palpates the breast tissue in concentric circles starting at the outer borders of the breast tissue along the sternum, clavicle, and axilla and then moving in toward the areola. The areola should be compressed gently to check for nipple discharge. Supraclavicular and infraclavicular and axillary regions should be palpated for lymph nodes.

Teaching adolescents to perform breast selfexaminations is controversial. Experts have recommended adolescent self-examination as a means of helping them develop comfort with their changing bodies and for future cancer detection. Experts have also questioned whether self-examination might in fact result in anxiety, increased physician visits, and unnecessary invasive procedures since the vast majority of breast masses in adolescents are benign. The U.S. Preventive Services Task Force found little evidence that teaching or performing routine breast self-examination in adolescents reduces breast cancer mortality. Despite the lack of data for or against teaching or performing breast self-examinations during adolescence, there is some consensus that young women at increased risk of breast cancer-adolescents with a history of malignancy, adolescents who are at least 10 years postradiation therapy to the chest, and adolescents 18-21 years of age whose mothers carry the BRCA1 or BRCA2 gene should perform monthly breast self-examinations after each menstrual period.

BREAST MASSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Primary breast cancer during adolescence is exceptionally rare.
- ► Fibroadenomas are the most common breast masses.
- Typical features of fibroadenemas include: 2–3 cm, nontender, rubbery, smooth, well-circumscribed, mobile mass.

The majority of breast masses in adolescents are benign (Table 4–6). Rare malignancies of adolescent girls include juvenile secretory carcinoma, intraductal carcinoma, rhabdomyosarcoma, malignant cystosarcoma phylloides, and metastatic tumor. Retrospective studies indicate that biopsies of breast masses in adolescents most commonly show fibroadenoma (67%), fibrocystic change (15%), and abscess or mastitis (3%).

T	able 4-6. Breast masses in adolescent females.
	Common
	Fibroadenoma
	Fibrocystic changes
	Breast cysts (including subareolar cysts)
	Breast abscess or mastitis
	Fat necrosis (after trauma)
	.ess common (benign)
	Lymphangioma
	Hemangioma
	Intraductal papilloma
	Juvenile papillomatosis
	Giant fibroadenoma
	Ninnle adenema er keratema
	Mammany duct octasia
	Intramammary lymph node
	Linoma
	Hematoma
	Hamartoma
	Galactocele
	Rare (malignant or malignant potential)
	Juvenile secretory carcinoma
	Intraductal carcinoma
	Cystosarcoma phylloides
	Sarcomas (fibrosarcoma, malignant fibrous histiocytoma,
	rhabdomyosarcoma)
	Metastatic cancer (hepatocellular carcinoma, lymphoma,
	neuroblastoma, rhabdomyosarcoma)

1. Fibroadenoma

Fibroadenomas are the most common breast masses of adolescent girls. These and other breast lesions are listed in Tables 4–6 and 4–7. Fibroadenomas are composed of glandular and fibrous tissue. A fibroadenoma is typically nontender and diagnosed clinically with examination findings of a rubbery, smooth, well-circumscribed, mobile mass most

Table 4–7.	Characteristics and management of breast
lesions in ad	olescent females.

Fibroadenoma	2- to 3-cm, rubbery, well-circumscribed, mobile, nontender. Commonly found in upper outer quadrant of the breast. Management is observation.
Giant juvenile fibroadenoma	Large, > 5 cm fibroadenoma with overlying skin stretching and dilated superficial veins. Benign but requires excision for confirmation of diagnosis and for cosmetic reasons.
Breast cysts	Usually caused by ductal ectasia or blocked Montgomery tubercles, both of which can have associated nipple discharge. Ultrasound can help differentiate from solid mass. Most resolve spontaneously.
Fibrocystic changes	More common with advancing age after adolescence. Mild swelling and palpable nodularity in upper outer quadrants. Associated with cyclic premenstrual mastalgia.
Abscess	Often associated with overlying mastitis and/or purulent nipple discharge. Culture abscess material and/or nipple discharge before starting antibiotics.
Cystosarcoma phyllodes	Large, rapidly growing tumor associated with overlying skin changes, dilated veins, and skin necrosis. Requires excision. Most often benign but can be malignant.
Intraductal papilloma	Palpable intraductal tumor, which is often subareolar with associated nipple discharge, but may be in the periphery of the breast in adolescents. Requires surgical excision.
Juvenile papillomatosis	Rare breast tumor characterized by a grossly nodular breast mass described as having a "Swiss-cheese" appearance. Requires surgical excision.
Fat necrosis	Localized inflammatory process in the breast; typically follows trauma (sports or seat belt injuries). Subsequent scarring may be confused with changes similar to those associated with malignancy.

ADOLESCENCE

often in the upper outer quadrant of the breast, although fibroadenomas can be found in any quadrant. Ten to twentyfive percent of girls will have multiple or bilateral lesions. Fibroadenomas are typically slow growing with average size 2-3 cm. They may remain static in size for months to years with 10%-40% completely resolving during adolescence. The dense fibroglandular tissue of the adolescent breast may cause false-positive results on standard mammograms. Thus, ultrasonography is the best imaging modality with which to evaluate a breast mass in an adolescent if further evaluation beyond the clinical examination is necessary. Fibroadenomas less than 5 cm can be monitored for growth or regression over 3-4 months. Further evaluation will be dictated by the patient's course with semiannual clinical examinations for a few years followed by annual examinations for a mass that is regressing. Patients with concerning breast masses including fibroadenomas that are larger than 5 cm, undiagnosed breast masses that are enlarging or have overlying skin changes, and any suspicious breast mass in a patient with a history of previous malignancy should be referred to a breast care specialist.

2. Fibrocystic Breast Changes

Fibrocystic breast changes are much more common in adults than adolescents. Symptoms include mild swelling and palpable nodularity most commonly in the upper outer quadrants. Mastalgia is typically cyclic, usually occurring just before menstruation. Reassuring the young woman about the benign nature of the process may be all that is needed. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen or naproxen sodium help alleviate symptoms. Oral contraceptive pills (OCPs) can also be beneficial. Supportive bras may provide symptomatic relief. Studies have shown no association between methylxanthine and fibrocystic breasts; however, some women report reduced symptoms when they discontinue caffeine.

3. Breast Abscess

- Common causes of mastitis and breast abscess during adolescence include manipulation of periareolar hair and nipple piercing, with subsequent infection with normal skin flora.
- Typical features include breast pain and overlying erythema and warmth.
- Breast ultrasound may be helpful to differentiate between mastitis and breast abscess.

Although breast-feeding is the most common cause of mastitis, shaving or plucking periareolar hair, nipple piercing, and trauma occurring during sexual activity are predisposing factors in teenagers. The most common causative organisms are normal skin flora. The female with a breast abscess usually complains of unilateral breast pain, and examination reveals overlying inflammatory changes. The examination may be misleading in that the infection may extend deeper into the breast than suspected. Staphylococcus aureus is the most common pathogen. β-Hemolytic streptococci, Escherichia coli, and Pseudomonas aeruginosa have also been implicated. Fluctuant abscesses should be incised and drained and fluid cultured. Antimicrobial coverage for S aureus (including methicillinresistant strains) should be given initially (generally orally, unless infection is severe) and the patient should be monitored closely for response to therapy until culture and sensitivity results are available.

Healing time after nipple piercing is 3–6 months. Health risks associated with nipple piercing, in addition to breast abscess, include allergic reactions to the jewelry, keloid scar formation, and increased risk of hepatitis B and C and HIV. Complications associated with abscess formation secondary to nipple piercing include endocarditis, cardiac valve injury, cardiac prosthesis infection, metal foreign body reaction in the breast tissue, and recurrent infection.

NIPPLE DISCHARGE & GALACTORRHEA

- Milky nipple discharge is typically galactorrhea; bloody or serosanguinous discharge may indicate a duct problem.
- Galactorrhea is typically benign and caused by chronic nipple stimulation, certain prescription psychiatric drugs, or illicit drug use.

Ductal ectasia is a common cause of nipple discharge in the developing breast and is associated with dilation of the mammary ducts, periductal fibrosis, and inflammation. It can present with bloody, brown, or sticky multicolored nipple discharge and/or a cystic breast mass, which is usually in the subareolar region. Blocked ducts and fluid collections usually resolve spontaneously but can become infected, producing mastitis. Patients should look for erythema, warmth, and tenderness indicating mastitis. Oral antibiotics covering skin flora should be initiated if infection is suspected. Serous or serosanguineous nipple discharge is common and can be associated with fibrocystic breast changes. Montgomery tubercles are small glands located at the outer aspect of the areola that can drain clear or brownish fluid through an ectopic opening on the areola and may be associated with a small subareolar mass. These lesions and discharge typically resolve spontaneously. Intraductal papillomas arising from proliferation of ductal cells projecting into the duct lumen are a rare cause of bloody or serosanguineous nipple discharge and can also present with a subareolar or peripheral mass. These lesions are associated with increased risk of malignancy in adults.

Galactorrhea is distinguishable from other causes of nipple discharge by its milky character and tendency to involve both breasts. It is usually benign. The most common causes include chronic stimulation or irritation of the nipple, medications and illicit drugs (drugs causing galactorrhea are listed in Table 4-8), pregnancy, childbirth, or abortion. Prolactin-secreting tumors (prolactinomas) and hypothyroidism are common pathologic causes of galactorrhea during adolescence. Less common causes of hyperprolactinemia and galactorrhea include diseases in or near the hypothalamus or pituitary that interfere with the secretion of dopamine or its delivery to the hypothalamus. Included are tumors of the hypothalamus and/or pituitary, both benign (eg, craniopharyngiomas) and malignant (eg, metastatic disease), infiltrative diseases of the hypothalamus (eg, sarcoidosis), and pituitary stalk damage (eg, section due to head trauma or surgery or compression). Stimulation of the intercostal nerves (eg, chest wall surgery or herpes zoster infection), renal failure (decreased prolactin clearance), polycystic ovarian syndrome, and emotional or physical stress can also cause hyperprolactinemia, which can induce galactorrhea.

Clinical Findings

Breast ultrasonography can be helpful in determining the cause of nipple discharge and breast masses. Depending

 Table 4–8.
 Medications and herbs associated with galactorrhea.

Anticonvulsants (valproic acid) Antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants) Anxiolytics (alprazolam) Antihypertensives (atenolol, methyldopa, reserpine, verapamil) Antipsychotics Typical (haloperidol, phenothiazine, pimozide) Atypical (risperidone, olanzapine, molindone) Antiemetics (prochlorperazine) Herbs (anise, blessed thistle, fennel, fenugreek seed, nettle) Hormonal contraceptives Isoniazid Illicit drugs (amphetamines, cannabis, opiates) Motility agents (metoclopramide) Muscle relaxants (cyclobenzaprine) upon additional findings from the history and examination, evaluation of galactorrhea may include a pregnancy test, prolactin level, and thyroid function studies. If there is a question as to whether the discharge is true galactorrhea, fat staining of the discharge can be confirmatory. Elevated TSH confirms the diagnosis of hypothyroidism. Elevated prolactin and normal TSH, often accompanied by amenorrhea, in the absence of medication known to cause hyperprolactinemia suggests a hypothalamic or pituitary tumor. In such cases, magnetic resonance imaging (MRI) of the brain and consultation with a pediatric endocrinologist are indicated.

Treatment

Observation with serial examination is recommended for nipple discharge associated with breast mass unless a papilloma is suspected by the presence of bloody or serosanguineous nipple discharge with or without a subareolar or peripheral mass. This entity requires further evaluation and excision by a breast surgeon. Treating the underlying cause of galactorrhea is usually effective. Galactorrhea due to hypothyroidism should be treated with thyroid hormone replacement. An alternative medication can be prescribed in cases of medication-induced galactorrhea. Adolescents with galactorrhea without a breast mass who have normal prolactin and TSH levels can be followed clinically and counseled about supportive measures such as avoidance of nipple stimulation, stress reduction, and keeping a menstrual calendar to monitor for oligomenorrhea, which might indicate a systemic hormonal problem such as hyperprolactinemia or thyroid disease. In many cases, symptoms resolve spontaneously and no underlying diagnosis is made. Medical management of prolactinomas with dopamine agonists such as bromocriptine is the favored approach.

GYNECOMASTIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Gynecomastia is common in males during puberty and may last 1–3 years.
- Typical features include a palpable fibroglandular mass located concentrically beneath the nipple-areolar complex. It may be unilateral or bilateral.
- Clinical observation is appropriate; however, further evaluation may be necessary for atypical cases including: prepubertal gynecomastia, eccentric position, rapid breast enlargement, presence of testicular mass, or prolonged persistence.

121

Gynecomastia, benign subareolar glandular breast enlargement, affects up to 65% of adolescent males. It typically appears at least 6 months after the onset of secondary sex characteristics with peak incidence during SMR stages 3 and 4. Breast tissue enlargement usually regresses within 1-3 years, and persistence beyond age 17 years is uncommon. Approximately half of young men with gynecomastia have a positive family history of gynecomastia. The pathogenesis of pubertal gynecomastia has long been attributed to a transient imbalance between estrogens that stimulate proliferation of breast tissue and androgens which antagonize this effect. Leptin has recently been implicated in the development of gynecomastia as levels are higher in healthy nonobese adolescent males with gynecomastia when compared to controls. There are several proposed mechanisms in which leptin acts biochemically to alter the estrogen-androgen ratio.

Clinical Findings

Palpation of the breasts is necessary to distinguish adipose tissue (pseudogynecomastia) from the glandular tissue found in true gynecomastia, which is palpable as a fibroglandular mass located concentrically beneath the nipple-areolar complex. Gynecomastia is bilateral in almost two-thirds of patients. Findings that indicate more serious disease include hard or firm breast tissue, unilateral breast growth, eccentric masses outside of the nipple-areolar complex, and overlying skin changes. A genitourinary examination is needed to evaluate pubertal SMR, testicular volume and masses, or irregularities of the testes.

In the absence of abnormalities on history or physical examination, clinical monitoring of male gynecomastia for 12-18 months is sufficient. Laboratory evaluation is warranted if the patient with gynecomastia is prepubertal, appears undervirilized, has an eccentric breast mass, has a rapid progression of breast enlargement, has a testicular mass, or has persistence of gynecomastia beyond the usual observation period. The initial laboratory evaluation includes thyroid function tests, testosterone, estradiol, human chorionic gonadotropin (hCG), and LH. Additional studies depending on preliminary findings include karyotype, liver and renal function studies, dehydroepiandrosterone sulfate, and prolactin. Any patient with a testicular mass or laboratory results suggesting possible tumor, such as high serum testosterone, hCG, or estradiol, should have a testicular ultrasound. Further evaluation includes adrenal or brain imaging if a prolactinsecreting pituitary tumor or adrenal tumor is suspected.

Differential Diagnosis

Gynecomastia may be drug-induced (Table 4–9). Testicular, adrenal, or pituitary tumors, Klinefelter syndrome, secondary hypogonadism, partial or complete androgen insensitivity syndrome, hyperthyroidism, or chronic diseases (eg, cystic fibrosis, ulcerative colitis, liver disease, renal failure,

Table 4–9.	Drugs	associated v	with	gynecomastia.
------------	-------	--------------	------	---------------

	Examples
Antiandrogens	Cyproterone, finasteride, flutamide, ketoconazole, nilutamide, spironolactone
Antineoplastic and immunomodulators	Alkylating agents, bleomycin, cisplatin, cyclosporine, imatinib, methotrexate, nitrosurea, vincristine
Antiulcer drugs	Cimetidine, metoclopramide, omeprazole, ranitidine
Cardiovascular drugs	Amiodarone, angiotensin-converting enzyme inhibitors, calcium channel blockers, digitoxin, reserpine, spironolactone
Drugs of abuse	Alcohol, amphetamines, marijuana, opiates
Hormones	Anabolic androgenic steroids, estrogens, testosterone, chorionic gonadotropin
Infectious agents	Antiretrovirals, ketoconazole, isoniazid, metronidazole
Psychoactive medications	Diazepam, tricyclic antidepressants, haloperidol, atypical antipsychotics, phenothiazines

and AIDS) leading to malnutrition may be associated with gynecomastia. Breast cancer in the adolescent male is extraordinarily rare.

Treatment

If gynecomastia is idiopathic, reassurance about the common and benign nature of the process can be given. Resolution may take up to 2 years. Surgery is reserved for those with persistent severe breast enlargement and/or significant psychological trauma. In cases of drug-induced gynecomastia, the inciting agent should be discontinued if possible. The patient should be referred to an endocrinologist or oncologist if other pathologic etiologies are diagnosed.

GYNECOLOGIC DISORDERS IN ADOLESCENCE

Physiology of Menstruation

The ovulatory menstrual cycle is divided into three consecutive phases: follicular (days 1–14), ovulatory (midcycle), and luteal (days 16–28). During the follicular phase, pulsatile gonadotropin-releasing hormone from the hypothalamus stimulates anterior pituitary secretion of FSH and LH. Under the influence of FSH and LH, a dominant ovarian follicle emerges by day 5–7 of the menstrual cycle, and the other follicles become atretic. Rising estradiol levels produced by the maturing follicle cause proliferation of the endometrium. By the midfollicular phase, FSH begins to decline secondary to estradiol-mediated negative feedback, while LH continues to rise as a result of estradiol-mediated positive feedback.

Rising LH initiates progesterone secretion and luteinization of the granulosa cells of the follicle. Progesterone in turn further stimulates LH and FSH. This leads to the LH surge, which causes the follicle to rupture and expel the oocyte. During the luteal phase, LH and FSH gradually decline. The corpus luteum secretes progesterone. The endometrium enters the secretory phase in response to rising levels of estrogen and progesterone, with maturation 8–9 days after ovulation. If pregnancy and placental hCG release do not occur, luteolysis begins; estrogen and progesterone levels decline and the endometrial lining is shed as menstrual flow approximately 14 days after ovulation. In the first 2 years after menarche, the majority of cycles (50%–80%) are anovulatory. Between 10% and 20% of cycles are anovulatory for up to 5 years after menarche.

Pelvic Examination

Indications for a pelvic examination in an adolescent include abdominal or pelvic pain, intra-abdominal or pelvic mass, abnormal vaginal bleeding or other menstrual disorders, pathologic vaginal discharge, or need for cervical cytology screening. The American College of Obstetricians and Gynecologists advocates starting Papanicolaou (Pap) cytology screening at age 21 years for both sexually experienced and sexually inexperienced women. This is based on the low incidence of cervical cancer in younger women and the potential for adverse effects associated with follow-up of young women with abnormal cytology screening results. Similarly, although reflex testing for high-risk cervical human papillomaviruses (HPV) genotypes for women with an ASC-US (atypical squamous cells of undetermined significance) cytology result can help guide the frequency of follow-up screening, co-testing for HPV is not recommended for women younger than 30 years because of the very high prevalence of high-risk HPV infections, a high rate of spontaneous clearance, and the low incidence of cervical cancer in sexually active women in this age group. Pregnancy during adolescence does not alter screening guidelines. The Centers for Disease Control and Prevention (CDC) recommends that HIV-positive adolescents should have cervical cytology screening twice (every 6 months) within the first year after initial HIV diagnosis even if younger than 21 years and, if both tests are normal, annual screening thereafter. Algorithms for managing abnormal cervical cytology can be found at the American Society for Colposcopy and Cervical Pathology website: http://www.asccp.org/asccp-guidelines. Guidelines for management of abnormal cytology in HIV positive women can be obtained from the CDC and partner organizations at https://aidsinfo.nih.gov/guidelines/html/4/adultand-adolescent-oi-prevention-and-treatment-guidelines/ 343/hpv.

The adolescent may be apprehensive about the first pelvic examination. Sensitive counseling and age-appropriate education about the purpose of the examination, pelvic anatomy, and the components of the examination should occur in an unhurried manner. The use of diagrams and models may facilitate discussion. Time should be allotted for the adolescent to ask questions. Ideally, the examination should occur in a controlled and comfortable setting. The adolescent may request to have her mother or family member present during the examination for reassurance; however, in many instances an adolescent will request that the examination occur confidentially. Having another female staff present to support the adolescent in this setting may be helpful. A female staff chaperone should be present with male examiners.

The pelvic examination begins by placing the patient in the dorsal lithotomy position after equipment and supplies are ready (Table 4–10). Patients with orthopedic or other physical disabilities require accommodation for proper positioning and comfort. The examiner inspects the external genitalia, noting sexually maturity rating, estrogenization of the vaginal mucosa (moist, pink, and more elastic mucosa),

Table 4–10. Items for pelvic examination.

General	Gloves, good light source, appropriate-sized speculums, sterile cotton applicator swabs, large swabs to remove excess bleeding or discharge, patient labels, hand mirror for patient education
Wet prep of vaginal discharge	pH paper, microscope slides and cover slips, NaCl and KOH solutions
Pap smear	Pap smear liquid media or slides with fixative; cervical spatula and endocervical cytologic brush; or broom for collection
STI testing	Gonorrhea and Chlamydia test media with specific collection swabs
Bimanual examination	Gloves, water-based lubricant

shape of the hymen, the size of the clitoris (2–5 mm wide is normal), any unusual rashes or lesions on the vulva such as folliculitis from shaving, warts or other skin lesions, and genital piercing or body art. It can be helpful to ask an adolescent if she has any questions about her body during the inspection as she might have concerns that she was too shy to ask (eg, normalcy of labial hypertrophy). In cases of alleged sexual abuse or assault, the presence of any lesions, including lacerations, bruises, scarring, or synechiae about the hymen, vulva, or anus, should be noted.

The patient should be prepared for insertion of the speculum to help her remain relaxed. The speculum should be inserted into the vagina posteriorly with a downward direction to avoid the urethra. A medium Pedersen speculum is most often used in sexually experienced patients; a narrow Huffman is used for virginal patients. In a virginal female prior to the speculum examination, a one-finger examination in the vagina can help the provider identify the position of the cervix and can give the patient an appreciation for the sensation she can expect with placement of the speculum. Warming the speculum with tap water prior to insertion can be more comfortable for the patient and also provide lubrication. Simultaneously touching the inner aspect of the patient's thigh or applying gentle pressure to the perineum away from the introitus while inserting the speculum helps distract attention from the placement of the speculum. The vaginal walls and cervix are inspected for anatomical abnormalities, inflammation, and lesions and the quantity and quality of discharge adherent to the vaginal walls and pooled in the vagina are noted. The presence of a cervical ectropion is commonly observed in adolescents as erythema surrounding the cervical os. The ectropion is the extension of the endocervical columnar epithelium outside the cervical os onto the face of the cervix.

Specimens are obtained in the following order: vaginal pH, saline and KOH wet preparations, cervical cytology (Pap) screening if indicated, and endocervical swabs for gonorrhea and *Chlamydia* (Table 4–11). STIs are discussed in further detail in Chapter 44. The speculum is then removed, and bimanual examination is performed with one or two fingers in the vagina and the other hand on the abdomen to palpate the uterus and adnexa for size, position, and tenderness.

Menstrual Disorders

1. Amenorrhea

Primary amenorrhea is defined as having no menstrual periods or secondary sex characteristics by age 13 years or no menses in the presence of secondary sex characteristics by age 15 years. In the adolescent who has achieved menarche, secondary amenorrhea is defined as the absence of menses for three consecutive cycles or for 6 months in a patient with irregular cycles. **Table 4–11.** Diagnostic tests and procedures performedduring speculum vaginal examination.

Vaginal pH	Use applicator swab to sample vaginal discharge adherent to the wall or in the vaginal pool if a speculum is in place; immediately apply it to pH paper for reading.
Saline and KOH wet preparations	Sample discharge as above with different swabs, smear small sample on glass slide, apply small drop of saline or KOH and immediately cover with coverslip, and evaluate under microscope.
Pap smear ^a	Gently remove excessive discharge from surface of cervix. Exocervical cells are sampled with a spatula by applying gentle pressure on the cervix with the spatula while rotating it around the cervical os. Endocervical cells are sampled by gently inserting the cytologic brush into the cervical os and rotating it. Both cell types are collected by the broom when it is centered over the cervical os and rotated.
STI testing ^a	Insert specific test swabs (eg, Dacron for most <i>Chlamydia</i> test media) into the cervical os and rotate to obtain endocervical samples for <i>Chlamydia</i> and gonorrhea, or if using approved test for vaginal collection, insert the swab into the vagina and rotate, touching the vaginal wall. Vaginal testing for <i>Trichomonas vaginalis</i> is also available.

STI, sexually transmitted infection.

^aRefer to manufacturer instructions for sample collection and processing.

A. Evaluation of Primary and Secondary Amenorrhea

In evaluating amenorrhea, it is helpful to consider anatomical levels of possible abnormalities from the hypothalamus to the genital tract (Table 4–12).

A stepwise approach, using clinical history, growth charts, physical examination, and appropriate laboratory studies will allow providers to determine the etiology of amenorrhea in most adolescents. Evaluation begins with a thorough developmental and sexual history. Establishing a pubertal timeline including age at thelarche, adrenarche, growth spurt, and menarche is helpful in evaluating pubertal development. Although there can be variations in the onset, degree, and timing of these stages, the progression of stages is predictable. Adrenal androgens are largely responsible for axillary and pubic hair. Estrogen is responsible for breast development; maturation of the external genitalia, vagina, and uterus; and menstruation. Lack of development suggests pituitary or ovarian failure or gonadal dysgenesis. Determining the patient's gynecologic age (time in years and months since menarche) is helpful in assessing the maturity of the hypothalamic-pituitary-ovarian axis.

CHAPTER 4

Table 4–12. Differential diagnosis of amenorrhea by anatomic site of cause.

Hypothalamic-pituitary axis
Hypothalamic suppression
Chronic disease
Stress
Malnutrition
Strenuous athletics
Drugs (haloperidol, phenothiazines, atypical antipsychotics)
Central nervous system lesion
Pituitary lesion: adenoma, prolactinoma
Craniopharyngioma, brainstem, or parasellar tumors
Head injury with hypothalamic contusion
Infiltrative process (sarcoidosis)
Vascular disease (hypothalamic vasculitis)
Congenital conditions ^a
Kallmann syndrome (anosmia)
Ovaries
Gonadal dysgenesis ^a
Turner syndrome (XO)
Mosaic (XX/XO)
Injury to ovary
Autoimmune disease (oophoritis)
Infection (mumps)
Toxins (alkylating chemotherapeutic agents)
Irradiation
Trauma, torsion (rare)
Polycystic ovary syndrome
Ovarian failure
Uterovaginal outflow tract
Müllerian dysgenesis ^a
Congenital deformity or absence of uterus, uterine tubes,
or vagina
Imperforate hymen, transverse vaginal septum, vaginal agenesis,
agenesis of the cervix ^a
Androgen insensitivity syndrome (absent uterus) ^a
Uterine lining defect
Asherman syndrome (intrauterine synechiae postcurettage
or endometritis)
Tuberculosis, brucellosis
Defect in hormone synthesis or action (virilization may be present)
Adrenal hyperplasia ^a
Cushing disease
Adrenal tumor
Ovarian tumor (rare)
Drugs (steroids, ACTH)

ACTH, adrenocorticotropic hormone.

^aIndicates condition that usually presents as primary amenorrhea.

A menstrual history includes date of last menstrual period (LMP), frequency and duration of periods, amount of bleeding, and premenstrual symptoms. Irregular menstrual cycles are common in the first 1–2 years after menarche. Two-thirds of adolescents with a gynecologic age more than 2 years have regular menstrual cycles.

Relevant components of the past medical and surgical histories include the neonatal history, treatment for malignancies, presence of autoimmune disorders or endocrinopathies, and current medications (prescribed and overthe-counter). Family history includes age at menarche of maternal relatives, familial gynecologic or fertility problems, autoimmune diseases, or endocrinopathies. A review of systems should focus on symptoms of hypothalamic-pituitary disease such as weight change, headache, visual disturbance, galactorrhea, polyuria, and/or polydipsia. A history of cyclic abdominal and/or pelvic pain in a mature adolescent with amenorrhea may indicate an anatomic abnormality such as an imperforate hymen. Acne and hirsutism are clinical markers of androgen excess. Both hypo- and hyperthyroidism can cause menstrual irregularities. Changes in weight, quality of skin and hair, and stooling pattern may indicate a thyroid problem. A confidential social history should include sexual activity, contraceptive use, the possibility of pregnancy, and use of tobacco, drugs, or alcohol. The patient should also be questioned about major stressors, symptoms of depression and anxiety, dietary habits including any disordered eating or weight-loss behaviors, and athletic participation.

A thorough physical examination should include the components listed in Table 4–13. If a patient cannot tolerate a pelvic or bimanual examination, the presence of the uterus can be assessed by rectoabdominal examination or

Table 4–13. Components of the physical examination for amenorrhea.

General appearance	Syndromic features (eg, Turner syndrome with webbed neck, shield chest, widely spaced nipples, increased carrying angle of the arms)
Anthropometrics	Height, weight, BMI and percentiles for age, vital signs (HR, BP)
Ophthalmologic	Visual field cuts, papilledema
Neck	Thyromegaly
Breast	SMR staging, galactorrhea
Abdomen	Masses
Genital	SMR staging, estrogenization of vaginal mucosa (pink and moist vs thin red mucosa of hypoestrogenization), hymenal patency, clitoromegaly (width > 5 mm)
Pelvic and bimanual	Vaginal depth by insertion of a saline moistened applicator swab into the vagina or by bimanual examination (normal >2 cm); palpation of the uterus and ovaries by bimanual examination
Skin	Acne, hirsutism, acanthosis nigricans

BMI, body mass index; BP, blood pressure; HR, heart rate; SMR, sexual maturity rating.

ultrasonography. Ultrasound provides evaluation of pelvic anatomy and possible genital tract obstruction, measurement of the endometrial stripe as an indicator of estrogen stimulation, and identification of ovarian cysts or masses. Figure 4–6 illustrates an approach to the laboratory and radiologic evaluation of primary or secondary amenorrhea. Initial studies should include a urine pregnancy test, complete blood count, TSH, prolactin, and FSH. If there

▲ Figure 4–6. Evaluation of primary amenorrhea and secondary amenorrhea. CNS, central nervous system; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; UA, urine analysis.

CHAPTER 4

is evidence of hyperandrogenemia (acne, hirsutism) and PCOS is suspected, total and free testosterone and dehydroepiandrosterone sulfate (DHEAS) should be obtained. If systemic illness is suspected, a urinalysis and a chemistry panel (including renal and liver function tests) and erythrocyte sedimentation rate should be obtained. If short stature and delayed puberty are present, a bone age and karyotype should be done.

If pelvic examination or ultrasonography reveals normal female external genitalia and pelvic organs and the patient is not pregnant, the patient should be given a challenge of oral medroxyprogesterone, 10 mg daily for 10 days. Positive response to the progestin challenge with withdrawal bleeding is suggestive of the presence of a normal, estrogenprimed uterus.

Elevated serum prolactin indicates a possible prolactin secreting tumor. Prolactin testing is sensitive and can be elevated with stress, eating, or sexual intercourse. A mildly elevated test should be repeated prior to MRI of the brain for a prolactinoma. Elevated FSH indicates ovarian insufficiency or gonadal dysgenesis and a karyotype for Turner syndrome or Turner mosaic should be obtained. Autoimmune oophoritis should be assessed by antiovarian antibodies if the chromosome analysis is normal. Normal or low serum gonadotropins indicate hypothalamic suppression and functional amenorrhea if the patient's weight is normal and there is a reasonable explanation such as vigorous exercise. Functional amenorrhea, although relatively common, is a diagnosis of exclusion. Low serum gonadotropin concentration can also be caused by malnutrition as in anorexia nervosa, endocrinopathies, and chronic diseases or by a central nervous system tumor.

If the physical examination or ultrasound reveals an absent uterus, chromosomal analysis and serum testosterone should be obtained to differentiate between Mullerian dysgenesis and androgen insensitivity. Mullerian dysgenesis or Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is the congenital absence of the vagina with variable uterine development. These women have normal serum testosterone levels. Pelvic MRI is helpful to clarify the nature of the vaginal agenesis and to differentiate it from low-lying transverse vaginal septum, agenesis of the uterus and vagina, and imperforate hymen. Individuals with androgen insensitivity are phenotypically female but have an absent upper vagina, uterus, and fallopian tubes; a male karyotype; and an elevated serum testosterone (normal range for males).

The management of primary or secondary amenorrhea depends on the underlying pathology. Hormonal treatment is used in patients with hypothalamic, pituitary, and ovarian causes. Surgical repair may be required in patients with outflow tract anomalies.

B. Polycystic Ovary Syndrome

- Typical features of polycystic ovary syndrome include: menstrual irregularities, clinical signs of hyperandrogenism (eg, hirsutism and moderate-to-severe acne), and overweight or obesity.
- In addition to the laboratory evaluation for secondary amenorrhea, testing for hyperandrogenemia includes: total and free testosterone, dehydroepiandrosterone sulfate, and androstenedione.
- Obese adolescents with polycystic ovary syndrome should be screened for lipid abnormalities, glucose intolerance and/or type 2 diabetes, obstructive sleep apnea and depression and anxiety.

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder of reproductive-aged women. It affects 6%–15% of women of reproductive age. PCOS is characterized by ovarian dysfunction, disordered gonadotropin secretion, and hyperandrogenism, which cause irregular periods, hirsutism, and acne. Many adolescents with PCOS are overweight and the association of PCOS with insulin resistance in adults is well established. Adolescents with PCOS are at increased risk for obesity-related morbidities including type 2 diabetes mellitus, cardiovascular disease including dyslipidemia, obstructive sleep apnea, low self-esteem, depression and anxiety; and adult reproductive health problems including infertility and endometrial cancer.

Hyperandrogenemia occurs during normal puberty and also as a function of prolonged anovulatory cycles as the hypothalamic-pituitary-ovarian axis matures during the first few years of typical pubertal development. The normalcy of this hyperandrogenemia confounds the diagnosis of PCOS in early adolescence if the adult criteria of evidence of chemical hyperandrogenemia are applied. Therefore, many authors recommended avoiding testing androgen levels until 2 years after menarche for symptomatic adolescents. The current diagnostic criteria for PCOS in adolescents include clinical signs and symptoms of androgen excess, increased androgen levels, and exclusion of other causes of hyperandrogenemia in the setting of oligomenorrhea.

Table 4–14 outlines a standard laboratory evaluation for PCOS. If other etiologies of virilization such as late-onset congenital adrenal hyperplasia (history of premature pubarche, high DHEAS, clitoromegaly) are suspected, a first morning 17-hydroxyprogesterone should be collected to look for 21-hydroxylase deficiency. Urine cortisol or a dexamethasone **Table 4–14.** Laboratory evaluation for polycystic ovary syndrome (PCOS).

Pregnancy test	
Testosterone (total and free)	> 200 ng/dL suggests tumor
Sex hormone-binding globulin (SHBG)	
Dehydroepiandrosterone sulfate (DHEAS)	> 700 mcg/dL suggests tumor
Androstenedione	

suppression test is performed if Cushing syndrome is suspected. If the patient is overweight and/or has acanthosis nigricans, a fasting lipid panel and glucose testing are recommended. A 2-hour oral glucose tolerance test (OGTT) to evaluate for impaired glucose tolerance should also be considered as a normal fasting glucose may be falsely reassuring. A hemoglobin A1C test may be considered if a patient is unable or unwilling to complete an OGTT. Additionally, as obstructive sleep apnea, depression and anxiety have been associated with the diagnosis of PCOS, clinicians should screen for patients for these comorbidities. Consultation with a pediatric endocrinologist can assist in further evaluation and management of significantly elevated androgens and possible endocrinopathies.

Encouraging lifestyle changes that will promote weight loss is a primary goal of therapy for PCOS in adolescence. Weight loss is associated with improved menstrual regulation, decreased symptoms of hyperandrogenemia, and improved obesity-related comorbidities. Use of combination hormonal contraceptives will improve menstrual regularity, decrease ovarian and adrenal androgen production, and increase sex hormone–binding globulin (SHBG). There are no current guidelines for the use of insulin-sensitizing medications such as metformin to treat PCOS in adolescents; however, it is prescribed for impaired glucose tolerance or type 2 diabetes. Providers should be aware that metformin will improve the frequency of ovulation, and contraception should also be prescribed for sexually active teens.

2. Dysmenorrhea

- The majority of adolescent girls experience primary dysmenorrhea.
- Typical features include lower abdominal cramps radiating to the lower back and thighs and nausea and/or

vomiting starting a few days before the onset of menses and lasting a few days into the period.

Use of scheduled NSAIDs and contraceptives to suppress ovulation are mainstays of treatment.

Dysmenorrhea or pain with menstrual periods is the most common gynecologic complaint of adolescent girls, with up to 90% of adolescent girls reporting some symptoms. Fifteen percent of adolescent women describe their symptoms as severe. The prevalence of dysmenorrhea increases with gynecologic age due to its association with ovulatory cycles. Dysmenorrhea can be designated as primary or secondary depending upon the absence or presence of underlying pelvic pathology (Table 4–15). Potent prostaglandins are the mediators of dysmenorrhea, producing uterine contractions, tissue ischemia, and hypersensitivity of pain fibers in the uterus.

In addition to taking a gynecologic and sexual history, an accurate characterization of the pain (timing with menses, intensity, duration, use of pain medications) is important in determining functional impairment. The pelvic examination can usually be deferred in nonsexually active adolescents with probable primary dysmenorrhea. Adolescents should be encouraged to keep track of their menstrual cycles using a calendar to predict when a period is imminent, thereby allowing for more proactive use of NSAIDs 1-2 days before the start of the anticipated period or with the first indication of discomfort. NSAIDs are typically continued for an additional 2-3 days after onset of pain. Recommended medications are ibuprofen 400-600 mg every 6 hours or naproxen 500 mg twice a day. If the patient does not respond to NSAIDs, suppression of ovulation with OCPs or other combined hormonal contraceptives such as the transdermal patch or intravaginal ring can be effective. OCPs and the intravaginal ring can also be used continuously for extended cycling to decrease the frequency of menstrual periods. This is accomplished by skipping the placebo pill week and immediately starting a new package of birth control pills or skipping the standard 1-week break after removal of the intravaginal ring and immediately placing a new ring. Depot medroxyprogesterone acetate (DMPA) and long-acting reversible contraceptives (LARCs) including the etonogestrel implant and levonorgestrel intrauterine system are also effective and may be preferable for patients who may have challenges with compliance. If patients have persistent symptoms despite use of a contraceptive for suppression of ovulation and scheduled NSAIDs, further evaluation for secondary dysmenorrhea is indicated. A pelvic examination, pelvic imaging with ultrasonography or MRI, and diagnostic laparoscopy may be necessary for diagnosis. Secondary dysmenorrhea is more likely to be associated with chronic pelvic pain, midcycle pain, dyspareunia, and metrorrhagia.

Table 4–15. Dysmenorrhea in the adolescent.

	Etiology	Onset and Duration	Symptoms	Pelvic Examination	Treatment
Primary Dysmeno	orrheaª				
Primary	Excessive amount of prostaglandin $F_2\alpha$, which attaches to myometrium, causing uterine contractions, hypoxia, and ischemia. Also, directly sensitizes pain receptors.	Begins just prior to or with the onset of menstrual flow and lasts 1–2 days. Typically does not start until 1–2 y after menarche, when cycles are more regularly ovulatory.	Lower abdominal cramps radiating to lower back and thighs. Associated nausea, vomiting, and diarrhea due to excess prostaglandins.	Normal. May wait to examine if never sexually active and history is consistent with primary dysmenorrhea.	Mild—menstrual calendar, start NSAIDs day before bleeding or at the onset of bleeding or pain if timing of cycle is difficult to predict. Moderate to severe—NSAIDs and OCPs or other birth control product to suppress ovulation.
Secondary Dysme	enorrhea ^b				
Infection	Most often due to an STI such as <i>Chlamydia</i> or gonorrhea.	Recent onset of pelvic pain. Can also have chronic pain with prolonged untreated infection.	Pelvic pain, excessive or irregular menstrual bleeding, unusual vaginal discharge.	Mucopurulent or purulent discharge from cervical os, cervical friability, cervical motion, uterine or adnexal tenderness, positive wet prep for bacterial vaginosis, positive test for STI.	Appropriate antibiotics.
Endometriosis	Ectopic implants of endometrial tissue in pelvis or abdomen; may result from retrograde menstruation. Definitive diagnosis requires laparoscopy.	Generally starts > 2 y after menarche, is not significantly responsive to standard NSAID and suppression of ovulation therapies, and worsens through time.	Cyclic or acyclic chronic pelvic pain.	Mild to moderate tenderness typically in the posterior vaginal fornix or along the uterosacral ligaments.	Suppression of ovulation with combined hormonal contraceptive methods. Continuous use may provide additional control. If pain persists, refer to a gynecologist for further evaluation of chronic pelvic pain and consideration of gonadotropin-releasing hormone agonists.
Complica- tion of pregnancy	Spontaneous abortion, ectopic pregnancy.	Acute onset.	Pelvic or abdominal pain associated with vaginal bleeding following missed menstrual period.	Positive hCG, enlarged uterus, or adnexal mass.	Pelvic US if hemodynamically stable to evaluate for intrauterine pregnancy. Immediate obstetric or surgical consult with concern for ectopic pregnancy.
Congenital anomalies	Outflow tract anomalies: imperforate hymen, transverse or longitudinal vaginal septum, septate uterus.	Onset at menarche.	Cyclic pelvic or abdominal pain which can become chronic.	Imperforate hymen may be visible on external examination. Pelvic US for general anatomy. Pelvic MRI is most sensitive and specific test for septums.	Gynecology consult for further evaluation and management.
Pelvic adhesions	Previous abdominal surgery or pelvic inflammatory disease.	Delayed onset after surgery or PID.	Abdominal pain, may or may not be associated with menstrual cycles; possible alteration in bowel pattern.	Variable.	Gynecology consult for possible lysis of adhesion.

DMPA, depot medroxyprogesterone acetate; hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging; NSAID, nonsteroidal anti-inflammatory drug; OCP, oral contraceptive pill; PID, pelvic inflammatory disease; STI, sexually transmitted infection; US, ultrasound. ^aNo pelvic pathology.

^bUnderlying pathology present.

3. Abnormal Uterine Bleeding

- Typical features of abnormal uterine bleeding include heavy menstrual bleeding for longer than 7 days or blood loss that exceeds 80 mL per menses.
- The severity of abnormal uterine bleeding is categorized according to hemodynamic status and degree of anemia and classified as mild, moderate, or severe.
- Acute management depends on the severity of the problem and its specific etiology and typically consists of hormonal management.

Abnormal uterine bleeding (AUB) describes any aberration of menstrual volume, regulation, frequency, and duration. Examples of AUB include periods that are characterized by heavy menstrual bleeding (HMB) such as menorrhagia (prolonged bleeding that occurs at regular intervals) and menometrorrhagia (heavy prolonged bleeding that occurs irregularly and more frequently than normal). The differential diagnosis of common and less common etiologies in adolescences are listed in Table 4–16.

Condition	Examples
Anovulation	
Sexually transmitted infections	Cervicitis, pelvic inflammatory disease
Pregnancy complications	Ectopic, miscarriage
Bleeding disorders	von Willebrand disease, platelet function abnormalities, thrombocytopenia, coagulopathy
Endocrine disorders	Hypo-/hyperthyroidism, hyperprolactinemia, adrenal insufficiency, PCOS
Anatomic abnormalities	Congenital anomalies, ovarian cysts or tumors, cervical polyps
Trauma	Vaginal laceration
Foreign body	Retained tampon
Chronic illness	Liver, renal, inflammatory bowel, lupus
Malignancy	Leukemia
Drugs	Contraception, anticoagulants

Table 4–16. Differential diagnosis of AUB in adolescents.

PCOS, polycystic ovary syndrome.

Evaluation

In addition to a menstrual and sexual history, the bleeding pattern should be characterized by cycle length, duration, and quantity of bleeding (eg, number of soaked pads or tampons in 24 hours, number of menstrual accidents). Bleeding for longer than 7 days or blood loss that exceeds 80 mL per menses is considered as abnormal. The patient should be assessed for symptoms of anemia including fatigue, lightheadedness, syncope, tachycardia, and for other abnormal bleeding (gingivae, stool, easy bruising). The physical examination includes an assessment of hemodynamic stability with orthostatic heart rate and blood pressure measurements. Mucous membranes and skin should be evaluated for pallor; the heart for tachycardia and murmur; the abdomen for organomegaly; and the external genitalia for signs of trauma or congenital anomalies. If the patient has never been sexually active and the external examination is normal, a pelvic examination is usually unnecessary. In a sexually experienced female, a pelvic and bimanual examination to examine the vagina, cervix, and adnexa may be helpful to elucidate the diagnosis. Initial laboratory studies should include a pregnancy test, complete blood cell count, prothrombin time, partial thromboplastin time, TSH, fibrinogen level, and iron studies. If the patient has signs of hemodynamic compromise potentially requiring blood transfusion, blood type and cross-match should be obtained. Among adolescents with HMB, up to 20% are reported to have an underlying bleeding disorder. Evaluation for underlying bleeding disorders such as von Willebrand deficiency should be considered for patients who endorse any of the following: insignificant wounds that lead to prolonged bleeding; heavy, prolonged, or recurrent bleeding after surgery or dental procedures; epistaxis greater than 10 minutes in duration or requiring medical attention; unexplained bleeding from the gastrointestinal tract; HMB with iron deficiency; postpartum hemorrhage; and/or a family history of bleeding disorders. Abnormalities in platelet function and/or aggregation can also be considered and consultation with a pediatric hematologist for further evaluation of these potential etiologies can be helpful. For patients suspected of having PCOS, total and free testosterone, DHEAS and androstenedione should be obtained. For sexually experienced females, cervical or vaginal or urine-based testing for Chlamydia and gonorrhea should be obtained.

Treatment

The severity of AUB is categorized according to hemodynamic status and degree of anemia and classified as mild, moderate, or severe (Table 4–17). The goals of treatment include (1) establishment and/or maintenance of hemodynamic stability, (2) correction of acute or chronic anemia, (3) resumption of normal menstrual cycles, (4) prevention

Table 4–17	Managemen	t of AUB.
------------	-----------	-----------

	Mild	Moderate	Severe
Hgb value (g/dL)	Hgb >12	Hgb 9–12	Hgb < 9
Acute treatment	Menstrual calendar; iron supplementation. NSAID with menses may help reduce flow. Consider OCPs if patient is sexually active and desires contraception.	OCP bid until bleeding stops, continue active pill qd for 21 days followed by 1 wk of placebo pills.	Admit to hospital if Hgb < 7 g/dL or patient is hemodynamically unstable. Transfusion based on degree of hemodynamic instability and ability to control bleeding. Conjugated estrogens, 25 mg IV every 4 h for up to 48 h. Provide scheduled IV antiemetic. When bleeding stops, step down to 50 mcg OCP PO qid (or tid), then taper as below. If bleeding doesn't stop, gynecology consultation for further evaluation and possible dilation and curettage. Or One 30–35 mcg OCP PO qid until bleeding stops, then decrease to tid for 2 days (and up to 7 days), then bid for 2 days (and up to 7 days), then qd (skipping placebo pills) until Hct > 30%. Antiemetic 2 h prior to OCPs as needed for nausea.
Long-term management	Monitor menstrual calendar and Hgb. Follow-up in 2–3 mo.	Iron supplementation. Monitor Hgb closely for improvement. May need to revert to bid OCP dosing if bleeding persists. If bleeding controlled, cycle with OCPs (28 days pack) or other combined hormonal contraceptive agent for minimum 3–6 mo.	Iron supplementation. Serial hematocrits. If Hct > 30%, cycle with OCPs (28-day pack) or other combined hormonal contraceptive agent for minimum 3–6 mo. Consider placement of levonorgestrel intrauterine system once anemia improved as alternative to short-acting method.

AUB, abnormal uterine bleeding; bid, twice daily (every 12 hours); Hct, hematocrit; Hgb, hemoglobin; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; OCP, oral contraceptive pill; PO, by mouth; qd, daily; qid, four times per day (every 6 hours); tid, three times per day (every 8 hours).

of recurrence, and (5) prevention of long-term consequences of anovulation. Management depends on the severity of the problem and its specific etiology (see Table 4-17). Monophasic OCPs containing a potent progestin such as norgestrel 0.3 mg with ethinyl estradiol 30 mcg or levonorgestrel 0.15 mg with ethinyl estradiol 30 mcg are frequently used for patients without medical contraindications to exogenous estrogens. (See Table 4-21 for information about individual characteristics or preexisting medical conditions that are contraindications for the use of exogenous estrogen.) The active pills in monophasic formulations contain the same concentration of progestins and estrogen and are preferred over multiphasic formulations which contain variable concentrations of estrogen which could potentially increase the risk of breakthrough bleeding. It is important to remind adolescents and their families that compliance with medications to control bleeding and treat anemia is imperative. Adolescents should be treated until the anemia is resolved and often for an additional 6 months or longer if there is an underlying problem such as platelet function abnormality or von Willebrand disease. For patients with contraindications to the use of exogenous estrogens, there are progestin-only methods available for acute management and maintenance treatment of AUB (Table 4–18).

4. Mittelschmerz

Mittelschmerz is midcycle discomfort resulting from ovulation. The cause of the pain is unknown but irritation of the peritoneum due to spillage of fluid from the ruptured follicular cyst at the time of ovulation has been suggested. The patient presents with a history of midcycle, unilateral dull or aching abdominal pain lasting a few minutes to as long as 8 hours. Rarely, the pain mimics that of acute appendicitis, torsion or rupture of an ovarian cyst, or ectopic pregnancy. The patient should be reassured and treated symptomatically.

5. Premenstrual Syndrome & Premenstrual Dysphoric Disorder

It is estimated that 51%-86% of adolescent women experience some premenstrual symptoms. Premenstrual syndrome (PMS) is a cluster of physical and psychological **Table 4–18.** Progesterone-only hormone regimens for management of AUB.

Hormone	Tapering Regimen
Norethindrone acetate	5–10 mg PO every 4 h until bleeding stops, then qid for 4 days, then tid for 3 days, then bid for 2 days–2 wk, then qd. Once anemia improved, can transition to DMPA 150 mg IM q12 weeks or levonorgestrel intrauterine system placement. Progesterone-only OCPs can also be an alternative, they but require excellent compliance.
Medroxyprogesterone	10 mg PO every 4 h (max 80 mg) until bleeding stops, then qid for 4 days, then tid for 3 days, then bid for 2 days–2 wk, then qd. Once anemia improved, can transition to DMPA 150 mg IM q12 weeks or levonorgestrel intrauterine system placement. Progesterone-only OCPs can also be an alternative, they but require excellent compliance.

bid, twice daily (every 12 hours); DMPA, depot medroxyprogesterone acetate; DUB, dysfunctional uterine bleeding; IM, intramuscular; PO, by mouth; qd, daily; qid, four times per day (every 6 hours); tid, three times per day (every 8 hours).

symptoms that occur during the luteal phase of the menstrual cycle and resolve with menstruation. Physical symptoms include bloating, breast tenderness, fatigue, headache, myalgia, increased appetite, and food craving. Premenstrual emotional symptoms may include fatigue, mood lability, anxiety, depression, irritability, hostility, sleep dysfunction, and impaired social function. PMS can be diagnosed when at least one disabling physical or psychological symptom is documented prospectively for at least two consecutive menstrual cycles, is restricted to the luteal phase of the menstrual cycle, resolves by the end of menses, results in functional impairment, and is not an exacerbation of another underlying disorder. Severe PMS with functional impairment affects 1.8%-5.8% of women of reproductive age and is classified in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM5), as premenstrual dysphoric disorder (PMDD). The clinical diagnosis of PMDD requires a combination of a minimum of five physical and psychological symptoms in the majority of cycles that must be present in the final week before onset of menses, start to improve within a few days after the onset of menses, and become minimal or absent in the week postmenses.

The pathophysiology of PMS is not well understood; however, there is some evidence of dysregulation of serotonergic activity and/or of GABAergic receptor functioning during the luteal phase of the menstrual cycle with heightened sensitivity to circulating progesterone metabolites. PMS and PMDD are highly associated with unipolar depressive disorder and anxiety disorders, such as obsessivecompulsive disorder, panic disorder, and generalized anxiety disorder. During adolescence, it may be difficult to determine if the affective symptoms represent a mood or anxiety disorder, a premenstrual exacerbation of a psychiatric disorder, or simple PMS.

Current treatment for PMS in adolescence is based on findings from adult studies and includes lifestyle recommendations and pharmacologic agents that suppress the rise and fall of ovarian steroids or augment serotonin. SSRIs are increasingly used as first-line therapy for PMS and PMDD in adults, and a recent Cochrane review of SSRIs in severe adult PMS determined that SSRIs administered continuously or during the luteal phase were effective in reducing premenstrual symptoms. Once a diagnosis is made, proven effective interventions including education about pathophysiology, lifestyle changes (eg, increasing physical activity and smoking cessation), stress reduction, cognitive behavioral therapy, and nutritional counseling to improve calcium intake and/or calcium supplementation should be attempted. If contraception or cycle control is important, a combined hormonal contraceptive pill may be beneficial. The pill containing 20 mcg ethinyl estradiol and 3 mg drospirenone with a 24/4 formulation has been shown to be therapeutic in studies of adult women with PMDD. If these interventions do not adequately control symptoms, luteal phase or continuous administration of SSRIs can be considered. Case reports indicate that adolescents with PMDD respond well to luteal phase dosing of fluoxetine at the standard adult dosage of 20 mg/day. SSRIs are not formally approved by the FDA for treatment of PMS or PMDD in adolescents.

6. Ovarian Cysts

Functional ovarian cysts account for the majority of benign ovarian tumors in postpubertal adolescents and are a result of the normal process of ovulation. They may be asymptomatic or may cause menstrual irregularities or pelvic pain. Large cysts can cause constipation or urinary frequency. Follicular cysts are the most common functional cysts. They are usually unilateral, less than 3 cm in diameter, and resolve spontaneously in 1-2 months. Cyst pain occurs as the diameter of the cyst increases, stretching the overlying ovarian cortex and capsule. If the patient's discomfort is tolerable, she can be reexamined monthly and observed for resolution. Hormonal contraceptive products that suppress ovulation can be started to prevent additional cysts from forming. Patients with cysts should be counseled about the signs and symptoms of ovarian and/ or tubal torsion, which are serious complications. Adnexal

torsion presents with the sudden onset of pain, nausea, and vomiting. Low-grade fever, leukocytosis, and the development of peritoneal signs with rebound and guarding can be found. Torsion is a surgical emergency due to the risk of ischemia and death of the ovary. Patients should be referred to a gynecologist for potential laparoscopy if the cyst has a solid component and measures more than 6 cm by ultrasonography, if there are symptoms or signs of hemorrhage or torsion, or if the cyst fails to regress within 2 months. Corpus luteum cysts occur less commonly and may be large, 5-10 cm in diameter. The patient may have associated amenorrhea, or as the cyst becomes atretic, heavy vaginal bleeding. There may be bleeding into the cyst or rupture with intraperitoneal hemorrhage. To determine whether the bleeding is self-limited, serial hematocrit measurements and ultrasounds can be used. If the patient is stable, hormonal contraception that suppresses ovulation can be started to prevent additional cyst formation and the patient may be monitored for 3 months for resolution. Laparoscopy may be indicated if the cyst is larger than 6 cm or if there is severe pain or hemorrhage.

CONTRACEPTION

According to the CDC 2015 Youth Risk Behavior Survey, 41% of high school students reported having had sexual intercourse and 30% reported being currently sexually active. Fifty-seven percent reported using a condom at their latest intercourse. Most young people have sex for the first time at about the age of 17, but do not marry until their middle or late twenties. This means that young adults are at risk of unwanted pregnancy and STIs for nearly a decade. A sexually active female who does not use contraceptives has almost a 90% chance of becoming pregnant within a year.

Abstinence & Decision Making

Talking with teenagers about sexual intercourse and its implications can help teens make informed decisions regarding engaging in sexual activity. The American Academy of Pediatrics endorses a comprehensive approach to sexuality education that incorporates encouraging abstinence while providing appropriate risk reduction counseling regarding sexual behaviors. Counseling should include discussions about confidentiality, STI prevention and testing, and contraceptive methods including abstinence and emergency contraception (Table 4-19). Best-practice guidelines recommend that an adolescent sexual history be taken with the adolescent alone in an honest and caring manner with a nonjudgmental attitude and a comfortable, matter-of-fact approach to asking questions. The CDC has a useful Guide to Taking a Sexual History for providers, which covers the "five Ps" of sexual health: partners, practices, protection from STIs, past history of STIs, and prevention of pregnancy (see http://www.cdc.gov/std/treatment/SexualHistory.pdf). Encouraging adolescents to use contraception when they do engage in sexual intercourse does not lead to higher rates of sexual activity. Adolescents often delay seeing a clinician for contraceptive services after initiating sexual activity. Concern about lack of confidentiality is an important reason for this delay.

Methods Counseling

The goals of counseling adolescents about contraception include promoting safe and responsible sexual behavior through delaying the initiation of sexual activity, reinforcing consistent condom use for those who are sexually active, and discussing other contraceptive options to provide protection from unwanted pregnancy. Motivational interviewing can be used to address the ambivalence and discrepancies among adolescents' sexual and contraceptive behaviors, their sexual and relationship values, and future life goals. Providers should familiarize themselves with their state policies regarding the ability of minors to consent for sexual and

reproductive health care services. These data are accessible on the Internet from the Guttmacher Institute (http://www. guttmacher.org) and the Center for Adolescent Health and the Law (http://www.adolescenthealthlaw.org).

Providers should consider the adolescent's lifestyle, potential challenges to compliance, the patient's need for confidentiality around the use of contraception, previous experiences with contraception and reasons for discontinuation, and any misconceptions regarding contraceptive options. Barriers to health care access including transportation and financial limitations should be identified. Prescribing contraception for other medical reasons (eg, management of dysmenorrhea) can create opportunities for providers and adolescent patients to make parents aware of the use of the medication while maintaining confidentiality around the sexual behaviors.

Mechanism of Action

The primary mechanism of action for combined hormonal contraceptives containing estrogen and progestin (OCPs,

transdermal patch, intravaginal ring) and the progestinonly methods (pills, DMPA, and the etonogestrel implant) is inhibition of ovulation. Thickening of the cervical mucus also makes sperm penetration more difficult, and atrophy of the endometrium diminishes the chance of implantation. (The mechanisms of action for intrauterine systems and devices are discussed later in this chapter in the section Intrauterine Systems & Devices.)

Starting all birth control methods during the menstrual period (either first day of bleeding or first Sunday of bleeding) produces the most reliable suppression of ovulation. Conventional OCPs, transdermal patches, and intravaginal rings typically require that the adolescent wait for her next period to begin before starting. Data show that many women who receive prescriptions or even samples of medication never begin the prescribed method. Furthermore, these women could become pregnant while waiting to start. "Quick start" is an alternative approach to starting contraception that allows the patient to begin contraception on the day of the appointment regardless of menstrual cycle day, following a negative pregnancy test. This approach has been studied in adolescent women and increases adherence with the method of choice. Unfortunately, these studies also highlight the generally poor long-term compliance with contraceptive treatment in this age group.

Medical Considerations

Evaluation of an adolescent female requesting contraception should include a review of current and past medical conditions, current medications and allergies, menstrual history, confidential social history including sexual history, and family medical history. Important components of a sexual history include age at first intercourse, number of partners in lifetime, history of STIs and pelvic inflammatory disease (PID), condom use, current and past use of other contraceptives and reasons for discontinuation, and pregnancy history and outcomes. It is helpful to have a baseline weight, height, BMI, and blood pressure. A pelvic examination is not necessary before initiating contraception. However, if the woman is sexually active and has missed menstrual periods or has symptoms of pregnancy, a pregnancy test is warranted. Screening for STIs should be offered if a sexually experienced woman is asymptomatic and testing for STIs is indicated if she is symptomatic.

The World Health Organization's publication, *Improv*ing Access to Quality Care in Family Planning: Medical Eligibility Criteria for Contraceptive Use is an evidencebased guide providing criteria for initiating and continuing contraceptive methods based on a risk assessment of an individual's characteristics or known preexisting medical condition. Table 4–20 lists absolute (a condition which **Table 4–20.** Contraindications to combined oral contraceptive (COC) pills.

Absolute contraindications Pregnancy
Breast-feeding (within 6 wk of childbirth)
Hypertension SBP > 160 mm Hg or DBP > 100 mm Hg
History of thrombophiebitis; current thromboembolic disorder,
Known thrombogenic mutations (factor V Leiden: prothrombin
mutation; protein S, protein C, and antithrombin deficiencies)
Systemic lupus erythematosus
Complicated valvular heart disease (with pulmonary hypertension; atrial fibrillation; history of bacterial endocarditis)
Diabetes with nephropathy; retinopathy; neuropathy
Liver disease: active viral hepatitis; severe cirrhosis; tumor
(hepatocellular adenoma or hepatoma)
Breast cancer (current)
Major surgery with prolonged immobilization
Relative contraindications
Postpartum (first 3 wk)
Breast-feeding (6 wk–6 mo following childbirth)
Hypertension (adequately controlled HTN; any history of HTN
where BP cannot be evaluated; SBP 140–159 mm Hg or
DPB 90–99 mm Hg)
Migraine neadacne without aura (for continuation of COC)
Active gallbladder disease or history of COC-induced cholestasis
Use of drugs that affect liver enzymes (rifampin, phenytoin,
carbamazepine, barbiturates, primidone, topiramate,
oxcarbazepine, lamotrigine, ritonavir-boosted protease
inhibitors)

BP, blood pressure; DBP, diastolic blood pressure; HTN, hypertension; SBP, systolic blood pressure.

represents an unacceptable health risk if the contraceptive method is used) and relative (a condition where the theoretical or proven risks usually outweigh the advantages of using the method) contraindications to using combined hormonal birth control pills. These contraindications can be extended to other combined hormonal products that contain estrogen and progestins including the transdermal patch and intravaginal ring. The CDC has also published the US Medical Eligibility Criteria for Contraceptive Use which was adapted from the WHO publication and allows the consideration of use of combined hormonal contraceptive products for women who are currently receiving anticoagulation therapy.

It is important to assess patients for possible risk factors for venous thromboembolic events (VTEs) prior to initiating any contraceptive product containing estrogen. The risk of VTE for reproductive-aged women is extremely low (4 per 100,000 women per year for nonpregnant women not using

Table 4–21. Screening questions for inherited thrombophilia.

Have you or a first-degree relative	ever had blood clots in the legs or lungs? ever been hospitalized for blood clots in the legs or lungs?

Did you or a family member require blood thinning medication?	

contraceptive product containing estrogen). The use of estrogen increases the risk of VTE for nonpregnant women (10-30 per 100,000 women per year); however, pregnancy itself markedly increases the risk of VTE (60 per 100,000 women per year). In light of the low population risk of VTE, it is not cost-effective to screen all reproductive-aged women for inherited thrombophilia (factor V Leiden, prothrombin mutation, protein S, protein C, and antithrombin deficiencies). Table 4-21 shows helpful screening questions for personal and family history of VTE. If a close relative had a VTE, determine whether testing for inherited thrombophilia was conducted. If a specific defect was identified, testing the patient for that defect prior to initiating a product containing estrogen is warranted. If testing is unknown but the family history is highly suggested of inherited thrombophilia, testing for all of the inherited thrombophilic disorders prior to initiating estrogen should be considered. Additionally, if testing is indicated but not possible, providers should consider alternative contraceptive products that do not contain estrogen.

Tips for Prescribing & Monitoring Contraceptive Use

It is important to thoroughly review the advantages, disadvantages, potential side effects, and instructions for use of contraceptive methods in a concise and age-appropriate manner with adolescent patients. Written instructions that are clear and at an appropriate educational level can also be helpful (www.youngwomenshealth.org is a useful source for instructions). Some offices utilize consent forms to further ensure that the adolescent has a full understanding of the chosen contraceptive method. Teens need to be reminded that hormonal contraception will not protect them from STI transmission (including HIV infection) and condoms need to be used consistently. Encouraging teens to be creative about personal reminders such as setting a cell phone alarm to take a pill can help with compliance. Teens often discontinue birth control for nonmedical reasons or minor side effects and should be encouraged to contact their providers if any questions or concerns about the chosen method arise to avoid unintentional pregnancy. Frequent follow-up visits every few months with a provider may also improve adherence. These visits also provide opportunities for further reproductive health education and STI screening.

Barrier Methods

Male condoms have been used more widely in the last several decades as a result of educational and marketing efforts driven by the AIDS epidemic. All sexually active adolescents should be counseled to use condoms correctly and consistently with all intimate behaviors (oral, vaginal, and anal intercourse). Condoms offer protection against STIs by providing a mechanical barrier. Polyurethane condoms can be used by adolescents with an allergy to latex. Spermicides containing nonoxynol-9 are no longer recommended, as exposure to spermicide can cause genital irritation which may facilitate the acquisition of STIs including HIV. Patients should be counseled to use water-based lubricants with condoms.

Vaginal barrier methods include the female condom, diaphragm, and cervical cap. The female condom is a polyurethane vaginal pouch that can be used as an alternative to the male condom. Female condoms have lower efficacy in preventing pregnancy and STIs and are more expensive than male condoms. Diaphragms and cervical caps may not be feasible for adolescents as they require prescription, professional fitting, and skill with insertion.

Combined Hormonal Methods

Oral Contraceptive Pills, Transdermal Patch, & Intravaginal Ring

Combined oral contraceptive pills (COCs) are the most commonly used contraceptive method in the adolescent age group. COCs are also utilized for noncontraceptive indications (Table 4–22). All COCs contain estrogen (ethinyl estradiol). "Low-dose" COCs contain 20–35 mcg of ethinyl estradiol per pill. There are a variety of progestins used in COCs, most made from testosterone with differing androgenic profiles. Drospirenone is a progestin derived from spironolactone that possesses antiandrogenic and antimineralocorticoid activity. This formulation has appeal for use with patients who have PCOS but should not be prescribed for patients with risk of hyperkalemia (those who have renal, hepatic, or adrenal insufficiency or take certain medications including angiotensin-converting **Table 4–22.** Noncontraceptive health benefits of oral contraceptive pills.

enzyme inhibitors and angiotensin II receptor antagonists). Extended cycle regimens are available which allow women to decrease menstrual frequency from four menstrual cycles per year to formulations that provide hormonal pills daily for the whole year, eliminating menstrual periods altogether. New formulations with fewer placebo pills (4 vs the standard 7) decrease the duration of the menstrual period. There is also a chewable COC for those who cannot swallow pills.

In general, contraceptive side effects are mild and improve or lessen during the first 3 months of use. Table 4-23 shows the more common estrogenic, progestogenic, and combined (estrogenic and progestogenic) effects of COCs. In general, these symptoms can also be extended to the other combined hormonal methods. If a patient taking contraceptive pills has persistent minor side effects for more than 3 months, a different type of COC can be tried to achieve the hormonal effects desired (eg, decreasing the estrogen content or changing progestin). Breakthrough bleeding is a common side effect in the first few months of COC use and generally resolves without intervention. If breakthrough bleeding is persistent, the provider should rule out other possible etiologies such as missed pills, pregnancy, infection, or interaction with other medications. For women who have spotting or bleeding before completing the active hormonal pills, increasing the progestin content will provide more endometrial support. For those with continued spotting or bleeding after the period, increasing the estrogen content will provide more endometrial support.

Transdermal Patch

The transdermal patch, Ortho Evra, releases 20 mcg of ethinyl estradiol and 150 mcg of norelgestromin daily. One patch is worn for 7 days and changed weekly for 3 consecutive weeks. The patch is an attractive alternative

to COCs for adolescents who have difficulty remembering to take a pill every day; however, the higher bioavailability of estrogens delivered transdermally (60% higher than with 35 mcg COCs) has raised concern that the patch might increase the risk of VTE over other estrogen-containing contraceptive products. Studies evaluating this risk have shown conflicting results. The FDA updated the safety labeling for Ortho Evra in September 2009 to include its interpretation of these studies showing a zero to twofold increase in the risk of thromboembolic events. The FDA maintains that Ortho Evra is a well-tolerated and effective contraceptive for women with low-risk profile for VTE. As with other estrogen-containing contraceptive products, patients should be advised to avoid smoking and consider planned discontinuation of these methods around major surgery and prolonged immobilization. In clinical trials, the most common side effects included breast disorders (pain and swelling), headache, nausea, and skin irritation. The patch may be less effective in women weighing more than 90 kg and those with skin conditions preventing absorption.

Intravaginal Ring

The NuvaRing is a vaginal ring that releases 15 mcg of ethinyl estradiol and 120 mcg of etonogestrel per day.

The patient places the ring inside the vagina for 3 weeks, and removes it the first day of the fourth week to allow for withdrawal bleeding. A new ring is inserted each month. In clinical trials, the most common side effects included vaginitis and vaginal discharge, headache, weight gain, and nausea.

Progestin-Only Methods

Oral Contraceptive Pills

Progestin-only pills (POPs) do not contain estrogen. They are used in women with contraindications to estrogencontaining products such as the presence of inherited risk factors for thrombophilia or unacceptable estrogen-related side effects with COCs. The efficacy of POPs in preventing pregnancy is slightly less than COCs. They require strict compliance and regular dosing schedule due to the shorter half-life of the progestin. A patient must take POPs daily at the same time (within 3 hours). The primary mechanisms by which pregnancy is prevented includes thickening cervical mucous and thinning the endometrial lining. Ovulation is inhibited in approximately 50% of women. The main side effect of POPs is unpredictable menstrual patterns. The need for strict compliance and the possibility of breakthrough bleeding may make POPs a less desirable method for teens.

Injectable Hormonal Contraception

Depot medroxyprogesterone acetate (DMPA), or DepoProvera, is a long-acting injectable progestin contraceptive. It is injected into the gluteal or deltoid muscle every 12 weeks at a dose of 150 mg. The first injection should be given during the first 5 days of the menstrual cycle to ensure immediate contraceptive protection. The quick-start method may also be used with DMPA following a negative pregnancy test. Adolescents who have been sexually active within the previous 2 weeks of administration of DMPA using the quickstart method should be informed of the chance of pregnancy and instructed to return for a repeat pregnancy test 2 weeks after receiving DMPA. With a failure rate of less than 0.3%, long-acting nature reducing compliance issues, reversibility, and lack of estrogen-related side effects, it is an attractive contraceptive option for many adolescents. The hypoestrogenic state that results from DMPA suppression of the hypothalamic-pituitary-ovarian axis reduces the normal effect of estrogen to inhibit bone resorption. The FDA issued a black box warning in 2004 that long-term (> 2 years) use of DMPA was a cause of decreased bone density. This is of particular concern as adolescence is the critical time of peak bone accretion. Current recommendations are that long-term use of DMPA should be limited to situations where other contraceptive methods are inadequate. Although DMPA use is associated with decreased bone density, there are studies showing that bone mineral density recovers after stopping DMPA. There are no studies to date that can answer the question of whether decreased bone density from adolescent DMPA use increases the risk of osteoporosis and fractures in adulthood. The consensus of experts in the field at this time is that the advantages of using DMPA generally outweigh the theoretical risks of fractures later in life. As with every other contraceptive method, providers need to help their patients weigh the pros and cons of initiating and continuing with this method of contraception. Adolescents using DMPA should be counseled to take adequate dietary calcium (1300 mg/day) and vitamin D (400 IU/day), to avoid tobacco smoking and to have regular weight-bearing physical activity for overall bone health. Other adverse effects of DMPA include unpredictable menstrual patterns, weight gain (typically 5 lb/y for the first 2 years of use), and mood changes.

Contraceptive Implant

Adolescents most commonly use short-acting hormonal contraceptive methods described previously. Unfortunately, these methods have relatively high typical use failure rates (see Table 4–19) and low continuation rates. Higher failure rates combined with poor continuation rates decrease the efficacy of short-acting contraceptive methods in adolescents. Long-acting reversible contraceptives (LARCs), which include the contraceptive implants and intrauterine systems and devices, have lower rates of failure and discontinuation.

In one study comparing 1-year continuation rates for shortacting contraceptives versus LARCs, the continuation rate for short-acting methods was 55% versus 86% for LARCs. The pregnancy rate associated with use of short-acting contraceptives was 22 times higher than the rate of unintended pregnancy associated with the use of LARCs. Adolescents should be encouraged to consider LARCs as the best reversible methods for preventing unintended pregnancy, rapid repeat pregnancy, and abortion.

Implanon and Nexplanon are single-rod implant LARCs that contain the progestin etonogestrel, a metabolite of desogestrel. Nexplanon also contains barium sulfate which makes it radiopaque. Etonogestrel implants are placed subdermally and provide highly effective contraception for 3 years, with failure rates less than 1%. Implanon and Nexplanon suppress ovulation and thicken cervical mucous like DMPA, but do not suppress ovarian estradiol production or induce a hypoestrogenic state. The risk of decreased bone density is less than that associated with DMPA. Placement should occur during the first 5 days of the menstrual period or at any time if a woman is correctly using a different hormonal contraceptive method. Proper timing minimizes the likelihood that the implant is placed during an early pregnancy or in a nonpregnant woman too late to inhibit ovulation in the first cycle of use. Irregular menstrual bleeding is the single most common reason for stopping use in clinical trials. On average the volume of bleeding is similar to the woman's typical menstrual periods but the schedule of bleeding is irregular and unpredictable. Other side effects include headache, weight gain, acne, breast pain, and emotional lability. Return to fertility is rapid following removal. The efficacy of Implanon and Nexplanon has not been formally defined in women with elevated BMIs greater than 130% ideal and could theoretically be less effective in these women. Etonogestrel implants are not recommended for women who chronically take medications that are potent hepatic enzyme inducers because etonogestrel levels may be substantially reduced in these women.

Intrauterine Systems & Devices

Intrauterine systems (IUSs) and devices (IUDs) are LARCs approved for use in nulliparous as well as parous teens and have high efficacy with failure rates of less than 1%. There are four forms of IUS that release the progestin levonorgestrel: Mirena, which releases 20 mcg of levonorgestrel per day and is approved for contraception for up to 5 years; Skyla, which releases an average of 6 mcg/day and is approved for contraception for up to 3 years; Liletta, which releases 18.6 mcg/day initially and declines progressively to 12.6 mcg/day at 3 years after insertion and is approved for contraception for up to 3 years; and Kyleena, which has a release rate of 17.5 mcg/day after 24 days, declining to 7.4 mcg/day after 5 years and is approved for contraception for up to 5 years. The levonorgestrel IUSs

have many contraceptive actions including thickening of cervical mucous, inhibiting sperm capacitation and survival, suppressing the endometrium, and suppression of ovulation in some women. Given that the contraceptive effect of levonorgestrel in the IUS devices is mainly due to its local effect versus systemic absorption, ovulation is not always suppressed and cysts related to normal ovulation can occur. Irregular bleeding is common in the first few months following insertion because endometrial suppression takes several months to evolve. Bleeding is then markedly decreased and secondary amenorrhea can occur. Other side effects include abdominal and/or pelvic pain, acne, ovarian cysts, and headache. In addition to pregnancy prevention, women with the IUS report reduced symptoms of dysmenorrhea and reduced pain from endometriosis. Cramping is common during insertion and spontaneous expulsion can occur. Uterine perforation during insertion is an uncommon risk.

The copper T 380A IUD, ParaGard, does not contain hormones and can provide contraception for up to 10 years. Its contraceptive actions include the release of copper ions which inhibit sperm migration and development of a sterile inflammatory reaction which is toxic to sperm and ova and prevents implantation. Menstrual pain and heavy bleeding are the most common reasons for discontinuation.

A common misconception about IUS and IUD use is that they increase the risk of PID. Current research shows that the risk of PID is increased above baseline only for the first 20 days after insertion. IUS and IUD have also not been shown to increase the risk of tubal infertility or ectopic pregnancy. Contraindications for placement of IUS/IUD include pregnancy, PID, or postabortion sepsis within the past 3 months, current STI, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of the genital tract, uterine anomalies, or leiomyomata distorting the uterine cavity making insertion incompatible. Allergy to any component of the IUS/IUD is a contraindication. Patients with disorders of copper metabolism (Wilson disease) should not use the copper-containing IUD. Adolescents should be screened for STIs prior to insertion of an IUS or IUD.

Emergency Contraception

Emergency contraception (EC) is the only contraceptive method designed to prevent pregnancy after unprotected or underprotected intercourse (Table 4–24). Indications for EC include unprotected vaginal intercourse, failure of contraceptive methods (broken condoms, missing three or more active COC pills, detached contraceptive patch, removed vaginal ring, or late DMPA injection), and sexual assault. EC medications include products labeled and approved for use as EC by the FDA (levonorgestrel and ulipristal acetate) and the "off-label" use of COCs (the Yuzpe method).

Estrogen and Progestin	Dose: Repeat in 12 h
Ovral, Ogestrel	2 white pills
Levlen, Nordette	4 orange pills
Lo/Ovral, Low-Ogestrel, Levora, Quasense, Cryselle	4 white pills
Jolessa, Portia, Seasonale, Trivora	4 pink pills
Triphasil, Tri-Levlen	4 yellow pills
Seasonique	4 light blue-green pills
Enpresse	4 orange pills
Alesse, Lessina, Levlite	5 pink pills
Aviane	5 orange pills
Lutera	5 white pills

Levonorgestrel EC, marketed as Plan B One-Step and its generic formulations, Take Action, Next Choice One Dose and My Way, is a one-pill progesterone-only regimen that contains 1.5 mg of levonorgestrel, taken immediately after unprotected intercourse. The exact mechanism of levonorgestrel EC is unknown but is thought to inhibit ovulation, disrupt follicular development, or interfere with the maturation of the corpus luteum. EC is not teratogenic and does not interrupt a pregnancy that has already implanted in the uterine lining. Therefore, pregnancy testing before use is not required. It is recommended that patients take these products within 72 hours of unprotected intercourse. EC has been studied up to 120 hours following unprotected intercourse; however, its efficacy diminishes with time from the event. EC is 90% effective if used within 24 hours, 75% effective if used within 72 hours, and approximately 60% effective if used within 120 hours. It is therefore important to counsel patients to take the medication as soon as possible following unprotected intercourse or contraception failure. EC could potentially prevent approximately 80% of unintended pregnancies and should be part of anticipatory guidance given to sexually active adolescents of both genders. These products are available without prescription and for purchase over the counter by adolescents aged 17 years and older; however, proof of age is not required for purchase. A follow-up appointment should be conducted 10-14 days after administration of EC for pregnancy testing, STI screening, and counseling regarding reproductive health and contraceptive use. A helpful resource for information about EC can be found at http://ec.princeton.edu/index.html.

If an approved EC medication is not available, certain COCs containing levonorgestrel or norgestrel can also be used for EC in a two-dose regimen separated by 12 hours; this approach is known as the Yuzpe method (see Table 4–24). An antiemetic drug takes 30 minutes prior to pills containing estrogen may help control nausea. A pregnancy test is not required prior to prescription and administration of EC.

Ulipristal, marketed as Ella, is a single pill containing 30 mg of ulipristal acetate that is available by prescription only and can be used within 120 hours after unprotected intercourse. Ulipristal binds to the human progesterone receptor and prevents binding of progesterone. Unlike levonorgestrel EC, a pregnancy test must be performed to exclude existing pregnancy before taking ulipristal because of the risk of fetal loss if used in the first trimester. Patients should also be counseled that a pregnancy test is indicated if their period is more than 7 days later than expected after taking ulipristal. Patients should be instructed to return for evaluation of the rare occurrence of ectopic pregnancy if severe abdominal pain occurs 3–5 weeks after use.

Providers should also be aware that insertion of Para-Gard (copper IUD) within 5 days of unprotected intercourse is an additional method of emergency contraception available in the United States.

PREGNANCY

In the United States, over 562,000 women younger than 20 years become pregnant every year. The majority of teen pregnancies are unintended. Approximately 60% of adolescent pregnancies result in live births, 26% end in abortion, and 14% in miscarriage. In the United States in 2011, the teenage pregnancy rate reached its lowest point in more than 30 years and was less than half of the peak rate in 1990, which has been attributed to changes in contraceptive practices including increased use of LARCs. However despite this trend, racial and ethnic disparities persist and in 2011, the pregnancy rate among non-Hispanic white teens (35.3 per 1000) was less than half that among non-Hispanic blacks (92.6 per 1000) and Hispanics (73.5 per 1000). Lower socioeconomic status and lower maternal education are risk factors for teen pregnancy regardless of racial or ethnic group. The birth rate for adolescents in 2011, 31.3 births per 1000 women was the lowest it has ever been for all racial and ethnic groups since the peak rate of 61.8 in 1991.

Presentation

Pregnancy is the most common cause of secondary amenorrhea and should be considered as a cause of even one missed period. The level of denial about the possibility of pregnancy is high and adolescents with undiagnosed pregnancies may present with abdominal pain, nausea or vomiting, breast tenderness, urinary frequency, dizziness, or other nonspecific symptoms. In addition to denial, difficult social situations can delay diagnosis and contribute to delay in seeking prenatal care. Young newly pregnant adolescents may fear violence from their partner or abandonment by their family. Clinicians should have a low threshold for suspecting pregnancy and obtaining pregnancy tests.

Diagnosis

Pregnancies are dated from the first day of the LMP. The estimated due date can be calculated by adding 7 days to the LMP, subtracting 3 months and adding 1 year. Pregnancy dating calendars are widely available on the Internet. A speculum examination is not mandatory at the time of pregnancy diagnosis for an asymptomatic adolescent. If there

is vaginal spotting or bleeding, unusual vaginal discharge, symptoms of STI, pelvic pain, or abdominal pain, a speculum examination is required. The differential diagnostic possibilities include infection, miscarriage, ectopic pregnancy, and other disorders of early pregnancy. An 8-week gestational age uterus is about the size of an orange and a 12-week uterus is about the size of a grapefruit on bimanual examination. The uterine fundus is just palpable at the symphysis pubis at 12 weeks' gestational age, midway between the symphysis and umbilicus at 16 weeks and typically at the umbilicus at 20 weeks. If the uterus is smaller than expected for pregnancy dates, possible diagnoses include inaccurate dates, false-positive test, ectopic pregnancy, or incomplete or missed abortion. A uterus that is larger than expected may be caused by inaccurate dates, twin gestation, molar pregnancy, or a corpus luteum cyst of pregnancy. Enzyme-linked immunosorbent assay test kits specific for the β-hCG subunit and sensitive to less than 50 mIU/mL of serum hCG can be performed on urine (preferably the day's first voided specimen, because it is more concentrated) in less than 5 minutes and are accurate by the expected date of the missed period in almost all patients. Serum radioimmunoassay, also specific for the β -hCG subunit, is accurate within 7 days after fertilization and is helpful in ruling out ectopic pregnancy or threatened abortion. Serum hCG doubles approximately every 2 days in the first 6-7 weeks of the pregnancy and a gestational sac is identifiable using transvaginal ultrasonography at hCG levels of 1000-2000 mIU/mL. In the absence of an accurate LMP, ultrasonography for confirmation of the presence of an intrauterine pregnancy and accurate dating can be obtained.

Management

A. Counseling at the Time of Pregnancy Testing

When an adolescent presents for pregnancy testing, it is helpful, before performing the test, to find out what she hopes the result will be and what she thinks she will do if the test is positive. The diagnosis of pregnancy may be met with shock, fear, anxiety, happiness, or most likely a combination of emotions. The clinician must discuss all pregnancy options with the patient including termination or continuing with the pregnancy and either placing the infant for adoption or raising the infant. Patients should be informed of the gestational age and time frames required for the different options. If providers are not comfortable discussing the option of termination, the adolescent should be referred to a provider who is comfortable with comprehensive options counseling. Many teenagers need help in telling and involving their parents. It is also important to ascertain the teen's safety and make appropriate referral to social services if there are legitimate concerns. If the patient knows what she wants to do, she should be referred to the appropriate resources. If a teenager is ambivalent about her plans, it is helpful to follow up in 1 week to be certain that a decision has been made. Avoiding a decision reduces the adolescent's options and may result in poor pregnancy outcomes. Providers can help ensure that the patient obtains prenatal care if she has chosen to continue the pregnancy. In addition, counseling about healthful diet; folic acid supplementation (400 mcg/day); and avoiding alcohol, tobacco, and other drugs is important.

B. Pregnancy Outcomes

Young maternal age, low maternal prepregnancy weight, poor weight gain, delay in prenatal care, maternal depression, exposure to domestic violence, and low socioeconomic status contribute to low birth weight and increased neonatal mortality. The poor nutritional status of some teenagers, substance abuse, and high incidence of STIs also play a role in poor outcomes. Teenagers are at greater risk than adults for preeclampsia, eclampsia, iron deficiency anemia, cephalopelvic disproportion, prolonged labor, premature labor, and maternal death.

Good family support, early prenatal care, and good nutrition can make a difference with several of these problems. The psychosocial consequences for the teenage mother and her infant are listed in Table 4–25. Teenagers who are pregnant require additional support from their caregivers. Multidisciplinary clinics for young mothers, if available, may be the best providers for pregnant adolescents. Adolescent mothers tend to be more negative and authoritative when disciplining their children. They may have inadequate knowledge of normal behavior and development. Providers can help by educating the adolescent mother during routine visits regarding appropriate discipline and expectations of her child's behavior.

Postpartum contraceptive counseling and follow-up may help prevent additional pregnancies. In untreated girls, the risk of a second unintended pregnancy within the next 2 years is approximately 30%. Combined hormonal contraceptive options can be started 6 weeks after delivery in non-breast-feeding adolescents; progestin-only methods can be started immediately postpartum, even in breastfeeding adolescents.

Ectopic Pregnancy

In the United States, approximately 1%–2% of pregnancies are ectopic. Adolescents have the highest mortality rate from ectopic pregnancy, most likely related to delayed diagnosis. Risk factors include history of PID or STIs. Repeat infections with *Chlamydia* increase risk for ectopic pregnancy, as does cigarette smoking. Conception while on progestin-only methods of contraception also increases the risk of ectopic pregnancy, because of the progestin-mediated decrease in tubal motility. The classic presentation is missed menstrual

Table 4–25.	Psychosocial	consequences	of pregnancy	for the adolescent	mother and her infant.
-------------	--------------	--------------	--------------	--------------------	------------------------

Mother	Infant	
Increased morbidity related to pregnancy	Greater health risks	
Greater risk of eclampsia, anemia, prolonged labor, premature labor	Increased chance of low birth weight or prematurity	
Increased chance of miscarriages, stillbirths	Increased risk of infant death	
Increased chance of maternal mortality	Increased risk of injury and hospitalization by age 5 y	
Decreased academic achievement	Decreased educational attainment	
Less likely to get high school diploma, go to college, or graduate	Lower cognitive scores	
Delayed education (average 2 y)	Decreased development	
Lower occupational attainment and prestige	Greater chance of being behind grade or needing remedial help	
Less chance of stable employment (some resolution over time)	Lower chance of advanced academics	
Lower job satisfaction	Lower academic aptitude as a teenager and perhaps a higher	
Lower income and wages	probability of dropping out of school	
Greater dependence on public assistance	Psychosocial consequences	
Less stable marital relationships	Greater risk of behavior problems	
Higher rates of single parenthood	Poverty	
Earlier marriage (though less common than in the past)	Higher probability of living in a nonintact home while in high school	
Accelerated pace of marriage, separation, divorce, and remarriage	Greater risk of adolescent pregnancy	
Faster pace of subsequent childbearing		
High rate of repeat unintended pregnancy		
More births out of marriage		
Closer spacing of births		
Larger families		

period, abdominal pain, and vaginal bleeding. A urine pregnancy test is usually positive by the time of presentation. The patient may have abdominal or pelvic tenderness, adnexal tenderness, and/or an adnexal mass on examination. The uterus is typically either normal sized or slightly enlarged. Diagnosis is based on serial serum quantitative hCG levels and transvaginal ultrasound. Patients should be referred urgently to an obstetrician gynecologist for management to avoid a ruptured ectopic pregnancy which is a surgical emergency. These patients often present in shock with an acute surgical abdomen. Breuner CC et al: Addendum-adolescent pregnancy: current trends and issues. Pediatr 2014;133(5):954–957 [PMID: 24777230].

Adolescent Substance Abuse

Paritosh Kaul, MD

Substance abuse tends to be a chronic, progressive disease. Initiation of substance use is becoming such a common feature of an American adult that many authorities call it normative behavior. At this stage, substance use is typically limited to experimentation with tobacco or alcohol (so-called gateway substances). During adolescence, young people are expected to establish an independent, autonomous identity. They try out a variety of behaviors within the safety of families and peer groups. This process often involves experimentation with psychoactive substances, usually in culturally acceptable settings. Continuation of substance abuse, however, is a nonnormative risk behavior with the potential to compromise adolescent development.

The American Psychiatric Association has outlined criteria to judge the severity of substance use disorders (SUD). The most recent version, DSM-5 (*Diagnostic and Statistical Manual-5*), has moved from the previous terms "substance abuse" and "substance dependency" to mild, moderate, and severe SUD. There are 11 features described in DSM-5. Patients with mild SUD have two or three features, whereas those with moderate have four or five features without loss of control or compulsive features. Patients with severe SUD have more than six features, including loss of control or compulsive features.

Common physiologic effects and symptoms of intoxication (which can occur at any stage of substance use) and withdrawal (a symptom of dependency) for the major classes of substances are shown in Tables 5–1 and 5–2.

American Psychiatric Association: *Diagnostic and Statistical Manual* of *Mental Disorders*: DSM-5. Washington, DC: American Psychiatric Association, 2013.

SCOPE OF THE PROBLEM

The best current source of information on the prevalence of substance abuse among American adolescents is the Monitoring the Future study (2017), which tracks substance abuse-related behaviors in a sample of over 40,000 8th, 10th, and 12th graders in the United States. This study probably understates the magnitude of the problem of substance abuse because it excludes high-risk adolescent groups-school dropouts, runaways, and those in the juvenile justice system. Two other periodic surveys are the Youth Risk Behavior Survey (biannual) of students in grades 9-12 and National Survey of Drug Use and Health that is a home-based computer-assisted interview of individuals 12 years or older. Substance abuse among American youth rose in the 1960s and 1970s, declined in the 1980s, peaked in the 1990s, and has declined in the early 2000s. Perhaps the most striking finding in 2016 is that, across the broad spectrum of drugs, use of most decreased and few exhibited a statistically significant increase in use. Cigarette and alcohol use continued to show significant declines, reaching their lowest levels in the history of the Monitoring the Future study. Annual prevalence of use of any illicit drug declined in the three grades assessed combined; this decline was largely due to decreased use of marijuana in 8th and 10th grades. Among 12th graders, however, the annual prevalence of marijuana use has held quite steady for several years, at 35.6%. For the three grades combined, annual prevalence of marijuana showed a significant decline of 1.1% in 2016.

The Monitoring the Future survey and others show that alcohol is the most frequently abused substance in the United States. Experimentation with alcohol typically begins in or before middle school. It is more common among boys than girls. It is most common among whites, less common among Hispanics and Native Americans, and least common among blacks and Asians. Two-thirds (61%) of adolescents consume alcohol before graduating from high school. Approximately one-tenth (9%) of eighth graders and 46% of high school students report being drunk at least once in their life. Marijuana is the most commonly used illicit drug in the United States. First experiences with marijuana and the substances

Fuer / susile	
Eyes/pupils	
Mydriasis	Amphetamines, MDMA, or other stimulants; cocaine; glutethimide; jimson weed; LSD. Withdrawal from alcohol and opioids
Miosis	Alcohol, barbiturates, benzodiazepines, opioids, PCP
Nystagmus	Alcohol, barbiturates, benzodiazepines, inhalants, PCP
Conjunctival injection	LSD, marijuana
Lacrimation	Inhalants, LSD. Withdrawal from opioids
Cardiovascular	
Tachycardia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypertension	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypotension	Barbiturates, opioids. Orthostatic: marijuana. Withdrawal from depressants
Arrhythmia	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; opioids; PCP
Respiratory	
Depression	Opioids, depressants, GHB
Pulmonary edema	Opioids, stimulants
Core body temperature	
Elevated	Amphetamines, MDMA, or other stimulants; cocaine; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines, opioids
Decreased	Alcohol, barbiturates, benzodiazepines, opioids, GHB
Peripheral nervous system respo	nse
Hyperreflexia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; methaqualone; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hyporeflexia	Alcohol, barbiturates, benzodiazepines, inhalants, opioids
Tremor	Amphetamines or other stimulants, cocaine, LSD. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine
Ataxia	Alcohol, amphetamines, MDMA, or other stimulants; barbiturates; benzodiazepines; inhalants; LSD; PCP; GHB
Central nervous system response	
Hyperalertness	Amphetamines, MDMA, or other stimulants; cocaine
Sedation, somnolence	Alcohol, barbiturates, benzodiazepines, inhalants, marijuana, opioids, GHB
Seizures	Alcohol, amphetamines, MDMA, or other stimulants; cocaine; inhalants; methaqualone; opioids (particularly meperidine, propoxyphene). Withdrawal from alcohol, barbiturates, benzodiazepines
Hallucinations	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Gastrointestinal	
Nausea, vomiting	Alcohol, amphetamines or other stimulants, cocaine, inhalants, LSD, opioids, peyote, GHB. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine, opioids

Fable 5–1. Physiologic effects of	commonly abused mood-alte	ering substances by	y organ/system
-----------------------------------	---------------------------	---------------------	----------------

GHB, γ-hydroxybutyrate; LSD, lysergic acid diethylamide; MDMA, methylenedioxymethamphetamine (ecstasy); PCP, phencyclidine hydrochloride. Adapted with permission from Schwartz B, Alderman EM: Substances of abuse. Pediatr Rev 1997 June; 18(6):204–215.

CHAPTER 5

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
Alcohol (ethanol)	Depressant; 10 g/drink Drink: 12-oz beer, 4-oz wine, 1½-oz liquor; one drink increases blood level by approximately 0.025 g/dL (varies by weight)	Legal: 0.05–0.1 g/dL (varies by state) Mild (< 0.1 g/dL): disinhibition, euphoria, mild sedation, and impaired coordination Moderate (0.1–0.2 g/dL): impaired mentation and judgment, slurred speech, ataxia Severe: > 0.3 g/dL: confusion, stupor > 0.4 g/dL: coma, depressed respiration	Mild: headache, tremors, nausea and vomiting ("hangover") Severe: fever, sweaty, seizure, agitation, hallucination, hypertension, tachycardia Delirium tremens (chronic use)	Hepatitis, cirrhosis, cardiac disease, Wernicke encephalopathy, Korsakoff syndrome
Marijuana (cannabis)	THC; 4%–6% in marijuana; 20%–30% in hashish	Low: euphoria, relaxation, impaired thinking. High: mood changes, depersonalization, hallucinations Toxic: panic, delusions, paranoia, psychosis	Irritability, disturbed sleep, tremor, nystagmus, anorexia, diarrhea, vomiting	Cough, gynecomastia, low sperm count, infertility, amotivational syndrome, apathy
Cocaine	Stimulant; releases biogenic amines; concentration varies with preparation and route of administration	Hyperalert, increased energy, confident, insomnia, anxiety, paranoia, dilated pupils, tremors, seizures, hypertension, arrhythmia, tachycardia, fever, dry mouth Toxic: coma, psychosis, seizure, myocardial infarction, stroke, hyperthermia, rhabdomyolysis	Drug craving, depression, dysphoria, irritability, lethargy, tremors, nausea, hunger	Nasal septum ulceration, epistaxis, lung damage, intravenous drug use
Opioids (heroin, mor- phine, codeine, methadone, opium, fentanyl, meperidine, propoxyphene)	Depressant; binds central opioid receptor; variable concentrations with substance	Euphoria, sedation, impaired thinking, low blood pressure, pinpoint pupil, urinary retention Toxic: hypotension, arrhythmia, depressed respiration, stupor, coma, seizure, death	Only after > 3 wk of regular use: drug craving, rhinorrhea, lacrimation, muscle aches, diarrhea, anxiety, tremors, hypertension, tachycardia	Intravenous drug use: cellulitis, endocarditis, embolisms, HIV
Amphetamines	Stimulant; sympathomimetic	Euphoria, hyperalert state, hyperactive, hypertension, arrhythmia, fever, flushing, dilated pupils, tremor, ataxia, dry mouth	Lethargy, fatigue, depression, anxiety, nightmares, muscle cramps, abdominal pain, hunger	Paranoia, psychosis
MDMA (ecstasy)	Stimulant, psychedelic; releases serotonin, dopamine, and norepinephrine; inhibits reuptake of neurotransmitters; increases dopamine synthesis; inhibits MAO	Enhanced empathy, euphoria, increased energy and self-esteem, tachycardia, hypertension, increased psychomotor drive, sensory enhancement, illusions, difficulty concentrating and retaining information, headaches, palpitations, flushing, hyperthermia Toxic: frank psychosis, coma, seizures, intracranial hemorrhage, cerebral infarction, asystole, pulmonary edema, multisystem organ failure, acute renal or henatic failure ARDS_DIC_SIADH death	None	Paranoid psychosis

Table 5-2. Effects of commonly abused mood-altering substances by agent.

(Continued)

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
GHB (liquid ecstasy)	Depressant, endogenous CNS transmitter; influences dopaminergic activity, higher levels of GABA-B activity	10 mg/kg: sleep 30 mg/kg: memory loss 50 mg/kg: general anesthesia Toxic: CNS and respiratory depression, aggressiveness, seizures, bradycardia, apnea	Only after chronic use with dosing every 3 h. Early: mild tremor, tachycardia, hyper-tension, diaphoresis, moderate anxiety, insomnia, nausea, vomiting Progressive: confusion, delirium, hallucinations, autonomic instability, death	Wernicke-Korsakoff syndrome
Sedative-hypnotics (barbiturates, enzodiazepines, methaqualone)	Depressant	Sedation, lethargy, slurred speech, pinpoint pupils, hypotension, psychosis, seizures Toxic: stupor, coma, cardiac arrest, seizure, pulmonary edema, death	Only after weeks of use: agitation, delirium, psychosis, hallucinations, fever, flushing, hyper-/ hypotension, death	Paranoia
Hallucinogens (LSD, peyote, mesca- line, mushrooms, nutmeg, jimson weed)	Inhibition of serotonin release	Illusions, depersonalization, hallucination, anxiety, paranoia, ataxia, dilated pupils, hypertension, dry mouth Toxic: coma, terror, panic, "crazy feeling"	None	Flashbacks
Phencyclidine	Dissociative anesthetic	Low dose (< 5 mg): illusions, hallucinations, ataxia, hypertension, flushing Moderate dose (5–10 mg): hyperthermia, salivation, myoclonus High dose (> 10 mg): rigidity, seizure, arrhythmia, coma, death	None	Flashbacks
Inhalants (toluene, benzene, hydro- carbons, and fluorocarbons)	Stimulation progressing to depression	Euphoria, giddiness, impaired judgment, ataxia, rhinorrhea, salivation, hallucination Toxic: respiratory depression, arrhythmia, coma, stupor, delirium, sudden death	None	Permanent damage to nerves, liver, heart, kidney, brain
Nicotine	Releases dopamine, 1 mg nicotine per cigarette	Relaxation, tachycardia, vertigo, anorexia	Drug craving, irritability, anxiety, hunger, impaired concentration	Permanent damage to lung, heart, cardiovascular system
Anabolic steroids ^a	Bind steroid receptor Stacking: use many types simultaneously Pyramiding: increase dosage	Increased muscle bulk, strength, endurance, increased drive, hypogonadism, low sperm count, gynecomastia, decreased libido, virilization, irregular menses, hepatitis, early epiphysial closure, aggressiveness	Drug craving, dysphoria, irritability, depression	Tendon rupture, cardiomyopathy, atherosclerosis, peliosis hepatis (orally active C17 derivatives of testosterone are especially hepatotoxic)

Table 5–2.	Effects of commonly	abused mood-altering	substances by	agent. (Continued)
------------	---------------------	----------------------	---------------	--------------------

ARDS, acute respiratory distress syndrome; CNS, central nervous system; DIC, disseminated intravascular coagulation; GABA, γ -aminobutyric acid; GHB, γ -hydroxybutyrate; HIV, human immunodeficiency virus; LSD, lysergic acid diethylamide; MAO, monoamine oxidase; MDMA, methylenedioxymethamphetamine; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; THC, δ -9-tetrahydrocannabinol.

^aDespite conventional assumptions, scientific studies show that anabolic steroids do not improve aerobic athletic performance and improve strength only in athletes trained in weight lifting before they begin using steroids and who continue to train and consume a high-protein diet.

listed in Table 5-2 typically occur during middle or early high school. The lifetime prevalence of marijuana use reported by 12th graders in 2016 was 28.6%. Daily use of marijuana increased until 2011 and has decreased since, with 3% of high school seniors being a daily or near daily user. Synthetic marijuana, often called spice and K-2, was scheduled by the Drug Enforcement Agency in 2011. Despite this intervention, annual synthetic marijuana use remains unchanged at 11.3% making it the second most widely used class of illicit drug use after marijuana. In the past decade, LSD, methamphetamine and cocaine use has decreased. Recently, ecstasy use has increased after a steady decline of several years. In the past 10 years, there has also been an increase in the recreational use of prescription medications and over-the-counter (OTC) cough and cold medications among adolescents. In one study, 1 in 10 high school seniors reported nonmedical use of prescription opioids, and almost half (45%) used opioids to "relieve physical symptoms" in the past year. Although Vicodin use decreased among 12th graders to 2.9% in 2016, it remains one of the most widely used illicit drugs. Overall, the psychotherapeutic drugs (amphetamines, sedatives, tranquilizers, and narcotics other than heroin) make up a large part of the overall US drug problem. Medication used in the management of chronic pain, depression, anxiety, and attention-deficit/hyperactivity disorder can all be drugs of abuse.

Studies indicate that variations in the popularity of a substance of abuse are influenced by changes in the perceived risks and benefits of the substance among adolescent users. For example, the use of inhalants was rising until 2006, when both experience and educational efforts resulted in a perception of these substances as being "dangerous." As the perception of danger decreases, old drugs may reappear in common use. This process is called "generational forgetting." Currently, uses of LSD, inhalants, and ecstasy all reflect the effects of generational forgetting. Legalization of marijuana in certain states in the United States may increase the scope and breadth of the substance abuse problem. A recent study has shown an increase in medical marijuana use among adolescents in substance abuse programs. The American Academy of Pediatrics (AAP) reaffirmed its position against the legalization of marijuana and its opposition to "medical marijuana"; it offers recommendations to protect children and adolescents in states that have legalized marijuana for medical or recreational purposes.

Supplement Use & Abuse

Use of supplements or special diets to enhance athletic performance dates to antiquity. Today, many elite and casual athletes use ergogenic (performance-enhancing) supplements in an attempt to improve performance. The most popular products used by adolescents are anabolic-androgenic steroids, steroid hormone precursors, creatine, human growth hormone, diuretics, and protein supplements. Anabolic-androgenic steroids increase strength and lean body mass and lessen muscle breakdown. However, they are associated with side effects, including acne, liver tumors, hypertension, premature closure of the epiphysis, ligamentous injury, and precocious puberty. In females, they can cause hirsutism, male pattern baldness, and virilization; in boys, they can cause gynecomastia and testicular atrophy. Creatine increases strength and improves performance in brief, high-intensity exercises but can cause dehydration, muscle cramps, and has potential for renal toxicity. Human growth hormone may increase lean body mass and decrease fat mass, but has limited effect on strength and athletic performance. Potential risks include coarsening of facial features and cardiovascular disease. Strength athletes (ie, weight lifters) use protein powders and shakes to enhance muscle repair and mass. The amount of protein consumed often greatly exceeds the recommended daily allowance for weight lifters and other resistance-training athletes (1.6-1.7 g/kg/day). Excess consumption of protein provides no added strength or muscle mass and can provoke renal failure in the presence of underlying renal dysfunction. The AAP cautions against the use of performance-enhancing substances.

As the use of supplements and herbs increases, it is increasingly important for pediatric care providers to be familiar with their common side effects. The Internet has become a source for information about and distribution of these products. The easy accessibility, perceived low risk, and low cost of these products significantly increase the likelihood that they will become substances of abuse by adolescents.

MORBIDITY DATA

Use and abuse of alcohol or other mood-altering substances in adolescents in the United States are tightly linked to adolescents' leading causes of death, that is, motor vehicle accidents, unintentional injury, homicide, and suicide. Substance abuse is also associated with physical and sexual abuse. Drug use and abuse contribute to other high-risk behaviors, such as unsafe sexual activity, unintended pregnancy, and sexually transmitted disease. Adolescents may also be involved with selling of drugs.

Risks associated with tobacco, alcohol, and cocaine are listed in Table 5-2. Less well known are the long- and shortterm adolescent morbidities connected with the currently most popular illicit drugs, marijuana and ecstasy. The active ingredient in marijuana, δ -9-tetrahydrocannabinol (THC), transiently causes tachycardia, mild hypertension, and bronchodilation. Regular use can cause lung changes similar to those seen in tobacco smokers. Heavy use decreases fertility in both sexes and impairs immunocompetence. It is also associated with abnormalities of cognition, learning, coordination, and memory. It is possible that heavy marijuana use is the cause of the so-called a motivational syndrome, characterized by inattention to environmental stimuli and impaired goal-directed thinking and behavior. Early and frequent use of marijuana during adolescence, compared with occasional use or nonuse, has been associated with development of a higher incidence of psychiatric problems. Analysis of confiscated marijuana recently has shown increasing THC concentration and adulteration with other substances.

Evaluation of the impact of legalization of marijuana on the adolescent and pediatric population has just begun. A study looking at marijuana-related diagnostic codes and marijuana exposure-related calls in Colorado after legalization showed an increase in hospitalizations with marijuana-related codes from 274 (2010) to 593 (2015) per 100,000 and a fivefold higher incidence of mental health emergency room visits with marijuana-related codes. Calls related to marijuana exposure increased by 79.7%. As more states legalize marijuana, it will be important to

address potential consequences. Many of the issues related to legalization are detailed in the AAP technical report (reference below), and different medical marijuana policies among US states are outlined on the AAP website (reference below).

The popularity and accessibility of ecstasy is again increasing among adolescents. Chronic use is associated with progressive decline of immediate and delayed memory, and with alterations in mood, sleep, and appetite that may be permanent. Even first-time users may develop frank psychosis indistinguishable from schizophrenia. Irreversible cardiomyopathy, noncardiogenic pulmonary edema, and pulmonary hypertension may occur with long-term use. Acute overdose can cause hyperthermia and multiorgan system failure.

Prenatal and environmental exposure to abused substances also carries health risks. Parental tobacco smoking is associated with low birth weight in newborns, sudden infant death syndrome, bronchiolitis, asthma, otitis media, and fire-related injuries. Maternal use of marijuana during pregnancy is associated with an increased risk of sudden infant death syndrome. In utero exposure to alcohol may produce fetal malformations, intrauterine growth restriction, and brain injury.

PREDICTING THE PROGRESSION FROM USE TO ABUSE

Initially, most adolescents use mood-altering substances intermittently or experimentally. The challenge to pediatric health care providers is to recognize warning signs, identify potential abusers early, and intervene in an effective fashion before acute or chronic use produces morbidity. The prediction of progression from use to abuse is best viewed within the biopsychosocial model. Substance abuse is a symptom of personal and social maladjustment as often as it is a cause. Because there is a direct relationship between the number of risk factors listed in Table 5–3 and the frequency of substance abuse, a combination of risk factors is the best indicator of risk. Even so, most teenagers with multiple risk characteristics never progress to substance abuse. It is unclear why only a minority of young people exhibiting the high-risk characteristics listed in Table 5–3 go on to abuse substances, but presumably the protective factors listed in Table 5–3 give most adolescents the resilience to cope with stress in more socially adaptive ways. Being aware of the risk domains in Table 5–3 will help physicians identify young-sters most apt to need counseling about substance abuse.

Individual							
Genetic predisposition Psychological diagnoses (attention-deficit/hyperactivity disorder; antisocial personality) Depression and low self-esteem Alienation and rebelliousness Sexual or physical abuse Early onset of deviant behavior or delinquency Early onset of sexual behavior Aggressive	Positive self-concept, good self-esteem Intolerance of deviance Internally motivated, takes charge of problems						

EVALUATION OF SUBSTANCE ABUSE

ESSENTIALS OF DIAGNOSIS AND TYPICAL FEATURES

- Clues to possible substance abuse include truancy, failing grades, problems with interpersonal relationships, delinquency, depressive affect, chronic fatigue, and unexplained physical complaints.
- Comorbidities, especially psychiatric disorders such as affective disorder, anxiety disorder, and mania, are common among substance-abusing patients.
- When the psychosocial history suggests the possibility of substance use, gather information about extent and circumstances of the problem.
- Pharmacologic screening should be reserved for situations in which the patient's behavioral dysfunction and/or medical condition are of sufficient concern to outweigh practical and ethical drawbacks of testing.

Office Screening

The AAP Committee on Substance Abuse recommends that pediatricians include discussions of substance abuse as part of their anticipatory care. This should include screening for substance abuse with parents at the first prenatal visit. Given the high incidence of substance abuse and the subtlety of its early signs and symptoms, a general psychosocial assessment is the best way to screen for substance abuse among adolescents. The universal screening approach outlined in the American Medical Association (AMA) Guidelines for Adolescent Preventive Services (GAPS) is a good guide for routine screening and diagnosis. Interviewing and counseling techniques and methods for taking a psychosocial history are discussed in Chapter 4. In an atmosphere of trust and confidentiality, physicians should ask routine screening questions of all patients and be alert for addictive diseases, recognizing the high level of denial often present in addicted patients. Clues to possible substance abuse include truancy, failing grades, problems with interpersonal relationships, delinquency, depressive affect, chronic fatigue, recurrent abdominal pain, chest pains or palpitations, headache, chronic cough, persistent nasal discharge, and recurrent complaints of sore throat. Substance abuse should be included in the differential diagnosis of all behavioral, family, psychosocial, and medical problems. A family history of drug addiction or abuse should raise the level of concern about drug abuse in the pediatric patient. Possession of promotional products such as T-shirts and caps with cigarette or alcohol logos should also be a red flag because teenagers who own these items are more likely to use

the products they advertise. Pediatricians seeing patients in emergency departments, trauma units, or prison should have an especially high index of suspicion.

In the primary care setting, insufficient time and lack of training are the greatest barriers to screening adolescents for substance abuse. Brief questionnaires can be used if time does not allow for more detailed investigation. A screening instrument that has been rigorously studied in primary care settings is the CAGE questionnaire. CAGE is a mnemonic derived from the first four questions that asks the patient questions regarding their substance use. These are their need to cut down annoyance if asked about it, feeling guilty about the use, and the need of the drug/alcohol as an eye opener. A score of 2 or more is highly suggestive of substance abuse. Although constructed as a screening tool for alcohol abuse in adults, the CAGE questionnaire can be adapted to elicit information about use of other mood-altering substances by pediatric patients and their close contacts (eg, parents and older siblings). Clinicians may find it helpful to use such questionnaires to stimulate discussion of the patient's self-perception of his or her substance use. For example, if an adolescent admits to a previous attempt to cut down on drinking, this provides an opportunity to inquire about events that may have led to the attempt. Unfortunately, despite guidance to screen adolescents for substance abuse, recent studies demonstrate that clinicians do not regularly ask/ advise adolescents about substance use.

Interest in an integrated, algorithm-based approach called Screening, Brief Intervention, and Referral to Treatment (SBIRT) has increased as a means to bridge the gap between universal prevention programs in the primary care setting and specialty substance abuse programs. The three main goals of the SBIRT screening are to determine whether teens have used any alcohol or drugs; to determine where adolescents are on the substance use spectrum; and, finally, for the health care provider to initiate a brief discussion with their teenage patients about substance use and provide them with education, advice, and referrals within a motivational interviewing model.

Diagnosis

When the psychosocial history suggests the possibility of substance use, the primary tasks of the diagnostic interview are the same as for the evaluation of other medical problems (Table 5–4).

First, specific information about the extent and circumstances of the problem is gathered. Eliciting information through multiple-choice questions is a useful technique. For example, "Has anything really good ever happened to you when you are high? Some of my patients like to get high because they feel good; others find it helps them relax and be sociable with friends; and some find it helps them forget their problems. Are any of these things true for you?"

Second, the provider should determine why the patient has progressed from initiation to the continuation or maintenance phase of substance abuse. The cause may be different at different periods of development. Although peer group characteristics are one of the best predictors of substance use among early and middle adolescents, this is not so among older adolescents and young adults.

Table 5–4. Evaluation of positive psychosocial screens for substance abuse.

I. Define the extent of the problem by determining:
Age at onset of substance use
Which substances are being used
Circumstances of use
Where?
When?
With whom?
To what extent substances are being used
How frequently?
How much (quantity)?
With what associated symptoms (eg, tolerance, withdrawal)
With what result?
What does the patient gain from becoming high?
Does the patient get into risky situations while high?
Does the patient engage in behaviors while high that are
later regretted?
II. Define the cause of the problem

Although few children and adolescents will have been abusing substances long enough to have developed overt signs and symptoms, it is important to look for them on physical examination. Positive physical findings can be a tool to penetrate a patient's denial and convince him or her of the significance of alcohol or drug use.

Margret CP et al: Assessment and treatment of adolescent substance use disorders: alcohol use disorders. Child Adolesc Psychiatr Clin N Am 2016 Jul;25(3):411–430 [PMID: 27338964].

Comorbidity

Comorbidities, especially other psychiatric disorders, are common among substance-abusing patients (Table 5–5). Affective disorder, anxiety disorder, and mania are most strongly associated with alcohol and drug dependence. Attention-deficit/hyperactivity has also been closely linked with adolescent substance abuse. Adolescents with depression are likely to use drugs in an attempt to feel pleasure, but this type of self-medication may exacerbate their underlying condition. Although it is often difficult to determine which diagnosis is primary, it is important for pediatric health care providers to recognize the possibility of a comorbid condition and provide appropriate treatment. Finally, in addition to identifying psychiatric comorbidities, it is imperative that providers look for medical conditions that mimic symptoms of drug withdrawal or intoxication.

Pharmacologic Screening

The use of urine and blood testing for detecting substance abuse is controversial. The consensus is that pharmacologic screening should be reserved for situations in which behavioral dysfunction is of sufficient concern to outweigh the practical and ethical drawbacks of testing. The AAP recommends testing under certain circumstances (eg, an inexplicably obtunded patient in the emergency department), but discourages routine screening for the following reasons: (1) voluntary screening is rarely truly voluntary owing to the negative consequences for those who decline to participate; (2) infrequent users or individuals who have not used substances recently may be missed; (3) confronting substance-abusing individuals with objective evidence of their use has little or no effect on behavior; and (4) the role of health care providers is to provide counseling and treatment, not law enforcement, so drug testing should not be done for the purpose of detecting illegal use. If testing is to be performed, the provider should discuss the plan for screening with the patient, explain the reasons for it, and obtain informed consent. The AAP does not consider parental request and permission sufficient justification for involuntary screening of mentally competent minors. It also opposes widespread drug testing in schools because of a lack of solid evidence for its effectiveness.

If testing is to be performed, it is imperative that it be done accurately and that the limitations of testing be understood. Tests range from inexpensive chromatographic spot tests, which can be performed in the office, to gas chromatography and mass spectrometry, which require specialized laboratory equipment and are usually reserved for forensic investigations. Most commercial medical laboratories use the enzyme multiplication immunoassay technique, in which a sample of the fluid to be tested is added to a test reagent containing a known quantity of radiolabeled index drug. If the index drug is present in the patient's urine or serum, it competes with the radiolabeled drug for binding sites on the test kit antibody. The unbound or excess drug can then be quantified with a spectrophotometer. Most of the commonly abused mood-altering substances, with the exception of solvents and inhalants, can be detected by this method.

Interpretation of results is complicated by false-positives resulting from antibody cross-reactions with some medications and substances (Table 5–6) or from a patient's passive exposure to illicit substances. The most common cause of false-negative tests is infrequent use. Table 5–7 shows the duration of detectability in the urine after last use by class of substance and duration of use. Detectability ranges from a few hours for alcohol to several weeks for regular marijuana use. False-negative results can also occur if the patient alters or adulterates the test specimen. Some of the commercial products used to adulterate samples include glutaraldehyde, nitrite, pyridinium chlorochromate, peroxidase, and peroxide (stealth). Household products such

prevent drug detection in the urine. Close observation during collection and testing the temperature, specific gravity, and pH of urine samples may detect attempts at deception.

Home drug-testing products are available for parents and can be procured via the Internet; however, these products have limitations and potential risks. The AAP recommends that home (and school-based) drug testing not be implemented until the safety and efficacy of these procedures can be established. It further recommends that parents be encouraged to consult the adolescent's primary care provider rather than relying on home drug-testing products.

TREATMENT & REFERRAL

ESSENTIALS OF DIAGNOSIS AND TYPICAL FEATURES

- Substance-abusing teenagers will generally require repeated discussions about discontinuing substance.
- Assessment of the patient's readiness to change is a critical first step in office-based intervention.
- Providers should tailor their counseling messages to the patient's stage of readiness to change.
- When referral for treatment is indicated, substanceabusing teenagers are best treated in teen-oriented treatment facilities.
- Key elements of an effective adolescent drug treatment program include a comprehensive and integrated treatment approach, family involvement, a developmentally appropriate program, and engagement and retention of teens.

Office-Based Treatment

The AMA and the AAP recommend that all children and adolescents receive counseling about the dangers of substance use and abuse from their primary care providers.

By offering confidential health care services and routinely counseling about the risks associated with drug abuse, primary care providers can help most patients avoid the adverse consequences of experimentation with mood-altering substances. However, more intervention is required for youngsters in environments where substance abuse is regarded as acceptable recreational behavior. Counseling strategies appropriate for patients who wish to change their behavior may be ineffective for patients who do not consider use of mood-altering substances to be a problem. It may therefore be preferable to begin discussions about treatment by helping youngsters consider alternative ways of meeting the needs that substance use is currently addressing. The clinician in this way may help the patient devise alternatives that are more attractive than substance use. Brief interventions for adolescents have yielded some improvement among high-risk youth. However, few substance-abusing teenagers will choose to quit because of a single conversation, even with a highly respected health care provider. The message is most effective when offered repeatedly from many sources-family, peers, guidance counselors, and teachers. Motivational interviewing and computer-facilitated screening and brief advice for substance-abusing teens have shown promise.

Assessment of the patient's readiness to change is a critical first step in office-based intervention. Clinicians should consider the construct presented in Table 5–8. In theory, individuals pass through this series of stages in the course of changing problem behaviors. To be maximally effective,

Table 5–8. Stages of change and intervention tasks.

Patient Stage	Motivation Tasks
Precontemplation	Create doubt, increase the patient's awareness of risks and problems with current patterns of substance use
Contemplation	Help the patient weigh the relative risks and benefits of changing substance use; evoke reasons to change and risks of not changing; strengthen the patient's self-efficacy for changing current use
Determination	Help the patient determine the best course of action to change substance use from among available alternatives
Action	Help the patient establish a clear plan of action toward changing substance use
Maintenance	Help the patient identify and use strategies to prevent relapse
Relapse	Help the patient renew the process of change starting at contemplation

Reproduced with permission from Werner MJ: Principles of brief intervention for adolescent alcohol, tobacco, and other drug use. Pediatr Clin North Am 1995 Apr;42(2):335–349.

providers should tailor their counseling messages to the patient's stage of readiness to change.

Once it has been established that a patient is prepared to act on information about treatment, the next step is to select the program that best fits his or her individual needs. Most drug treatment programs are not designed to recognize and act on the individual vulnerabilities that have predisposed the patient to substance abuse. When programs are individualized, even brief (5- to 10-minute) counseling sessions may promote reductions in cigarette smoking and drinking. This strategy appears to be most effective when the health care provider's message is part of an office-wide program so that the entire staff reinforces the cessation message with every patient.

Smoking Cessation in Pediatrics

Although more than half of adolescents who smoke regularly say they want to quit and have tried to quit, only a minority report that they have been advised or helped to do so by a health care provider. Practitioners unfamiliar with approaches to smoking cessation may feel that smoking cessation interventions are time consuming, not reimbursable, and impractical in a busy office. An easy guideline for health care providers is the "five A's" for tobacco cessation (Table 5–9), published by the Public Health Service and endorsed by the AAP.

Smoking cessation is a process that takes time. Relapse must be regarded as a normal part of quitting rather than evidence of personal failure or a reason to forgo further attempts. Patients can actually benefit from relapses if they are helped to identify the circumstances that led to the relapse and to devise strategies to prevent subsequent relapses or respond to predisposing circumstances in a different manner.

Ask about tobacco use from all patients
Advise all tobacco users to quit
Assess willingness and motivation for tobacco user to make a
quit attempt
Assist in the quit attempt
Arrange for follow-up

Adapted with permission from Fiore MC et al: *Treating Tobacco Use and Dependence. Clinical Practice Guidelines.* U.S. Department of Health and Human Services, Public Health Service; 2000.

Nicotine is a physically and psychologically addictive substance. Providers should be aware that adolescents may not exhibit the same symptoms of nicotine dependence as adults and that dependence may be established within as little as 4 weeks. Replacement therapy improves smoking cessation rates and may relieve withdrawal symptoms. Both nicotine gum and transdermal nicotine patch replacement therapies are recommended for teens. Those who are not comfortable prescribing and monitoring nicotine-replacement therapies should limit their involvement with patients who smoke to those who do not exhibit signs of nicotine dependency (eg, patients who smoke less than a pack of cigarettes a day or do not feel a craving to smoke their first cigarette within 30 minutes after waking). Patients who exhibit nicotine dependency can be referred to community smoking cessation programs, including "smoking quit lines." In addition to nicotine-replacement therapies, sustained-release forms of the antidepressants bupropion, clonidine, and nortriptyline have been shown in randomized trials to help smokers quit and to decrease relapse rates fivefold.

Referral

There is no consensus about which substance-abusing patients can be adequately treated in the office, which require referral, and which require hospitalization. Factors to be considered prior to referral are summarized in Table 5–10. When doubt exists about the seriousness of the problem or the advisability of office management, consultation with a specialist should be sought.

Table 5–10. Factors to consider prior to referral for substance abuse.

Duration and frequency of substance use The type of substances being used
Presence of other psychological disorders
Attention-deficit/hyperactivity disorder
Depression
Antisocial personality disorder
Presence of other social morbidities
School failure
Delinquency
Homelessness
Ongoing or past physical or sexual abuse
Program evaluation
View on substance abuse as primary disorder vs symptom
Offers comprehensive evaluation of patient and can manage
associated problems identified in initial assessment (eg,
comorbid conditions)
Adherence to abstinence philosophy
Patient-staff ratios
Separate adolescent and adult treatment programs
Follow-up and continuing care

Although most primary pediatric providers will not assume responsibility for the treatment of substance-abusing youngsters, clinicians can be instrumental in motivating patients to seek treatment and in guiding them to appropriate treatment resources. Substance-abusing teenagers are best treated in teen-oriented treatment facilities. Despite the similarities between adult and adolescent substance abuse, adult programs are usually developmentally inappropriate and ineffective for adolescents. Many adolescents are concrete thinkers and their inability to reason deductively, especially about emotionally charged issues, makes it difficult for them to understand the abstract concepts (such as denial) that are an integral component of most adult-oriented programs. This invariably frustrates counselors who misinterpret lack of comprehension as resistance to therapy and concrete responses as evidence of deceit.

Treatment programs range from low-intensity, outpatient, school-based student-assistance programs, which rely heavily on peers and nonprofessionals, to residential, hospital-based programs staffed by psychiatrists and other professionals. Outpatient counseling programs are most appropriate for motivated patients who do not have significant mental health or behavioral problems and are not at risk for withdrawal. Some investigators have raised the concern that in pediatric settings, users who lack significant mental health or behavioral comorbidities may actually experience a strengthening of the drug subculture by associating in group therapy with users who have a greater burden of comorbidities. More intensive day treatment programs are available for those who require a structured environment. Inpatient treatment should be considered for patients who need medical care and detoxification in addition to counseling, education, and family therapy.

Finally, special dual-diagnosis facilities are available for substance-abusing patients who also have other psychological conditions. These patients are difficult to diagnose and treat because it is often unclear whether their symptoms are a consequence of substance use or a symptom of a comorbid psychological disorder. Recognition of such disorders is critical because they must be treated in programs that include psychiatric expertise.

Approaches to the treatment of substance abuse in children and adolescents are typically modeled after adult treatment programs. Key elements of an effective adolescent drug treatment program include: assessment and treatment matching, a comprehensive and integrated treatment approach, family involvement, a developmentally appropriate program, engagement and retention of teens, qualified staff, gender and cultural competence, continuing care, and satisfactory treatment outcomes. Several studies of adolescent substance abuse treatment programs have shown that many do not adequately address all of the important components of therapy.

PREVENTION

Prevention of substance abuse has been a public health priority since the 1980s. Pediatric health care providers are important advocates and educators of the community and government on developmentally appropriate programs. *Primary-level* programs focus on preventing the initiation of substance use. The Drug Awareness and Resistance Education (DARE) program is a familiar example of a primary prevention program that attempts to educate elementary and middle school students about the adverse consequences of substance abuse and enable them to resist peer pressures. Secondary-level programs target populations at increased risk for substance use. Their aim is to prevent progression from initiation to continuance and maintenance, relying on individualized intervention to reduce the risk and enhance protective factors listed in Table 5–3. This approach enables the provider to focus scarce resources on those who are most likely to benefit from them. Alateen, which supports the children of alcoholic parents, typifies secondary level prevention.

Tertiary-level prevention programs target young people who have been identified as substance abusers. Their aim is to prevent the morbid consequences of substance use. One example is the identification of adolescents who misuse alcohol and drugs at parties and providing them with a safe ride home. Because prevention is more effective when targeted at reducing the initiation of substance use than at decreasing use or associated morbidity, tertiary prevention is the least effective approach.

Very few population-based programs undergo rigorous scientific evaluation, and few programs have been shown to be effective. Although tertiary prevention programs are the least effective approach, it is the consensus among drug educators that primary prevention programs, such as D.A.R.E., also have limited effect. Parents and others should understand that most adolescents who abuse alcohol and drugs do not do so just for the high. Rather, these behaviors are often purposeful, developmentally appropriate coping strategies. To the extent that these behaviors meet young people's developmental needs, they are not apt to be abandoned unless equally attractive alternatives are available. For example, even though many teenagers cite stress and anxiety as reasons for smoking, teen-oriented smoking cessation programs rarely address the young smoker's need for alternative coping strategies by offering stress management

training. Similarly, for the youngster growing up in an impoverished urban environment, the real costs of substance abuse may be too low and the rewards too high to be influenced by talk and knowledge alone. It is unreasonable to expect a talk-based intervention to change attitudes and behaviors in a direction that is opposite to that of the child's own social milieu. The efficacy of the most promising prevention models and interventions is apt to decay over time unless changes in the social environment provide substanceabusing children and adolescents with realistic alternative ways to meet their developmental needs.

Eating Disorders

Eric J. Sigel, MD

INTRODUCTION

Adolescents as well as younger children engage in disordered eating behavior at an alarming rate, and many develop partial or full-blown eating disorders (EDs). The spectrum of EDs includes anorexia nervosa (AN), bulimia nervosa (BN), binge-eating disorder (BED), atypical anorexia nervosa, and avoidant/restrictive food intake disorder (ARFID). These disorders are best defined in a biopsychosocial context.

ETIOLOGY

There is strong evidence for a genetic basis for EDs. The incidence of AN is 7% in first-degree relatives of anorexic patients compared with 1%–2% in the general population. The concordance rate in monozygotic twins is 55% compared with 7% in dizygotic twins. Twin studies estimate the heritability of AN as 33%–84% and BN as 28%–83%. Most studies also find a higher incidence of EDs among first-degree relatives of bulimic patients.

There is evidence of altered serotonergic and dopaminergic function and alterations in neuropeptides and gut peptides in AN and BN. It remains unclear whether abnormalities of neurotransmitters contribute to the development of EDs or are a consequence of the physiologic changes associated with the disorders. Patients with BN or BED appear to have a blunted serotonin response to eating and satiety. With a decreased satiety response, patients continue to eat, leading to a binge. Treatment with selective serotonin reuptake inhibitors (SSRIs) tends to equilibrate satiety regulation. An alteration in dopamine has also been recognized, although its significance is not clear. Adiponectin is elevated in AN, although it is unclear whether this is merely secondary to the malnourished state. Cholecystokinin is decreased in BN, perhaps contributing to the lack of postingestion satiety that perpetuates a binge. Ghrelin, a gut peptide, is elevated in patients with AN, and it does not decrease normally after a meal in these patients. Obestatin, a gut peptide that inhibits appetite, is elevated in AN as well.

Leptin physiology is deranged in patients with AN. Abnormalities of leptin may mediate energy changes that affect the hypothalamic-pituitary axis and play a role in perpetuating AN. Leptin levels increase excessively as individuals with AN regain weight. The abnormally high levels of leptin may contribute to the difficulty AN patients have when trying to regain weight, as higher leptin levels signal the body to decrease energy intake. Leptin also plays a significant role in some of the sequelae of AN, with low levels signaling the hypothalamus to inhibit reproductive hormone production.

Some experts have hypothesized that the intrauterine hormonal milieu may explain the differences in prevalence of ED between females and males. Procopio and Marriott have studied the risk of developing AN in the same sex and opposite-sex twin pairs when one twin has AN. There was approximately an eightfold risk of developing AN in males with a female twin with AN compared to the risk of developing AN in males who had a male twin with AN. Though the study could not separate environmental influences, evidence from animal models suggests that increased exposure to estrogen and/or decreased exposure to androgens influence brain development and may play a role in determining which individuals are at risk for AN.

Traditional psychological theory has suggested many environmental factors that might promote the development of EDs. Enmeshment of mother with daughter to the point that the teenager cannot develop her own identity (a key developmental marker of adolescence) may be a predisposing factor. The teenager may cope by asserting control over food, as she senses her lack of control in the developmental realm. A second theory involves fatherdaughter distancing. As puberty progresses and a girl's sexuality blossoms, a father may experience difficulty in dealing with his daughter as a sexual being and may respond by withdrawing emotionally and physically. The teenage girl may intuitively recognize this and subconsciously decrease her food intake in order to become prepubertal again. A third theory is related to puberty itself.

Some teenagers may fear or dislike their changing bodies. By restricting food intake they lose weight, stop menstruating, and effectively reverse pubertal development.

Society has promoted the message that being thin or muscular is necessary for attractiveness and success. The ease of access to diet products—foods and diet pills—as well as Internet instructions (proanorexia sites) makes it simple for adolescents to embark on a quest for thinness or muscularity.

Genetic predisposition, environmental factors, and psychological factors likely combine to create a milieu that promotes development of EDs.

INCIDENCE

Anorexia nervosa is the third most common chronic illness of adolescent girls in the United States. The incidence has been increasing steadily in the United States since the 1930s. Although ascertaining exact incidence is difficult, most studies show that 1%–2% of teenagers develop AN and 2%–4% develop BN. Adolescents outnumber adults 5 to 1, although the number of adults with EDs is rising. Incidence is also increasing among younger children. Prepubertal patients often have associated psychiatric diagnoses. Males comprise about 10% of patients with EDs, though this prevalence appears to be increasing as well, associated with the increased media emphasis on muscular, chiseled appearance as the male ideal.

Preadolescents with EDs, in comparison to teenagers with EDs, are more likely to be male and present with rapid weight loss and lower percentile body weight and less likely to engage in bulimic behaviors.

Teenagers' self-reported prevalence of ED behavior is much higher than the official incidence of AN or BN. According to the Youth Risk Behavior Survey of US teenagers (2013), 63% of females and 33% of males had attempted to lose weight during the preceding 30 days. Thirteen percent had fasted for more than 24 hours to lose weight, and 5% had used medications to lose weight (6.6% of girls and 3.4% of boys). Self-induced vomiting or laxative use was reported by 6.6% of females and 2.2% of males. Forty-six percent of females and 30% of males reported at least one binge episode during their lifetime. Although the number of youth with full-spectrum EDs is low, it is alarming that so many youth experiment with unhealthy weight control habits. These behaviors may be precursors to the development of EDs, and clinicians should explore these practices with all adolescent patients.

- Peebles R et al: How do children with eating disorders differ from adolescents with eating disorders at initial evaluation? J Adolesc Health 2006;39:800 [PMID: 17116508].

PREDISPOSING FACTORS & CLINICAL PROFILES

Children involved in gymnastics, figure skating, and ballet activities that emphasize thin bodies—are at higher risk for AN than are children in sports that do not emphasize body image. Adolescents who believe that being thin represents the ideal frame for a female, those who are dissatisfied with their bodies, and those with a history of dieting are at increased risk for EDs. Sudden changes in dietary habits, such as becoming vegetarian, may be a first sign of anorexia, especially if the change is abrupt and without good reason.

The typical bulimic patient tends to be impulsive and engages in risk-taking behavior such as alcohol use, drug use, and sexual experimentation. Bulimic patients are often an appropriate weight for height or slightly overweight. They have average academic performance. Youth with diabetes have an increased risk of BN. In males, wrestling predisposes to BN, and homosexual orientation is associated with binge eating.

ANOREXIA NERVOSA

According to the National Eating Disorders Association the diagnostic criteria for AN, adapted from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) and is described as follows.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES: ANOREXIA NERVOSA

- Restriction of energy intake relative to requirements leading to low body weight in the context of age, sex, physical health, and developmental trajectory.
- Strong fear of gaining weight or becoming fat, even though underweight.
- Disturbance in the way one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of current low body weight.

https://www.nationaleatingdisorders.org/anorexia-nervosa

There are two major types of AN. In the restricting type, patients do not regularly engage in binge eating or purging. In the binge-purge type, AN is combined with binge eating or purging behavior, or both. Distinguishing between the two is important as they carry different implications for prognosis and treatment. Although patients may not demonstrate all features of AN, they may still exhibit the deleterious symptoms associated with AN. A third form—atypical AN—exists as well, accounting for 18% of all ED diagnoses in one study. These individuals demonstrate typical AN behaviors, but are within or above normal weight.

Clinical Findings

A. Symptoms and Signs

Clinicians should recognize the early symptoms and signs of AN because early intervention may prevent the full-blown syndrome from developing. Patients may show some typical AN behaviors, such as reduction in dietary fat and intense concern with body image, even before weight loss or amenorrhea occurs.

Making the diagnosis of AN can be challenging because adolescents may try to conceal their illness. Assessing the patient's body image is essential to determining the diagnosis. Table 6–1 lists screening questions that help tease out a teenager's perceptions of body image. Other diagnostic screening tools (eg, EDs Inventory) assess a range of eating and dieting behaviors. Parental observations are critical in determining whether a patient has expressed dissatisfaction over body habitus and which weight loss techniques the child has used. If the teenager is unwilling to share his or her concerns about body image, the clinician may find clues to the diagnosis by carefully considering other presenting symptoms or signs. Weight loss from a baseline of normal

Table 6–1. Screening questions to help diagnose anorexia and bulimia nervosa.

How do you feel about your body?
Are there parts of your body you might change?
When you look at yourself in the mirror, do you see yourself as
overweight, underweight, or satisfactory?
If overweight, how much do you want to weigh?
If your weight is satisfactory, has there been a time when you were
worried about being overweight?
If overweight (underweight), what would you change?
Have you ever been on a diet?
What have you done to help yourself lose weight?
Do you count calories or fat grams?
Do you keep your intake to a certain number of calories?
Have you ever used nutritional supplements, diet pills, or laxatives
to help you lose weight?
Have you ever made yourself vomit to get rid of food or lose
weight?

body weight is an obvious red flag for the presence of an ED. Additionally, AN should be considered in any girl with secondary amenorrhea who has lost weight.

Physical symptoms and signs are usually secondary to weight loss and proportional to the degree of malnutrition. The body effectively goes into hibernation, becoming functionally hypothyroid (euthyroid sick) to save energy. Body temperature decreases, and patients report being cold. Bradycardia develops, especially in the supine position. Dizziness, light-headedness, and syncope may occur as a result of orthostasis and hypotension secondary to impaired cardiac function. Left ventricular mass is decreased, stroke volume is compromised, and peripheral resistance is increased, contributing to left ventricular systolic dysfunction. Patients can develop prolonged QTc syndrome and increased QT dispersion (irregular QT intervals), putting them at risk for cardiac arrhythmias. Peripheral circulation is reduced. Hands and feet may be blue and cool. Hair thins, nails become brittle, and skin becomes dry. Lanugo develops as a primitive response to starvation. The gastrointestinal (GI) tract may be affected; inability to take in normal quantities of food, early satiety, and gastroesophageal reflux can develop as the body adapts to reduced intake. The normal gastrocolic reflex may be lost due to lack of stimulation by food, causing bloating and constipation. Delayed gastric emptying may develop. Nutritional rehabilitation improves gastric emptying and dyspeptic symptoms in AN restricting type, but not in those who vomit. Neurologically, patients may experience decreased cognition, inability to concentrate, increased irritability, and depression, which may be related to structural brain changes and decreased cerebral blood flow.

Determining BMI is critical for assessing degree of malnutrition. A gown-only weight after urination is the most accurate way to assess weight. Patients tend to wear bulky clothes and may hide weights in their pockets or drink excessive fluid (water-loading) to trick the practitioner. BMI below the 25th percentile indicates risk for malnutrition, and below 5th percentile indicates significant malnutrition. Median body weight (MBW) should be calculated as it serves both as the denominator in determining what percent weight an individual is, as well as to provide a general goal weight during recovery. MBW for height is calculated by using the 50th percentile of BMI for age.

A combination of malnutrition and stress causes hypothalamic hypogonadism. The hypothalamic-pituitary-gonadal axis shuts down as the body struggles to survive, directing finite energy resources to vital functions. This may be mediated by the effect of low serum leptin levels on the hypothalamic-pituitary axis. Pubertal development and skeletal growth may be interrupted, and adolescents may experience decreased libido.

Amenorrhea will continue to be an important clinical sign that the body is malnourished. Amenorrhea occurs for two reasons. The hypothalamic-pituitary-ovarian axis shuts down under stress, causing hypothalamic amenorrhea. In addition, adipose tissue is needed to convert estrogen to its activated form. When weight loss is significant, there is not enough substrate to activate estrogen. Resumption of menses occurs only when both body weight and body fat increase.

Approximately, 73% of postmenarchal girls resume menstruating if they reach 90% of MBW. An adolescent female needs about 17% body fat to restart menses and 22% body fat to initiate menses if she has primary amenorrhea. Some evidence suggests that target weight gain for return of menses is approximately 1 kg higher than the weight at which menses ceased.

B. Laboratory Findings

All organ systems may suffer some degree of damage in the anorexic patient, related both to severity and duration of illness (Table 6–2). Initial screening should include complete blood count with differential; serum levels of electrolytes, blood urea nitrogen, creatinine, phosphorus, calcium, magnesium, and thyroid-stimulating hormone; liver function tests; and urinalysis. Increase in lipids, likely due to abnormal liver function, is seen in 18% of those with AN, with subsequent return to normal once weight is restored. An electrocardiogram (ECG) should be performed, because significant electrocardiographic abnormalities may be present, most importantly prolonged QTc syndrome. Bone densitometry should be done if illness persists for 6 months, as patients begin to accumulate risk for osteoporosis.

Differential Diagnosis

If the diagnosis is unclear (ie, the patient has lost a significant amount of weight but does not have typical body image distortion or fat phobia), the clinician must consider

Га	b	le 6	5-2.	Laboratory	findings:	anorexia	nervosa.
----	---	------	------	------------	-----------	----------	----------

Increased blood urea nitrogen and creatinine secondary to renal insufficiency
Decreased white blood cells, platelets, and less commonly
red blood cells and hematocrit secondary to bone marrow
suppression or fat atrophy of the bone marrow
Increased AST and ALT secondary to malnutrition
Increased cholesterol, thought to be related to altered fatty acid metabolism
Decreased alkaline phosphatase secondary to zinc deficiency
Low- to low-normal thyroid-stimulating hormone and thyroxine
Decreased follicle-stimulating hormone, luteinizing hormone,
estradiol, and testosterone secondary to shutdown of
hypothalamic pituitary-gonadal axis
Abnormal electrolytes related to hydration status
Decreased phosphorus
Decreased insulin-like growth factor
Increased cortisol
Decreased urine specific gravity in cases of intentional water
intoxication

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

the differential diagnosis for weight loss in adolescents. This includes inflammatory bowel disease, diabetes, hyperthyroidism, malignancy, depression, and chronic infectious disease such as human immunodeficiency virus (HIV). Less common diagnoses include adrenal insufficiency and malabsorption syndromes such as celiac disease. The history and physical examination should direct specific laboratory and radiologic evaluation.

Complications (Table 6–3)

A. Short-Term Complications

1. Early satiety—Patients may have difficulty tolerating even modest quantities of food when intake increases; this usually resolves after the patients adjust to larger meals. Gastric emptying is poor. Pancreatic and biliary secretion is diminished.

2. Superior mesenteric artery syndrome—As patients become malnourished, the fat pad between the superior mesenteric artery and the duodenum shrinks and compression of the transverse duodenum may cause obstruction and vomiting, especially with solid foods. The upper GI series shows to-and-fro movement of barium in the descending and transverse duodenum proximal to the obstruction. Treatment involves a liquid diet or nasoduodenal feedings until restoration of the fat pad has occurred, coincident with weight gain.

3. Constipation—Patients may be very constipated. Two mechanisms contribute—loss of the gastrocolic reflex and loss of colonic muscle tone. Typically stool softeners are

not effective because the colon has decreased peristaltic amplitude. Agents that induce peristalsis, such as bisacodyl, as well as osmotic agents, such as polyethylene glycol-electrolyte solution (MiraLax), are helpful. Constipation can persist for up to 6–8 weeks after refeeding. Occasionally enemas are required.

4. Refeeding syndrome—This syndrome is described in the Treatment section.

5. Pericardial effusion—The degree of malnutrition correlates with increasing prevalence of pericardial effusion. One study demonstrated that 22% of those with AN had silent pericardial effusions, with 88% of effusions resolving after weight restoration.

B. Long-Term Complications

1. Osteoporosis—Approximately 50% of females with AN have reduced bone mass at one or more sites. The lumbar

spine has the most rapid turnover and is the area likely to be affected first. Teenagers are particularly at risk as they accrue 40% of their bone mineral during adolescence. Low body weight is most predictive of bone loss. The causes of osteopenia and osteoporosis are multiple. Estrogen and testosterone are essential to potentiate bone development. Bone minerals begin to resorb without estrogen. Elevated cortisol levels and decreased insulin-like growth factor-1 also contribute to bone resorption. Amenorrhea is highly correlated with osteoporosis. Studies show that as few as 6 months of amenorrhea is associated with osteopenia or osteoporosis. Males have similar bone loss related to their degree of malnutrition, likely due to decreased testosterone and elevated cortisol.

Until recently, the only proven treatment for bone loss in girls with AN has been regaining sufficient weight and body fat to restart the menstrual cycle. Studies did not support use of hormone replacement therapy delivered orally to improve bone recovery; however, a recent randomized controlled trial

160

demonstrated that physiologic doses of estrogen, delivered transdermally, over 18 months did improve bone density. Clinicians may consider transdermal estrogen treatment if patients are recalcitrant to intervention and do not restore weight in a timely manner. Bisphosphonates, used to treat postmenopausal osteoporosis, are currently being studied in adolescents. Two small randomized controlled trials have shown small positive effects on bone density with alendronate and risedronate, although clinical effectiveness has not yet been determined. Newer treatments with possible effectiveness, including recombinant insulin-like growth factor-1 injection and dehydroepiandrosterone, are under investigation.

2. Brain changes—As malnutrition becomes pronounced, brain tissue—both white and gray matter—is lost, with a compensatory increase in cerebrospinal fluid in the sulci and ventricles. Follow-up studies of weight-recovered anorexic patients show a persistent loss of gray matter, although white matter returns to normal. Functionally, there does not seem to be a direct relationship between cognition and brain tissue loss, although studies have shown a decrease in cognitive ability and decreased cerebral blood flow in very malnourished patients. Making patients and family aware that brain tissue can be lost may improve their perception of the seriousness of this disorder.

3. Effects on future children—This area has just recently been studied. Findings suggest that there may be feeding issues for infants who are born to mothers who have a history of either AN or BN. Infants born to mothers with a history of AN have more feeding difficulties at 0 and 6 months and tend to be lower weight (30th percentile on average). Infants born to mothers with current or past BN are more likely to be overweight and have faster growth rates than controls. Pediatricians should ascertain an ED history from mothers of patients who are having feeding issues.

C. Mortality

Patients with EDs are at a higher risk of death than the general population and those with AN have the highest risk of dying among those with EDs. Meta-analysis estimates the standardized mortality ratio associated with AN to be 5.9. Death in anorexic patients is due to suicide, abnormal electrolytes, and cardiac arrhythmias.

Treatment

A. General Approach

Factors that determine treatment interventions are severity of illness, duration of illness, specific manifestations of disease, previous treatment approaches and outcomes, program availability, financial resources, and insurance coverage. Treatment options include outpatient management, day treatment hospitalization, inpatient medical or psychiatric hospitalization, and residential treatment. The key to determining level of intervention is the degree of malnutrition, the rapidity of weight loss, the degree of medical compromise, and the presence of life-threatening electrolyte abnormalities. No absolute criteria determine level of intervention. The practitioner must examine the degree of medical compromise and consider immediate risks and the potential for an individual to reverse the situation on his or her own. Treatment is costly. Many patients do not have insurance benefits that adequately cover the cost of treatment, leaving parents and practitioners with profound dilemmas as to how to best provide treatment in the face of financial constraints. Legally, however, EDs are now recognized as a parity mental health diagnosis similar to the other biologically based mental health illnesses in many states, which has increased the ease of obtaining insurance coverage.

A multidisciplinary approach is most effective and should include medical monitoring, nutrition therapy, and individual and family psychotherapy by experienced practitioners. Family therapy is an important means of helping families understand the development of the disease and addressing issues that may be barriers to recovery. Both types of psychotherapy are encouraged in most treatment programs, and recovery without psychotherapy is unusual. The average length of psychotherapy is roughly 6–9 months, although some individuals continue therapy for extended periods. Adjunctive modalities include art and horticulture therapy, therapeutic recreation, and massage therapy.

Manualized family therapy, developed in Britain by Maudsley and adapted by Lock and LeGrange, has shifted the therapeutic approach to adolescents with AN. Traditional therapy allowed the adolescent to control his or her eating and the parents to remain uninvolved with the food portion of recovery. The manualized approach gives power and control back to parents.

Treatment is prescribed for 20 weekly sessions. The first 10 weeks are devoted to empowering parents, putting them in control of their child's nutrition and exercise. Parents are educated about the dangers of malnutrition and are instructed to supervise each meal. The next phase, sessions 11–16, returns control over eating to the adolescent once he or she accepts the demands of the parents. The last phase of treatment, sessions 17–20, occurs when the patient is maintaining a healthy weight and shifts the focus away from the ED, examining instead the impact that the ED has had on establishing a healthy adolescent identity. This approach is reported to result in good or intermediate outcomes in 90% of treated adolescents.

Careful instruction in nutrition helps the teenager and family dispel misconceptions about nutrition, identify realistic nutritional goals, and normalize eating. Initially, nutrition education may be the most important intervention as the teenager slowly works through his or her fears of fat-containing foods and weight gain. The teenager begins to trust the nutrition therapist and restore body weight, eventually eating in a well-balanced, healthy manner.

B. Inpatient Treatment

Table 6–4 lists the criteria for hospital admission generally used in the medical community. It is usually quite difficult for a patient who is losing weight rapidly (> 2 lb/wk) to reverse the weight loss because the body is in a catabolic state.

Goals of hospitalization include arresting weight loss and stabilizing hemodynamics. Nutrition is the most vital inpatient medicine. Clinicians can safely begin with a meal plan containing approximately 250 kcal more than the patient has been routinely eating, which can usually be accomplished orally. Recent studies suggest that meal plans can begin with as high as 1750 kcal regardless of baseline intake. Meal plans should be well balanced with appropriate proportions of carbohydrate, protein, and fat. Oral meals are usually tolerated, although it is important to be supervised by medical staff. If the patient resists, nasogastric or intravenous alimentation can be used. Aside from caloric needs, the clinician needs to consider the patient's hydration and include the appropriate amount of fluid with the meal plan. Dehydration should be corrected slowly. The oral route is usually adequate. Aggressive intravenous fluid administration should be avoided because left ventricular mass is compromised and a rapid increase in volume may not be tolerated. Regulating fluid intake is important, because water intoxication can contribute to abnormal electrolytes and falsified weights.

Table 6–4. Criteria for hospitalization for eating disordered patients.

One or more of the following justify hospitalization:

- 1. Body weight: < 75% median body weight.
- 2. Dehydration
- Electrolyte disturbance (hypokalemia, hyponatremia, hypophosphatemia)
- 4. EKG abnormalities (prolonged QTC, severe bradycardia)
- Physiologic Instability
 Supine heart rate < 45 beats/min
 Symptomatic hypotension or syncope
 Hypothermia
- 6. Failure of outpatient management
- 7. Acute food refusal
- 8. Uncontrolled bingeing and purging
- 9. Acute medical complications of malnutrition (syncope, seizures, cardiac failure, pancreatitis)
- Comorbid psychiatric or medical condition that prohibits or limits appropriate outpatient treatment (severe depression, suicidal ideation, obsessive-compulsive disorder, type 1 diabetes)

During the initial introduction of food, the clinician should monitor the patient for refeeding syndrome, a phenomenon that occurs if caloric intake is increased too rapidly. Signs of refeeding syndrome are decreased serum phosphorus (as the body resumes synthesis of adenosine triphosphate), decreased serum potassium (as increased insulin causes K⁺ to shift from extracellular fluid into K⁺-depleted cells), and, rarely, edema related to fluid shifts or congestive heart failure.

Although specific guidelines do not exist, many practitioners begin phosphorus supplementation if patients are severely malnourished (< 70% MBW) or their intake has been consistently less than 500 kcal/day.

Caloric intake can be increased 250 kcal/day as long as refeeding syndrome does not occur. Weight goals vary depending on programmatic approach. Typically, intake is adjusted to reach a goal of 0.1-0.25 kg/day weight gain.

Overnight monitoring for bradycardia is helpful in assessing degree of metabolic compromise. Usually the more rapid and severe the weight loss, the worse the bradycardia. Improving bradycardia correlates with weight recovery. Orthostatic hypotension is most severe around hospital day 4, improving steadily and correcting by the third week of nutritional rehabilitation. An ECG should be obtained because the patient is at risk for prolonged QTc syndrome and junctional arrhythmias related to the severity of bradycardia.

It usually takes 2–3 weeks to reach the initial goals of hospitalization—steady weight gain, toleration of oral diet without signs of refeeding syndrome, corrected bradycardia (heart rate > 45 beats/min for three consecutive nights), and correction of orthostasis. Specific weight criteria are used by many programs when considering discharge. This depends partly on admission weight. Ideally a patient gains at least 5% of his or her MBW. Some programs set discharge at 80%, 85%, or 90% MBW. Patient outcomes are improved with discharge at a higher body weight. Some evidence exists that patients do better if discharged at 95% MBW. In many practitioners' experience, relapse rates are high if patients are discharged at less than 75% MBW.

C. Pharmacotherapy

Practitioners frequently use psychotropic medications for treatment of AN, despite the lack of evidence supporting efficacy. Several open-label trials suggest that atypical antipsychotics (risperidone, olanzapine, quetiapine) may be helpful. One review found that olanzapine (2.5–15 mg/day) was associated with improved body weight, decreased delusional thinking, improvement in body image, and decreased agitation and premeal anxiety. However, a randomized controlled trial did not show any difference in outcomes between risperidone and placebo.

SSRIs repeatedly have been shown to not be helpful in the initial therapy of AN. A recent study showed that use of SSRIs may decrease bone mineral density when used in malnourished patients. However, once the patient has achieved approximately 85% MBW, SSRIs (fluoxetine, citalopram, or sertraline) may help prevent relapse.

Zinc deficiency is common in AN, and several studies support its use as a supplement during the initial phases of treatment. Because zinc deficiency adversely affects neurotransmitters, administering zinc helps restore neurotransmitter action to baseline. Additionally, zinc may restore appetite and improve depressive mood. Zinc should be administered for approximately 2 months from the beginning of therapy, with at least 14 mg of elemental zinc daily.

Because of global nutritional deficits, a multivitamin with iron is also recommended daily. Symptomatic treatment for constipation and reflux should be used appropriately until symptoms resolve.

D. Outpatient Treatment

Not all patients with AN require inpatient treatment, especially if parents and clinicians recognize the warning signs early. These patients can receive treatment as outpatients, employing the same multidisciplinary team approach. Manualized family-based treatment is ideal for the outpatient setting if a trained therapist is available. Appropriate nutrition counseling is vital in guiding a patient and family through the initial stages of recovery. As the nutrition therapist is working at increasing the patient's caloric intake, a practitioner needs to monitor the patient's weight and vital signs. Often, activity level needs to be decreased to help reverse the catabolic state. A reasonable weight gain goal may be 0.2–0.5 kg/wk. If weight loss persists, careful monitoring of vital signs, including supine heart rate, is important in determining whether an increased level of care is needed. Concomitantly, the patient should be referred to a psychotherapist and, if indicated, assessed by a psychiatrist.

E. Treatment Goals and Outcomes

Goals of treatment include reaching a healthy body weight, elimination of medical sequelae, and resumption of menses. Symptoms can wax and wane over an extended period for several years. Approximately 50% of adolescents recover in a relatively short period of time. Thirty percent may take several years to get back to a state of health, although symptoms may reappear on occasion. About 20% of adolescents can go on to develop chronic, unremitting AN.

BULIMIA NERVOSA

The diagnostic criteria for BN are discussed in section Essentials of Diagnosis and Typical Features. Binge eating is either eating excessive amounts of food during a normal mealtime or having a meal that lasts longer than usual. Bulimic individuals feel out of control while eating, unable or unwilling to recognize satiety signals. Any type of food may be eaten in a binge, although typically it includes carbohydrates or junk food. Extreme guilt is often associated with the episode. At some point, either prior to or during a binge, bulimic individuals often decide to purge as a means of preventing weight gain. The most common ways to purge are self-induced vomiting, exercise, and laxative use.

Some individuals will vomit multiple times during a purge episode, after using large amounts of water to cleanse their system. This can induce significant electrolyte abnormalities such as hyponatremia and hypokalemia, which may put the patient at acute risk for arrhythmia or seizure. Other methods of purging include diuretics, diet pills, cathartics, and nutritional supplements that promote weight loss, such as Metabolife or Sensa.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES: BULIMIA NERVOSA

- Recurrent episodes of binge eating, characterized by both of the following:
 - Eating in a discrete period an amount of food that is larger than most people would eat during a similar period under like circumstances.
 - A sense of lack of control during the episode (eg, feeling that one cannot stop eating or control what or how much one is eating).
- Recurrent inappropriate compensatory behavior to prevent weight gain (eg, self-induced vomiting; misuse of laxatives, diuretics, or other products; excessive exercise; fasting).
- Binge eating and inappropriate compensatory behaviors occur at least once a week for 3 months (on average).

https://www.nationaleatingdisorders.org/bulimia-nervosa

Diagnosing BN can be difficult unless the teenager is forthcoming or parents or caregivers can supply direct observations. Bulimic patients are usually average or slightly above average in body weight and have no physical abnormalities. Screening all teenagers for body image concerns is crucial. If the teenager expresses concern about being overweight, the clinician needs to screen the patient about dieting methods. Asking whether patients have binged, feel out of control while eating, or whether they cannot stop eating can clarify the diagnosis. Parents may report that significant amounts of food are missing or disappearing more quickly than normal. If the physician is suspicious, direct questioning about all the ways to purge should follow. Indicating first that the behavior is not unusual can make questioning less threatening and more likely to elicit a truthful response. For example, the clinician might say, "Some teenagers who try to lose weight make themselves vomit after eating. Have you ever considered or done that yourself?" (See Table 6-1 for additional screening questions.)

Clinical Findings

A. Symptoms and Signs

Symptoms are related to the mechanism of purging. GI problems are most prominent. Abdominal pain is common. Gastroesophageal reflux occurs as the lower esophageal sphincter becomes compromised due to repetitive vomiting. Frequent vomiting may also cause esophagitis or gastritis, as the mucosa is irritated by acid exposure. Early satiety, involuntary vomiting, and complaints that food is "coming up" on its own are frequent. Hematemesis and esophageal rupture have been reported. Patients may report diarrhea or constipation, especially if laxatives have been used. Sialadenitis (parotid pain and enlargement) may be caused by frequent vomiting. Erosion of dental enamel results from increased oral acid exposure during vomiting. Because comorbid depression is common in BN, patients may report difficulty sleeping, decreased energy, decreased motivation, and headaches. Light-headedness or syncope may develop secondary to dehydration.

It is important to note that most purging methods are ineffective. When patients binge, they may consume thousands of calories. Digestion begins rapidly. Although the patient may be able to vomit some of the food, much is actually digested and absorbed. Laxatives work in the large intestine, leading to fluid and electrolyte loss, but consumed calories are still absorbed from the small intestine. Use of diuretics may result in decreased fluid weight and electrolyte imbalance.

On physical examination, bulimic patients may be dehydrated and have orthostatic hypotension. Sialadenitis, tooth enamel loss, dental caries, and abdominal tenderness are the most common findings. Abrasion of the proximal interphalangeal joints may occur secondary to scraping the fingers against teeth while inducing vomiting. Rarely, a heart murmur is heard which may be due to mitral valve prolapse. Irreversible cardiomyopathy can develop secondary to ipecac use.

B. Laboratory Findings

Electrolyte disturbances are common. The method of purging results in specific abnormalities. Vomiting causes metabolic alkalosis, hypokalemia, and hypochloremia. Laxatives cause metabolic acidosis, hypokalemia, and hypochloremia. Diuretic use may lead to hypokalemia, hyponatremia, hypocalcemia, and metabolic alkalosis. Amylase may be increased secondary to chronic parotid stimulation.

Complications

A. Short-Term Complications

Complications in normal-weight bulimic patients are related to the mechanisms of purging, and many of these

complications are listed under Symptoms and Signs. If the bulimic patient is significantly malnourished, complications may be the same as those encountered in the anorexic patient. Other complications of bulimia include esophageal rupture, acute or chronic esophagitis, and, rarely, Barrett esophagitis. Chronic vomiting can lead to metabolic alkalosis, and laxative abuse may cause metabolic acidosis. Diet pill use can cause insomnia, hypertension, tachycardia, palpitations, seizures, and sudden death.

Patients who stop taking laxatives can have severe constipation. Treating constipation can be difficult psychologically, because the practitioner may need to prescribe agents similar to the drugs of abuse used during the ED.

B. Mortality

The mortality rate in bulimic patients is similar to that in anorexic patients. Death usually results from suicide or electrolyte derangements.

Treatment

Treatment of BN depends on the frequency of bingeing and purging and the severity of biochemical and psychiatric derangement. If K⁺ is less than 3.0 mEq/L, inpatient medical admission is warranted. Typically extracellular K⁺ is spared at the expense of intracellular K⁺, so a patient may become hypokalemic several days after the serum K⁺ concentration appears to be corrected. Usually cessation of purging is sufficient to correct K⁺ concentration and is the recommended intervention for K⁺ above 3.0 mEq/L. If K⁺ is 2.5–2.9 mEq/L, oral supplementation is suggested. If K⁺ is less than 2.5 mEq/L, intravenous therapy is recommended. Supplements can be stopped once K⁺ levels are more than 3.5 mEq/L. Total body K⁺ can be assumed to be normal when serum K⁺ corrects and remains normal 2 days after supplements are stopped. Continued hospitalization depends on the patient's psychological status.

Some bulimic patients who abuse laxatives may become chronically dehydrated. The renin-angiotensin-aldosterone axis is activated, and the antidiuretic hormone level may be elevated to compensate. These hormones do not normalize immediately when laxatives are stopped, and fluid retention of up to 10 kg/wk may result. This puts patients at risk for congestive heart failure and can scare them as their weight increases dramatically. Diuresis often occurs after 7–10 days.

Hospitalization of bulimic patients is also recommended if there has been failure of outpatient management. The binge- purge cycle is addictive and can be difficult for patients to interrupt on their own. Hospitalization can offer a forced break from the cycle, allowing patients to normalize their eating, interrupt the addictive behavior, and regain the ability to recognize satiety signals. Outpatient management can be pursued if patients are medically stable. Cognitive-behavioral therapy is crucial to help bulimic patients understand their disease. Nutrition therapy offers patients ways to regulate eating patterns so that they can avoid the need to binge. Medical monitoring should be done to check electrolytes periodically, depending on the purging method used.

SSRIs are generally helpful in treating the binge-purge cycle. Fluoxetine has been studied most extensively; a dose of 60 mg/day is most efficacious in teenagers. Other SSRIs appear to be effective as well and may be used in patients experiencing side effects of fluoxetine. Treatment for gastroesophageal reflux and gastritis should be used when appropriate. The pain and swelling of enlarged parotid glands can be helped by sucking on tart candy and by the application of heat.

Goals of treatment are to interrupt the binge/purge cycle, with the goal of reaching remission as a targeted outcome.

BINGE-EATING DISORDER

Binge-eating disorder (BED) is now described in the DSM-5. Studies show that most adults who have BED (a prevalence of 2%–4%) develop symptoms during adolescence. Following are the diagnostic criteria for BED.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES: BINGE-EATING DISORDER

- Recurring episodes of binge eating:
 - Eating significantly more food in a short period than most people would eat under similar circumstances.
 - Episodes marked by feelings of lack of control.
- Binge eating is associated with marked distress.
- Binge eating occurs at least once a week over three months (on average).

https://www.nationaleatingdisorders.org/sites/default/files/ ResourceHandouts/MultiPageRGB.pdf

Clinical Findings

A. Symptoms and Signs

BED most often is found in overweight or obese individuals. Eighteen percent of such patients report binging at least once in the past year. Patients with BED have an increased incidence of depression and substance abuse. The possibility of BED should be raised for any significantly overweight patient. Specific questionnaires are available for evaluating patients suspected of BED.

B. Laboratory Findings

The clinician should assess causes and complications of obesity, and laboratory evaluation should include thyroid function tests and measurement of cholesterol and triglyceride levels.

Treatment

A combination of cognitive-behavioral therapy and antidepressant medication has been helpful in treating BED in adults. Use of SSRIs for BED in adolescents has not been studied, but in adults fluoxetine and citalopram help decrease binge episodes, improve depressive symptoms, and possibly decrease appetite. This evidence suggests that SSRIs in adolescents with BED may be helpful as well. BED has been recognized only recently, and outcomes have not been studied. Little is known regarding long-term prognosis.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

ARFID is a new diagnosis in the DSM-5 that extends the DSM-4 diagnosis of feeding disorder of infancy or early childhood. The hallmark feature is avoidance or restriction of oral food intake, in the absence of criteria for AN (body image disturbance, fear of weight gain/body fat). For teenagers, food avoidance may be associated with more generalized emotional difficulties that do not meet diagnostic criteria for ANFID are discussed in section **Essentials of Diagnosis and**

Typical Features below. Similar health affects to AN may be found in youth with ARFID, depending on the degree of malnutrition and how an individual became malnourished.

- Eating or feeding disturbance (including lack of interest in eating, avoidance due to sensory characteristics of food; concern for aversive consequences of eating) demonstrated by failure to meet appropriate nutritional and/or energy needs and associated with one or more of:
 - Weight loss (or failure to achieve expected weight gain or faltering growth)
 - Nutritional deficiency
 - Dependence on enteral feeding or oral nutritional supplementation
 - Interference with psychosocial functioning
- Disturbance not explained by lack of available food or culturally-sanctioned practice
- Eating disturbance does not occur exclusively during anorexia nervosa or bulimia nervosa, and there is no disturbance in experience of one's body weight or shape
- ► Eating disturbance not attributable to concurrent medical condition or explained by a different mental disorder, *or*, when eating disturbance occurs in the context of another condition or disorder, severity of eating disturbance exceeds that associated with the other condition or disorder

PROGNOSIS, QUALITY ASSESSMENT, & OUTCOMES METRICS

Outcome in EDs, especially AN, has been studied extensively. Prior metrics generally defined remission or recovery as being at a healthy body weight and a return of menses. As diagnostic criteria for AN changed, a national collaborative effort that included 14 ED programs defined AN recovery based on reaching at least 90% median BMI, without consideration of return of menses. Most studies have focused on specific inpatient treatment programs, and few have evaluated less ill patients who do not need hospitalization. About 40%–50% of patients receiving treatment recover; 20%–30% have intermittent relapses; and 20% have chronic, unremitting illness. As time from initial onset lengthens, the recovery rate decreases and mortality associated with AN and BN increases. A study from the Swedish registry of EDs The course of AN often includes significant weight fluctuations over time, and it may be a matter of years until recovery is certain. The course of BN often includes relapses of bingeing and purging, although bulimic patients initially recover faster than do anorexic patients. Up to 50% of anorexic patients may develop bulimia, as well as major psychological complications, including depression, anxiety, and substance abuse disorders. Bulimic patients also develop similar psychological illness but rarely develop anorexia. Long-term medical sequelae, aside from low body weight and amenorrhea, have not been systematically studied, although AN is known to have multiple medical consequences, including osteoporosis and structural brain changes.

It is unclear whether age at onset affects outcome, but shorter length of time between symptom onset and therapy tends to improve outcome. Various treatment modalities can prove effective. Favorable outcomes have been found with brief medical hospitalization and long psychiatric or residential hospitalization. Higher discharge weight, as well as more rapid weight gain during inpatient treatment (> 0.8 kg/wk), seems to improve the initial outcome. It is difficult to compare treatment regimens, because numbers are small and the type of patient and illness varies among studies. No existing studies compare outpatient to inpatient treatment or the effects of day treatment on recovery.

Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Adam Burstein, DO Kimberly Kelsay, MD Ayelet Talmi, PhD

INTRODUCTION

Pediatric primary care settings are often the first points of entry into behavioral health systems for the 14%-20% of children and adolescents affected by mental or behavioral health issues. Beyond addressing identified and diagnosable mental health conditions, pediatric primary care settings are tasked with: (1) screening and surveillance, (2) early identification, and (3) triage and referral around complex behavioral health issues for the child, their family, and the environments with which the child interacts. Primary care providers see approximately 75% of children with psychiatric disturbances and half of all pediatric office visits involve behavioral, psychosocial, or educational concerns. Parents and children often prefer discussing these issues with someone they already know and trust. As a result, pediatric primary care providers play an important role in the prevention, identification, initiation, management, and coordination of mental health, as well as behavioral and development care for children and adolescents. Unfortunately, the shortage of mental health providers, stigma attached to receiving mental health services, chronic underfunding for behavioral/mental health services, institutional barriers within the public mental health system, and disparate insurance benefits contribute to the fact that only 2% of children with diagnosable disorders are seen by mental health specialists.

Despite being strategically positioned as the gatekeepers for identifying mental health and behavioral concerns, primary care providers typically identify fewer than 20% of children with emotional and behavioral problems during routine health supervision visits. In addition, these problems may not be identified when they initially emerge and are more amenable to treatment. This gatekeeper role has become increasingly important over the past decade as advances in mental health awareness and treatment have improved opportunities for early identification and intervention. The role is especially critical because child psychiatry remains an underserved medical specialty, with only 8,300 practicing child and adolescent psychiatrists in the United States. In contrast, more than 50,000 boardcertified pediatricians and innumerable midlevel pediatric providers are in a unique position to identify issues affecting the emotional health of children and to initiate treatment or referrals to other providers.

Emotional problems that develop during childhood and adolescence can significantly impact development and may continue into adulthood. In fact, most adult psychiatric disorders involve childhood onset. Many disorders do not present as an all-or-none phenomenon, rather they progress from less severe concerns, such as adjustment problems or perturbations in functioning, to significant disturbances and severe disorders. Pediatricians have the capacity to manage emotional problems and behavioral conditions early on, when improvement can be achieved with less intensive interventions. If pediatricians and schools do not appropriately identify mental health problems, provide education about the benefits of intervention, and encourage and initiate intervention, childhood-onset disorders are more likely to persist, cause worsening impairment, and lead to a downward spiral of school and social difficulties, poor employment opportunities, and poverty in adulthood, as well as increased health care utilization and costs as adults. These outcomes are even more pronounced for children and adolescents from underserved. low socio-economic status backgrounds.

Pediatricians and other pediatric health professionals may be the first, or sometimes only, medical professional to identify a behavioral/mental health problem and thus require specialized training, resources, and supports to help children and families navigate systems and engage in treatment. Pediatricians working in specialty care settings, hospitalists, and intensivists will also encounter children

and adolescents with emotional and behavioral problems. As such, this chapter includes information about approaches to care within these settings. This chapter reviews prevention, surveillance, and screening for mental and behavioral health concerns; situations that may arise in the context of such assessments; psychiatric illnesses that are often diagnosed during childhood or adolescence; current treatment recommendations; and indications for referral to mental health professionals.

MODELS OF CARE ENCOMPASSING BEHAVIORAL HEALTH IN THE PRIMARY CARE SETTING

Mental health, behavior, and development are routinely addressed in the context of pediatric primary care. The continuum of behavioral health services in primary care settings spans from providing anticipatory guidance around development, behavior, and socio-emotional well-being, to screening and identification of concerns, to making external referrals and/or providing on-site services to address the identified issues.

Routine pediatric care of emotional and behavioral problems is typically related to the knowledge and comfort level of the individual pediatric provider and available resources within the primary care setting (eg, onsite mental health support) and in the surrounding community. The efficacy of surveillance in the form of developmentally appropriate anticipatory guidance and counseling varies. Providers spend an average of 2.5 minutes on surveillance, with the majority of that time spent on safety and general developmental issues. Within this model, the majority of emotional and behavioral problems are not readily identified. Even when they are identified, the logistics of identifying resources and referrals present problems. One recently published study identified barriers such that when pediatricians had referred to external mental health services, less than 12% of patients completed care, compared to over 76%

who completed care when treated within the setting of their primary care provider.

Traditional models of identification within the primary care setting and referral to external, community-based services are most prevalent, but there are a number of different models currently being utilized by providers to better access mental health services in a primary care setting. Telephonic consultation or telepsychiatry with mental health consultation teams in a stepped care approach allows enhanced access to mental health providers, especially for providers seeing children in rural communities. Many states are moving toward providing primary care providers with ready access to mental health consultation by phone, and further care such as telepsychiatry or in-person visit with the patient if indicated, similar to the system piloted in Massachusetts. Consultation to pediatric care providers also facilitates ongoing education with the eventual goal of pediatric providers learning to manage many behavioral health concerns on their own.

Co-location or enhanced care models are further along the continuum of behavioral health integration. The colocation of behavioral health clinicians in primary care settings affords access to scheduled appointments with clinicians working in offices within close proximity to the primary care setting. This allows for warm-handoffs between primary care and behavioral health providers but does not necessarily improve coordination of care. Functionally, this type of practice operates like an outpatient mental health service with the potential to improve access (eg, patients can see their physical and behavioral health providers in the same setting) and decrease stigma associated with obtaining mental health services because of the shared practice location for both behavioral and physical health services.

Collaborative or integrated care provides high-quality, transdisciplinary care through the integration of behavioral health providers within the primary care clinic. The integrated clinician operates as a member of the care team, providing more specialized, on-site services when needed (eg, brief therapy, consultation) and facilitating referrals to external mental health resources. Integrated behavioral health services increase access to immediate supports and reduce barriers, including transportation challenges, systems navigation, and stigma associated with going to see a community-based mental health specialist. This model provides comprehensive and coordinated care, improves communication among care team members, and enhances referral uptake for communitybased services. Successful components of this model include a leadership team, primary clinicians, mental health and developmental specialists, administrators, clinical informatics specialists, and care managers. Integrated care implies that visits are primarily conducted jointly, care is coordinated among physical and behavioral health providers, and that mental health professionals are always available for case consultation. The American Academy of Child and Adolescent Psychiatry has an excellent resource, http://integratedcareforkids.org.

PREVENTION, EARLY IDENTIFICATION, & DEVELOPMENTAL CONTEXT

Developmental contexts and the environments in which children and adolescents grow up play a significant role in their development and well-being. Environments provide access to resources, relationships, and supports in addition to being settings for learning, growth, and development. Longitudinal and retrospective research studies link adverse experiences in childhood to significant, lifelong health problems. In a study of more than 17,000 adults insured through Kaiser Permanente, researchers found that experiencing adversity in childhood (eg, child abuse, neglect, household dysfunction) was correlated with poor health outcomes (eg, substance use, heart disease, depression, adolescent pregnancy), lower quality of life, and decreased lifespan. Understanding social determinants of health helps the provider attend to the needs of particular children in a practice setting that serves as a medical home. Increasingly, however, the major threats to the health of US childrenthe new morbidity-arise from problems that cannot be adequately addressed by the practice model alone. These problems include unacceptably high infant mortality rates in certain communities, extraordinary levels of intentional and unintentional injuries, increasing rates of childhood obesity, chemical dependency, behavioral and developmental consequences of inappropriate care and experience, family dysfunction, sexually transmitted diseases, unplanned pregnancies, and lack of a medical home. The American Academy of Pediatrics (AAP) policy statement, "we must become partners with others, or we will become increasingly irrelevant to the health of children," implies that the work of pediatricians extends to advocacy and community work. Today's community pediatrician seeks to provide a far more realistic and complete clinical picture by taking responsibility for all children in a community, providing preventive and curative services, and understanding the determinants and consequences of child health and illness, as well as the effectiveness of services provided.

Bright Futures is a national health promotion and disease prevention initiative that addresses children's health needs in the context of family and community. In addition to use in pediatric practice, many states implement Bright Futures principles, guidelines, and tools to strengthen the connections between state and local programs, pediatric primary care, families, and local communities. The *Bright Futures Guidelines*, now in its fourth edition, was developed to provide comprehensive health supervision guidelines, including recommendations on immunizations, routine health screenings, and anticipatory guidance. In addition, Bright Futures for Mental Health provides numerous guidelines, tools, and strategies for improving mental health identification, assessment, initiation, management, and coordination.

It is exciting that prevention and early intervention programs are showing promise in helping to reduce risk for patients and their families. Evidenced-based and promising programs and strategies include, but are not limited to:

LIFESTYLE RECOMMENDATIONS

Proper screening, assessment, diagnosis, and treatment of issues are fundamental aspect of practice. In addition, it is equally important that a primary care provider become familiar with factors that can help promote health, both physical and mental. Therefore, activities that support a healthy lifestyle can positively impact health and, in some cases, may help prevent a future problem. Many studies demonstrate clear physical and behavioral health benefits from regular exercise, optimal nutrition, meditation, yoga, and participation in prosocial activities. Other contributing factors that directly impact overall health include adequate sleep and use of relaxation techniques. The AAP recommends engaging families in conversations to encourage consumption of fruits and vegetables, avoid sugar-containing drinks, encourage physical activity and to make family plan around screen time. While these guidelines focus on physical health, successful implementation and adherence to them resides within the relationships and environments in which children live.

Summary of the Pediatrician's Role

Given these calls for a new pediatric role as the gatekeeper for social-emotional health and well-being, the expanding
 Table 7–1.
 The pediatric primary care provider's role in mental health.

Role	Specific Activities
Prevention	Screen and address social risk factors on intake Screen and refer for early socioemotional risk
Identification	Shared family concern Surveillance Screening
Assessment	Interview and physical Assessment tools Comorbid conditions
Initiation	Education about condition and treatment options • Continued collaboration and assessment with family • Refer to mental health for further evaluation • Refer for therapy • Start medication
Management	Monitor condition for improvement Monitor for side effects
Coordination	With social work, therapist, psychologist, or psychiatrist
Collaboration	With mental health service providers With child protection With local schools

role of the primary care pediatric provider encompasses the following broad categories: prevention, identification, assessment, initiation, management, coordination, and collaboration (Table 7–1).

IDENTIFICATION & ASSESSMENT DURING HEALTH SUPERVISION VISITS

Historically, the most efficient indicator in eliciting psychosocial problems is the history provided by parents or guardians and interview and observation of the child. The possible approaches to identification of problems include surveillance, screening, and assessment. *Surveillance* consists of the following elements: checking in, eliciting concerns, asking open-ended questions, listening for red flags, identifying risk factors, and monitoring closely over time. Like vital signs, which represent an essential component of the physical evaluation, the essential components of the primary care surveillance for mental health concerns should generally include a review of the youth's general functioning in different aspects of their life. Five questions forming the mnemonic **PSYCH** can be addressed to parents and youth as a surveillance means of uncovering areas of concern.

- 1. **P**arent-child interaction: How are things going with you and your parents? Or, in early childhood: What's it like to take care of your baby/toddler?
- 2. School: How are things going in school (or child care; ask about academics, behaviors, and social interactions)?
- 3. Youth: How are things going with peer relationships/ friendships (how does child get along with same-aged peers)?
- 4. Casa: How are things going at home (including siblings, family stresses, and relationship with parents)?
- 5. Happiness: How would you describe your mood? How would you describe your child's mood?

Many pediatric practices are hampered by lack of continuity and not enough time for in-depth surveillance. Given limited time available for pediatric visits (ie, families spend only a few minutes of in-person time with their pediatric provider during routine health supervision visits), and the fact that only 18% of parents who report elevated behavior problems in children actually tell their providers about it, surveillance should be paired with universal screening for development, mental health, behavior, psychosocial, and environmental risk factors. Surveillance is further hampered by not being a separate and billable service under current Medicaid and insurance reimbursement plans, whereas formal screening is.

Screening involves using standardized instruments to identify areas of risk, delay, or concern. Newborn hearing, vision, and developmental screenings are common in today's pediatric practice. However, the morbidity associated with developmental, emotional, and psychosocial problems requires that social-emotional and psychosocial screening also be performed to identify the presence of symptoms of emotional, behavioral, or relationship disorders and those environmental factors that negatively influence development. Screening tools are brief, easy to use, and can be administered as a questionnaire or using an interview format. A positive screen warrants referral for a more thorough assessment. The use of screening tools can also lead to early identification and interrupt the advancement of symptoms. Newer methods of eliciting socioemotional and behavior concerns have been developed (see section below on Tools). Helpful information can also be obtained from broad screening checklists and symptom-specific questionnaires such as depression or anxiety self-report inventories. Questions can be incorporated into the general pediatric office screening forms or specific questionnaires can be used. Beyond identification, successful screening requires attention to appropriate referrals, referral uptake and completion, and communication back to the referring entity regarding the results of the evaluation. These activities often require additional care coordination resources that could be provided through non-medical staff such as family navigators and community health workers. Pediatric primary care providers need information about eligibility for services in order to successfully monitor and address behavioral and developmental issues.

Tools for Mental Health Screening in the Primary Care Office Setting

Given the low rates of identification of psychosocial problems using pediatric surveillance, the use of standardized screening tools has become standard practice. Typically, broad screeners that elicit information regarding multiple domains are employed first and are followed by targeted screens to address symptomatology, severity, impairment, and context of specific psychosocial problems.

Resources for obtaining screening tools https://www.mcpap.com/Provider/ScreeningNToolkits.aspx http://www.brightfutures.org/mentalhealth/pdf/tools.html http://www.palforkids.org http://www.schoolpsychiatry.org http://www.wpic.pitt.edu/research http://www.theswyc.org http://www.sdainfo.com

A. General or Broad Screening Tools

1. Strengths and difficulties questionnaires (SDQs)— The SDQs are brief behavioral screening questionnaires targeting patients 3–16 years old with parent, teacher, and child self-report versions available. Several versions are available and can readily be used by researchers, clinicians, and educators. They are well validated and available on the Internet without cost in over 40 languages. The domains assessed include emotional problems, conduct problems, hyperactivity/inattention, peer-relationship problems, and social behaviors. For further information, refer to the website http://www.sdqinfo.org.

Vostanis P: Strengths and Difficulties Questionnaire: research and clinical applications. Curr Opin Psychiatry 2006 Jul;19(4): 367–372 [PMID: 16721165].

2. Pediatric Symptoms Checklist (PSC)—The PSC is a one-page questionnaire listing a broad range of children's emotional and behavioral problems that reflects parents' impressions of their children's psychosocial functioning. An adolescent self-report version is also available for children ages 11 and older. The PSC was developed initially for children older than age 5, but cutoff scores for preschool and school-aged children indicating clinical levels of dysfunction have been empirically derived. The questionnaire is easy to score, free of charge, and available in English and Spanish from the website http://www.brightfutures.org/mentalhealth/pdf/professionals/ped_sympton_chklst.pdf.

172

Kostanecka A et al: Behavioral health screening in urban primary care settings: construct validity of the PSC-17. J Dev Behav Pediatr 2008 Apr;29(2):124–128 [PMID: 18408533].

3. Parents' Evaluation of Developmental Status

(**PEDS**)—The PEDS is a validated screener for socioemotional, developmental, and behavioral concerns in children aged 1 month to 8 years. Parents answer yes/no about their concerns in various areas of their child's development. Scoring the PEDS is more labor-intensive than other general screeners and the instrument must be purchased. Its benefits include extensive validity data and useful pathways for level of concern and referral. It is available in English, Vietnamese, and Spanish. For further information, see the website http://www.pedstest.com.

Brothers KB, Glascoe FP, Robertshaw NS: PEDS: developmental milestones—an accurate brief tool for surveillance and screening. Clin Pediatr (Phila) 2008;47(3):271–279 [Epub 2007 Dec 5] [PMID: 18057141].

4. Ages and Stages, Socio-emotional (ASQ: SE)—The Ages and Stages, SE is a companion to the Ages and Stages Developmental Screen. It is an easy-to-use tool with a deep, exclusive focus on infant, toddlers, and younger children's social and emotional behavior. After a one-time cost, the instrument is reproducible, making it cost-effective. It is culturally sensitive for use across diverse pediatric populations. Screens are available for the 6-, 12-, 18-, 24-, 36-, 48-, and 60-month visits, and in English, French, Spanish, and Korean.

5. Family Psychosocial Screen—Pediatric Intake Form, *Bright Futures*, https://www.brightfutures.org/mentalhealth/pdf/professionals/ped_intake_form.pdf. Retrieved April 27, 2017.

6. WE CARE—Available in appendix of article. (Garg A, Butz AM, Dworkin PH, Lewis RA, Thompson RE, Serwint JR: Improving the management of family psychosocial problems at low-income children's well-child care visits: the WE CARE Project. Pediatrics 2007;120(3):547–558 [PMID: 17766528].)

C. Adolescent Screening Tools

The American Academy of Pediatrics and the U.S. Preventive Services Task Force recommend routine screening for depression and substance abuse for youth 12 and older and 14 and older, respectively. Adolescents are more likely to reveal problems when completing screening tools than through general discussions with their pediatric provider.

https://www.aap.org/en-us/advocacy-and-policy/aap-healthinitiatives/Mental-Health/Documents/MH_ScreeningChart.pdf

1. Patient Health Questionnaire 9 (PHQ-9) modified for teens can be completed in less than 5 minutes and scored in less than 3 minutes, is freely available and screens for both depression and suicide.

http://www.pedpsychiatry.org/pdf/depression/PHQ-9%20 Modified%20for%20Teens.pdf. Accessed April 27, 2017.

2. CRAFFT can be administered as an interview or completed by adolescents and screens for substance use problems and disorders. It is in the public domain and can be accessed at http://www.ceasar-boston.org/CRAFFT/pdf/ CRAFFT_SA_English.pdf.

Jellinek MS: Universal mental health screening in pediatrics: toward better knowing, treating, or referring. J Am Acad Child Adolesc Psychiatry 2013;52(11):1131–1133 [PMID: 24157387].

Knight JR1, Sherritt L, Shrier LA, Harris SK, Chang G: Validity of the CRAFFT substance abuse screening test among adolescent clinic patients. Arch Pediatr Adolesc Med 2002 Jun; 156(6):607–614.

Assessment of Behavioral & Emotional Signs & Symptoms

When an emotional problem or mental illness is mentioned by the patient or parents, elicited by an interview, or identified by a screening instrument, the next step should include a more thorough triage. In a clinic with integrated care, a mental health professional may step in to complete this part of the evaluation. However, in other models such as telephone consultation, the pediatrician is often the one who completes this further assessment. The goal of this, more detailed assessment includes determining if the patient is safe to leave the office or if immediate intervention is required. Additionally, assessment information is used to make targeted referrals and recommendations for follow-up.

Situations Requiring Emergent or More Extensive Psychiatric Assessment

If there is any concern about the child's safety, the provider must also evaluate the risk of danger to self (eg, suicidal attempts or ideation), danger to others (eg, assault, aggression, or homicidal ideation), and screen for other factors that could heighten the risk of danger to self or others, such as physical or sexual abuse or illicit substance use or abuse. The presence of drug or alcohol abuse in adolescent patients may require referral to community resources specializing in the treatment of these addictive disorders.

The following questions should be asked of the youth. The parents should be asked similar questions about what they have observed. Specific details about the circumstances should be asked if any question below is answered with "yes."

- 1. Have you ever been sad for more than a few days at a time such that it affected your sleep or appetite?
- Have you ever been so sad that you wished you weren't alive?
- 3. Have you ever thought of ways of killing yourself or made a suicide attempt?
- 4. Have you ever thought about killing someone else, or tried to kill someone?
- 5. Has anyone ever hit you and left marks? (If yes, ask who, when, under what circumstances, and if it was reported.)
- 6. Has anyone ever touched your private areas when they weren't supposed to, or in a way that made you feel uncomfortable? (If yes, ask who, when, under what circumstances, and if it was reported.)
- 7. Do you use alcohol, tobacco, or illicit drugs? (If yes, ask what, when, with whom, and how much.)

A. Civil Commitment and Involuntary Mental Health "Holds"

If further assessment indicates a need for inpatient hospitalization, it is optimal if the patient and guardian give consent for this care. In a situation in which the guardian is unwilling or unable to give consent for emergency department (ED)-based assessment or inpatient hospitalization of a child or adolescent, an involuntary mental health "hold" may become necessary.

The term *involuitary mental health* "hold" refers to a legal process that can be initiated by providers, police officers, and certified mental health professionals, which allows the individual to be prevented from leaving the ED or hospital for up to 72 hours. This allows the provider to establish a safe environment and prevent the individual from harming themselves or others, and allows sufficient time for a formal assessment to determine if the individual is a risk to him- or herself or others due to mental illness, requiring further treatment. Each state has laws specifying rules and regulations that must be followed as part of this process. A specific form must be completed and the patient and family informed of their rights. As this involves revoking the civil rights of a patient or their guardian, it is critical to implement the procedure correctly. All providers should be familiar with their state's laws regulating this process.

Although the precise wording and conditions of involuntary mental health holds may vary slightly from state to state, they are generally quite similar. A 72-hour involuntary mental health hold is obtained for the purpose of acute evaluation and determination of the patient's safety when the evaluator elicits sufficient information to confirm that a significant risk exists of danger to self or others. Additional criteria for involuntary psychiatric admission include a determination that the patient is "gravely disabled" by virtue of impaired judgment, which renders the patient unable to provide food, clothing, or shelter for him- or herself, or in the case of a child or adolescent, that he or she is unable to eat and perform normal activities of daily living. Patients who have a medical condition(s) requiring urgent or emergent treatment do not require a mental health hold. In this case, the primary team/provider should conduct a capacity evaluation

B. Mandatory Reporting of Abuse or Neglect or Threat to Others

Mandatory reporting by a provider of suspicion of physical or sexual abuse or neglect to the local human services agency is discussed in greater detail in Chapter 8. The "Tarasoff Rule" refers to a California legal case that led to a "duty to warn": Providers, or specific sites in some states, are mandated to warn potential victims of harm when plans are disclosed to them about serious threats to harm specific individuals or to perform harmful acts at specific sites. Documentation of a phone call and registered letter to the individual (or site) being threatened are mandated. Under such circumstances, arrangement for the involuntary civil commitment of the potential perpetrator of harm is likely to be in order as well.

Examples of more thorough questions and observations are given in Table 7–2. Targeted assessment screening tools are also useful in determining severity, comorbidity, and context of impairment.

Once it is established that the patient does not need immediate intervention, the provider should determine if the patient's family can return for another visit, or if further assessment can be managed within this visit. Integrated care provides the distinct advantage of immediate further assessment within the primary care setting.

Further Evaluation of Emotional or Behavioral Problem

The following is a general guide for providers who do not have access to integrated behavioral health care and are evaluating a behavioral or emotional problem to determine

Table 7–2. Possible topics for discussion and observation when assessing psychosocial problem.

Developmental history

- 1. Review the landmarks of psychosocial development
- 2. Summarize the child's temperamental traits
- 3. Review stressful life events and the child's reactions to them
 - a. Separations from primary caregivers or close family members b. Losses
 - c. Marital conflict, family violence, divorce
 - d. Illnesses, injuries, and hospitalizations
 - e. Moves, household changes
 - f. School transitions
 - g. Traumatic events
 - h. Financial changes (eg, employment issues) that impact daily living environment
 - i. Resource issues including food insecurity, housing instability, and inability to make ends meet
- 4. Obtain details of past mental health problems and their treatment

Family history

- 1. Marital/relationship history
 - a. Overall satisfaction with the marriage/partnership
 - b. Conflicts or disagreements within the relationship
 - c. Quantity and quality of time together away from children
 - d. Whether the child comes between or is a source of conflict between the parents
 - e. Marital history prior to having children
- 2. Parenting history
 - a. Feelings about parenthood
 - b. Whether parents feel united in parenting the child
 - c. "Division of labor" in parenting
 - d. Parental energy or stress level
 - e. Sleeping arrangements
 - f. Privacy
 - g. Attitudes about discipline
 - h. Interference with discipline from outside the family (eg, ex-spouses, grandparents)
- 3. Stresses on the family
 - a. Problems with employment
 - b. Financial problems
 - c. Resource needs
 - d. Changes of residence or household composition
 - e. Illness, injuries, and deaths
- 4. Family history of mental health problems and treatment
 - a. Depression? Who?
 - b. Bipolar Disorder? Who?
 - c. Suicide attempts? Who?

- d. Psychiatric hospitalizations? Who?
- e. "Nervous breakdowns"? Who?
- f. Substance abuse or problems? Who?
- g. Nervousness or anxiety? Who?
- h. Other concerns about behavior or mental health problems in family members? Who?

Observation of the parents

- 1. Do they agree on the existence of the problem or concern?
- 2. Are they uncooperative or antagonistic about the evaluation?
- 3. Do the parents appear depressed or overwhelmed?
- 4. Can the parents present a coherent picture of the problem and their family life?
- 5. Do the parents accept some responsibility for the child's problems, or do they blame forces outside the family and beyond their control?
- 6. Do they appear burdened with guilt about the child's problem?

Observation of the child

- 1. Does the child acknowledge the existence of a problem or concern?
- 2. Does the child want help?
- 3. Is the child uncooperative or antagonistic about the assessment?
- 4. What is the child's predominant mood or attitude?
- 5. What does the child wish could be different (eg, "three wishes")?
- Does the child display unusual behavior (activity level, mannerisms, fearfulness)?
- 7. What is the child's apparent cognitive level?

Observation of parent-child interaction

- 1. Do the parents show concern about the child's feelings?
- 2. Does the child control or disrupt the joint interview?
- 3. Do the parents set appropriate limits?
- 4. Does the child respond to parental limits and control?
- 5. Do the parents inappropriately answer questions addressed to the child?
- 6. Is there obvious tension between family members?

Data from other sources

- 1. Waiting room observations by office staff
- 2. School (teacher, nurse, social worker, counselor, day care provider)
- 3. Department of social services
- 4. Other caregivers: grandparents, etc.

appropriate next steps. Simple problems may not require all the steps described later. Table 7–2 reminds pediatricians of topics that might be helpful to consider when assessing problems. Given time limits, the pediatrician is encouraged to focus the discussion to inform decision making for next steps with the patient and family.

It is often useful to first see parents/caregivers, if present, and the child together and then, depending on the age, the child alone. In some cases, it may be necessary to speak with the parents privately, without the child present. This sequence enables the provider to observe interactions among family members, allows the child to feel more comfortable with the provider, and offers the parents and the child an opportunity to talk confidentially about their concerns. The provider can facilitate the assessment by acknowledging that the family is trying to cope and that the ultimate task

of assessment is to identify solutions that will help improve things for both the child and family. An attitude of nonjudgmental inquiry can be communicated with supportive statements such as, "Let's see if we can figure out what might be happening here and find some ways to make things better."

A. History of the Presenting Problem

First, obtain a detailed description of the problem.

- When did it start?
- Where and with whom does it occur?
- Were there unusual stresses, changes, or life events at that time?
- How is the child affected?
- How is the family's function affected?
- What does the child say about the problem?
- What attempts have been made to alleviate the problem?
- Do the parents have any opinions about the cause of the problem?

B. Techniques for Interviewing Children and Adolescents

1. Interviewing the preschool child—Preschool children should be interviewed with their parents. As the parents discuss their concerns, the provider can observe the child's behavior, including activity level and any unusual behaviors or symptoms. It is helpful to have toy human figures, animals, or puppets, and crayons and paper available that the child can use to express him- or herself. After hearing the history from the parents and observing and talking with the child, the provider can begin to develop an impression about the problem and formulate a treatment plan to discuss with the family. Although the child should not be interviewed separately, the parent may need to discuss sensitive issues with the provider privately. Some children can tolerate playing with another provider or staff member, while their parent talks to the provider.

2. Interviewing the school-aged child—Most schoolaged children have mastered separation anxiety sufficiently to tolerate at least a brief interview alone with the provider. In addition, they may have important information to share about their own worries. The child should be told beforehand by the parents or provider (or both) that the doctor will want to talk to the child about his or her feelings. Schoolaged children understand and even appreciate parental concern about unhappiness, worries, and difficulty in getting along with people. At the outset, it is useful to explore the child's thoughts about certain issues raised by the parents and ask whether the child thinks that a problem exists (eg, unhappiness, anxiety, or sleep disturbance), and if there are any other concerns. The provider should ask the child to describe the problem in his or her own words and ask what he or she thinks is causing the problem. It is important to ask the child how the problem affects the child and the family. At the end of the interview with the child, it is important to share or reiterate the central points derived from the interview and to state that the next step is to talk with the parents about ways to make things better for the child. At that time, it is good to discuss any concerns or misgivings the child might have about sharing information with parents so that the child's right to privacy is not arbitrarily violated. Most children want to make things better and thus will allow the provider to share appropriate concerns with the parents.

3. Interviewing the adolescent—The provider usually begins by meeting briefly with the parents and adolescent together to define the concerns. Because the central developmental task of adolescence is to create an identity separate from that of the parents, the provider must show respect for the teen's point of view. The provider should then meet alone with the adolescent or at least give the teen the option. After the provider has interviewed the adolescent and talked further with the parents, he or she should formulate thoughts and recommendations. Whenever possible, it is helpful to discuss these with the adolescent before presenting them to the parents and teen together. The issue of confidentiality must be discussed early in the interview: "What we talk about today is between you and me unless we decide together that someone should know or unless it appears to me that you might be in a potentially dangerous situation." Exceptions to confidentiality should also be discussed with the teen.

The interview with the adolescent alone might start with a restatement of the parents' concerns. The teen should be encouraged to describe the situation in his or her own words and say what he or she would like to be different. The provider should ask questions about the adolescent's primary concerns, predominant mood state, relationships with family members, level of satisfaction with school and peer relationships, plans for the future, drug and alcohol use, and sexual activity.

In concluding the interview, the provider should summarize his or her thoughts and develop a plan with the teenager to present to the parents. If teenagers participate in the solution, they are more likely to work with the family to improve the situation. This should include a plan either for further investigation or for ways of dealing with the problem and arranging subsequent appointments with the provider or an appropriate referral to a mental health care provider.

C. Targeted Screening Tools and Assessment Measures

As with broad screening tools, targeted screening tools or assessment instruments can be very valuable in the clinic since they are standardized and allow for the assessment of current symptoms and severity. They can also be useful for following or reassessing a patient's progress after initiation of treatment.

1. Vanderbilt assessment scales for attention-deficit/ hyperactivity disorder—These scales are included in the American Academy of Pediatrics/National Initiative for Children's Health Quality (AAP/NICHQ) Attention-Deficit/Hyperactivity Disorder Practitioner's Toolkit, available at http://www.nichq.org/childrens-health/adhd/ resources/vanderbilt-assessment-scales.

2. Center for epidemiologic studies depression scale for children (CES-DC)—Available at http://www.brightfutures. org/mentalhealth/pdf/professionals/bridges/ces_dc.pdf.

3. Self-report for childhood Anxiety-Related Emotional Disorders (SCARED)—Available at http://www.psychiatry. pitt.edu/research/tools-research/assessment-instruments.

4. Other Tools

A. BRIGHT FUTURES—The Bright Futures Tool Kit has numerous guidelines, tools, and other resources for identifying mental health concerns. Available at http://www.brightfutures.org/mentalhealth/pdf/tools.html.

B. EDINBURGH POSTNATAL DEPRESSION SCALE—The scale is used widely as a screening instrument for pregnancyrelated depression (PRD) and anxiety. It measures emotional and cognitive symptoms of PRD and anxiety and demonstrates moderate to good reliability and validity across diverse samples.

- Boyd RC, Le HN, Somberg R: Review of screening instruments for postpartum depression. Arch Womens Ment Health 2005;8(3):141–153 [PMID: 16133785].
- Cox JL, Holden JM, Sagovsky R: Detection of postnatal depression. Development of the 10-item Edinburgh Postnatal Depression Scale. Br J Psychiatry 1987;150:782–786 [PMID: 3651732].

c. DISORDER-SPECIFIC SCREENING TOOLS—Useful tools for evaluating other mental health concerns, such as obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and autism spectrum disorders, can be found at the following websites: http://www.mass.gov/eohhs/consumer/insurance/cbhi/cbhi-screening/ masshealth-approved-screening-tools/.

The Mental Status Examination

The Mental Status Examination (MSE) is a tool equivalent to the physical examination. It includes some standard aspects to help evaluate an individual, including observation of an individual's overall cognitive, emotional, and behavioral presentation. Through observations, interaction, and questions, the MSE identifies current behavioral presentation and areas of clinical concern (eg, suicidal thinking, hallucinations). Depending on the presenting problem, pediatricians may choose to document a complete MSE or a focused MSE. Please refer to standard elements of MSE (Table 7–3).

Diagnostic Formulation & Interpretation of Findings

Diagnosis, the final product of an assessment, starts with a description of the presenting problem, which is then evaluated within the context of the child's age, developmental abilities, the context in which a child exists, including adverse experiences and stressors that impact the child and the family, and the functioning of the family system.

In the absence of integrated mental health providers, the primary care provider uses the information gathered to distinguish among the following possible explanations for the emotional or behavioral problem(s):

- 1. The behavior falls within the range of normal given the child's developmental level.
- 2. The behavior is a temperamental variation.
- 3. The behavior is related to central nervous system impairment (eg, prematurity, exposure to toxins in utero, seizure disorder, or genetic disorders).
- 4. The behavior is a normal reaction to stressful circumstances (eg, medical illness, change in family structure, or loss of a loved one).
- 5. The behavior is related to relationship problems within the family.
- 6. The problem is complicated or exacerbated by an underlying medical condition.
- 7. The problem reaches threshold for a diagnosis.
- 8. Some combination of the above.

While it is not necessary to identify a diagnosis in order to refer a patient to a mental health provider, it is important to identify any diagnosis that may be addressed within the community pediatric setting, such as attention-deficit/ hyperactivity disorder (ADHD), mild anxiety, mild depression and mild adjustment disorders. This involves deciding whether particular behaviors or symptoms constitute a pattern consistent with a diagnosis. For example, how hyperactive must a 5-year-old child be before he or she is hyperactive enough to meet diagnostic criteria for ADHD? Providers use caregiver reports of behaviors and symptoms in combination with their clinical observations and assessments of duration, severity, and impairment to determine what, if any, is the correct diagnosis. When a child's functioning is impaired in major domains of life, such as learning, peer relationships, family relationships, authority relationships, and recreation,

Table 7–3. Standard elements of mental status examination.

Category	Description	Questions to Ask/Observations to Document
General appearance	Physical presentation, attitude and how the child carries themselves (observation, interaction).	Does the child look their stated age? Document physical size compared to peers, dysmorphic features, grooming, cooperation, level of distress, and quality of interaction.
Eye contact	Quality of eye contact in context (observation, interaction).	Observe and document quality of eye contact, eg, good, fair or poor. Is gaze fixed?
Psychomotor activity	Overall energy and physical movement (observation).	Document whether activity level is normal, slowed, or increased.
Musculoskeletal	Gait, range of motion (extremities), abnormal movements (observation and directed tasks).	Document gait and the presence of any rigidity, ataxia, tics, or other abnormal movements.
Speech/language	Rate, volume, tone, articulation, coherence and spontaneity; appropriate naming and word usage (observation).	Observe and document pattern and quality of speech.
Mood/affect	Subjective (child's stated mood); objective (clinician's observation of affect) and how well the two correspond (observation, direct questioning, and optional self-report questionnaire).	Is the child able to identify their mood, happy, sad, angry, anxious? Is the child's affect congruent with mood? What is the observed range of affect?
Thought process; associations	Rate, relevance and reasoning (observation).	Are the child's thoughts goal-directed, logical, tangential, or circumferential? How does the child reason and problem solve? Is thought process concrete or does the child demonstrate abstract reasoning?
Thought content	Content of what the child is actually saying (observation).	Does the child express suicidal or homicidal ideation, and if so, is there intent and a plan? Does the child experience obsessions? Does the child experience perceptual abnormalities such as, hallucinations or illusions.
Attention span	Child's ability to stay on task, focus, and concentrate (observation).	Does the child have an age-appropriate attention span? Is the child able to stay on task or are they easily distracted?
Insight; judgment	Child's psychological understanding of his/her situation; ability to make safe and appropriate choices based on situation (observation and response to directed questions).	What is the child's capacity for insight into his/her situation (intact, poor, impaired)?
Orientation	Awareness of oneself, location, date and reason for care (observation and response to directed questions).	Does the child know where he/she is, the date, who he/she is, who the parents are?
Fund of knowledge; memory	Common knowledge, ability to recall long-term events and recent details (observation and response to directed questions).	Response to direct questions about current events and memory.
Cognition	Intelligence	Results of cognitive testing (from outside source), assessment of intellectual capacity based on interaction, and other sources of information (average, below average, above average for age and level of education).

or when substantial deviation from typical developmental trajectories occurs, a differential diagnosis may be consid-ered based on the symptom profile. Identifying and discussing the diagnosis is often the begin-ning of initiating treatment. The provider's interpretation

of the presenting problem and diagnosis in the context of current family circumstances and available resources and supports enhances referral uptake, engagement in treatment, and coordinated care. The interpretive process includes the following components:

- 1. Psychoeducation: An explanation of how the presenting problem or symptom is a reflection of a suspected cause, and typical outcomes both with and without intervention.
- 2. A discussion of possible interventions, including the following options:
 - a. Close monitoring
 - b. Counseling provided by the primary care provider or integrated mental health provider
 - c. Referral to a mental health professional outside of the primary care clinic
 - d. Initiation of medication
 - e. Some combination of the above
- 3. A discussion of the parent's and adolescent's response to the diagnosis and potential interventions.

A joint plan involving the provider, parents, and child is then negotiated to address the child's symptoms and developmental needs in light of the family structure and stresses. If an appropriate plan cannot be developed, or if the provider feels that further diagnostic assessment is required, referral to a mental health practitioner should be recommended.

A. Referral of Patients to Mental Health Professionals

Primary care providers often refer patients to a child and adolescent psychiatrist or other qualified child mental health professional when the diagnosis or treatment plan is uncertain, or when medication is indicated and the pediatrician prefers that a specialist initiate or manage treatment of the mental illness (Table 7–4). For academic difficulties not associated with behavioral difficulties, a child educational psychologist or multidisciplinary learning disorder team may be most helpful in assessing patients for learning disorders and potential remediation. For cognitive difficulties associated with head trauma, epilepsy, or brain tumors, a referral to a pediatric neuropsychologist may be indicated.

Table 7–4. When to consider consultation or referral to a child and adolescent psychiatrist.

The diagnosis is not clear

- The pediatrician feels that further assessment is needed
- The pediatrician believes medication may be needed, but will not be prescribing
- The pediatrician has started medications and needs further psychopharmacologic consultation

Individual, family, or group psychotherapy is needed

Psychotic symptoms (hallucinations, paranoia) are present

- Bipolar affective disorder is suspected
- Chronic medical regimen nonadherence

Patients who are publicly insured or do not have mental health insurance coverage can usually be assessed and treated at their local mental health care center. Patients with private mental health insurance typically need to contact their insurance company for a list of local mental health professionals trained in the assessment and treatment of children and adolescents who are on their insurance panel. The referring pediatrician or staff should assist the family by providing information to put them in touch with the appropriate services. Personal relationships between staff or providers in the primary care office and community mental health administrators improve the success of referrals. Systems of care in which mental health professionals are co-located in the clinic remove barriers and improve access and care (see earlier discussion). In addition, there are many levels of care between involuntary inpatient psychiatric hospitalization and outpatient treatment including the following: day treatment hospitalization, home-based care, intensive outpatient, and primary care management. The pediatrician should arrange a follow-up visit, after a referral has been made, to monitor if the family was able to establish care with the mental health provider, and to help troubleshoot any barriers to care.

Pediatricians who feel comfortable implementing the recommendations of a mental health professional with whom they have a collaborative relationship should consider remaining involved in the management and coordination of treatment of mental illness in their patients. The local branches of the American Academy of Child and Adolescent Psychiatry and the American Psychological Association should be able to provide a list of mental health professionals who are trained in the evaluation and treatment of children and adolescents.

B. Other Resources

The Partnership Access Line (PAL) Washington website (www.palforkids.org) is another useful tool to assist the primary care provider in diagnosis and treatment of the more common psychiatric conditions. The PAL algorithms provide decision trees and guidance for treating specific diagnoses, considering alternative diagnoses in the differential, and reviewing medication treatment tables for specific information regarding psychopharmacologic treatments.

Integrated Care for Kids is a resource center to promote the integration of behavioral/mental health services by providing ready access to needed resources to interested professionals in different disciplines who are working in a variety of settings (http://integratedcareforkids.org).

PSYCHIATRIC DISORDERS OF CHILDHOOD & ADOLESCENCE

A psychiatric disorder is defined as a characteristic cluster of signs and symptoms (emotions, behaviors, thought patterns, and mood states) that are associated with subjective distress or maladaptive behavior. This definition presumes that the symptoms are of such intensity, persistence, and duration that the ability to adapt to life's challenges is compromised.

Psychiatric disorders originate in neurobiologic, genetic, psychological (life experience), and/or environmental sources. The neurobiology of childhood disorders is one of the most active areas of investigation in child and adolescent psychiatry. Although much remains to be clarified, data from genetic studies point to heritable transmission of ADHD, schizophrenia, mood and anxiety disorders, eating disorders, pervasive developmental disorders, learning disorders, and tic disorders, among others. About 3%–5% of children and 10%– 15% of adolescents will experience psychiatric disorders.

The Diagnostic and Statistical Manual of Mental Disorders, 5th ed (DSM-5), the formal reference text for psychiatric disorders, includes the criteria for each of the mental illnesses, including those that begin in childhood and adolescence. The five-axis model used in the previous manual, DSM-IV-TR has been replaced by the DSM-5, which only requires a single psychiatric diagnosis. Of note, primary care providers frequently see a spectrum of disturbances in their clinical practice, many not achieving full DSM-5 criteria.

Special Considerations in Prescribing Psychotropic Medications

As pediatricians will often manage mental health issues in the primary care setting, a large portion of the management may involve medication treatment. Each primary care provider must establish their comfort level in prescribing psychotropic medications. Table 7–5 includes commonly

Drug or Class	Comfort Initiating	Comfort Managing
Stimulants	+++	+++
α-Agonists	++	+++
Antidepressants	+	++
Atypical antipsychotics	Recommend psychiatrist involvement	++
Typical antipsychotics	Requires psychiatrist involvement	+/-

ANXIETY DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fear or anxiety that is excessive or persisting beyond developmentally appropriate period.
- ► Fear or anxiety is accompanied by behavioral disturbances or physical manifestations.
- Symptoms cause functional impairment or significant distress.

Anxiety is described as the anticipation of future threat and fear is described as the emotional response to real or perceived imminent threat. Both are protective emotions, part of the normal repertoire of children. Distinguishing developmentally appropriate fears and anxiety from those

Table 7–6. Psychoactive medications approved by the FDA for use in children and adolescents.^a

associated with anxiety disorders can be challenging and requires knowledge of normative development. Generally, fears or anxiety that persists beyond the expected developmental period, or cause significant distress or impairment suggest an anxiety disorder. Some anxiety disorders are more likely to be precipitated by stress, but many are not. An anxious temperament can be identified as early as infancy, and children with such temperaments are more likely to develop anxiety disorders, especially if they are living with anxious parents. Community-based studies of school-aged children and adolescents suggest that nearly 10% of children have some type of anxiety disorder. Anxiety disorders are important to identify and treat early as untreated disorders often persist or evolve into other anxiety disorders.

Identification & Diagnosis

Comorbidity is common with anxiety disorders: Children with one anxiety disorder are likely to have another anxiety disorder and have increased risk for other psychiatric disorders such as depression. It is therefore important to carefully screen children with an anxiety disorder to insure that another disorder is not missed. In addition, children with anxiety, presenting to a pediatrician, are more likely to present with a physical complaint, such as headaches or abdominal pain than with identified anxiety (Table 7–7). While medical causes of anxiety are rare, it is important not to misdiagnose a physical symptom as anxiety; for example, to ascribe the gastrointestinal (GI) upset of inflammatory bowel disease, to anxiety. Screening should also assess for

Table 7–7. Signs and symptoms of anxiety in children.

Psychological
Fears and worries
Increased dependence on home and parents
Avoidance of anxiety-producing stimuli
Decreased school performance
Increased self-doubt and irritability
Frightening themes in play and fantasy
Psychomotor
Motoric restlessness and hyperactivity
Sleep disturbances
Decreased concentration
Ritualistic behaviors (eg, washing, counting)
Psychophysiologic
Autonomic hyperarousal
Dizziness and lightheadedness
Palpitations
Shortness of breath
Flushing, sweating, dry mouth
Nausea and vomiting
Panic
Headaches and stomach aches

medications and substances that can cause anxiety. Substances include caffeine, marijuana, amphetamines, cocaine, and alcohol during withdrawal. Medications that have been associated with anxiety include steroids, tacrolimus, angiotensin-converting enzyme inhibitors, anticholinergics, dopamine agonists, β -adrenergic agonists, serotonin selective reuptake inhibitors, thyroid medications, and procaine derivatives. Medical illnesses that can lead to symptoms suggestive of anxiety include those associated with hyperthyroid states, hypoglycemia, hypoxia, and more rarely, pheochromocytoma.

Treatment

Treatment must be tailored to the developmental age of the child. Treatment of younger children focuses on helping parents understand their child's symptoms, developing skills to help their child manage distress, while also helping parents tolerate their child's distress. As soon as children have the developmental capacity to engage in assessing their own anxiety and in learning coping strategies, they are incorporated into therapy.

Cognitive behavioral therapy (CBT) with exposure has the most evidence regarding the successful treatment of anxiety. Exposure refers to planned progressive presentation of low- to mid-level anxiety-provoking stimulus. The aim is to desensitize the child to the stimulus. CBT can be delivered in group settings, or with an individual child and parents. The basic goals include helping children identify and quantify anxiety symptoms, identify maladaptive cognitions, learn cognitive, and behavioral coping strategies to begin exposures to situations or items associated with medium- to low-level anxieties. Parents or caregivers also learn these skills in order to help children or youth practice in settings outside the therapy office. The ultimate goal is to enable the child to face the particular anxiety or set of anxieties that are causing distress or dysfunction, experience a decrease in anxiety, and resume normal functioning.

When anxiety symptoms do not remit with cognitive, behavioral, and environmental interventions, and continue to significantly affect life functioning, psychopharmacologic agents may be helpful. There is evidence that SSRIs are effective in treating anxiety disorders in children as young as 6 years of age, but these medications do not have FDA approval for this indication. The anxiolytic effect of SSRIs can be as rapid as a few days, whereas the effects of benzodiazepines are immediate. Pediatricians are aware of this immediate effect, but the use of benzodiazepines while waiting for the anxiolytic effects of SSRIs is discouraged with youth because the developing brain is at increased risk for dependency and iatrogenic substance abuse. Alpha agonists are an alternative that can be used on a scheduled or asneeded based, and usually are better tolerated without concern for physiologic dependence. Please refer to medication

	Flue	oxetine considered	d first line due to s	tronger evidence l	oase in children	
Sertraline (Zoloft)	25, 50, 100 mg 20 mg/mL	25 mg/day (200 mg max) [*]	25–50 mg**	Yes	No	May be prone to side effects when stopping
Escitalopram (Lexapro)	5, 10, 20 mg 5 mg/5 mL	5 mg/day (20 mg max) [*]	5–10 mg**	Yes	Yes (for adolescents)	The active isomer of citalopram.
Escitalopram and Sertraline considered second line per the evidence base in children						
Citalopram (Celexa)	10, 20, 40 mg 10 mg/5 mL	10 mg/day (40 mg max) [*]	10–20 mg**	Yes	No	Few drug interactions
Bupropion (Wellbutrin)	75, 100 mg 100, 150, 200 mg SR forms 150, 300 mg XL forms	75 mg/day (later dose this BID) (400 mg max)*	75–100 mg**	No	No	Can have more agitation risk. Avoid if eat d/o. Also has use for ADHD treatment.
Mirtazapine (Remeron)	15, 30, 45 mg	15 mg/day (45 mg max) [*]	15 mg**	No	No	Sedating, increases appetite
Venlafaxine (Effexor)	25, 37.5, 50, 75, 100 mg 37.5, 75, 150 mg ER forms	37.5 mg/day (225 mg max)*	37.5–75 mg**	No (May have higher SI risk than others for children)	No	Only recommended for older adolescents. Withdrawal symptoms can be severe.
Other above considered third line treatments per the evidence base in children						

Starting doses in children less than 13 may need to be lowered using liquid forms.

Successful medication trials should continue for 6 to 12 months.

*Recommend decrease maximum dosage by around 1/3 for pre-pubertal children

**Recommend using the lower dose increase increments for younger children

Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, spring 2018. version 7.1. Seattle Children's Hospital.

used for treatment of depressive disorders (Table 7–8) as they are commonly used in the treatment for anxiety as well.

Prognosis

Early treatment of anxiety disorders can be very effective and decreases the risk for negative impact on developmental trajectories or the development of other psychiatric disorders. The standard of care is CBT for milder cases and a combination of CBT/antidepressant for more severe cases or cases that do not respond to CBT alone.

The life course of anxiety disorders is as follows. Anxiety disorders that present in childhood tend to wax and wane during childhood, but patients who present with more severe symptoms often develop several anxiety disorders during adolescence and are at risk for depression, substance abuse and other negative developmental outcomes. Parenting style may contribute to anxiety; specifically, autonomy granting is more likely to result in less anxious children, whereas harsh or rejecting parenting results in more anxious children. Treatment of parental anxiety disorders when present improves the outcome of the child's anxiety disorder.

As mentioned earlier, the PAL Washington is a great resource for primary care providers. The site includes treatment algorithms and related information for the diagnosis and treatment of commonly encountered mental health disorders. To illustrate this point, the treatment algorithm for anxiety disorders is included in Figure 7–1.

Figure 7–1. Treatment algorithm for children and adolescents with anxiety. (Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, spring 2018. version 7.1. Seattle Children's Hospital.)

1. Separation Anxiety

- Persistent excessive worry about losing or being separated from attachment figures, due to harm, illness, or death befalling either the attachment figure or the patient.
- Reluctance or refusal to leave the attachment figure or sleep away from the attachment figure.
- Fear of being home without attachment figure.
- Physical complaints when separation occurs or is anticipated.

General Considerations

Younger children may not be symptomatic until the separation is imminent, and may not experience explicit fears related to separation. As children get older, they may experience specific fears such as fears of kidnapping, parents getting into car accidents, being separated due to natural disasters, etc. Behaviors associated with separation anxiety also vary by age; young children are more likely to present with difficulties around the separation of sleep and for older children other separations, such as school, sleep overs, and camp, may be the focus of anxiety. In addition to appearing anxious, children with separation anxiety can appear sad, aggressive, or experience physical symptoms when facing the anxiety-provoking separation. Separation anxiety disorder is more prevalent in younger children (4% 6-month prevalence compared with 1.6% 6-month prevalence in adolescence).

Identification & Diagnosis

Anxiety about separation from attachment figures is part of early normative development. Separation anxiety disorder must be distinguished from normal development, must occur for more than 4 weeks for children, and lead to impairment or significant distress.

Treatment

Parents often try to alleviate symptoms caused by separation anxiety and are important to include in treatment. Treatment of separation anxiety includes CBT that is modified to address the developmental level of the child. Children who do not respond to therapy may require medication such as an SSRI. Children younger than school age are generally not treated with medication.

Other Considerations

The differential for separation anxiety is broad and includes other anxiety disorders, mood disorders, oppositional defiant disorder, conduct disorder, psychotic disorder, and personality disorders. Pediatricians are likely to encounter children with school refusal, a common behavioral manifestation of separation anxiety. It is important to recognize and intervene early with school refusal as the longer a child is out of school, the more difficult it is to help the child return to school. Symptoms of school refusal often include physical symptoms and or behavioral outbursts as school time approaches. Parents often notice symptoms abate on the weekend, vacations, or if the child is no longer expected to attend school. Mild cases may be handled with the help of the pediatrician's office, but more severe cases may need the help of a mental health specialist.

School refusal can also be related to other anxiety disorders, learning disorders, mood disorders, psychotic disorders, oppositional defiant disorder, conduct disorder and environmental stressors such as bullying or poor student teacher fit. Identifying the etiology of school refusal helps providers appropriately target the level and type of intervention.

Prognosis

Separation anxiety often abates by adolescence, but adolescents who experienced separation anxiety disorder in childhood are at increased risk to develop other disorders.

2. Selective Mutism Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Consistent failure to speak in social settings (such as school) where this is expected, despite speaking in other settings.

General Considerations

Selective mutism is more frequent in younger children. Symptoms may be present before 5, but usually do not lead to problems until the child enters school. Immigrant children or other children who initially learned one language and are expected to function in the school setting in a second language may present with selective mutism.

Identification & Diagnosis

Children with selective mutism usually speak with close family members and may also speak with a "best" friend. They may be quite outgoing within this comfortable setting, but are often shy outside of this setting, and can be comfortable with social roles that do not require verbal communication. Children with selective mutism can become angry and aggressive when facing a demand to speak. Screening for selective mutism is useful as families may not be aware of the problem, or may not appreciate that it is interfering with function at school. To meet criteria for selective mutism, symptoms must interfere with function in school, work, or social communication, and must last longer than 1 month, not including the first month of school. Symptoms cannot be due to autism, a communication disorder or psychotic disorders.

Treatment

This disorder can be perplexing for parents and teachers as the child's engagement in speaking can vary significantly across settings. Treatment therefore usually begins with psychoeducation. Children with selective mutism can be difficult to engage due to their shyness, so clinicians must be adept at using both verbal and nonverbal methods to form an alliance with the child. CBT with exposure aimed at increasing verbal interactions can be very successful. Patients with more severe symptoms, or symptoms that do not respond to therapy, may benefit from an SSRI.

Other Considerations

The differential diagnosis includes other disorders that can interfere with speech, such as autism, communication disorders, and psychotic disorders. Children with selective mutism can have other comorbid anxiety disorders, such as social anxiety disorder, separation anxiety, and specific phobia.

Recognition and treatment of selective mutism is critical as the longer a child avoids verbal communication in settings outside of the family, the more entrenched this behavior becomes. Children with untreated selective mutism are at risk for depression, social anxiety disorder, and substance abuse as adolescents.

3. Specific Phobias

- Excessive fear or worry about a certain thing, experience, or situation.
- The thought about or exposure to this trigger causes excessive anxiety.

General Considerations

Specific phobias are common, impacting 5% of children and 16% of adolescents. Simple phobias often lessen over time, but more severe, persistent forms can be debilitating.

Identification & Diagnosis

Specific phobia is an intense fear of a particular thing, experience, or situation that lasts for at least 6 months. This object or situation is a cause of great distress nearly every time the individual anticipates or is exposed to the stimulus. The perceived harm or threat is well out of proportion to the actual stimulus. To handle the distress, the child avoids the object or situation, therefore reinforcing the anxiety. The distress caused by the stimulus can also present as a panic attack, fainting, or irritability. Young children may present with increased clinginess.

Treatment

The mainstay of treatment for specific phobias is CBT aimed at reducing anxiety or fear of the phobic stimulus.

Other Considerations

Children commonly experience more than one specific phobia and as the number of phobias increases, so does the degree of impairment. The differential diagnosis includes other anxiety disorders, trauma, and stress-related disorders, eating disorders, schizophrenia, and other psychotic disorders.

Significant childhood separation events are associated with later onset of phobia. Addressing specific phobia is important as untreated specific phobia have one of the higher rates of stability over time among childhood anxiety disorders.

4. Panic Disorder

Recurrent, unexpected panic attacks, described as an abrupt onset of intense fear, that crescendos over the course of minutes and is accompanied by physical symptoms.

General Considerations

Panic disorder is more likely to present after the onset of puberty with a prevalence rate of 2%–3% during adolescence. Unlike many other anxiety disorders, there is more likely to be a stressor preceding the onset of panic disorder. Children who experience separation anxiety disorder are at increased risk to develop panic disorder.

Identification & Diagnosis

The physical symptoms of panic disorder are symptoms of a surge in the adrenergic system and include palpitations, sweating, shortness of breath, choking, chest pain or tightness, GI distress, dizziness or associated feelings, chills or heat, numbness, or tingling. Cognitive symptoms can include feelings of unreality, fear of going crazy, or of dying. To meet criteria for a panic attack, at least four of the above symptoms must be present, and individuals with panic disorder experience a fear of or related to future attacks that leads to maladaptive behavior. Youth with panic disorder are most likely to present to the pediatrician with fears related to physical symptoms of autonomic arousal, such as a fear that there is something wrong with their heart. Adolescents are less likely than adults to report panic attacks and thus specific questions questionnaires should be used when adolescents present with anxiety.

Although over time, individuals with panic disorder can come to expect panic attacks tied to certain cues, they must experience at least some unexpected panic attacks that seem to come out of the blue.

Treatment

CBT for youth with panic disorder focuses on the cognitions associated with the panic attack as well as the physiologic distressing symptoms. Exposure targets may include situations that trigger panic attacks, or some of the physiologic symptoms experienced during an attack. The frequency of treatment can vary depending on the acuity of the patient, with lower levels of care provided during weekly outpatient therapy and higher levels provided several times a week through intensive outpatient treatment programs or daily in day treatment programs. Patients who do not respond to therapy alone may benefit from an SSRI. Benzodiazepines have been used with adults but are discouraged for use with youth in the primary care setting.

Other Considerations

The differential diagnosis of panic attacks includes a physical cause of panic symptoms. This must be ruled out when appropriate. Panic disorder can be debilitating as youth can go to extensive lengths to avoid cues. Youth who avoid going out in public by themselves, should be diagnosed with agoraphobia in addition to panic disorder. Although panic disorder increases the risk of developing a substance abuse disorder, withdrawal of some substances can also lead to panic symptoms. For adolescents who are actively using, this can be difficult to distinguish. Panic attacks can present as part of other anxiety disorders, but the panic attacks in other disorders are cued by the underlying fear or anxiety, such as public performance in social anxiety disorder, or anticipation of an event in generalized anxiety disorder. Panic disorder is higher among individuals with other anxiety disorders, depression, and bipolar disorder.

Prognosis

Panic symptoms and panic disorder are both important to recognize and treat. Untreated panic disorder has the highest rate of stability over time among childhood anxiety disorders. Individuals with panic symptoms that occur in the context of another disorder are at increased risk to develop depression.

5. Agoraphobia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- An excessive fear of being in a situation where panic-like symptoms might occur.
- Avoidance of situations that can cause panic attacks.

General Considerations

Agoraphobia can be debilitating. In children and adolescents, it is more likely to present as school refusal than fear of the other situations listed below. Children and adolescents may be reluctant to report symptoms, so a careful screening is warranted for anxious children, or children who are refusing to attend school. In community samples, agoraphobia is more likely to occur in later adolescence; 1.7% of adolescents suffer from agoraphobia, but this may be an underestimate because of the difficulty of assessing youth. Similar to panic disorder, initial symptoms often are triggered by a stressful event.

Identification & Diagnosis

The most well-known fear associated with agoraphobia is fear of open spaces, including the market place. For individuals with agoraphobia, other situations can also trigger intense fear, such as using public transportation, standing in line or being in a crowd, being in an enclosed space, or outside the home alone. Individuals with agoraphobia experience two or more of these fears that last for over 6 months and lead to distress or impairment. Full panic disorder symptoms do not have to be present to meet criteria for agoraphobia.

Treatment

Treatment of individuals with agoraphobia can be very challenging, as treatment typically requires leaving home. Online treatments are available with limited data on efficacy. The current standard remains CBT with exposure, and SSRI for individuals who do not respond to treatment or are severely impacted by agoraphobia.

Other Considerations

The differential diagnosis includes other anxiety disorders, PTSD, depression, and medical conditions. For example,

CHAPTER 7

adolescents with postural orthostatic tachycardia syndrome (POTS) may fear leaving the house, due to a fear of fainting, or individuals with inflammatory bowel disease may fear diarrhea.

Prognosis

Individuals with agoraphobia are at risk for comorbid disorders including other anxiety disorders and depression, and males have a high incidence of substance abuse.

6. Generalized Anxiety Disorder (GAD)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Multiple, intense, disproportionate, or irrational worries, often about future events.
- ► Worry is accompanied by other symptoms.
- ► The worry is difficult to control.

General Considerations

Individuals with generalized anxiety disorder often recall a lifetime of anxiety, but community samples find GAD rarely presents before adolescence; the prevalence of GAD in adolescence is 0.9%. Potential reasons for this discrepancy include that the symptoms of anxiety may not meet full criteria for GAD at an earlier age, or symptoms may be underestimated by parents or guardians. Individuals who develop GAD at an early age are more likely to have greater impairment.

GAD is highly heritable, overlapping with the risk for depression and neuroticism. In addition anxious overprotective parenting increases the risk of GAD, but is not necessary for the development of the disorder.

The differential diagnosis of symptoms of anxiety is presented in Table 7–9.

Identification & Diagnosis

Young children with generalized anxiety often worry about their competence or performance while older youth may worry about additional issues such as family finances or being on time. Worry and anxiety that is not pathological must be distinguished from the worries or anxieties of GAD. In addition, children with GAD experience at least one symptom of fatigue, restlessness or poor concentration, irritability, feeling on edge, or sleep disturbance. GAD can also be accompanied by other somatic symptoms and the

Table 7–9. Differential diagnosis of symptoms of anxiety.

Normal developmental anxiety

- A. Stranger anxiety (5 mo $-2\frac{1}{2}$ y, with a peak at 6-12 mo)
- B. Separation anxiety (7 mo-4 y, with a peak at 18-36 mo)
- C. The child is fearful or even phobic of the dark and monsters (3-6 y)
- "Appropriate" anxiety
- A. Anticipating a painful or frightening experience
- B. Avoidance of a reminder of a painful or frightening experience
- C. Child abuse
- Anxiety disorder (see Table 7–11), with or without other comorbid psychiatric disorders
- Substance abuse
- Medications and recreational drugs
- A. Caffeinism (including colas and chocolate)
- B. Sympathomimetic agents
- C. Idiosyncratic drug reactions
- Hypermetabolic or hyperarousal states
- A. Hyperthyroidism
- B. Pheochromocytoma
- C. Anemia
- D. Hypoglycemia
- E. Hypoxemia
- Cardiac abnormality
- A. Dysrhythmia
- B. High-output state
- C. Mitral valve prolapsed

pediatrician is more likely to encounter children with GAD who present with symptoms of GI difficulties or headaches. To meet criteria for GAD, the symptoms must cause significant distress or disturbance of function and be present for at least 6 months.

Treatment

As with other anxiety disorders psychotherapy is the firstline treatment, with the possible addition of an SSRI if the response is insufficient.

Other Considerations

It can be challenging to distinguish GAD from other anxiety disorders. Substance-induced anxiety should be considered with adolescents who experience a sudden onset of anxiety. Individuals with GAD are at increased risk to experience depression.

Prognosis

The combination of medication and therapy can be very effective for treating youth with GAD. Individuals with GAD are at increased risk for depression.

188

7. Social Anxiety Disorder

- Excessive worrying in social settings.
- Inability to perform in front of others as expected for age.
- Avoidance of events or settings that are social in nature or involve large groups.

General Considerations

Social anxiety disorder is characterized by significant, persistent fear in social settings, or performance situations. The disorder results in overwhelming anxiety and inability to function when exposed to unfamiliar people and/or scrutiny. This is usually a problem of older children and adolescents.

Identification & Diagnosis

Anxiety symptoms in children with social anxiety disorder are related specifically to the social setting and not better explained by another anxiety disorder. Common manifestations of this disorder include consistent avoidance of social functions, and persistent somatic complaints that occur in a social setting and resolve in the absence of social exposure. The symptoms significantly disrupt the child's—and frequently the family's—life, and parents often describe a pattern of overly accommodating their child's avoidance and/ or incentivizing their child to attend routine social, extracurricular, or family functions.

Treatment

Similar to the other anxiety categories, the mainstay of treatment for social anxiety disorder is CBT therapy. The goal is to modify behavior and diminish the anxiety in social settings through the use of specific cognitive and behavioral techniques. As with other anxiety disorders, if ongoing CBT therapy is not effective at mitigating the anxiety, then psychopharmacologic agents may be helpful. SSRIs are the only class of medication to have demonstrated efficacy for children with social anxiety disorder.

Other Considerations

Children with social anxiety disorder are at increased risk for depression and school avoidance. They can also experience panic attacks, and there is high comorbidity between substance use disorders and anxiety disorders, especially social anxiety disorder.

Prognosis

Early age of onset, more severe avoidance and the presences of panic symptoms are all predictors of persistence over time. Treatment with CBT or a combination of CBT and medication can be very effective for the majority of youth with social anxiety disorder.

OBSESSIVE-COMPULSIVE & RELATED DISORDERS

1. Obsessive-Compulsive Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent obsessive thoughts, impulses, or images that are experienced as intrusive at times.
- Repetitive compulsive behaviors or mental acts are performed to prevent or reduce distress stemming from obsessive thoughts.
- Obsessions and compulsions cause marked distress, are time-consuming, and interfere with normal routines.

General Considerations

Obsessive-compulsive disorder (OCD) is related to anxiety disorders, but tends to cluster genetically with other compulsive disorders such as compulsive skin picking, trichotillomania (hair pulling) and hoarding. Onset often occurs during childhood, and untreated OCD can have a lifelong course. Males have an earlier age of onset, with childhood cases usually occurring before the age of 10 years. OCD often leads to avoidance of situations that trigger obsessions, and for children and adolescents, this can interfere with development.

Identification & Diagnosis

The obsessions that lead to OCD are defined as recurrent, persistent, intrusive thoughts, urges, or images that cause significant distress. The individual tries to avoid, suppress, or ignore the obsessions or to mitigate them through action or thought. The obsessions and compulsions of OCD consume more than an hour per day. Obsessions vary by individuals, but tend to cluster into the following groups: intrusive "forbidden" images such as sexual, aggressive or religiously taboo images, thoughts of contamination, need for symmetry, fears of harming others, fears of harm to oneself or loved ones. Individuals often experience more than one cluster and types of obsessions can change over time. In addition to compulsive symptoms, youth who are experiencing obsessions may also experience panic, depressive, irritable, and suicidal symptoms. Sudden onset of symptoms should alert pediatricians to screen for Group A streptococcal infections, as pediatric autoimmune disorders associated with these infections have been implicated in the development of OCD for some children.

Caretakers can often identify children who have compulsions, but obsessions can be difficult to recognize because they are experienced internally. Youth who recognize that obsessions and compulsions are strange may not spontaneously reveal symptoms unless specifically asked.

Treatment

Many individuals with OCD feel that their symptoms are "crazy" or alternatively, they do not want to consider giving up their compulsions as they feel these will lead to intense distress. Psychoeducation is an important first step in treatment of OCD to help put symptoms in perspective and outline treatment progression. OCD is best treated with a combination of CBT specific to OCD and with medications in more severe cases. SSRIs are effective in diminishing OCD symptoms, but higher doses may be needed than those used to treat anxiety disorders or depression. Fluvoxamine and sertraline have FDA approval for the treatment of pediatric OCD. The tricyclic antidepressant clomipramine has FDA approval for the treatment of OCD in adults. Severe cases have been treated with gamma knife brain surgery interrupting the circuit involved in OCD.

Other Considerations

OCD often occurs with other compulsive disorders such as trichotillomania (the recurrent pulling out of hair), compulsive skin picking, body dysmorphic disorder, or hoarding. Youth with OCD are at increased risk to have comorbid anxiety, ADHD, depression, and tics. The differential diagnosis includes all of the above as well as eating disorders, psychotic disorders and obsessive compulsive personality disorder. The perseveration of children with autism spectrum disorders can also be confused with OCD.

Prognosis

The combination of CBT plus medication is most effective for patients who do not respond to either treatment alone. It is important to recognize and treat OCD early, as early age of onset and greater impairment are predictors of poor prognosis. Hoarding is particularly difficult to treat.

2. Excoriation Disorder

- Recurrent skin picking resulting in lesions despite efforts to stop.
- The skin picking causes significant distress or impairment in school, social or other areas of function.

General Considerations

Excoriation disorder (ED), also known as skin picking disorder, or dermatillomania, is one of the newer diagnoses in the DSM-V. This disorder is a subset of obsessive-compulsive and related disorders. As with other additions to the DSM-V, this disorder has been around for over a century, however, it was not included in previous DSMs. There are some that believe that ED is closest to OCD in etiology, however, others believe it is better categorized as an "addiction disorder," like alcohol and drug use disorders.

Identification & Diagnosis

The disorder is characterized by repeated skin picking leading to multiple lesions on the skin, despite ongoing efforts to reduce or stop this behavior. ED, similar to trichotillomania (TTM), is not associated with obsessions or preoccupations, as in OCD. Diagnosis of this disorder is characterized by clinically significant distress affecting social, occupational or other areas of functioning. Distress includes, but is not limited to experiencing a loss of control, embarrassment, or shame. Symptoms are likely affected by increased stress, anxiety and boredom. In addition, various substances, namely dopamine agonists, for example, methamphetamines and cocaine can lead to skin picking.

Treatment

Psychotherapy can be beneficial and should be the first line of treatment in most cases. For severe cases, or cases not responding the therapy, there is mixed evidence supporting the use of SSRIs and evidence and evidence for *N*-acetylcysteine in adults. Comorbid conditions should be identified and treated. Currently, there are clinical trials looking at treating this disorder by targeting other receptors, such as opioid antagonists and glutaminergic agonists, however, these are still in preliminary phases.

Other Considerations

The differential diagnosis includes trichotillomania, substance use disorder, major depressive disorders, anxiety disorder, OCD, Tourette's or tic disorder, body dysmorphic disorder, substance-induced skin picking, psychosis and neurodevelopmental disorders, such as Prader-Willi. There is a high comorbidity with OCD and TTM, in addition to major depressive disorder.

Prognosis

The disorder is much more common in females than males, with about a 3:1 ratio. Typical age of onset is teen years, likely associated with picking of acne. The lifetime prevalence for excoriation disorder in adults is at or above 1.4%. The course is chronic, yet symptoms can wax and wane for months to years at a time.

- Selles RR, McGuire JF, Small BJ, Storch EA. A systematic review and meta-analysis of psychiatric treatments for excoriation (skin-picking) disorder. Gen Hosp Psychiatry 2016;41:29–37 [PMID: 27143352].

Posttraumatic Stress Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Signs and symptoms of hyperarousal and reactivity.
- Avoidant behaviors and numbing of responsiveness.
- Flashbacks to a traumatic event such as nightmares, intrusive thoughts, or repetitive play.
- Follows traumatic events such as exposure to violence, physical or sexual abuse, natural disasters, car accidents, dog bites, and unexpected personal tragedies.

General Considerations

Factors that predispose individuals to the development of PTSD include proximity to the traumatic event or loss, a history of exposure to trauma, preexisting depression or anxiety disorder, being abused by a caregiver, or witnessing a threat to a caregiver. PTSD can develop in response to natural disasters, terrorism, motor vehicle crashes, and significant personal injury, in addition to physical, sexual, and emotional abuse. Natural disasters such as hurricanes, fires, flooding, and earthquakes, create situations in which large numbers of affected individuals are at heightened risk for PTSD. Individuals who have a previous history of trauma, or an unstable social situation are at greatest risk of PTSD.

Long overdue, attention is now being paid to the substantial effects of family and community violence on the psychological development of children and adolescents. Abused children are especially likely to develop PTSD and to suffer wide-ranging symptoms and impaired functioning. As many as 25% of young people exposed to violence develop symptoms of PTSD and children with some symptoms of PTSD can suffer significant distress and functional impairment, even when not meeting full criteria for PTSD.

Identification & Diagnosis

Children and adolescents with PTSD show persistent fear, anxiety, and hypervigilance. They may regress developmentally and experience fears of strangers, the dark, and being alone, and avoid reminders of the traumatic event.

CHAPTER 7

For young children with magical thinking, this can involve avoiding objects or events that may not be obviously linked to the traumatic event. Children with PTSD re-experience elements of the events in the form of nightmares and flashbacks. In their symbolic play, one can often notice repetition of some aspect of the traumatic event. Children with a history of traumatic experiences or neglect in infancy and early childhood are likely to show signs of reactive attachment disorder and have difficulty forming relationships with caregivers.

Treatment

Before considering treatment, it is critical to ensure that the child is living in a safe environment. If there is concern regarding current or past abuse, this must be reported to social services. The cornerstone of treatment for PTSD is education of the child and family regarding the nature of the disorder so that the child's emotional reactions and regressive behavior are not mistakenly viewed as volitional. The child needs support, reassurance, and empathy. Treatment also includes building a developmentally appropriate narrative of the event to help the child understand their experience. Efforts should be made to establish or maintain daily routines as much as possible, especially after a trauma or disaster that interrupts the family's environment. In the case of media coverage of a disaster or event, children's viewing should be avoided or limited. Individual and family psychotherapy are central features of treatment interventions. Specific fears usually wane with time, and behavioral desensitization may help. Trauma-focused CBT is considered first-line treatment for PTSD. There is preliminary evidence that eye movement desensitization and reprocessing (EMDR) may also be useful.

For children with more severe and persistent symptoms, assessment for treatment with medication is indicated. Children who have lived for an extended time in abusive environments or who have been exposed to multiple traumas are more likely to require treatment with medications. Currently, there is not a medication that has FDA approval for treating PTSD for children. Child psychiatrists may choose medications to target specific symptoms (eg, anxiety, depression, nightmares, and aggression). Some of the medications used to treat children with PTSD include clonidine or guanfacine (Tenex), mood stabilizers, antidepressants, and neuroleptics.

Other Considerations

Evidence is growing to support a connection between victimization in childhood and problems in adulthood, including health problems, substance abuse, unstable personality and mood disorders. It is important to treat PTSD not only to relieve the suffering of youth with PTSD, but also to mitigate long-term negative sequelae.

Prognosis

The best prognostic indicator for children exposed to trauma is a supportive relationship with a caregiving adult. Frequently caregivers exposed to trauma also have PTSD and need referral for treatment so that they can also assist in their child's recovery. Timely access to therapy enhances prognosis. Children with more severe PTSD may require intermittent therapy to identify and treat symptoms that emerge during different stages of development.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Inattentive, Hyperactive, & Combined Type

- Significant impairment in attention or concentration.
- And/or significant hyperactivity and impulsivity in excess of that expected for age.
- Must be present in two or more settings.

General Considerations

Attention-deficit/hyperactivity disorder (ADHD) is one of the most commonly seen and treated psychiatric conditions in children and adolescents. Although there is no definitive cause or cure for this disorder, with adequate screening and monitoring, it can be identified and effectively treated.

Identification & Diagnosis

Symptoms of ADHD fall into two categories: hyperactive and impulsive or inattentive. If a child has a significant number of symptoms in both categories, a diagnosis of ADHD, combined type is given. Functional impairment is required across at least two settings. Accurate diagnosis includes obtaining information regarding symptoms and functional impairment from two sources, typically parents and teachers. Standardized forms in the public domain such as Vanderbilt parent and teacher evaluation and follow up forms are helpful in the process. It is important to keep in mind that intermittent symptoms of hyperactivity and/or inattention without functional impairment do not warrant a diagnosis of ADHD.

Not all hyperactivity and/or inattention can be attributed to ADHD. Some of the most common psychiatric conditions that have similar presenting problems to ADHD include mood disorder (ie, bipolar and depression), anxiety disorders, oppositional defiant disorder, adjustment disorder and PTSD. Learning disorders and other neurodevelopmental disorders can present with symptoms suggestive of ADHD. There are also a number of medical diagnoses with presenting problems similar to ADHD, including head injury, hyperthyroidism, fetal alcohol syndrome, and lead toxicity. Inadequate nutrition and sleep deprivation, including poor quality of sleep, can also cause inattention. It is important to have the correct diagnosis prior to initiating treatment for ADHD.

Treatment

Medication is a primary treatment for school age children and adolescents with ADHD. For children diagnosed with ADHD under the age of 6, behavioral therapy is the first line of treatment. Stimulants are the most effective and most commonly prescribed medications for ADHD. Approximately 75% of children with ADHD experience symptom improvement when given stimulant medications. Children with ADHD who do not respond favorably to one stimulant may respond to another. Children and adolescents with ADHD without prominent hyperactivity (ADHD, predominantly inattentive type) are also likely to be responsive to stimulant medications. When stimulants are not well tolerated or effective, nonstimulants may be used as an alternative. Among nonstimulant medications, atomoxetine, a selective noradrenergic reuptake inhibitor and guanfacine ER, a central α_{2A} -adrenergic receptor agonist, both have FDA approval for the treatment of ADHD in children. Please refer to tables of stimulants and nonstimulants when considering which medication to use (Tables 7–10 and 7–11).

Other Considerations

ADHD comorbidities are common and include anxiety disorders, mood disorders, oppositional defiant disorder, and conduct disorder. While stimulant medication, the firstline treatment for ADHD, has the potential for abuse, individuals who are treated for ADHD are significantly less likely to abuse substances compared to those who have not been treated. Also, a large majority of children and adolescents with ADHD are not formally diagnosed, and of those who are diagnosed, only 55% actually receive ongoing treatment.

Special Considerations Regarding the Use of Stimulant Medication

Common adverse events include anorexia, weight loss, abdominal distress, headache, insomnia, dysphoria and tearfulness, irritability, lethargy, mild tachycardia, and mild elevation in blood pressure. Less common side effects include interdose rebound of ADHD symptoms, behavioral stereotypy, tachycardia, hypertension, depression, mania, and psychotic symptoms. Reduced growth velocity can occur, however, for individual patient's ultimate height is not usually compromised. Treatment with stimulant medications does not predispose to future substance abuse. Young children are at increased risk for side effects from stimulant medications. Additive stimulant effects are seen with sympathomimetic amines (ephedrine and pseudoephedrine).

Reports of sudden death and serious cardiovascular adverse events among children taking stimulant medication raised concerns about their safety. The labels for methylphenidate and amphetamine medications were changed in 2006 to note reports of stimulant-related deaths in patients with heart problems and advised against using these products in individuals with known serious structural abnormalities of the heart, cardiomyopathy, or serious heart rhythm abnormalities. There continues to be insufficient data to confirm whether taking stimulant medication causes cardiac problems or sudden death. The FDA advises providers to conduct a thorough physical examination, paying close attention to the cardiovascular system, and to collect information about the patient's history and any family history of cardiac problems. If this scrutiny suggests a problem, providers should consider a screening electrocardiogram or an echocardiogram. Caution should also be taken if there is a personal or family history of substance abuse or addictive disorders, as these medications can be abused. Students attending college/university may be at increased risk to divert their stimulants to peers. Stimulants should be used with caution in individuals with psychotic disorders, as they can significantly worsen psychotic symptoms. Likewise stimulants should be used with caution in individuals with bipolar affective disorder as they can worsen mood dysregulation.

Short-Acting Stimulants										
Drug Name	Duration		Dosages		Stimulant Class		Usual Starting Dose		FDA Max Daily Dose	
Methylphenidate (Ritalin, Methylin)	4–6 hours		5, 10, 20 mg		Methyl. 5 mg 3–5 y		5 mg BID 3–5 y	1/2 dose if	60 mg

Initial medical screening should include observation for involuntary movements and measurement of height, weight, pulse, and blood pressure. (See also Chapter 3.) Pulse, blood pressure, height, and weight should be recorded every 3-4 months and at times of dosage increases and abnormal movements such as motor tics should be assessed at each visit.

Prognosis

Research indicates that 60%-85% of those diagnosed with ADHD in childhood continue to carry the diagnosis into

adolescence. The literature varies greatly about progression of ADHD into adulthood. Most studies show that a majority of adolescents diagnosed with ADHD in adolescence continue to have functional impairment in adulthood, whether or not they meet full criteria for the disorder. While many have devised ways to cope with their symptoms in a manner that does not require medication, about one-third of adults previously diagnosed with ADHD in childhood require ongoing medication management.

1/2 life). Still is sedating.

MOOD DISORDERS

1. Depression

- Dysphoric mood, mood lability, irritability, or depressed appearance, persisting for weeks to months at a time.
- Characteristic neurovegetative signs and symptoms (eg, changes in sleep, appetite, concentration, and activity levels).
- Suicidal ideation, feeling of hopelessness.

General Considerations

The incidence of depression in children increases with age, from 1% to 3% before puberty to around 8% for adolescents. The rate of depression in females approaches adult levels by age 15. The lifetime risk of depression ranges from 10% to 25% for women and 5% to 12% for men. The incidence of depression in children is higher when other family members have been affected by depressive disorders. The sex incidence is equal in childhood, but with the onset of puberty the rates of depression for females begin to exceed those for males by 5:1.

Identification & Diagnosis

Clinical depression can be defined as a persistent state of unhappiness or misery that interferes with pleasure or productivity. Depression in children and adolescents is as likely to be characterized by an irritable mood state

Depressive Symptom	Clinical Manifestations
Anhedonia	Loss of interest and enthusiasm in play, socializing, school, and usual activities; boredom; loss of pleasure
Dysphoric mood	Tearfulness; sad, downturned expression; unhappiness; slumped posture; quick temper; irritability; anger
Fatigability	Lethargy and tiredness; no play after school
Morbid ideation	Self-deprecating thoughts, statements; thoughts of disaster, abandonment, death, suicide, or hopelessness
Somatic symptoms	Changes in sleep or appetite patterns; difficulty in concentrating; bodily complaints, particularly headache and stomachache

 Table 7–12.
 Clinical manifestations of depression in children and adolescents.

accompanied by tantrums or verbal outbursts as it is to be a sad mood. Typically, a child or adolescent with depression begins to look unhappy and may make comments such as "I have no friends," "life is boring," "there is nothing I can do to make things better," or "I wish I were dead." Behavior patterns change from baseline and can include social isolation, deterioration in schoolwork, loss of interest in usual activities, anger, and irritability. Sleep and appetite patterns commonly change, and the child may complain of tiredness and nonspecific pain such as headaches or stomach aches (Table 7–12).

Clinical depression is typically identified by asking about the symptoms. Children are often more accurate than their caregivers in describing their own mood state. When several depressive symptoms cluster together over time, are persistent (2 weeks or more), and cause impairment, a major depressive disorder may be present. When depressive symptoms are of lesser severity but have persisted for 1 year or more, a diagnosis of dysthymic disorder should be considered. Milder symptoms of short duration in response to some stressful life event may be consistent with a diagnosis of adjustment disorder with depressed mood.

The American Academy of Pediatrics recommends annual screening for depression in children age 12 and older using a standardized measure. The Center for Epidemiologic Study of Depression–Child Version (CESD-C), Child Depression Inventory (CDI), Beck Depression Rating Scale, and Reynolds Adolescent Depression Scale and Patient Health Questionnaire-9 modified for teens (PHQ-9) are selfreport rating scales that are easily used in primary care to assist in assessment and monitoring response to treatment. Several are available in the public domain.

Treatment

Treatment includes developing a comprehensive plan to treat the depressive episode and help the family to respond more effectively to the patient's emotional needs. Referrals should be considered for individual and possibly adjunctive family therapy. CBT improves depressive symptoms in children and adolescents. This includes a focus on building coping skills to change negative thought patterns that predominate in depressive conditions. It also helps identify, label, and verbalize feelings and misperceptions. In therapy, efforts are also made to resolve conflicts between family members and improve communication skills within the family.

Mild to moderate depressive symptoms often improve with psychotherapy alone. When the symptoms of depression are moderate and persistent, or severe, antidepressant medications may be indicated (see Table 7–8). A positive family history of depression increases the risk of early-onset depression in children and adolescents and the chances of a positive response to antidepressant medication. Depression in toddlers and young children is best approached with parent–child relational therapies.

The carefully conducted treatment of adolescent depression study (TADS) is a major source of evidence for clinic guidelines regarding the treatment of depression in children and adolescents. This study found that CBT combined with fluoxetine led to the best outcomes in the treatment of pediatric depression during the first 12 weeks of treatment. Although our knowledge is still evolving, these findings suggest that when recommending or prescribing an antidepressant, the provider should consider concurrently recommending cognitive-behavioral or interpersonal therapy. Providers should discuss the options for medication treatment, including which medications have FDA approval for pediatric indications (see Table 7-6). Target symptoms should be carefully monitored for improvement or worsening, and it is important to ask and document the responses about any suicidal thinking and self-injurious behaviors.

Special Considerations Regarding the Use of Antidepressant Medication

There are some special considerations when prescribing the various classes of antidepressant medication. Table 7–8 outlines the distinct differences between some of the most commonly used antidepressant medications.

A. Selective Serotonin Reuptake Inhibitors (SSRI)

Each SSRI has different FDA indications. Providers can choose to treat with an SSRI that has not received FDA approval for a specific indication or age group. Typical considerations for using a medication without FDA approval include the side-effect profile and/or whether another family member has responded to a specific medication. In these instances, providers should inform the patient and family that they are using a medication off-label.

The therapeutic response for SSRIs should be expected 4–6 weeks after a therapeutic dose has been reached. The starting dose for a child younger than 12 years is generally half the starting dose for an adolescent. SSRIs are usually given once a day, in the morning with breakfast. One in ten individuals may experience sedation and prefer to take the medication at bedtime. Caution should be used in cases of known liver disease or chronic or severe illness where multiple medications may be prescribed, because all SSRIs are metabolized in the liver. In addition, caution should be used when prescribing for an individual with a family history of bipolar disorder, or when the differential diagnosis includes bipolar disorder, because antidepressants can induce manic or hypomanic symptoms.

Adverse effects of SSRIs are often dose-related and time-limited: GI distress and nausea (can be minimized by taking medication with food), headache, tremulousness, decreased appetite, weight loss, insomnia, sedation (10%), and sexual dysfunction (25%). Irritability, social disinhibition, restlessness, and emotional excitability can occur in approximately 20% of children taking SSRIs. It is important to systematically monitor for side effects. SSRIs other than fluoxetine should be discontinued slowly to minimize withdrawal symptoms including flu-like symptoms, dizziness, headaches, paresthesias, and emotional lability.

All SSRIs inhibit the hepatic microsomal enzyme system. The order of inhibition is: fluoxetine > fluvoxamine > paroxetine > sertraline > citalopram > escitalopram. This can lead to higher-than-expected blood levels of concomitant medications. Taking tryptophan while on an SSRI may result in a serotonergic syndrome of psychomotor agitation and GI distress. A potentially fatal interaction that clinically resembles neuroleptic malignant syndrome may occur when SSRIs are administered concomitantly with monoamine oxidase inhibitors (MAOIs). Fluoxetine has the longest halflife of the SSRIs and should not be initiated within 14 days of the discontinuation of a monoamine oxidase inhibitor, or a monoamine oxidase inhibitor initiated within at least 5 weeks of the discontinuation of fluoxetine. One should be cautious of prescribing SSRIs in conjunction with ibuprofen and other NSAIDs for concerns of GI bleeding.

B. Serotonin Norepinephrine Reuptake Inhibitors (SNRI)

Serotonin norepinephrine reuptake inhibitors (SNRIs), which include venlafaxine, duloxetine, desvenlafaxine, and milnacipran, are antidepressants that primarily inhibit reuptake of serotonin and norepinephrine. Desvenlafaxine is the major active metabolite of the antidepressant venlafaxine. It is approved for the treatment of major depression in adults. Contraindications for this class of medication include hypertension, which is typically dose related. The most common adverse effects are nausea, nervousness, and sweating. SNRIs should be discontinued slowly to minimize withdrawal symptoms: including flu-like symptoms, dizziness, headaches, paresthesias, and emotional lability.

C. Other Antidepressants

Bupropion is an antidepressant that inhibits uptake of norepinephrine and dopamine. It is approved for treatment of major depression in adults. Like the SSRIs, bupropion has very few anticholinergic or cardiotoxic effects. The medication has three different formulations, and consideration for use is based on tolerability and compliance. Bupropion can interfere with sleep, so dosing earlier in the day is paramount to adherence and decreasing side effects. Contraindications of this medication include history of seizure disorder or bulimia nervosa. The most common adverse effects include psychomotor activation (agitation or restlessness), headache, GI distress, nausea, anorexia with weight loss, insomnia, tremulousness, precipitation of mania, and induction of seizures with doses above 450 mg/day.

Mirtazapine is an α_2 -antagonist that enhances central noradrenergic and serotonergic activity. It is approved for the treatment of major depression in adults. Mirtazapine should not be given in combination with MAOIs. Very rare side effects are acute liver failure (1 case per 250,000–300,000), neutropenia, and agranulocytosis. More common adverse effects include dry mouth, increased appetite, constipation, weight gain, and increased sedation.

Tricyclic antidepressants (TCAs) are an older class of antidepressants, which include imipramine, desipramine, clomipramine, nortriptyline, and amitriptyline. With the introduction of the SSRIs and alternative antidepressants, use of the TCAs has become uncommon for the treatment of depression and anxiety disorders. The TCAs have more significant side-effect profiles and require substantial medical monitoring, including the possibility of cardiac arrhythmias. Overdose can be lethal. TCAs are still used to treat medical and psychiatric issues, such as chronic pain syndromes, headache, or enuresis as well as depression, anxiety, bulimia nervosa, OCD, and PTSD. Imipramine and desipramine are FDA approved for the treatment of major depression in adults and for enuresis in children age 6 years and older. Contraindications include cardiac disease or arrhythmia, unexplained syncope, seizure disorder, family history of sudden cardiac death or cardiomyopathy, and known electrolyte abnormality (with bingeing and purging). Initial medical screening includes taking a thorough family history for sudden cardiac death and the patient's history for cardiac disease, arrhythmias, syncope, seizure disorder, or congenital hearing loss (associated with prolonged QT interval). Other screening procedures include serum electrolytes and blood urea nitrogen in patients who have eating disorders,

Heart rate	110/min
Systolic blood pressure	130 mm Hg
Diastolic blood pressure	85 mm Hg
PR interval	0.2 s
QRS interval	0.12 s, or no > 30% over baseline
QT corrected	0.45 s

cardiac examination, and a baseline ECG. Ongoing medical follow-up includes monitoring pulse and blood pressure (ie, screening for tachycardia and orthostatic hypotension) with each dosage increase, and obtaining an ECG to monitor for atrioventricular block with each dosage increase. After reaching steady state, record pulse, blood pressure, and ECG every 3–4 months. TCAs may potentiate the effects of central nervous system depressants and stimulants. Barbiturates and cigarette smoking may decrease plasma levels while phenothiazines, methylphenidate, and oral contraceptives may increase plasma levels. SSRIs given in combination with TCAs will result in higher TCA blood levels. Please refer to Table 7–13 on upper limits of cardiovascular parameters with tricyclic antidepressants.

Other Considerations

The risk of suicide is the most significant risk associated with depressive episodes. In addition, adolescents are likely to self-medicate their feelings through substance abuse, or indulge in self-injurious behaviors such as cutting or burning themselves (without suicidal intent). School performance usually suffers during a depressive episode, as children are unable to concentrate or motivate themselves to complete homework or projects. The irritability, isolation, and withdrawal that often result from the depressive episode can lead to loss of peer relationships and tense dynamics within the family. Please refer to section on identifying and addressing suicide risk for additional information.

Depression often coexists with other mental illnesses such as ADHD, oppositional defiant disorder, conduct disorder, anxiety disorders, eating disorders, and substance abuse disorders. Medically ill patients also have an increased incidence of depression. Every child and adolescent with a depressed mood state should be asked directly about suicidal ideation and physical and sexual abuse. Depressed adolescents should also be screened for hypothyroidism and substance abuse.

In 2005, the FDA issued a "black box warning" regarding suicidal thinking and behavior for all antidepressants prescribed for children and adolescents. The FDA compiled data from 24 short-term trials of 4-16 weeks that included the use of antidepressants for major depressive disorder and obsessive compulsive disorder. Across these studies, the average risk of suicidal thinking and behavior during the first few months of treatment was 4% or twice the placebo risk of 2%. No suicides occurred in these trials. Although children face an initial increased risk of suicidal thinking and behaviors during the first few months of treatment, there is now substantial evidence that antidepressant treatment, over time, is protective against suicide. For example, following the addition of the "black box warning" for all antidepressants in October 2005, a 20% decrease in prescriptions for those younger than age 20 occurred. During the same time period, there was an 18% increase in suicides. Furthermore, the suicide rates in children and adolescents were lowest in areas of the country that had the highest rate of SSRI prescriptions. This suggests best practice is to educate the family regarding both the risks and benefits of antidepressant treatment and monitor carefully for any increase in suicidal ideation or selfinjurious urges, as well as improvement in target symptoms of depression, especially in the first 4 weeks and subsequent 3 months after beginning their use.

Prognosis

A comprehensive treatment intervention, including psychoeducation for the family, individual and family psychotherapy, medication assessment, and evaluation of school and home environments, often leads to complete remission of depressive symptoms over a 1- to 2-month period. If medications are started and prove effective, they should be continued for 6-12 months after remission of symptoms to prevent relapse. Early-onset depression (before age 15) is associated with increased risk of recurrent episodes and the potential need for longer-term treatment with antidepressants. Education of the family and child/or adolescent will help them identify depressive symptoms sooner and decrease the severity of future episodes with earlier interventions. Some studies suggest that up to 30% of preadolescents with major depression manifest bipolar disorder at 2-year follow-up. It is important to reassess the child or adolescent with depressive symptoms regularly for at least 6 months and to maintain awareness of the depressive episode in caring for this child in the future.

2. Bipolar Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Periods of abnormally and persistently elevated, expansive, or irritable mood, and heightened levels of energy and activity.
- Associated symptoms: grandiosity, diminished need for sleep, pressured speech, racing thoughts, impaired judgment.
- Not caused by prescribed or illicit drugs.
- The symptoms most commonly reported first are depressive symptoms.

General Considerations

Bipolar disorder (previously referred to as manic-depressive disorder) is an episodic mood disorder manifested by alternating periods of mania and major depressive episodes or, less commonly, manic episodes alone. Children and adolescents often exhibit a variable course of mood instability combined with aggressive behavior and impulsivity. At least 20% of bipolar adults experience onset of symptoms before age 20 years. Onset of bipolar disorder before puberty is uncommon; however, symptoms often begin to develop and may be initially diagnosed as ADHD or other disruptive behavior disorders. The lifetime prevalence of bipolar disorder in middle to late adolescence approaches 1%.

Identification & Diagnosis

In about 70% of patients, the first symptoms are primarily those of depression. In the remainder, manic, hypomanic, or mixed states dominate the presentation. Patients with mania display a variable pattern of elevated, expansive, or irritable mood along with rapid speech, high energy levels, difficulty in sustaining concentration, and a decreased need for sleep. The child or adolescent may also have hypersexual behavior. It is critical to rule out abuse, or be aware of abuse factors contributing to the clinical presentation. Patients often do not acknowledge any problem with their mood or behavior. The clinical picture can be quite dramatic, with florid psychotic symptoms of delusions and hallucinations accompanying extreme hyperactivity and impulsivity. Other illnesses on the bipolar spectrum are bipolar type II, which is characterized by recurrent major depressive episodes alternating with hypomanic episodes (lower intensity manic episodes that do not cause social impairment and do not typically last as long as manic episodes) and cyclothymic disorder, which is diagnosed when the child or adolescent has had 1 year of hypomanic symptoms alternating with depressive symptoms that do not meet criteria for major depression.

It is also common for individuals diagnosed with bipolar spectrum disorders to have a history of inattention and hyperactivity problems in childhood, with some having a comorbid diagnosis of ADHD. While ADHD and bipolar disorder are highly comorbid, inattention and hyperactivity symptoms accompanied by mood swings can be an early sign of bipolar disorder before full criteria for the disorder have emerged and clustered together in a specific pattern.

Differentiating ADHD, bipolar disorder, and major depressive disorder can be a challenge, and confusion about the validity of the disorder in younger children still exists. The situation is further complicated by the potential for the coexistence of ADHD and mood disorders in the same patient.

A history of the temporal course of symptoms can be most helpful. ADHD is typically a chronic disorder of lifelong duration. However, it may not be a problem until the patient enters the classroom setting. Mood disorders are typically characterized by a normal baseline followed by an acute onset of symptoms usually associated with acute sleep, appetite, and behavior changes. If inattentive, hyperactive, or impulsive behavior was not a problem in the previous year, it is unlikely to be ADHD. Typically, all these disorders are often heritable, so a positive family history can be informative in formulating a diagnosis. Successful treatment of relatives can offer guidance for appropriate treatment.

In prepubescent children, mania may be difficult to differentiate from ADHD and other disruptive behavior disorders. In both children and adolescents, preoccupation with violence, decreased need for sleep, impulsivity, poor judgment, intense and prolonged rages or dysphoria, hypersexuality, and some cycling of symptoms suggest bipolar disorder. Table 7–14 further defines points of differentiation between ADHD, conduct disorder, and bipolar disorder.

	~		
Symptom	ADHD	Conduct Disorder	Bipolar Disorder
School problems	Yes	Yes	Yes
Behavior problems	Yes	Yes	Yes
Defiant attitude	Occasional	Constant	Episodic
Motor restlessness	Constant	May be present	May wax and wane
Impulsivity	Constant	May be present	May wax and wane
Distractibility	Constant	May be present	May wax and wane
Anger expression	Short-lived (minutes)	Plans revenge	Intense rages (minutes to hours)
Thought content	May be immature	Blames others	Morbid or grandiose ideas
Sleep disturbance	May be present	No	May wax and wane
Self-deprecation	Briefly, with criticism	No	Prolonged, with or without suicidal ideation
Obsessed with ideas	No	No	Yes
Hallucinations	No	No	Diagnostic, if present
Family history	May be a history of school problems	May be a history of antisocial behavior	May be a history of mood disorders

Table 7–14. Differentiating behavior disorders.

The Young Mania Rating Scale and The Child Mania Rating Scale may be helpful in eliciting concerning symptoms and educating families and patients, and in aiding timely referral to local mental health resources.

Children and adolescents with bipolar disorder are more likely to be inappropriate or aggressive toward peers and family members. Their symptoms almost always create significant interference with academic learning and peer relationships. The poor judgment associated with manic episodes predisposes individuals to dangerous, impulsive, and sometimes criminal activity. Legal difficulties can arise from impulsive acts, such as excessive spending, and acts of vandalism, theft, or aggression, that are associated with grandiose thoughts. Affective disorders are associated with a 30-fold greater incidence of successful suicide. Substance abuse may be a further complication, often representing an attempt at self-medication for the mood problem.

Treatment

Most patients with bipolar disorder respond to pharmacotherapy with either mood stabilizers, such as lithium, atypical antipsychotics, or antiepileptic drugs. Lithium, risperidone, aripiprazole, quetiapine, asenapine, and olanzapine have been approved by the FDA for the treatment of acute and mixed manic episodes in adolescents. Other mood stabilizers, carbamazepine and valproate, are less effective. In addition, lithium and aripiprazole are approved for preventing recurrence. It is recommended that primary care providers refer all patients with suspected bipolar mood disorder to a mental health provider for diagnostic clarification and treatment. In situations where bipolar mood disorder is evident, a referral to a psychiatrist is recommended. In cases of severe impairment, hospitalization is required to maintain safety and initiate treatment. Supportive psychotherapy for the patient and family and education about the recurrent nature of the illness are critical. Family therapy should also include improving skills for conflict management and appropriate expression of emotion.

In addition to prescribing medications that have FDA approval for use in children with bipolar disorder (lithium and the atypical antipsychotic medications), providers may choose to use other medications off-label after nonresponse to first-line treatment or because of side-effect profiles. In these cases, it is recommended that a psychiatrist initiate and monitor early treatment. Once the goal of stabilization has been attained, it is reasonable for a primary care provider to provide maintenance therapy.

Other Considerations

Physical or sexual abuse and exposure to domestic violence can also cause children to be mood labile, hyperactive, and aggressive, and PTSD should be considered by reviewing the history for traumatic life events in children with these symptoms. Diagnostic considerations should also include substance abuse disorders, and an acute organic process, especially if the change in personality has been relatively sudden, or is accompanied by other neurologic changes. Individuals with manic psychosis may resemble those with schizophrenia. Psychotic symptoms associated with bipolar disorder should clear with resolution of the mood symptoms, which should also be prominent. Hyperthyroidism should be ruled out.

Prognosis

It is not uncommon for the patient to need lifelong medication. In its adult form, bipolar disorder is an illness with a remitting course of alternating depressive and manic episodes. The time span between episodes can be years or months depending on the severity of illness and ability to comply with medication interventions. In childhood, the symptoms may be more pervasive and not fall into the intermittent episodic pattern until after puberty.

3. Disruptive Mood Dysregulation Disorder (DMDD)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Persistent irritability and severe behavioral outbursts at least three times a week for 1 year or more.
- The mood in between these symptoms is persistently negative (ie, irritable, angry or sad), which is observable by others.
- The tantrums and negative moods are present in at least two settings.
- Onset of illness prior to 10 years old.
- Chronological or developmental age of at least 6 years old.
- A disruption in functioning in more than one setting (eg, home, school and/or socially).

General Considerations

DMDD is a new diagnosis in the DSM-5. Historically, many of these chronically irritable children would have been diagnosed with some variation of bipolar mood disorder. Studies of the family history, functional brain studies and developmental progression suggest that these children are different from individuals with bipolar disorder. The prevalence is estimated to be 2%–5% and may decrease from childhood to adolescence. Early studies suggest males are at increased risk for this disorder.

Identification & Diagnosis

Children with DMDD experience severe tantrums in addition to chronic irritability. The tantrums must be inconsistent with the developmental age of the child. Currently, this diagnosis cannot be given to individuals over the age of 18. In cases where symptoms overlap between DMDD and ODD, DMDD supersedes ODD. Children who have experienced a manic or hypomanic episode cannot be given this diagnosis. Tantrums that occur only in relation to anxiety-provoking situations, or when routines are interrupted suggest anxiety, ASD or OCD and do not meet criteria for DMDD.

Treatment

Medication trials are in early stages for this relatively new diagnosis, but identifying and treating comorbid conditions such as anxiety or ADHD may be helpful. Therapy is important for children and their families.

Other Considerations

The differential diagnosis for DMDD is similar to other mood disorders. In addition, special attention and consideration should include screening for ADHD, anxiety, trauma, and significant interpersonal and relational deficits. Those with DMDD are at a higher risk than the general population to develop major depressive disorder and anxiety disorders as adults.

Children with DMDD have low frustration tolerance and may misread neutral social cues as threatening. They often function poorly in school and have impaired relations with peers and family. The parents or caregivers of these children are often very distressed and these children are likely to present to mental health clinics. Many parents will decrease the demands and limits placed on these children in an attempt to avoid tantrums. This can include withdrawing their children from developmentally appropriate health promoting activities. Children with DMDD often have dangerous behaviors that lead to psychiatric hospitalization.

With the addition of this diagnosis, researchers are now able to gather data to aid with the diagnosis, treatment, and outcome measures.

SUICIDE IN CHILDREN & ADOLESCENTS

The suicide rate in young people has remained high for several decades. In 2014, suicide became the second leading cause of death among children and adolescents aged 10-24 years in the United States. The suicide rate among adolescents aged 15-19 years quadrupled from approximately 2.7 to 12.5 per 100,000 since the 1960s. It is estimated that each year, approximately 2 million US adolescents attempt suicide, yet only 700,000 receive medical attention for their attempt. Suicide and homicide rates for children in the United States are two to five times higher than those for the other 25 industrialized countries combined, primarily due to the prevalence of firearms in the United States. For children younger than 10 years, the rate of completed suicide is low, but has also increased. Adolescent girls make three to four times as many suicide attempts as boys of the same age, but the number of completed suicides is three to four times greater in boys. Firearms are the most commonly used method in successful suicides, accounting for 40%-60% of cases; hanging, carbon monoxide poisoning, and drug overdoses each account for approximately 10%-15% of cases.

Suicide is almost always associated with a psychiatric disorder and should not be viewed as a philosophic choice about life or death or as a predictable response to overwhelming stress. Most commonly it is associated with a mood disorder and the hopelessness that accompanies a severe depressive episode. Suicide rates are higher for Native American and Native Alaskan populations than for white, black, and Latino/ Hispanic populations. Although suicide attempts are more common in individuals with a history of experiencing trauma, behavior problems, and academic difficulties, other suicide victims are high achievers who are temperamentally anxious and perfectionistic and who commit suicide impulsively after a failure or rejection, either real or perceived. Mood disorders (in both sexes, but especially in females), substance abuse disorders (especially in males), a history of trauma, and conduct disorders are commonly diagnosed at psychological autopsy in adolescent suicide victims. Some adolescent suicides reflect an underlying psychotic disorder, with the young person usually committing suicide in response to auditory hallucinations or psychotic delusions.

The vast majority of young people who attempt suicide give some clue to their distress or their tentative plans to commit suicide. Most show signs of dysphoric mood (anger, irritability, anxiety, or depression). For those who are screened, there is often a history of elevated distress reported on a screening instrument. Over 60% make comments such as "I wish I were dead" or "I just can't deal with this any longer" within the 24 hours prior to death. In one study, nearly 70% of subjects experienced a crisis event such as a loss (eg, rejection by a girlfriend or boyfriend), public shaming, a failure, or an arrest prior to completed suicide. With ubiquitous social networking technologies and the presence of digital profiles, posting distress messages electronically and aggression in the form of cyber-bullying are important to identify and discuss when conducting risk assessments and gathering information about relationships, supports, and sources of stress.

Assessment of Suicide Risk

Routine screening for children 12 and older now includes questions regarding suicide. If a child or adolescent expresses suicidal thinking, the treating provider must ask if he or she has an active plan, intends to complete that plan, and has made previous attempts. **Suicidal ideation accompanied by any plan warrants immediate referral for a psychiatric crisis assessment.** This can usually be accomplished at the nearest emergency room (ER).

Assessment of suicide risk calls for a high index of suspicion and a direct interview with the patient and his or her parents or guardians. The highest risk of suicide is among white, adolescent boys. High-risk factors include previous suicide attempts, self-injurious behavior, a suicide note, and a viable plan for suicide with the availability of lethal means, close personal exposure to suicide, conduct disorder, and substance abuse. Other risk factors are signs and symptoms of major depression or dysthymia, a family history of suicide, a recent death in the family, suicide of student at the patient's school and a view of death as a relief from the pain in the patient's life.

Intervention

Suicidal ideation and any suicide attempt must be considered a serious matter. The patient should not be left alone, and the treating provider should express concern and convey a desire to help. If a behavioral health clinician (BHC) is embedded in the practice, the BHC can aid in assessing the patient. Either the provider or the BHC should meet with the patient and the family, both alone and together, and listen carefully to their problems and perceptions. It is helpful to explicitly state that with the assistance of mental health professionals, solutions can be found. The practice should err on the side of caution, in deciding whether further referral or an emergency evaluation is indicated. Similar to reporting suspicion of child abuse, although the practice may not have the expertise or time to determine full suicide risk, primary care providers can determine that further evaluation is indicated. A thorough suicide assessment requires some level of expertise, a considerable amount of time and contact with multiple sources of information. The majority of patients who express suicidal ideation and all who have made a suicide attempt should be referred for psychiatric evaluation and possible hospitalization. Referral for further assessment is always appropriate when there is concern about suicidal thinking and behavior.

Regardless of whether a practice has an embedded behavioral health clinician, it is useful to have a practicespecific algorithm for suicidal youth. The algorithm should include the steps to be taken for youth who need to be sent to an emergency room, youth who need an urgent or less urgent referral, or youth that will be followed in the practice. The algorithm should specify who in the practice is responsible for each step. This should include who will call for emergency transport, if indicated, and who will flag a patient's record to ensure the patient follows up with care recommendations. Additionally, the primary care practice will need to follow-up and document the outcome of the emergency assessment (eg, hospitalization, community referrals) in the patient's record and schedule a follow-up visit in the primary care setting as soon as is feasible given the disposition.

Suicide prevention efforts include heightened awareness in the community and schools to identify at-risk individuals and increase access to services, including hotlines and counseling services. Restricting young people's access to firearms is a critical factor, as firearms are responsible for 85% of deaths due to suicide or homicide in youth in the United States. Other means restriction methods include instructing families to lock up all medications. Many families are not aware that overdoses of over the counter medications such as acetaminophen can be lethal. In addition to increasing public awareness of the issue, media depictions of death by suicide, including news reporting and fictionalized accounts, could serve as a conversation starter for discussion of how an adolescent is understanding and thinking about this social issue. It is important to minimize sensationalism of deaths by suicide and have an open dialogue about what happened. This is particularly critical in communities that have recently experienced a death by suicide where there is increased vulnerability to the occurrence of additional incidents.

Finally, the treating provider should be aware of his or her own emotional reactions to dealing with suicidal

CHAPTER 7

adolescents and their families. Providers may be reluctant to cause a family stress or go against their will and require an emergency evaluation. Providers may have unfounded fears about precipitating suicide by direct and frank discussions of suicidal risk. Reviewing difficult cases with colleagues, developing formal or informal relationships with psychiatrists, and attending workshops on assessment and management of depression and suicidal ideation can decrease the anxiety and improve competence for primary care providers.

DISRUPTIVE, IMPULSE-CONTROL & CONDUCT DISORDERS

1. Oppositional Defiant Disorder

- ► A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months.
- ► Loses temper, argues with adults, defies rules.
- Blames others for own mistakes and misbehavior.
- Angry, easily annoyed, vindictive.
- Does not meet criteria for conduct disorder.

General Considerations

Oppositional defiant disorder is more common in families where caregiver dysfunction (eg, substance abuse, parental psychopathology, significant psychosocial stress) is present. It is also more prevalent in children with a history of multiple changes in caregivers, inconsistent, harsh, or neglectful parenting, or serious marital discord.

Identification & Diagnosis

Oppositional defiant disorder usually is evident before 8 years of age and may be an antecedent to the development of conduct disorder. The symptoms usually first emerge at home, but then extend to school and peer relationships. The disruptive behaviors of oppositional defiant disorder are generally less severe than those associated with conduct disorder and do not include hurting other individuals or animals, destruction of property, or theft.

Treatment

Interventions include careful assessment of the psychosocial situation and recommendations to support parenting skills and optimal caregiver functioning. Assessment for comorbid psychiatric diagnoses such as learning disabilities, depression, and ADHD should be pursued and appropriate interventions recommended.

2. Conduct Disorder

- A persistent pattern of behavior that includes the following:
 - · Defiance of authority.

- · Violating the rights of others or society's norms.
- Aggressive behavior toward persons, animals, or property.

General Considerations

Disorders of conduct affect approximately 9% of males and 2% of females younger than 18 years. This is a very heterogeneous population, and overlap occurs with ADHD, substance abuse, learning disabilities, neuropsychiatric disorders, mood disorders, and family dysfunction. Many of these individuals come from homes where domestic violence, child abuse, drug abuse, shifting parental figures, and poverty are environmental risk factors. Although social learning partly explains this correlation, the genetic heritability of aggressive conduct and antisocial behaviors is currently under investigation.

Identification & Diagnosis

The typical child with conduct disorder is a boy with a turbulent home life and academic difficulties. Defiance of authority, fighting, tantrums, running away, school failure, and destruction of property are common symptoms. With increasing age, fire-setting and theft may occur, followed in adolescence by truancy, vandalism, and substance abuse. Sexual promiscuity, sexual perpetration, and other criminal behaviors may develop. Hyperactive, aggressive, and uncooperative behavior patterns in the preschool and early school years tend to predict conduct disorder in adolescence with a high degree of accuracy, especially when ADHD goes untreated. A history of reactive attachment disorder is an additional childhood risk factor. The risk for conduct disorder increases with inconsistent and severe parental disciplinary techniques, parental alcoholism, and parental antisocial behavior.

Treatment

Effective treatment can be complicated by the psychosocial problems often found in the lives of children and adolescents with conduct disorders. These problems may also interfere with achieving compliance with treatment recommendations. Efforts should be made to stabilize the environment and improve functioning within the home, particularly as it relates to parental functioning and disciplinary techniques. Identification of learning disabilities and placement in an optimal school environment is critical. Any associated neurologic and psychiatric disorders should be addressed.

Residential treatment may be necessary for individuals whose symptoms do not respond to lower level interventions, or whose environment is not able to meet their needs for supervision and structure. Juvenile justice system involvement is common in cases where conduct disorder behaviors lead to illegal activities, theft, or assault.

Medications such as mood stabilizers, neuroleptics, stimulants, and antidepressants have all been studied in youth with conduct disorders, yet none has been found to be consistently effective. Each patient suspected of conduct disorder should be screened for other common psychiatric disorders and a history of trauma prior to the initiation of medication. Providers should use caution when prescribing various medications off-label for disruptive behavior. Early involvement in programs, such as Big Brothers, Big Sisters, scouts, and team sports, in which consistent adult mentors and role models interact with youth, decreases the chances that the youth will develop antisocial personality disorder. Multisystemic therapy (MST) is being used increasingly as an intervention for youth with conduct disorders and involvement with the legal system. MST is an intensive home-based model of care that seeks to stabilize and improve the home environment and to strengthen the support system and coping skills of the individual and family.

Other Considerations

Young people with conduct disorders, especially those with more violent histories, have an increased incidence of neurologic signs and symptoms, psychomotor seizures, psychotic symptoms, mood disorders, ADHD, and learning disabilities. Efforts should be made to identify these associated disorders because they may require specific therapeutic interventions. Conduct disorder is best conceptualized as a final common pathway emerging from a variety of underlying psychosocial, genetic, environmental, and neuropsychiatric conditions.

Prognosis

The prognosis is based on the ability of the child's support system to mount an effective treatment intervention consistently over time. The prognosis is generally worse for children in whom the disorder presents before age 10 years; those who display a diversity of antisocial behaviors across multiple settings; and those who are raised in an environment characterized by parental antisocial behavior, alcoholism or other substance abuse, and conflict. Nearly half of individuals with a childhood diagnosis of conduct disorder develop antisocial personality disorder as adults.

HIGH-RISK PATIENTS & HOMICIDE

Aggression & Violent Behavior in Youth

The tragic increase in teenage violence, including school shootings, is of particular concern to health professionals, as well as to society at large. There is strong evidence that screening and initiation of interventions by primary care providers can make a significant difference in violent behavior in youth. Although the prediction of violent behavior remains a difficult and imprecise endeavor, providers can support and encourage several important prevention efforts.

The vast majority of the increase in youth violence, including suicides and homicides, involves the use of firearms. Thus, the presence of firearms in the home, the method of storage and safety measures taken when present, and access to firearms outside the home should be explored regularly with all adolescents as part of their routine medical care.

It is important to note that violent behavior is often associated with suicidal impulses. In the process of screening for violent behavior, suicidal ideation should not be overlooked. Any comment about wishes to be dead, or hopelessness, should be taken seriously and assessed immediately.

Interventions for parents include encouraging parents and guardians to be aware of their child's school attendance and performance. Parents should be encouraged to take an active role and learn about their children's friends, be aware of who they are going out with, where they will be, what they will be doing, and when they will be home. Most students involved in school violence might have been identified earlier and potentially may have benefited from interventions to address problems in social and educational functioning in the school environment. Communities and school districts nationwide have increased their efforts to identify and intervene with students whom teachers, peers, or parents recognize as having difficulty.

Threats & Warning Signs Requiring Immediate Consultation

Any and all threats that children make can be alarming. However, it is important to respond to the more serious and potentially lethal threats. These threats should be taken with the utmost seriousness and parents/guardians should see a mental health provider immediately. Such threats include threats/warnings about hurting or killing someone or oneself, threats to run away from home and/or threats to damage or destroy property.

Factors Associated With Increased Risk of Violent and/or Dangerous Behavior

Not all threats signify imminent danger. There are several potential predictors to consider when assessing the dangers of a child or adolescent, such as past history of violence or aggressive behavior, including uncontrollable angry outbursts; access to guns or other weapons; history of getting caught with a weapon in school; and family history of violent behaviors. These are likely predictors of future violent behavior. In addition, children who witness abuse and violence at home and/or have a preoccupation with themes and acts of violence (eg, TV shows, movies, music, violent video games, etc) are also at high risk of such behavior. Victims of abuse (ie, physical, sexual, and/or emotional) are more susceptible to feeling shame, loss, and rejection. The difficulty of dealing with abuse can further exacerbate an underlying mood, anxiety, or conduct disorder. Children who have been abused are more likely to be perpetrators of bullying and engage in verbal and physical intimidation toward peers. They also may be much more prone to blame others and are unwilling to accept responsibility for their own actions. Substance use is another major factor frequently associated with violent, aggressive, and/or dangerous behavior, particularly because it impacts judgment and is often associated with decreased inhibition and increased impulsivity. Socially isolated children also carry a high risk for violent and dangerous behavior. These include children with little to no adult supervision, poor connection with peers, and little to no involvement in extracurricular activities. These individuals may be more likely to seek out deviant peer groups for a sense of belonging.

How Providers & Parents Can Respond to Concerns of Violence and/or Dangerous Behavior

If a provider or parent suspects that a child is at risk for violent and/or dangerous behavior, the most important intervention is to talk with the child immediately about alleged threat and/or behavior. One should consider the child's past behavior, personality, and current stressors when evaluating the seriousness and likelihood of them engaging in a destructive or dangerous behavior. If the child already has a mental health provider, he/she should be contacted immediately. If they are not reachable, the parent(s)/guardian(s) should take the child to the closest ED for a crisis evaluation. It is always acceptable to contact local police for assistance, especially if harm to others is suspected. Another indication that warrants a crisis evaluation is if a child refuses to talk, is argumentative, responds defensively, or continues to express violent or dangerous thoughts/plans. Continuous, face-toface adult supervision is essential while awaiting professional intervention. After evaluation, it is imperative to follow up with recommendations from mental health provider(s) to ensure safety and ongoing management.

SOMATIC SYMPTOM & RELATED DISORDERS

- Medically unexplained symptoms are no longer required for these disorders other than conversion disorder. Most disorders in this category are characterized by focus on symptoms within a medical setting.
- Distress and/or functional impairment are present in somatic symptom disorder while functional impairment is more common in conversion disorder.

General Considerations

The category of somatic symptoms and related disorders includes somatic symptom disorder, illness anxiety disorder, conversion disorder (functional neurological symptom disorder) psychological factors affecting other medical conditions, factitious disorder and factitious disorder imposed by another (Table 7–15).

Patients with these disorders are commonly encountered in primary care and can be conceptualized as suffering; differences in presentation are likely related to cultural, contextual factors, individual experiences (such as trauma) and individual differences such as pain sensitivity. Families and cultures that value physical suffering while devaluing or ignoring psychological distress, reinforce the development of these disorders. Family members who are ill, physically disabled, or suffer from any of these disorders, can serve as
 Table 7–15.
 Somatoform disorders in children and adolescents.

Disorder	Major Clinical Manifestations		
Somatic symptom disorder, factitious disorder, other specified somatic symp- tom and related disor- der, unspecified somatic symptom and related disorder	A somatic symptom or symptoms cause significant distress, worry and concern and may take up considerable time and energy.		
Conversion disorder (func- tional neurological symptom disorder)	Symptom onset follows psychologically stressful event; symptoms express unconscious feelings and result in secondary gain.		
Illness anxiety disorder	Somatic symptoms if present are mild. Focus is on fear of having or developing an illness leading to maladaptive behaviors.		
Psychological factors affecting other medical conditions	Psychological or behavioral factors negatively impact a medical illness.		
Factitious disorder or facti- tious disorder imposed on another	Deliberate false presentation of oneself or another (or causing in oneself or another) signs or symptoms of a physical or psychological problem.		

models for children. More extreme parental dysfunction can manifest as factitious disorder imposed on another with the child as the victim.

Identification & Diagnosis

Somatic symptom disorder often presents in school age children and adolescents with the somatic symptom of headaches or gastrointestinal distress. Conversion symptoms by definition involve alterations in voluntary motor or sensory function and are often more transient in pediatric patients than adults. Common symptoms include unusual sensory phenomena, paralysis, and movement or seizure-like disorders. A conversion symptom is thought to be an expression of underlying psychological conflict. The specific symptom may be symbolically determined by the underlying conflict and may resolve the dilemma created by the underlying wish or fear (eg, a seemingly paralyzed child need not fear expressing his or her underlying rage or aggressive retaliatory impulses).

Children with conversion disorder may be surprisingly unconcerned about the substantial disability deriving from their symptoms. Symptoms include unusual sensory phenomena, paralysis, vomiting, abdominal pain, intractable headaches, and movement or seizure-like disorders. For both somatic symptom disorder and conversion disorder, the physical symptoms often begin with a stressful event at school, with peers or within the context of a family experiencing stress, such as serious illness, a death, or family discord.

Treatment

Medical providers are often the first to see the patient and identify these disorders. Many of these patients can be treated within the pediatric primary care setting, utilizing the relationship between the pediatric provider and the family to maximize outcomes. For those who need referral to other settings, ongoing care by the pediatrician can help insure families engage in other indicated treatments.

In most cases, conversion symptoms resolve quickly when the child and family are reassured that the symptom is a way of reacting to stress. The child is encouraged to continue with normal daily activities, knowing that the symptom will abate when the stress is resolved. Treatment of conversion disorders includes acknowledging the symptom rather than telling the child that the symptom is not medically justified and responding with noninvasive interventions such as physical therapy while continuing to encourage normalization of the symptoms. If the symptom does not resolve with reassurance, further investigation by a mental health professional is indicated. Comorbid diagnoses such as depression and anxiety disorders should be addressed, and treatment with psychopharmacologic agents may be helpful.

Somatic symptom disorder patients may respond to the same treatment. If the family structure or the patient cannot tolerate psychological approaches, somatic symptom patients may respond to regular, short, scheduled medical appointments to address the complaints at hand. In this way they do not need to precipitate emergencies to elicit medical attention. The medical provider should avoid invasive procedures unless clearly indicated and offer sincere concern and reassurance. The provider should also avoid telling the patient "it's all in your head" and should not abandon or avoid the patient, as somatic symptom disorder patients are at great risk of seeking multiple alternative treatment providers and potentially unnecessary treatments. Although, not a DSM disorder, many parents worry about their child developing or having a serious illness. These families may also benefit from the above approach, in conjunction with encouragement for the pediatric patient to engage in health promoting activities such as involvement in sports. Parents who do not feel supported are also at risk to seek alternative opinions and procedures for their child.

Treatment for patients who are suffering from psychological factors impacting illness should be targeted to the underlying problem, such as treatment of anxious avoidance, motivational interviewing to target substance abuse or adherence problems.

Health care providers who suspect factitious disorder imposed on another may need to involve a specialist to confirm the diagnosis. Communication between providers is critical to helping these patients. Child protective services and legal counsel may also need to be alerted. Although parents who are perpetrating factitious disorder imposed on another can appear concerned about the wellbeing of their child, studies have found child victims' mental health and well-being improved when they were removed from more extreme perpetrating caregivers.

Other Considerations

Somatic symptoms are often associated with anxiety and depressive disorders (see Tables 7–7 and 7–15). Occasionally, psychotic children have somatic preoccupations and even somatic delusions.

Children with conversion disorder may have some secondary gain associated with their symptoms. Several reports have pointed to the increased association of conversion disorder with sexual overstimulation or sexual abuse. As with other emotional and behavioral problems, health care providers should always screen for physical and sexual abuse.

Prognosis

Prognosis is dependent on family factors, age, and disorder. Parents who support the view that symptoms can be related to stress can help patients engage in appropriate treatments. Younger patients with conversion symptoms have better prognosis than older patients with somatic symptom disorder. Patients who have had the disorder for a longer period of time may be less responsive to treatment. Psychiatric consultation can be helpful and for severely incapacitated patients, is indicated.

ADJUSTMENT DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ► The precipitating event or circumstance is identifiable.
- The symptoms have appeared within 3 months after the occurrence of the stressful event.
- Although the child experiences distress or some functional impairment, the reaction is not severe or disabling.
- The reaction does not persist more than 6 months after the stressor has terminated.

General Considerations

The most common and most disturbing stressors in the lives of children and adolescents are the death of a loved one, marital discord, separation and divorce, family illness, a change of residence or school setting, experiencing a traumatic event, and, for adolescents, peer-relationship problems. These stressors naturally have a significant impact on children and adolescents.

Identification & Diagnosis

When faced with stress, children can experience many different symptoms, including changes in mood, changes in behavior, anxiety symptoms, and physical complaints. When the reaction is significantly out of proportion to the stressor and a decline in functioning is noted, a diagnosis of adjustment disorder is highly suspected. The two main categories of adjustment disorders include disturbance in emotions (ie, depression and anxiety) and/or conduct.

Treatment

The mainstay of treatment involves genuine empathy and assurance to the parents and the patient that the emotional or behavioral change is a predictable consequence of the stressful event. This validates the child's reaction and encourages the child to talk about the stressful occurrence and its aftermath. Parents are encouraged to help the child with appropriate expression of feelings, while defining boundaries for behavior that prevent the child from feeling out of control and ensure safety of self and others. Maintaining or reestablishing routines can also alleviate distress and help children and adolescents adjust to changing circumstances by increasing predictability and decreasing distress about the unknown.

Other Considerations

When symptoms emerge in reaction to an identifiable stressor but are severe, persistent, or disabling, depressive disorder, anxiety disorder, and conduct disorders must be considered.

Prognosis

The duration of symptoms in adjustment reactions depends on the severity of the stress; the child's personal sensitivity to stress and vulnerability to anxiety, depression, and other psychiatric disorders; and the available support system.

PSYCHOTIC DISORDERS

- Delusional thoughts
- Disorganized speech (rambling or illogical speech patterns)
- Disorganized or bizarre behavior
- Hallucinations (auditory, visual, tactile, olfactory)
- Paranoia, ideas of reference
- Negative symptoms (ie, flat affect, avolition, alogia)

General Considerations

The incidence of schizophrenia is about 1 per 10,000 per year. The onset of schizophrenia is typically between the

middle to late teenage and early 30s. Symptoms usually begin after puberty, although a full "psychotic break" may not occur until the young adult years. Childhood onset (before puberty) of psychotic symptoms due to schizophrenia is uncommon and usually indicates a more severe form of the spectrum of schizophrenic disorders. Childhoodonset schizophrenia is more likely to be found in boys.

Schizophrenia has a strong genetic component. Other psychotic disorders that may be encountered in childhood or adolescence include schizoaffective disorder and psychosis not otherwise specified (psychosis NOS). Psychosis NOS may be used as a differential diagnosis when psychotic symptoms are present, but the cluster of symptoms is not consistent with a schizophrenia diagnosis.

Identification & Diagnosis

Children and adolescents display many of the symptoms of adult schizophrenia. Hallucinations or delusions, bizarre and morbid thought content, and rambling and illogical speech are typical. Affected individuals tend to withdraw into an internal world of fantasy and may then equate fantasy with external reality. They generally have difficulty with schoolwork and with family and peer relationships. Adolescents may have a prodromal period of depression prior to the onset of psychotic symptoms. The majority of patients with childhood-onset schizophrenia have had nonspecific psychiatric symptoms or symptoms of delayed development for months or years prior to the onset of their overtly psychotic symptoms.

Obtaining a family history of mental illness is critical when assessing children and adolescents with psychotic symptoms. Psychological testing, particularly the use of projective measures, is often helpful in identifying or ruling out psychotic thought processes. Psychotic symptoms in children younger than age 8 years must be differentiated from manifestations of normal vivid fantasy life or abuse-related symptoms. Children with psychotic disorders often have learning and attention disabilities in addition to disorganized thoughts, delusions, and hallucinations. In psychotic adolescents, mania is differentiated by high levels of energy, excitement, and irritability. Any child or adolescent exhibiting new psychotic symptoms requires a medical evaluation that includes physical and neurologic examinations (including consideration of magnetic resonance imaging and electroencephalogram), drug screening, and metabolic screening for endocrinopathies, Wilson disease, and delirium.

Treatment

The treatment of childhood and adolescent schizophrenia focuses on four main areas: (1) decreasing active psychotic symptoms, (2) supporting development of social and cognitive skills, (3) reducing the risk of relapse of psychotic symptoms, and (4) providing support and education to parents and family members. Antipsychotic medications (neuroleptics) are the primary psychopharmacologic intervention. In addition, a supportive, reality-oriented focus in relationships can help to reduce hallucinations, delusions, and frightening thoughts. In situations where psychosis is evident, a referral to a psychiatrist is recommended. In cases of severe impairment, hospitalization is required to maintain safety and initiate treatment. A special school or day treatment environment may be necessary, depending on the child's or adolescent's ability to tolerate the school day and classroom activities. Support for the family emphasizes the importance of clear, focused communication and an emotionally calm climate in preventing recurrences of overtly psychotic symptoms.

Special Considerations Regarding the Use of Antipsychotic Medication

While it is expected that a psychiatrist initiate treatment, primary care providers undoubtedly treat children on antipsychotics and should become familiar with management and potential common and severe side effects of this class of medication. The "atypical antipsychotics" differ from conventional antipsychotics in their receptor specificity and effect on serotonin receptors. Conventional antipsychotics are associated with a higher incidence of movement disorders and extrapyramidal symptoms due to their wider effect on dopamine receptors. The atypical antipsychotics have a better side-effect profile for most individuals and comparable efficacy for the treatment of psychotic symptoms and aggression. Because of their increased use over conventional antipsychotics, the information that follows primarily focuses on safe use of atypical antipsychotics.

Common adverse effects of the atypical antipsychotics are cognitive slowing, sedation, orthostasis, and weight gain. Most side effects tend to be dose related. Less frequent, but important side effects are development of type 2 diabetes and change in lipid and cholesterol profile. The risk-benefit ratio of the medication for the identified target symptom should be carefully considered and reviewed with the parent or guardian. Providers should obtain baseline height, weight, and waist circumference, observe and examine for tremors and other abnormal involuntary movements, and establish baseline values for CBC and LFTs, lipid profile, and cholesterol. Antipsychotics can cause QT prolongation leading to ventricular arrhythmias. Therefore, it is important to obtain an ECG if there is a history of cardiac disease or arrhythmia. Medications that affect the cytochrome P-450 isoenzyme pathway (including SSRIs) may increase the neuroleptic plasma concentration and increase risk of QTc prolongation.

In addition to the above concerns, postmarketing clinical use has demonstrated significant reports of hyperglycemia, and diabetes mellitus. Table 7–16 presents the currently recommended monitoring calendar. Baseline and ongoing

Table 7-16. Health monitoring and antipsychotics.

^aMore frequent assessments may be warranted based on clinical status.

evaluations of significant markers are considered standard clinical practice. It is important to mention other side effects, which include irregular menses, gynecomastia, and galactorrhea due to increased prolactin, sexual dysfunction, photosensitivity, rashes, lowered seizure threshold, hepatic dysfunction, and blood dyscrasias.

Other troublesome side effects of antipsychotics include dystonia, akathisia (characterized by an urge to be in constant motion and difficulty sitting still), pseudoparkinsonism, and tardive dyskinesia (TD). These side effects typically occur in a stepwise fashion and are also dose related. The first three are reversible and typically are relieved by anticholinergic agents, such as benztropine (Cogentin) and diphenhydramine, or β -blockers, specifically for akathisia. The risk of TD is small in patients on atypical antipsychotics, and those on conventional antipsychotics for less than 6 months. There is no universally effective treatment. Withdrawal dyskinesias are reversible movement disorders that appear following withdrawal of neuroleptic medications. Dyskinetic movements develop within 1–4 weeks after withdrawal of the drug and may persist for months.

A severe side effect of antipsychotics is neuroleptic malignant syndrome (NMS). NMS is a very rare medical emergency associated primarily with the conventional antipsychotics, although it has also been reported with atypical antipsychotics. It is manifested by severe muscular rigidity, mental status changes, fever, autonomic lability, and myoglobinemia. NMS can occur without muscle rigidity in patients taking atypical antipsychotics and should be considered in the differential diagnosis of any patient on antipsychotics who presents with high fever and altered mental status. Mortality as high as 30% has been reported. Treatment includes immediate medical assessment and withdrawal of the neuroleptic and may require transfer to an intensive care unit.

The patient should be examined at least every 3 months for side effects, including observation for TD using the Abnormal Involuntary Movement Scale quarterly monitoring of blood pressure, weight gain, abdominal circumference, dietary and exercise habits, and, if indicated, fasting blood glucose and lipid panels. In cases of significant weight gain or abnormal laboratory values, patients should either be switched to an agent with a decreased risk for these adverse events or should receive specific treatments for the adverse events when discontinuation of the offending agent is not possible. In general, a child and adolescent psychiatrist should evaluate children with psychosis, initiate treatment and refer back to the pediatrician once symptoms are adequate control.

Other Considerations

Antipsychotics are also used for acute mania and as adjuncts to antidepressants in the treatment of psychotic depression (with delusions or hallucinations). Antipsychotics may also be used cautiously in refractory PTSD, in refractory OCD, and in individuals with markedly aggressive behavioral problems unresponsive to other interventions. In some instances, they may be useful for the body image distortion and irrational fears about food and weight gain associated with anorexia nervosa.

Prognosis

Schizophrenia is a chronic disorder with exacerbations and remissions of psychotic symptoms. Generally, earlier onset (prior to age 13 years), poor premorbid functioning (oddness or eccentricity), and predominance of negative symptoms (withdrawal, apathy, or flat affect) over positive symptoms (hallucinations or paranoia) predict more severe disability, while later age of onset, normal social and school functioning prior to onset, and predominance of positive symptoms are associated with better outcomes and life adjustment to the illness.

The American Academy has a practice parameter regarding the use of atypical antipsychotics in youth available at https://www.aacap.org/App_Themes/AACAP/docs/practice_parameters/Atypical_Antipsychotic_Medications_Web.pdf.

- Tourette syndrome and tic disorders: see Chapter 25.

Antonia Chiesa, MD Andrew P. Sirotnak, MD

INTRODUCTION

- Forms of maltreatment:
 - · Physical abuse
 - Sexual abuse
 - · Emotional abuse and neglect
 - Physical neglect
 - Medical care neglect
 - Medical child abuse (Munchausen syndrome by proxy)
- Common historical features in child abuse cases:
 - · Implausible mechanism provided for an injury
 - · Discrepant, evolving, or absent history
 - Delay in seeking care
 - Event or behavior by a child that triggers a loss of control by the caregiver
 - · History of abuse in the caregiver's childhood
 - Inappropriate affect of the caregiver
 - Pattern of increasing severity or number of injuries if no intervention
 - · Social or physical isolation of the child or the caregiver
 - · Stress or crisis in the family or the caregiver
 - · Unrealistic expectations of caregiver for the child
 - Behavior changes of child

In 2015, an estimated 4 million referrals were made to child protective service agencies, involving the alleged maltreatment of approximately 7.2 million children. Policies about how to screen incoming calls regarding abuse concerns and how to investigate suspicious cases varies among states. Some states investigate every case that is referred while others may screen out referrals based on certain criteria. More and more states are using an "alternative response" system to handle screened-in reports that are deemed low or moderate risk. While traditional investigative methods focus on identifying whether a child has been maltreated, these alternative response models prioritize services needs of the family over determining victimization. Data collection strategies have been altered to capture both forms of assessment.

Children 3 years of age and younger have the highest rates of maltreatment. The total number of children confirmed as maltreated by child protective services was estimated to be 683,000 in 2015, yielding an abuse victimization rate of 9.2 per 1000 American children. This statistic is referred to as the "unique count" where a child is counted only once regardless of the number of times the child is substantiated as a victim. Sexual abuse rates continue to decline. Rates for physical abuse and neglect increased slightly from the immediate past few years; however, all forms of child maltreatment have declined during the preceding decade. Neglect, again the most common form of abuse, was substantiated in 75.3% of cases, while 11.5% of cases involved physical abuse, and 10% involved sexual abuse. Overall, rates are down compared to prior decades. This parallels the trend in lower crime rate but other factors such as improvements in education, reporting, and system responses have also likely played a role in the reduction.

There were 1670 victims of fatal child abuse in 2015 from 50 states, resulting in a rate of 2.25 child abuse deaths per 100,000 children, slightly higher than the 2014. Fatalities occur with relatively low frequency, so rates are sensitive to changes in reporting and fluctuations in child population. The topic has garnered national attention, and in 2016 a national commission created by Congress completed a report outlining recommendations to reduce child deaths from abuse.

Substance abuse, poverty and economic strains, parental capacity and skills, and domestic violence are cited as the most common presenting problems in abusive families. Almost a third of substantiated maltreatment cases include domestic violence as a caregiver risk factor. Abuse and neglect of children are best considered in an ecological perspective, which recognizes the individual, family, social, and psychological influences that come together to contribute to the problem. Kempe and Helfer termed this the *abusive pattern*, in which the child, the crisis, and the caregiver's potential to abuse are components in the event of maltreatment. This chapter focuses on the knowledge necessary for the recognition, intervention, and follow-up of the more common forms of child maltreatment and highlights the role of pediatric professionals in prevention.

U.S. Department of Health and Human Services. Administration for Children, Youth, and Families. Child Maltreatment 2015. https://www.acf.hhs.gov/cb/resource/child-maltreatment-2015. Accessed March 3, 2017.

PREVENTION

Physical abuse is preventable in many cases. Extensive experience with an evaluation of high-risk families has shown that home visiting services to families at risk can prevent abuse and neglect of children. These services can be provided by public health nurses or trained paraprofessionals, although more data are available describing public health nurse intervention. Parent education and primary care providers' anticipatory guidance are also helpful, with attention to handling situations that stress parents (eg, colic, crying behavior, and toilet training), age-appropriate discipline, and general education about child developmental issues. Prevention of abusive injuries perpetrated by nonparent caregivers (eg, babysitters, nannies, and unrelated adults in the home) may be addressed by education and counseling of mothers about safe child care arrangements and choosing safe life partners. Hospital-based prevention programs that teach parents about the dangers of shaking an infant and how to respond to a crying infant have demonstrated some positive results; however, no one effort has been shown to be completely effective.

The prevention of sexual abuse is more difficult. Most efforts in this area involve teaching children to protect themselves and their "private parts" from harm or interference. The age of toilet training is a good time to provide anticipatory guidance to encourage parents to begin this discussion. The most rational approach is to place the burden of responsibility of prevention on the adults who supervise the child and the medical providers rather than on the children themselves. Knowing the parents' own history of any victimization is important, as the ability to engage in this anticipatory guidance discussion with a provider and their child may be affected by that history. Promoting Internet and social media safety and limiting exposure to sexualized materials and media should be part of this anticipatory guidance. Finally, many resources on this topic for parents can be found in the parenting and health sections of most bookstores.

Efforts to prevent emotional abuse of children have been undertaken through extensive media campaigns. No data are available to assess the effectiveness of this approach. The primary care physician can promote positive, nurturing, and nonviolent behavior in parents. The message that they are role models for a child's behavior is important. Screening for domestic violence during discussions on discipline and home safety can be effective in identifying parents and children at risk. Societal factors can influence a family's capacity to parent and care for a child. Issues of crime and safety within a community, the educational system and even the economy may indirectly affect family functioning.

CLINICAL FINDINGS

Child maltreatment may occur either within or outside the family. The proportion of intrafamilial to extrafamilial cases varies with the type of abuse as well as the gender and age of the child. Each of the following conditions may exist as separate or concurrent diagnoses.

Recognition of any form of abuse and neglect of children can occur only if child abuse is considered in the differential diagnosis of the child's presenting medical condition. The advent of electronic medical records can make documenting concerns and patterns of maltreatment more accessible for all care team members. The approach to the family should be supportive, nonaccusatory, and empathetic. The individual who brings the child in for care may not have any involvement in the abuse. Approximately one-third of child abuse incidents occur in extrafamilial settings. Nevertheless, the assumption that the caregiver is "nice," combined with the failure to consider the possibility of abuse, can be costly and even fatal. Raising the possibility that a child has been abused is not the same as accusing the caregiver of being the abuser. The health professional who is examining the child can explain to the family that several possibilities might explain the child's injuries or abuse-related symptoms. If the family or presenting caregiver is not involved in the child's maltreatment, they may actually welcome the necessary report and investigation.

In all cases of abuse and neglect, a detailed psychosocial history is important because psychosocial factors may indicate risk for or confirm child maltreatment. This history should include information on who lives in the home, other caregivers, domestic violence, substance abuse, and prior family history of physical or sexual abuse. Inquiring about any previous involvement with social services or law enforcement can help to determine risk.

Physical Abuse

Physical abuse of children is most often inflicted by a caregiver or family member but occasionally by a stranger. The most common manifestations include bruises, burns, fractures, head trauma, and abdominal injuries. A small but significant number of unexpected pediatric deaths, particularly in infants and very young children (eg, sudden unexpected infant death), are related to physical abuse.

A. History

The medical diagnosis of physical abuse is based on the presence of a discrepant history, in which the history offered by the caregiver is not consistent with the clinical findings. The discrepancy may exist because the history is absent, partial, changing over time, or simply illogical or improbable. A careful past medical, birth, and family history should also be obtained in order to assess for any other medical condition that might affect the clinical presentation. The presence of a discrepant history should prompt a request for consultation with a multidisciplinary child protection team or a report to the child protective services agency. This agency is mandated by state law to investigate reports of suspected child abuse and neglect. Investigation by social services and possibly law enforcement officers, as well as a home visit, may be required to sort out the circumstances of the child's injuries.

B. Physical Findings

The findings on examination of physically abused children may include abrasions, alopecia (from hair pulling), bites, bruises, burns, dental trauma, fractures, lacerations, ligature marks, or scars. Injuries may be in multiple stages of healing. Bruises in physically abused children are sometimes patterned (eg, belt marks, looped cord marks, or grab or pinch marks) and are typically found over the soft tissue areas of the body. Toddlers or older children typically sustain accidental bruises over bony prominences such as shins and elbows. Any unexplained bruise in an infant not

Table 8–1. Potential child abuse medical emergencies.

- Any infant with bruises (especially head, facial, or abdominal), burns, or fractures
- Any infant or child younger than 2 y with a history of suspected "shaken baby" head trauma or other inflicted head injury
- Any child who has sustained suspicious or known inflicted abdominal trauma
- Any child with burns in stocking or glove distribution or in other unusual patterns, burns to the genitalia, and any unexplained burn injury
- Any child with disclosure or sign of sexual assault within 48–72 h after the alleged event if the possibility of acute injury is present or if forensic evidence exists

developmentally mobile should be viewed with concern. Of note, the dating of bruises is not reliable and should be approached cautiously. (Child abuse emergencies are listed in Table 8–1.) Lacerations of the frenulum or tongue and bruising of the lips may be associated with force feeding or blunt force trauma. Pathognomonic burn patterns include stocking or glove distribution; immersion burns of the buttocks, sometimes with a "doughnut hole" area of sparing; and branding burns such as with cigarettes or hot objects (eg, grill, curling iron, or lighter). The absence of splash marks or a pattern consistent with spillage may be helpful in differentiating accidental from nonaccidental scald burns.

Head and abdominal trauma may present with signs and symptoms consistent with those injuries. Abusive head trauma (eg, shaken baby syndrome) and abdominal injuries may have no visible findings on examination. Symptoms can be subtle and may mimic other conditions such as gastroenteritis. Studies have documented that cases of inflicted head injury will be missed when practitioners fail to consider the diagnosis. The finding of retinal hemorrhages in an infant without an appropriate medical condition (eg, leukemia, congenital infection, or clotting disorder) should raise concern about possible inflicted head trauma. Retinal hemorrhages are not commonly seen after cardiopulmonary resuscitation in either infants or children.

C. Radiologic and Laboratory Findings

Certain radiologic findings are strong indicators of physical abuse. Examples are metaphyseal "corner" or "bucket handle" fractures of the long bones in infants, spiral fracture of the extremities in nonambulatory infants, rib fractures, spinous process fractures, and fractures in multiple stages of healing. Skeletal surveys in children aged 3 years or younger should be performed when a suspicious injury is diagnosed. Computed tomography or magnetic resonance imaging findings of subdural hemorrhage in infants—in the absence of a clear accidental history—are highly correlated with

CHAPTER 8

abusive head trauma. Abdominal computed tomography is the preferred test in suspected abdominal trauma. Any infant or very young child with suspected abuse-related head or abdominal trauma should be evaluated immediately by an emergency physician or trauma surgeon.

Coagulation studies and a complete blood cell count with platelets are useful in children who present with multiple or severe bruising in different stages of healing. Liver function tests should be considered to screen for abdominal injury. Coagulopathy conditions may confuse the diagnostic picture but can be excluded with a careful history, examination, laboratory screens, and hematologic consultation, if necessary.

Sexual Abuse

Sexual abuse is defined as the engaging of dependent, developmentally immature children in sexual activities that they do not fully comprehend and to which they cannot give consent, or activities that violate the laws and taboos of a society. It includes all forms of incest, sexual assault or rape, and pedophilia. This includes fondling, oral-genital-anal contact, all forms of intercourse or penetration, exhibitionism, voyeurism, exploitation, or prostitution, and the involvement of children in the production of pornography. Over the past decade, there has been a small downward trend nationally in rates of child sexual abuse; however, the exploitation and enticement of children via the Internet and social media and human trafficking cases have gained increases in recognition.

Table 8–2. Presentations of sexual abuse.

General or direct statements about sexual abuse
Sexualized knowledge, play, or behavior in developmentally immature children
Sexual abuse of other children by the victim
Behavioral changes
Sleep disturbances (eg, nightmares and night terrors)
Appetite disturbances (eg, anorexia, bulimia)
Depression, social withdrawal, anxiety
Aggression, temper tantrums, impulsiveness
Neurotic or conduct disorders, phobias or avoidant behaviors
Guilt, low self-esteem, mistrust, feelings of helplessness
Hysterical or conversion reactions
Suicidal, runaway threats or behavior
Excessive masturbation
Medical conditions
Recurrent abdominal pain or frequent somatic complaints
Genital, anal, or urethral trauma
Recurrent complaints of genital or anal pain, discharge, bleeding
Enuresis or encopresis
Sexually transmitted infections
Pregnancy
Promiscuity or prostitution, sexual dysfunction, fear of intimacy
School problems or truancy
Substance abuse

A. History

Sexual abuse may come to the clinician's attention in different ways: (1) The child may be brought in for routine care or for an acute problem, and sexual abuse may be suspected by the medical professional as a result of the history or the physical examination. (2) The parent or caregiver, suspecting that the child may have been sexually abused, may bring the child to the health care provider and request an examination to rule in or rule out abuse. (3) The child may be referred by child protective services or the police for an evidentiary examination following either disclosure of sexual abuse by the child or an allegation of abuse by a parent or third party. Table 8-2 lists the common presentations of child sexual abuse. Certain high-risk behaviors should prompt recognition of possible human trafficking, including substance abuse, runaway activity, multiple sexual partners, law enforcement history, or presenting to care without identification. If suspected, this should be addressed confidentially with the patient. It should be emphasized that with the exception of acute trauma, certain sexually transmitted infections (STIs), or forensic laboratory evidence, none of these presentations is specific. The presentations listed should arouse suspicion of the possibility of sexual abuse and lead the practitioner to ask the appropriate questions-again, in a compassionate and nonaccusatory manner. Asking the child nonleading, age-appropriate questions is important and is often best handled by the most experienced interviewer after a report is made. Community agency protocols may exist for child advocacy centers that help in the investigation of these reports. Concerns expressed about sexual abuse in the context of divorce and custody disputes should be handled in the same manner, with the same objective, nonjudgmental documentation. The American Academy of Pediatrics has published guidelines for the evaluation of child sexual abuse as well as others relating to child maltreatment.

B. Physical Findings

The genital and anal findings of sexually abused children, as well as the normal developmental changes and variations in prepubertal female hymens, have been described in journal articles and visual diagnosis guides. To maintain a sense of comfort and routine for the patient, the genital examination should be conducted in the context of a full body checkup. For nonsexually active, prepubertal girls, an internal speculum examination is rarely necessary unless there is suspicion of internal injury. The external female genital structures can be well visualized using labial separation and traction with the child in the supine frog leg or knee-chest position. The majority of victims of sexual abuse exhibit no physical findings. The reasons for this include delay in disclosure by the child, abuse that may not cause physical trauma (eg, fondling, oral-genital contact, or exploitation by pornographic photography), or rapid healing of minor injuries such as labial, hymenal, or anal abrasions, contusions, or lacerations. Nonspecific abnormalities of the genital and rectal regions such as erythema, rashes, and irritation may not suggest sexual abuse in the absence of a corroborating history, disclosure, or behavioral changes.

Certain STIs should strongly suggest sexual abuse. Neisseria gonorrhoeae infection or syphilis beyond the perinatal period is diagnostic of sexual abuse. Chlamydia trachomatis, herpes simplex virus, trichomoniasis, and human papillomavirus are all sexually transmitted, although the course of these potentially perinatally acquired infections may be protracted. Herpes simplex can be transmitted by other means; however, the presence of an infection should prompt a careful assessment for sexual abuse. Risk is higher in children older than five with isolated herpetic genital lesions. In the case of human papillomavirus, an initial appearance of venereal warts beyond the toddler age should prompt a discussion regarding concerns of sexual abuse. Human papillomavirus is a ubiquitous virus and can be spread innocently by caregivers with hand lesions; biopsy and viral typing is rarely indicated and often of limited availability. Finally, sexual abuse must be considered with the diagnosis of C trachomatis or human immunodeficiency virus (HIV) infections when other modes of transmission (eg, transfusion or perinatal acquisition) have been ruled out. Postexposure prophylaxis medications for HIV in cases of acute sexual assault should be considered only after assessment of risk of transmission and consultation with an infectious disease expert.

Nucleic acid amplification tests (NAATs) have been used with increasing frequency for screening of STIs in sexual abuse victims, including for children younger than 12 years. For prepubertal children, NAATs can be used for vaginal specimens or urine from girls. If a NAAT is positive, a second confirmatory NAAT test that analyzes an alternate target of the genetic material in the sample or a standard culture is needed. For boys and for extragenital specimens, culture is still the preferred method. Finally, the Centers for Disease Control and Prevention and the AAP Redbook list guidelines for the screening and treatment of STIs in the context of sexual abuse.

C. Examination, Evaluation, and Management

The forensic evaluation of sexually abused children should be performed in a setting that prevents further emotional distress. All practitioners should have access to a rape kit, which guides the practitioner through a stepwise collection of evidence and cultures. This should occur in an emergency department or clinic where chain of custody for specimens can be ensured. The most experienced examiner (pediatrician, nurse examiner, or child advocacy center) is preferable. If the history indicates that the adolescent may have had contact with the ejaculate of a perpetrator within 120 hours, a cervical examination to look for semen or its markers (eg, acid phosphatase) should be performed according to established protocols. Prior to any speculum examination of an assault victim, it is important to consider the child's physiologic and emotional maturation, and whether she has been sexually active or had a speculum examination in the past. A speculum examination in a prepubertal child is rarely indicated unless there is concern for internal injury and in those cases, it is generally advised to perform the examination under anesthesia and with the assistance of gynecology. More important, if there is a history of possible sexual abuse of any child within the past several days, and the child reports a physical complaint or a physical sign is observed (eg, genital or anal bleeding or discharge), the child should be examined for evidence of trauma. Colposcopy may be critical for determining the extent of the trauma and photodocumentation may be helpful in providing documentation for the legal system.

All the components of a forensic evidence collection kit may not be indicated in the setting of child sexual abuse (as opposed to adult rape cases); the clinical history and exposure risk should guide what specimens are collected. Beyond 120 hours, evaluation is tailored to the history provided. The involved orifices should be tested for *N gonorrhoeae* and *C trachomatis*, and vaginal secretions evaluated for *Trichomonas*. These infections and bacterial vaginosis are the most frequently diagnosed infections among older girls who have been sexually assaulted. RPR, hepatitis B, and HIV serology should be drawn at baseline and repeated up to 6 months after last contact. Pregnancy testing should be done as indicated.

Acute sexual assault cases that involve trauma or transmission of body fluid should have STI prophylaxis. Using adult doses of ceftriaxone (250 mg IM in a single dose), metronidazole (2 g orally in a single dose), and azithromycin (1 g orally in a single dose) should be offered when older or adolescent patients present for evaluation. (Pediatric treatment and dosing is calculated by weight and can be found in standard references.) Hepatitis B vaccination should be administered to patients if they have not been previously vaccinated and there should be consideration to providing hepatitis B immunoglobulin in certain high-risk cases. No effective prophylaxis is available for hepatitis C. Evaluating the perpetrator for a sexually transmitted infection, if possible, can help determine risk exposure and guide prophylaxis. HIV prophylaxis should be considered in certain circumstances (see Chapter 44). For postpubertal girls, contraception should be given if rape abuse occurred within 120 hours.

Although it is often difficult for persons to complete recommended follow-up examinations weeks after an assault, such examinations are essential to detect new infections, complete immunization with hepatitis B vaccination if needed, and continue psychological support.

Emotional Abuse & Neglect

Emotional or psychological abuse has been defined as the rejection, ignoring, criticizing, isolation, or terrorizing of children, all of which have the effect of eroding their self-esteem. The most common form is verbal abuse or denigration. Children who witness domestic violence should be considered emotionally abused, as a growing body of literature has shown the negative effects of intimate partner violence on child development.

The most common feature of emotional neglect is the absence of normal parent-child attachment and a subsequent inability to recognize and respond to an infant's or child's needs. A common manifestation of emotional neglect in infancy is nutritional (nonorganic) failure to thrive. Emotionally neglectful parents appear to have an inability to recognize the physical or emotional states of their children. For example, an emotionally neglectful parent may ignore an infant's cry if the cry is perceived incorrectly as an expression of anger. This misinterpretation leads to inadequate nutrition and failure to thrive.

Emotional abuse may cause nonspecific symptoms in children. Loss of self-esteem or self-confidence, sleep disturbances, somatic symptoms (eg, headaches and stomach aches), hypervigilance, or avoidant or phobic behaviors (eg, school refusal or running away) may be presenting complaints. These complaints may also be seen in children who experience domestic violence. Emotional abuse can occur in the home or day care, school, sports team, or other settings.

Physical Neglect & Failure to Thrive

Physical neglect is the failure to provide the necessary food, clothing, and shelter and a safe environment in which children can grow and develop. Although often associated with poverty or ignorance, physical neglect involves a more serious problem than just lack of resources. There is often a component of emotional neglect and either a failure or an inability, intentionally or otherwise, to recognize and respond to the needs of the child.

A. History

Even though in 2015 neglect was confirmed for over threequarters of all victims, neglect is not easily documented on history. Given that neglect is the most common form of abuse, providers should be proactive in their approach to recognition and treatment. Physical neglect—which must be differentiated from the deprivations of poverty—will be present even after adequate social services have been provided to families in need. The clinician must evaluate the psychosocial history and family dynamics when neglect is a consideration and is in a unique position to intervene when warning signs first emerge. A careful social services evaluation of the home and entire family may be required. The primary care provider must work closely with a social service agency and explain the known medical information to help guide their investigation and decision making.

The history offered in cases of growth failure (failure to thrive) is often discrepant with the physical findings. Infants who have experienced a significant deceleration in growth are probably not receiving adequate amounts or appropriate types of food despite the dietary history provided. Medical conditions causing poor growth in infancy and early childhood can be ruled out with a detailed history and physical examination with minimal laboratory tests. A psychosocial history may reveal maternal depression, family chaos or dysfunction, or other previously unknown social risk factors (eg, substance abuse, violence, poverty, or psychiatric illness). Placement of the child with another caregiver is usually followed by a dramatic weight gain. Hospitalization of the severely malnourished patient is sometimes required, but most cases are managed on an outpatient basis.

B. Physical Findings

Infants and children with nonorganic failure to thrive have a relative absence of subcutaneous fat in the cheeks, buttocks, and extremities. Other conditions associated with poor nutrient and vitamin intake may be present. If the condition has persisted for some time, these patients may also appear and act depressed. Older children who have been chronically emotionally neglected may also have short stature (ie, deprivation dwarfism). The head circumference is usually normal in cases of nonorganic failure to thrive. Microcephaly may indicate a prenatal condition, congenital disease, or chronic nutritional deprivation and increases the likelihood of more serious and possibly permanent developmental delay.

C. Radiologic and Laboratory Findings

Children with failure to thrive or malnutrition may not require an extensive workup. Assessment of the patient's growth curve, as well as careful plotting of subsequent growth parameters after treatment, is critical. Complete blood cell count, urinalysis, electrolyte panel, and thyroid and liver function tests are sufficient screening. Newborn screening should be documented as usual. Other tests should be guided by any aspect of the clinical history that points to a previously undiagnosed condition. A skeletal survey and head computed tomography scan may be helpful if concurrent physical abuse is suspected. The best screening method, however, is placement in a setting in which the child can be fed and monitored. Hospital or foster care placement may be required. Weight gain may not occur for several days to a week in severe cases.

Medical Care Neglect

Medical care neglect is failure to provide the needed treatment to infants or children with life-threatening illness or other serious or chronic medical conditions. Many states have repealed laws that supported religious exemptions as reason for not seeking medical care for sick children.

Medical Child Abuse

Previously referred to as Munchausen syndrome by proxy, medical child abuse is the preferred term for a relatively unusual clinical scenario in which a caregiver seeks inappropriate and unnecessary medical care for a child. Oftentimes, the caregiver either simulates or creates the symptoms or signs of illness in a child. However, the use of the term medical child abuse emphasizes harm caused to the child as opposed to the psychopathology or motivation of the caregiver. Cases can be complicated and a detailed review of all medical documentation and a multidisciplinary approach is required. Fatal cases have been reported.

A. History

Children may present with the signs and symptoms of whatever illness is factitiously produced or simulated. The child can present with a long list of medical problems or often bizarre, recurrent complaints. Persistent doctor shopping and enforced invalidism (eg, not accepting that the child is healthy and reinforcing that the child is somehow ill) are also described in the original definition of Munchausen syndrome by proxy.

B. Physical Findings

They may be actually ill or, more often, are reported to be ill and have a normal clinical appearance. Among the most common reported presentations are recurrent apnea, dehydration from induced vomiting or diarrhea, sepsis when contaminants are injected into a child, change in mental status, fever, gastrointestinal bleeding, and seizures.

C. Radiologic and Laboratory Findings

Recurrent polymicrobial sepsis (especially in children with indwelling catheters), recurrent apnea, chronic dehydration of unknown cause, or other highly unusual unexplained laboratory findings should raise the suspicion of Munchausen syndrome by proxy. Toxicological testing may also be useful.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for abuse and neglect may be straightforward (ie, traumatic vs nontraumatic injury). It can also be more elusive as in the case of multiple injuries that may raise concern for an underlying medical condition or in situations where complex, but nonspecific behavior changes or physical symptoms reflect the emotional impact of maltreatment.

The differential diagnosis of all forms of physical abuse can be considered in the context of a detailed trauma history, family medical history, radiographic findings, and laboratory testing. The diagnosis of osteogenesis imperfecta or other collagen/bone disorders, for example, may be considered in the child with skin and joint findings or multiple fractures with or without the classic radiographic presentation and is best made in consultation with a geneticist, an orthopedic surgeon, and a radiologist. Trauma-accidental or inflictedleads the differential diagnosis list for subdural hematomas. Coagulopathy; disorders of copper, amino acid, or organic acid metabolism (eg, Menkes syndrome and glutaric acidemia type 1); chronic or previous central nervous system infection; birth trauma; or congenital central nervous system malformation (eg, arteriovenous malformations or cerebrospinal fluid collections) may need to be ruled out in some cases. It should be recognized, however, that children with these rare disorders can also be victims of abuse or neglect.

There are medical conditions that may be misdiagnosed as sexual abuse. When abnormal physical examination findings are noted, knowledge of these conditions is imperative to avoid misinterpretation. The differential diagnosis includes vulvovaginitis, lichen sclerosus, dermatitis, labial adhesions, congenital urethral or vulvar disorders, Crohn disease, and accidental straddle injuries to the labia. In most circumstances, these can be ruled out by careful history and examination.

TREATMENT

A. Management

Physical abuse injuries, STIs, and medical sequelae of neglect should be treated immediately. Children with failure to thrive related to emotional and physical neglect need to be placed in a setting in which they can be fed and cared for. Likewise, the child in danger of recurrent abuse or neglect needs to be placed in a safe environment. Cases can be complicated and psychosocial difficulties are common; therefore, a multidisciplinary approach which works with the family to engage in solving their own problems is helpful. Cooperation and coordination with social work and mental health colleagues are crucial. Given the developmental and emotional implications, prompt referral to mental health resources for any patient with a history of child abuse or neglect is crucial; although not every child with a history of maltreatment will need long-term mental health treatment. There has been significant progress made in identifying, researching, and implementing effective, evidence-based treatment for emotional trauma. There are also effective interventions for improving parenting and attachment problems that are common in child maltreatment cases. Pediatricians should be aware of community partners and resources to help families in need of services.

B. Reporting

In the United States, clinicians and many other professionals who come in contact with or care for children are mandated reporters. If abuse or neglect is suspected, a report must be made to the local or state agency designated to investigate such matters. In most cases, this will be the child protective services agency. Law enforcement agencies may also receive such reports. The purpose of the report is to permit professionals to gather the information needed to determine whether the child's environment (eg, home, school, day care setting, or foster home) is safe. Recent studies document physician barriers to reporting, but providers should be mindful that good faith reporting is a legal requirement for any suspicion of abuse. Failure to report concerns may have legal ramifications for the provider or serious health and safety consequences for the patient. Many hospitals and communities make child protection teams or consultants available when there are questions about the diagnosis and management in a child abuse case. A listing of child abuse pediatric consultants is available from the American Academy of Pediatrics.

Finally, communication with social services, case management, and careful follow-up by primary care providers is crucial to ensuring ongoing safety of child.

PROGNOSIS

Depending on the extent of injury resulting from physical or sexual abuse, the prognosis for complete recovery varies. Serious physical abuse that involves head injury, multisystem trauma, severe burns, or abdominal trauma carries significant morbidity and mortality risk. Hospitalized children with a diagnosis of child abuse or neglect have longer stays and are more likely to die. Long-term medical and developmental consequences are common. For example, children who suffer brain damage related to abusive head injury can have significant neurologic impairment, such as cerebral palsy, vision problems, epilepsy, microcephaly, and learning disorders. Other injuries like minor bruises or burns, fractures, and even injuries resulting from penetrating genital trauma can heal well and with no sequelae.

The emotional and psychological outcomes for child victims are often the most detrimental. Research demonstrates that there are clear neurobiologic effects of child maltreatment and other types of early childhood toxic stress. Physiologic changes to the brain can adversely affect the mental and physical health development of children for decades. Adverse childhood experiences (ACEs) have been associated with chronic adult health problems, suicide, alcoholism and drug abuse, anxiety and depression, violence, and early death. The more ACEs in an individual's background, the higher the risk for these negative outcomes. Despite the potential consequences, the effects of maltreatment can be mitigated. There are effective, evidence-based interventions for child maltreatment. Some children may need extra help addressing emotional regulation, coping skills, and rebuilding trust. The primary care provider plays an important role in assuring appropriate medical and mental health care for maltreated children and families, and in advocating for victims across the child and young adult lifespan.

Ambulatory & Office Pediatrics

Meghan Treitz, MD Daniel Nicklas, MD Maya Bunik, MD, MSPH David Fox, MD

INTRODUCTION

Pediatric ambulatory outpatient services provide children and adolescents with preventive health care and acute and chronic care management services and consultations. In this chapter, special attention is given to the pediatric history and physical examination, normal developmental stages, screening laboratories, and a number of common pediatric issues.

The development of a physician-patient-parent relationship is crucially important if the patient and parent are to effectively confide their concerns. This relationship develops over time, with regular visits, and is facilitated by the continuity of clinicians and other staff members. This clinical relationship is based on trust that develops as a result of several experiences in the context of the office visit. Perhaps the greatest factor facilitating the relationship is for patients or parents to experience advice as valid and effective. Anticipatory guidance should be age-appropriate and timely in order to be most helpful. Important skills include choosing vocabulary that communicates understanding and competence, demonstrating commitment of time and attention to the concern, and showing respect for areas that the patient or parent does not wish to address (assuming that there are no concerns relating to physical or sexual abuse or neglect). Parents and patients expect that their concerns will be managed confidentially and that the clinician understands and sympathizes with those concerns. The effective physicianpatient-parent relationship is one of the most satisfying aspects of ambulatory pediatrics.

Tanner JL, Stein MT, Olson LM, Frintner MP, Radecki L: Reflections on well-child care practice: a national study of pediatric clinicians. Pediatrics 2009 Sep;124(3):849–857 [Epub 2009 Aug 10] [PMID: 19706587].

PEDIATRIC HISTORY

A unique feature of pediatrics is that the history represents an amalgam of parents' objective reporting of facts (eg, fever for 4 days), parents' subjective interpretation of their child's symptoms (eg, infant crying interpreted by parents as abdominal pain), and for older children their own history of events. Parents and patients may provide a specific and detailed history, or a vague history that necessitates more focused probing. Parents may or may not be able to distinguish whether symptoms are caused by organic illness or a psychological concern. Understanding the family and its hopes for and concerns about the child can help in the process of distinguishing organic, emotional, and/or behavioral conditions, thus minimizing unnecessary testing and intervention.

Although the parents' concerns need to be understood, it is essential also to obtain as much of the history as possible directly from the patient. Direct histories not only provide firsthand information but also give the child a degree of control over a potentially threatening situation and may reveal important information about the family.

Obtaining a comprehensive pediatric history is time consuming. Many offices provide questionnaires for parents to complete before the clinician sees the child. Data from questionnaires can make an outpatient visit more productive, allowing the physician to address problems in detail while more quickly reviewing areas that are not of concern. Questionnaires may be more productive than face-to-face interviews in revealing sensitive parts of the history. Developmental and mental health screening saves provider time and the results when reviewed with the parent or family member can yield critical information. However, failure to review and assimilate this information prior to the interview may cause a parent or patient to feel that the time and effort have been wasted.

AMBULATORY & OFFICE PEDIATRICS

Name Mother/pa S.S.#	rent (1)	Nickname Father/parent (Insurance	2)		D.O.B Sibs

Figure 9–1. Use of a summary sheet such as this at the front of the chart or the electronic medical record facilitates reorienting the caregiver and his or her partners to the patient. Some practices keep track of health supervision visits on this sheet to tell the physician whether the child is likely to have received the appropriate preventive services. A second page documenting immunizations should record data required by the National Childhood Vaccine Injury Act. When an allergy with potential for anaphylaxis is identified, the patient should wear a medical alert bracelet and obtain an epinephrine kit, if appropriate.

Elements of the history that will be useful over time should be readily accessible in the medical record. In absence of an electronic medical record, such information can be accumulated on a summary sheet, as illustrated in Figure 9-1. Demographic data; a problem list; information about chronic medications, allergies, and previous hospitalizations; and the names of other physicians providing care for the patient are commonly included. Documentation of immunizations,

including all data required by the National Childhood Vaccine Injury Act, should be kept on a second page. The components of a comprehensive pediatric history are listed in Table 9–1. The information should, ideally, be obtained at the first office visit. The first seven items may be included on a summary sheet at the front of the medical record. Items 8 and 9, and a focused review of systems, are dealt with at each acute or chronic care visit. The entire list

CHAPTER 9

Table 9–1. Components of the pediatric historical database.^a

1. Demographic data	Patient's name and nickname, date of birth, social security number, sex, race, parents' names (first and last), siblings' names, and payment mechanism.
2. Problem list	Major or significant problems, including dates of onset and resolution.
3. Allergies	Triggering allergen, nature of the reaction, treatment needed, and date allergy was diagnosed.
4. Chronic medications	Name, concentration, dose, and frequency of chronically used medications.
5. Birth history	Maternal health during pregnancy such as bleeding, infections, smoking, alcohol and any medications, complications of pregnancy; duration of labor; form of delivery; and labor complications. Infant's birth weight, gestational age, Apgar scores, and problems in the neonatal period.
6. Screening procedures	Results of newborn screening, vision and hearing screening, any health screen, or screening laboratory tests. (Developmental screening results are maintained in the development section; see item 14.)
7. Immunizations	Type(s) of vaccine, date administered, vaccine manufacturer and lot number, and name and title of the person administering the vaccine; site, previous reaction and contraindications (eg, immunodeficiency or an evolving neurologic problem), date on vaccine information statement (VIS), and date VIS was provided.
8. Reasons for visit	The patient's or parents' concerns, stated in their own words, serve as the focus for the visit.
9. Present illness	A concise chronologic summary of the problems necessitating a visit, including the duration, progression, exacerbating factors, ameliorating interventions, and associations.
10. Medical history	A statement regarding the child's functionality and general well-being, including a summary record of significant illnesses, injuries, hospitalizations, and procedures.
11. Diet	Eating patterns, likes and dislikes, use of vitamins, and relative amounts of carbohydrates, fat, and protein in the diet, percentage of fat of milk provided. Inquiry about intake of fast food, candy, and sugar drinks.
12. Family history	Information about the illnesses of relatives, preferably in the form of a family tree.
13. Social history	Family constellation, relationships, parents' educational background, religious preference, and the role of the child in the family; socioeconomic profile of the family to identify resources available to the child, access to services that may be needed, and anticipated stressors.
14. Development	(1) Attainment of developmental milestones (including developmental testing results); (2) social habits and milestones (toilet habits, play, major activities, sleep patterns, discipline, peer relationships); (3) school progress and documentation of specific achievements and grades.
15. Sexual history	Family's sexual attitudes, sex education, sexual development, sexual secondary characteristics, activity, sexually transmitted diseases, menstruation onset and characteristics and birth control measures.
16. Review of systems (ROS)	Common symptoms in each major body system.

^aThe components of this table should be included in a child's medical record and structured to allow easy review and modification. The practice name and address should appear on all pages.

should be reviewed and augmented with relevant updates at each health supervision visit.

PEDIATRIC PHYSICAL EXAMINATION

During the pediatric physical examination, time must be taken to allow the patient to become familiar with the examiner. Interactions and instructions help the child understand what is occurring and what is expected. A gentle, friendly manner and a quiet voice help establish a setting that yields a nonthreatening physical examination. The examiner should take into consideration the need for a quiet child, the extent of trust established, and the possibility of an emotional response (crying!) when deciding the order in which the child's organ systems are examined. Unpleasant procedures (eg, otoscopic examination) should be deferred until the end of the examination. Whether or not the physician can establish rapport with the child, the process should proceed efficiently and systematically.

Because young children may fear the examination and become fussy, simple inspection is important. For example, during an acute-care visit for fever, the examiner should observe the child's skin color and work of breathing prior to beginning the examination. During a health supervision visit, observation will provide the examiner with an opportunity to assess development and parent-child interactions. Clothing should be removed slowly and gently to avoid threatening the child. A parent or the child is usually the best person to do this. Modesty should always be respected, and gown or drapes should be provided. Examinations of adolescents should be chaperoned whenever a pelvic examination or a stressful or painful procedure is performed.

Examination tables are convenient, but a parent's lap is a comfortable location for a young child. For most purposes, an adequate examination can be conducted on a "table" formed by the parent's and examiner's legs as they sit facing each other.

Although a thorough physical examination is important at every age, certain components of the examination may change based on the age of the patient. An astute clinician can detect signs of important clinical conditions in an asymptomatic child. In infancy, for example, physical examination can reveal the presence of craniosynostosis, congenital heart disease, or developmental dysplasia of the hip. Similarly, examination of a toddler may reveal pallor (possible iron-deficiency anemia) or strabismus. The routine examination of an older child or adolescent may reveal scoliosis or acanthosis nigricans (a finding associated with insulin resistance).

HEALTH SUPERVISION VISITS

One of several timetables for recommended health supervision visits is illustrated in Figure 9-2. (Note: A PDF printable format of this figure is available from the American Academy of Pediatrics [AAP].) The federal Maternal and Child Health Bureau has developed comprehensive health supervision guidelines through their Bright Futures program. In areas where evidence-based information is lacking, expert opinion has been used as the basis for these plans. Recently revised Bright Futures Guidelines emphasizes working collaboratively with families, recognizing the need for attention toward children with special health care needs, gaining cultural competence, and addressing complementary and alternative care, as well as integrating mental health care into the primary care setting. Practitioners should remember that guidelines are not meant to be rigid; services should be individualized according to the child's needs.

During health supervision visits, the practitioner should review child development and acute and chronic problems, conduct a complete physical examination, order appropriate screening tests, and anticipate future developments. New historical information should be elicited through an interval history. Development should be assessed by parental report and clinician observation. In addition, systematic use of formal parent-directed screening tools, such as the Ages and Stages Questionnaire (ASQ) or the Parents' Evaluation of Developmental Status (PEDS), is recommended. Growth parameters should be carefully recorded, and weight, length, or height, head circumference (up to age 3), and body mass index (BMI) (for > 2 years) should be plotted and evaluated using established growth charts (see Chapter 3). Vision and hearing should be assessed subjectively at each visit, with objective assessments at intervals beginning after the child is old enough to cooperate with the screening test, usually at 4-5 years of age.

Because fewer than 4% of asymptomatic children have physical findings on routine health maintenance visits, a major portion of the health supervision visit is devoted to anticipatory guidance. This portion of the visit enables the health care provider to address behavioral, developmental, injury prevention, and nutritional issues; school problems; and other age-appropriate issues that will arise before the next well-child visit.

Hagan JF, Shaw JS, Duncan PM, eds: Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents. 4th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2017.

DEVELOPMENTAL & BEHAVIORAL ASSESSMENT

Addressing developmental and behavioral problems is one of the central features of pediatric primary care. The term *developmental delay* refers to the circumstance in which a child has not demonstrated a developmental skill (such as walking independently) by an age at which the vast majority of normally developing children have accomplished this task. Developmental delays are, in fact, quite common: approximately 18% of children younger than 18 years either have developmental delays or have conditions that place them at risk of developmental delays.

Pediatric practitioners are in a unique position to assess the development of their patients. This developmental assessment should ideally take the form of *developmental surveillance*, in which a skilled individual monitors development in multiple domains (gross motor, fine motor, language, and personal/social) over time as part of providing routine care. Developmental surveillance includes several key elements: listening to parent concerns; obtaining a developmental history; making careful observations during office visits; periodically screening all infants and children for delays using validated screening tools; recognizing conditions and circumstances that place children at increased risk of delays; and referring children who fail screening tests for further evaluation and intervention.

The prompt recognition of children with developmental delays is important for several reasons. Children with delays can be referred for a wide range of developmental therapies, such as those provided by physical, speech/language, and/or educational therapists. Children with delays, regardless of the cause, make better developmental progress if they receive appropriate developmental therapies than if they do not. Many infants and toddlers younger than 3 years with delays

The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

No part of this statement may be reproduced in any form or by any means without prior written permission from the American Academy of Pediatrics except for one copy for personal use.

Each child and family is unique; therefore, these Recommendations for Preventive Pediatric Health Care are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in a satisfactory fashion. Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits. Additional visits also may become necessary if circumstances suggest variations from normal.

These recommendations represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of continuity of care in comprehensive health supervision and the need to avoid fragmentation of care.

Refer to the specific guidance by age as listed in the *Bright Futures Guidelines* (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents.* 4th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2017).

▲ Figure 9–2. 2017 Recommendations for Pediatric Preventive Health care. (Reproduced with permission from Hagan JF, Shaw JS, Duncan PM, eds: *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents.* 4th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2017.)

KEY: • = to be performed ***** = risk assessment to be performed with appropriate action to follow, if positive

- If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up-to-date at the earliest possible time.
- A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding, per 'The Prenatal Visit' (http://pediatrics.aapublications.org/content/124/4/12227.tll).
- Newborns should have an evaluation after birth, and breastfeeding should be encouraged (and instruction and support should be offered).
- 4. Newborns should have an evaluation within 3 to 5 days of birth and within 48 to 72 hours after discharge from the hospital to include evaluation for feeding and jaundice. Breastfeeding newborns should receive formal breastfeeding evaluation, and their mothers should receive encouragement and instruction, as recommended in "Breastfeeding and the Use of Human Milk" (http://pediatrics.aappublications.org/content/129/3/e827.full). Newborns discharged less than 48 hours after delivery must be examined within 48 hours of discharge, per "Hospital Stay for Healthy Term Newborns"(http://pediatrics.aappublications.org/ content/125/2/405.full).
- Screen, per "Expert Committee Recommendations Regarding the Prevention, Assessment, and Treatment of Child and Adolescent Overweight and Obesity: Summary Report" (http://pediatrics.aappublications.org/content/120/ Supplement 4/S164.full).
- Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.
- 7. A visual acuity screen is recommended at ages 4 and 5 years, as well as in cooperative 3-year-olds. Instrument-based screening may be used to assess risk at ages 12 and 24 months, in addition to the well visits at 3 through 5 years of age. See "Visual System Assessment in Infants, Children, and Young Adults by Pediatricians" (http://pediatrics.aappublications.org/content/137/1/ 20153596) and "Procedures for the Evaluation of the Visual System by Pediatricians" (http://pediatrics.aappublications.org/content/137/1/20153597).
- Confirm initial screen was completed, verify results, and follow up, as appropriate. Newborns should be screened, per "Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" (http://pediatrics.aappublications.org/content/120/4/898.full).
- 9. Verify results as soon as possible, and follow up, as appropriate.
- Screen with audiometry including 6,000 and 8,000 Hz high frequencies once between 11 and 14 years, once between 15 and 17 years, and once between 18 and 21 years. See "The Sensitivity of Adolescent Hearing Screens Significantly Improves by Adding High Frequencies" (http://www.jahonline. org/article/S1054-139X(16)00048-3/fulltext).
- See "Identifying Infants and Young Children With Developmental Disorders in the Medical Home: An Algorithm for Developmental Surveillance and Screening" (http:// pediatrics.aappublications.org/content/118/1/405.full).

▲ Figure 9–2. (Continued)

- Screening should occur per "Identification and Evaluation of Children With Autism Spectrum Disorders" (http://pediatrics. aappublications.org/content/120/5/1183.full).
- This assessment should be family centered and may include an assessment of child social-emotional health, caregiver depression, and social determinants of health. See "Promoting Optimal Development: Screening for Behavioral and Emotional Problems" (http://pediatrics.aapublications.org/content/135/2/ 384) and "Poverty and Child Health in the United States" (http://pediatrics.aapublications.org/content/137/4/e20160339).
 A recommended assessment tool is available at http://www.
- ceasar-boston.org/CRAFFT/index.php.
- Recommended screening using the Patient Health Questionnaire (PHQ)-2 or other tools available in the GLAD-PC toolkit and at http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Documents/MH_ScreeningChart.pdf.
- Screening should occur per "Incorporating Recognition and Management of Perinatal and Postpartum Depression Into Pediatric Practice" (http://pediatrics.aappublications.org/content/ 126/5/1032).
- At each visit, age-appropriate physical examination is essential, with infant totally unclothed and older children undressed and suitably draped. See "Use of Chaperones During the Physical Examination of the Pediatric Patient" (http://pediatrics.aappubli cations.org/content/127/5/991.full).
- These may be modified, depending on entry point into schedule and individual need.
- 19. Confirm initial screen was accomplished, verify results, and follow up, as appropriate. The Recommended Uniform Newborn Screening Panel (http://www.hrsa.gov/advisorycommittees/mchbadvisory/ heritabledisorders/recommendedpanel/uniformscreeningpanel.pdf), as determined by The Secretary's Advisory Committee on Heritable Disorders in Newborns and Children, and state newborn screening laws/regulations (http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/ nbsdisorders.pdf) establish the criteria for and coverage of newborn screening procedures and programs.
- 20. Verify results as soon as possible, and follow up, as appropriate.
- Confirm initial screening was accomplished, verify results, and follow up, as appropriate. See "Hyperbilirubinemia in the Newborn Infant >35 Weeks' Gestation: An Update With Clarifications" (http://pediatrics.aappublications.org/content/124/4/1193).
- 22. Screening for critical congenital heart disease using pulse oximetry should be performed in newborns, after 24 hours of age, before discharge from the hospital, per "Endorsement of Health and Human Services Recommendation for Pulse Oximetry Screening for Critical Congenital Heart Disease" (http://pediatrics. aappublications.org/content/129//190.full).
- Schedules, per the AAP Committee on Infectious Diseases, are available at http://redbook.solutions.aap.org/SS/ Immunization_Schedules.aspx. Every visit should be an opportunity to update and complete a child's immunizations.
- See "Diagnosis and Prevention of Iron Deficiency and Iron-Deficiency Anemia in Infants and Young Children (0–3 Years of Age)" (http://pediatrics.aappublications. org/content/126/5/1040.full).

 For children at risk of lead exposure, see "Low Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention" (http://www.cdc.gov/nceh/lead/ACCLPP/Final Document 030712.pdf).

 \leftarrow • \rightarrow = range during which a service may be provided

- Perform risk assessments or screenings as appropriate, based on universal screening requirements for patients with Medicaid or in high prevalence areas.
- 27. Tuberculosis testing per recommendations of the AAP Committee on Infectious Diseases, published in the current edition of the AAP Red Book: Report of the Committee on Infectious Diseases. Testing should be performed on recognition of high-risk factors.
- See "Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents" (https://www.nhlbi.nih. gov/health-topics/integrated-guidelines-for-cardiovascular-healthand-risk-reduction-in-children-and-adolescents).
- Adolescents should be screened for sexually transmitted infections (STIs) per recommendations in the current edition of the AAP Red Book: Report of the Committee on Infectious Diseases.
- 30. Adolescents should be screened for HIV according to the USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/ uspstf/uspshivi.htm) once between the ages of 15 and 18, making every effort to preserve confidentiality of the adolescent. Those at increased risk of HIV infection, including those who are sexually active, participate in injection drug use, or are being tested for other STIs, should be tested for HIV and reassessed annually.

See USPSTF recommendations (http://www.uspreventiveservicestaskforce.org/uspstf/uspscerv.htm). Indications for pelvic examinations prior to age 21 are noted in "Gynecologic Examination for Adolescents in the Pediatric Office Setting" (http://oediatrics.aapoublications.org/content/126/3/583.full).

- 32. Assess whether the child has a dental home. If no dental home is identified, perform a risk assessment (https://www.aap.org/ RiskAssessmentTool) and refer to a dental home. Recommend brushing with fluoride toothpaste in the proper dosage for age. See "Maintaining and Improving the Oral Health of Young Children" (http://pediatrics.aappublications.org/content/134/6/1224).
- Perform a risk assessment (https://www.aap.org/BiskAssessmentTool). See "Maintaining and Improving the Oral Health of Young Children" (http://pediatrics.aappublications.org/content/134/6/1224).
- 34. See USPSTF recommendations (http://www.uspreventiveservicestaskforce. org/uspstf/uspsdnch.htm). Once teeth are present, fluoride varnish may be applied to all children every 3–6 months in the primary care or dental office. Indications for fluoride use are noted in "Fluoride Use in Caries Prevention in the Primary Care Setting"

(http://pediatrics.aappublications.org/content/134/3/626).

 If primary water source is deficient in fluoride, consider oral fluoride supplementation. See "Fluoride Use in Caries Prevention in the Primary Care Setting" (http://pediatrics.aappublications.org/content/ 134/3/626). CHAPTER 9

are eligible to receive a range of therapies and other services, often provided in the home, at no cost to families. Children aged 3 years and older with delays are eligible for developmental services through the local school system.

Several parent- and physician-administered developmental screening tools are available and should be utilized in order to more efficiently incorporate this process in the busy well-child care visit. The PEDS, ASQ, and the Child Development Inventories (CDI) are screening tests that rely on parent report. Other screening tools, such as the Denver II screening test, the Early Language Milestone Scale (see Chapter 3, Figure 3-1), and the Bayley Infant Neurodevelopmental Screener, involve the direct observation of a child's skills by a care provider. All developmental screening tests have their strengths and weaknesses. The Denver II is familiar to many pediatric providers and is widely used. However, whereas the Denver II has relatively high sensitivity for detecting possible developmental delays, the specificity is poorer, and this may lead to the over referral of normal children for further developmental testing.

In addition to general developmental screening, autismspecific screens (such as the Modified Checklist for Autism in Toddlers [MCHAT]) should be administered at the 18- and 24-month health supervision visits.

Regardless of the approach taken to developmental screening, there are a number of important considerations: (1) The range of normal childhood development is broad, and therefore a child with a single missing skill in a single developmental area is less likely to have a significant developmental problem than a child showing multiple delays in several developmental areas (eg, gross motor and language delays); (2) continuity of care is important, because development is best assessed over time; (3) it is beneficial to routinely use formal screening tests to assess development; (4) if developmental delays are detected in primary care, these patients need referral and close follow-up to insure evaluation completion for further testing and likely will benefit from receiving developmentally focused therapies and strategies; and (5) parents appreciate when attention is paid to their child's development and generally react positively to referrals for appropriate developmental therapies.

Several developmental charts with age-based expectations for normal development are presented in Chapter 3 (see Tables 3–1, 3–2, 3–3), as well as a discussion of the recommended medical and neurodevelopmental evaluation of a child with a suspected developmental disorder.

In addition to developmental issues, pediatric providers are an important source of information and counseling for parents regarding a broad range of behavioral issues. The nature of the behavioral problems, of course, varies with the child's age. Some common issues raised by parents, discussed in detail in Chapter 3, include colic, feeding disorders, sleep problems, temper tantrums, breath-holding spells, and noncompliance. Behavioral issues in adolescents are discussed in Chapter 4.

GROWTH PARAMETERS

Monitoring appropriate growth is pivotal in ambulatory pediatric practice.

Height, weight, and head circumference are carefully measured at each well-child examination and plotted on ageand sex-specific charts. The Centers for Disease Control and Prevention (CDC) recently recommended use of the World Health Organization (WHO) growth standards to monitor growth for infants and children ages 0–2 in the United States, in lieu of its own growth charts. The WHO standards are based on a sample of 8500 babies (from Brazil, Ghana, India, Norway, Oman, and the United States) who were predominantly breast-fed for at least 4 months, still nursing at 1 year and living in nonsmoking households. The methods used to create the CDC growth charts and the WHO growth charts are similar for children aged 2 years and older.

To ensure accurate weight measurements for longitudinal comparisons, infants should be undressed completely and young children should be wearing underpants only. Recumbent length is plotted on the chart until approximately 2 years of age. When the child is old enough to be measured upright, height should be plotted on the charts for ages 2–20 years. Routine measurements of head circumference may cease if circumferential head growth has been steady for the first 2 years of life. However, if a central nervous system (CNS) problem exists or develops, or if the child has growth deficiency, this measurement continues to be useful. Tracking the growth velocity for each of these parameters allows early recognition of deviations from normal.

It is useful to note that in the first year of life, it is common for height and weight measurements to cross over a percentile line. After approximately 18 months, most healthy children tend to follow the curve within one growth channel.

Determination of whether or not a child's weight falls within a healthy range also relies on growth charts. For children younger than 2 years, the weight-for-length chart is used. For children 2–18 years, a BMI chart is used, which is a measure that correlates well with adiposity- and obesityrelated comorbidities. The BMI is calculated as the weight (in kilograms) divided by the squared height (in meters). The BMI is useful for determining obesity (BMI \geq 95th percentile for age) and overweight (BMI between 85th and 95th percentiles), as well as underweight status (BMI \leq 5th percentile for age). It must be emphasized that "eyeballing" overweight/underweight is frequently inaccurate and should not substitute for careful evaluation of the data on growth charts.

BLOOD PRESSURE

Blood pressure screening at well-child visits starts at age 3 years. There are some conditions that warrant blood pressure monitoring at an earlier age:

- History of prematurity, very low birth weight, or other neonatal complication requiring intensive care
- Congenital heart disease (repaired or nonrepaired)
- Recurrent urinary tract infections, hematuria, or proteinuria
- · Known renal disease or urologic malformations
- · Family history of congenital renal disease
- Solid organ transplant
- · Malignancy or bone marrow transplant
- Treatment with drugs known to raise blood pressure (steroids, oral contraceptives)
- Other conditions associated with hypertension (neurofibromatosis, tuberous sclerosis, etc)
- · Evidence of elevated intracranial pressure

Accurate determination of blood pressure requires proper equipment (stethoscope, manometer and inflation cuff, or an automated system) and a cooperative, seated subject in a quiet room. Although automated blood pressure instruments are widely available and easy to use, blood pressure readings from these devices are typically 5 mm Hg higher for diastolic and 10 mm Hg higher for systolic blood pressure compared with auscultatory techniques. Therefore, the diagnosis of hypertension should not be made on the basis of automated readings alone. Additionally, blood pressure varies by the height and weight of the individual. Consequently, hypertension is diagnosed as a systolic or diastolic blood pressure greater than the 95th percentile based on the age and height (or weight) percentile of the patient using charts from the Fourth Report (see references).

The width of the inflatable portion of the cuff should be 40%-50% of the circumference of the limb. Overweight children need a larger cuff size to avoid a falsely elevated blood pressure reading. Cuffs that are too narrow will overestimate and those that are too wide will underestimate the true blood pressure. Hypertension should not be diagnosed based on readings at one visit, but rather three separate occasions of documented hypertension are required. Repeated measurements at different visits over time should be tracked using flow charts in an electronic medical record or equivalent in a paper chart. Children with repeated blood pressure readings from the 90th to the 95th percentile may be classified as having prehypertension. Those with greater than between the 95th and 99th percentile plus 5 mm of Hg are classified as Stage 1 hypertension, and those greater than the 99th percentile plus 5 mm of Hg are termed Stage 2 hypertension. National High Blood Pressure Education Program recommends that all children with blood pressure of greater than or equal to 95% should have a complete blood count (CBC), serum nitrogen, creatinine, electrolytes, fasting lipid panel, glucose, urinalysis, urine culture, renal ultrasound, echocardiogram, and retinal examination. Nonpharmacologic interventions include diet, exercise, and weight management. Indications for pharmacologic therapy may include the following:

- Symptomatic hypertension
- · Secondary hypertension
- · Hypertensive target-organ damage
- Diabetes (types 1 and 2)
- Persistent hypertension despite nonpharmacologic measures

Based on a recent systematic review for US Preventive Services Task Force, it is unclear whether screening for hypertension in children and teens reduces adverse outcomes in adults.

VISION & HEARING SCREENING

Examination of the eyes and an assessment of vision should be performed at every health supervision visit. Eye problems are relatively common in children: refractive errors (including myopia, hyperopia, and astigmatism), amblyopia (loss of visual acuity from cortical suppression of the vision of the eye), and/or strabismus (misalignment of the eyes) occur in 5%–10% of preschoolers. Assessment of vision should include visual inspection of the eyes and eyelids, alignment of eyes, and visual acuity.

Starting at birth, the movement and alignment of the eyes should be assessed and the pupils and red reflexes examined. The red reflex, performed on each pupil individually and then on both eyes simultaneously, is used to detect eye opacities (eg, cataracts or corneal clouding) and retinal abnormalities (eg, retinal detachment or retinoblastoma). By 3 months of age, an infant should be able to track or visually follow a moving object, with both eyes.

Starting at age 3, formal testing of visual acuity should be done if possible. This can be performed in the office with a variety of tests, including the tumbling E chart or picture tests such as Allen cards. In these tests, each eye is tested separately, with the nontested eye completely covered. Credit is given for any line on which the child gets more than 50% correct. Children who are unable to cooperate should be retested, ideally within 1 month, and those who cannot cooperate with repeated attempts should be referred to an ophthalmologist. Because visual acuity improves with age, results of the test are interpreted using the cutoff values in Table 9–2. However, any two-line discrepancy between the two eyes, even within the passing range (eg, 20/20 in one eye, 20/30 in the other in a child aged \geq 6 years) should be referred to an ophthalmologist.

Throughout childhood, clinicians should screen for undetected strabismus (ocular misalignment). The corneal light reflex test can be used starting at 3 months and the cover test can be used beginning at 6 months to assess for strabismus. The corneal light reflex test, the cover test, and visual acuity test are described further in Chapter 16.

Recommendations for vision screening and indications for referral are listed in Table 9-3. Referral to an

Table 9–2. Age-appropriate visual acuity. ^a									
Age (y)	Minimal Acceptable Acuity								
3–5	20/40								
≥ 6	20/30								

^aRefer to an ophthalmologist if minimal acuity is not met at a given age or if there is a difference in scores of two or more lines between the eyes.

Test	Age for Screening	Indication(s) for Referral
Inspection of eyes and lids	All	
Red reflex	Birth until child can read eye chart	Abnormal red reflex, asymmetry of the red reflexes, or partially obscured red reflex
Assessment of fixa- tion and following	Starting at 2 mo	Poor fixation/following by 3 mo
Corneal light reflex for assessing strabismus	3 mo to 5 y	Asymmetry of light reflex (in relation to iris and pupil)
Cover testing for assessing strabismus	6 mo to 5 y	Presence of refixation movement
Fundoscopic examination	Starting at 3 y	
Preliterate eye chart testing	Starting at 3–4 y	Unable to pass 20/40 for ages 3–5 or 20/30 for 6 and older. Also refer if there is a difference of two or more lines between the eyes.

Table 9-3. Recommended vision screening in the

primary care office.

ophthalmologist is also recommended for preterm infants for evaluation of retinopathy of prematurity (ROP), as well as children with a family history of amblyopia, strabismus, retinoblastoma, or retinal degeneration. Children with Down syndrome should be referred to an ophthalmologist at 6 months of age given their increased risk for refractive error, strabismus, and cataracts.

Hearing loss, if undetected, can lead to substantial impairments in speech, language, and cognitive development. Because significant bilateral hearing loss is one of the more common major anomalies found at birth, and early detection and intervention of hearing loss leads to better outcomes for children, universal hearing screening is provided to newborns in most parts of the United States. Hearing in infants is assessed using either evoked otoacoustic emissions or auditory brainstem-evoked responses. Because universal newborn hearing screening is sometimes associated with false-positive test results, confirmatory audiology testing is required for abnormal tests.

Informal behavioral testing of hearing, such as observing an infant's response to a shaken rattle, may be unreliable. In fact, parental concerns about hearing are of greater predictive value than the results of informal tests, and such concerns should be taken seriously. Prior to age 4, infants should be referred to an audiologist for testing if a concern arises. Conventional screening audiometry, in which a child raises her hand when a sound is heard, can be performed starting at age 4. Each ear should be tested at 500, 1000, 2000, and 4000 Hz and referred at threshold levels of greater than 20 dB at any of these frequencies. Any evidence of hearing loss should be substantiated by repeated testing, and if still abnormal, a referral for a formal hearing evaluation should be made.

The AAP periodicity schedule recommends routine hearing screening at 4, 5, 6, 8, and 10 years of age and several times during adolescence. Children with any risk factors for hearing loss should be closely followed and receive more frequent screening. A number of inherited or acquired conditions increase the risk of hearing loss. Sometimes hearing loss can be mistaken for inattention, and so hearing screening should be part of workup for attention problems. Additional details regarding hearing assessment are provided in Chapter 18.

Newborn Screening

Newborn screening involves population-wide testing for metabolic and genetic diseases. It has become an essential component in a public health program that screens over 4 million newborns every year. Blood samples are collected by heel stick from newborns before hospital discharge, and results are usually available within 1 week. Some states routinely repeat blood testing between 7 and 14 days of life, while others recommend it if the child is discharged in less than 24 hours. The state-to-state variation seen in newborn screen panels has begun to diminish as a result of national recommendations. In 2010, the Secretary Advisory Committee on Heritable Disorders in Newborns and Children recommended screening for 32 core conditions with another 26 detectable through differential diagnosis. Most states have adopted these guidelines.

Infants with a positive screening result should receive close follow-up, with additional confirmatory studies performed at a center with experience in doing these tests. Screening tests are usually accurate, but the sensitivity and specificity of a particular screening test must be carefully considered. If symptoms of a disease are present despite a negative result on a screening test, the infant should be tested further. Newborn screening has benefited thousands of infants and their families, preventing and diminishing the morbidity of many diseases. At the same time, the emotional cost of false-positive screening is a continuing challenge. Parents report high levels of stress during the evaluation process. Recommendations for useful resources, given the variability of information on the Internet, and prompt clinical services can help reduce this distress.

Lead Screening

The developing infant and child are at risk of lead poisoning or toxicity because of their propensity to place objects in the mouth and their efficient absorption of this metal. Children with lead toxicity are typically asymptomatic. High blood levels (> 70 mcg/dL) can cause severe health problems such as seizures and coma. Numerous neuropsychological deficits have been associated with increased lead levels. Blood lead levels less than 10 mcg/dL have been correlated with lower intelligence quotients. The primary source of lead exposure in this country remains lead-based paint, even though most of its uses have been banned since 1977. Lead levels have declined nationally from a mean of 16 mcg/dL in 1976 to less than 2 mcg/dL in 2008. However, considerable variation in lead levels exists in different regions of the United States, and a majority of children at risk of lead toxicity are not currently screened. Despite the wide variation in the prevalence of lead toxicity, the CDC recommends universal lead screening for children at ages 1 and 2 and targeted screening for older children living in communities with a high percentage of old housing (> 27% of houses built before 1950) or a high percentage of children with elevated blood lead levels (> 12% of children with levels > 10 mcg/dL). Previously, all Medicaid-enrolled children were screened, but now the recommendation is to screen those at risk because of local variations in lead exposure.

Communities with inadequate data regarding local blood lead levels should also undergo universal screening. Caregivers of children between 6 months and 6 years of age may be interviewed by questionnaire about environmental risk factors for lead exposure (Table 9–4), although the data to

CHAPTER 9

Table 9–4. Elements of a lead-risk questionnaire.

Recommended questions

- 1. Does your child live in or regularly visit a house built before 1950? This could include a day care center, preschool, the home of a baby sitter or relative.
- 2. Does your child live in or regularly visit a house built before 1978 with recent, ongoing, or planned renovation or remodeling?
- Does your child have a sister or brother, housemate, or playmate being followed for an elevated lead level?

Questions that may be considered by region or locality

- Does your child live with an adult whose job (eg, at a brass/ copper foundry, firing range, automotive or boat repair shop, or furniture refinishing shop) or hobby (eg, electronics, fishing, stained-glass making, pottery making) involves exposure to lead?
- 2. Does your child live near a work or industrial site (eg, smelter, battery recycling plant) that involves the use of lead?
- 3. Does your child use pottery or ingest medications that are suspected of having a high lead content?
- 4. Does your child have exposure to old, nonbrand-type toys or burning lead-painted wood?
- 5. Does your child play on an athletic field with artificial turf?

support the use of this screening are inconclusive. If risk factors are present, a blood lead level should be obtained. A venous blood sample is preferred over a capillary specimen. An elevated capillary (fingerstick) blood sample should always be confirmed by a venous sample. CDC now states that reference level of 5 mcg/dL should be used to identify children with blood lead levels that are much higher than most levels in children. This new recommendation is based on the US children ages 1–5 years who are in the highest 2.5% of children when tested for lead in their blood.

The cognitive development of children with confirmed high blood levels should be evaluated and attempts made to identify the environmental source. Iron deficiency should be treated if present. Chelation of lead is indicated for levels of 45 mcg/dL and higher and is urgently required for levels above 70 mcg/dL. All families should receive education to decrease the risk of lead exposure. With any elevated lead level (> 5 mcg/dL), rescreening should be performed at recommended intervals.

Iron Deficiency

Iron deficiency is the most common nutritional deficiency in the United States. Severe iron deficiency causes anemia, behavioral problems, and cognitive effects, but recent evidence suggests that even iron deficiency without anemia may cause behavioral and cognitive difficulties. Some effects, such as the development of abnormal sleep cycles, may persist even if iron deficiency is corrected in infancy.

Risk factors for iron deficiency include preterm or lowbirth-weight births, multiple pregnancy, iron deficiency in the mother, use of nonfortified formula or cow's milk before age 12 months, and an infant diet that is low in ironcontaining foods. Infants and toddlers consuming more than 24 oz/day of cow's milk are at risk, as are children with chronic illness, restricted diet, or extensive blood loss.

Primary prevention of iron deficiency should be achieved through dietary means, including feeding ground up meats and iron-containing cereals by age 6 months, avoiding lowiron formula during infancy, and limiting cow's milk to 24 oz per day in children aged 1–5 years.

Universal screening for anemia should occur at approximately 12 months of age by obtaining a hemoglobin or hematocrit. Premature and low-birth-weight infants may need testing before 6 months of age.

A full CBC to look at mean corpuscular volume (MCV) can aid in the evaluation. Serum ferritin is a useful test to evaluate iron-deficiency anemia, but it can also pick up iron deficiency in the absence of anemia. Because ferritin is an acute-phase reactant and can be falsely reassuring in the presence of inflammation, infection, or malignancy, some experts recommend obtaining a concurrent C-reactive protein (CRP) for accurate interpretation of the ferritin level. Elevated lead levels can cause iron-deficiency anemia and should be explored as a cause for at-risk infants and children.

Management of iron deficiency with or without anemia includes treatment doses of 3–6 mg/kg body weight of *elemental* iron.

Baker RD et al: American Academy of Pediatrics; Committee on Nutrition: Diagnosis and prevention and iron-deficiency anemia in infants and young children (0–3 years of age). Pediatrics 2010;126:1040 [PMID: 20923825].

Hypercholesterolemia & Hyperlipidemia

Cardiovascular disease is the leading cause of death in the United States, and research has documented that the atherosclerotic process begins in childhood. Genetic factors, diet, and physical activity all play a role in the disease process. Non-fasting lipid screening is recommended universally for children between the ages of 9 and 11. Fasting lipid screening is recommended between the ages of 2 to 8, and ages 12 to 16 if risk factors are present. Diet and weight management strategies are the primary interventions. However, for severe dyslipidemia (LDL \geq 190 mg/dL), pharmacologic therapy should be considered. However, consideration of pharmacotherapy should be made for severe dyslipidemia (LDL \geq 190 mg/dL), or at >160 mg/dL if there is a family history of heart disease, and in all patients at > 130 mg/dL depending on their level and amount of risk factors.

Kubo T et al: Usefulness of non-fasting lipid parameters in children. J Pediatr Endocrinol Metab 2017;30(1):77-83.

Tuberculosis

According to the CDC, 9272 cases of tuberculosis (TB) were reported in the United States in 2016. Risk of TB should be assessed at well-child visits, and screening should be based on high-risk status. High risk is defined as contact with a person with known or suspected TB; having symptoms or radiographic findings suggesting TB; birth, residence, or travel to a region with high TB prevalence (Asia, Middle East, Africa, Latin America); contact with a person with AIDS or HIV; or contact with a prisoner, migrant farm worker, illicit drug user, or a person who is or has been recently homeless. TB testing can be performed by a skin test or a blood test. The Mantoux test (five tuberculin units of purified protein derivative) is the only recommended skin test. The interferon-gamma release assays (IGRAs) are blood tests that can be useful for patients who have been immunized with bacille Calmette-Guerin (BCG) or for patients who may have difficulty returning for a second appointment to look for skin reaction.

Targeted screening for latent TB for high-risk individuals is the recommended approach based on available evidence. Risk of TB should be assessed at well-child visits, and screening should be based on high-risk status. The following screening questions have been validated to determine high-risk status:

- 1. Was your child born outside the United States? If yes, this question would be followed by: Where was your child born? If the child was born in Africa, Asia, Latin America, or Eastern Europe, a TB testing should be performed.
- 2. Has your child traveled outside the United States? If yes, this question would be followed by: Where did the child travel, with whom did the child stay, and how long did the child travel? If the child stayed with friends or family members in Africa, Asia, Latin America, or Eastern Europe for more than 1 week cumulatively, TB testing should be performed.
- 3. Has your child been exposed to anyone with TB disease? If yes, this question should be followed by questions to determine if the person had TB disease or latent TB infection (LTBI), when the exposure occurred, and

what the nature of the contact was. If confirmed that the child has been exposed to someone with suspected or known TB disease, TB testing should be performed. If it is determined that a child had contact with a person with TB disease, notify the local health department per local reporting guidelines.

- 4. Does your child have close contact with a person who has a positive TB test? If yes, go to question 3.

- Pediatric Tuberculosis Collaborative Group: Targeted tuberculin skin testing and treatment of latent tuberculosis infection in children and adolescents. Pediatrics 2004 Oct;114(Suppl 4): 1175–1201 [PMID: 10617723].

Screening of Adolescent Patients

Adolescents may present with chief complaints that are not the true concern for the visit. Repeating the question "Is there anything else you would like to discuss?" should be considered. Since suicide is a leading cause of morbidity and mortality in this age group, screening with the Pediatric Symptom Checklist for Youth is recommended (https:// www.brightfutures.org/mentalhealth/pdf/professionals/ ped_sympton_chklst.pdf).

Testing adolescents for blood cholesterol, TB, and HIV should be offered based on high-risk criteria outlined in this chapter and in Chapter 41. Females should have a screening hematocrit once after the onset of menses. During routine visits, adolescents should be questioned sensitively about risk factors (eg, multiple partners; early onset of sexual activity, including child sexual abuse) and symptoms (eg, genital discharge, infectious lesions, pelvic pain) of sexually transmitted infections (STIs). An annual dipstick urinalysis for leukocytes is recommended for sexually active adolescents. Because STIs are often not symptomatic, urine polymerase chain reaction (PCR) for gonorrhea and chlamydia and screening tests for trichomoniasis should be considered. Current guidelines recommend that the first Papanicolaou (Pap) test should be performed at age 21 years, regardless of onset of sexual activity. A complete pelvic examination should be performed when evaluating lower abdominal pain in an adolescent.

Please see Chapter 4 for additional details on adolescent preventive services.

ANTICIPATORY GUIDANCE

An essential part of the health supervision visit is anticipatory guidance. During this counseling, the clinician directs the parent's or the older child's attention to issues that may arise in the future. Guidance must be appropriate to age, focus on concerns expressed by the parent and patient, and address issues in depth rather than run through a number of issues superficially. Both oral and printed materials are used. When selecting written materials, providers should be sensitive to issues of literacy and primary language spoken by the family members. Areas of concern include diet, injury prevention, developmental and behavioral issues, and health promotion.

Injury Prevention

For children and adolescents aged 1–19 years, unintentional injuries are the number one cause of death. In every age category, males are at higher risk than females for unintentional injury.

Injury prevention counseling is an important component of each health supervision visit and can be reinforced during all visits. Counseling should focus on problems that are frequent and age appropriate. Passive strategies of prevention should be emphasized, because these are more effective than active strategies; for example, placing chemicals out of reach in high, locked cupboards to prevent poisoning will be more effective than instructing parents to watch their children closely.

Informational handouts about home safety, such as The Injury Prevention Program (TIPP; available from the AAP), can be provided in the waiting room. Advice can then be tailored to the specific needs of each family, with reinforcement from age-specific TIPP handouts.

A. Motor Vehicle Injuries

The primary cause of death of children in the United States is motor vehicle injuries. Although the rate of death from this cause is improving, still in 2015, about 35% of children aged 12 years or younger who were killed in motor vehicle accidents were unrestrained.

The type and positioning of safety seats can be confusing. While car seat and booster seat laws differ by state, a recent AAP policy statement describes the best practice recommendations. All infants and toddlers should ride in a rearfacing car safety seat until 2 years of age or until they reach the weight and height limits for convertible car safety seats (usually 35–40 pounds). Infants may ride in infant-only seats (which often have a carrying handle and snap into a base that is secured in the car) until they reach the height and weight limit for that seat, and then transition to a convertible car seat. Once a child reaches 2 years of age (or younger than 2 if outgrown the weight and height limit of a convertible car seat), he/she can be in a forward-facing car safety seat with a harness. The safest scenario is for a child to remain in a car safety seat with a harness as long as possible. Once a child reaches the weight or height limits of a forward-facing seat, he/she may be transitioned to a belt-positioning booster until the vehicle's lap-and-shoulder belt fits properly (child can sit with his back against the vehicle seat, bend his knees at the edge of the seat, have the belt positioned in the center of the shoulder and across the chest, and have the lap belt touching the thighs). These criteria are generally met once a child reaches height of 4 ft 9 in and is between the ages of 8 and 12 years. All children younger than 13 years should be restrained in the rear seats of the vehicle.

Unfortunately, restraint use shows a decreasing trend with advancing age: children from 1 to 8 years of age use restraints over 90% of the time, but those 8–12 years of age use restraints less than 85% of the time. African-American and Hispanic children use child safety seats less often than white children.

A final motor vehicle risk for health involves the use of portable electronic devices. Using a cell phone while driving is associated with a threefold increase in motor vehicle accidents. Texting while driving poses an even greater danger. All should avoid these risks and adults should model safe practices.

B. Bicycle Injuries

Each year, an average of nearly 400 children die from bicycle crashes, and over 450,000 are treated for bicycle-riding injuries. Over 150,000 children are treated annually in emergency departments for head injuries sustained while riding a bicycle. Many observational studies have shown a decreased risk of head injury with the use of bicycle helmets. Communitybased interventions, especially those that provide free helmets, have been shown to increase observed bike helmet wearing. Counseling by physicians in various settings has also been shown to increase bike helmet use. While there is no federal law mandating bicycle helmets, some states have passed legislation requiring bicycle helmets.

C. Skiing and Snowboarding Injuries

Recent studies have suggested that the burden of skiing injuries is high among children, and that children have the highest rate of injury of any age group: approximately 3 injuries per 1000 skier days. Traumatic brain injuries are the leading cause of death for pediatric age skiers. Case-control studies have shown a decrease in head injuries associated with helmet use.

D. Firearm Injuries and Violence Prevention

The United States has a higher rate of firearm-related death than any other industrialized country. For children younger than 15, the death rate from firearm-related injuries is nearly 12 times greater than that of 25 other industrialized nations. Some gun deaths may be accidental, but most are the result of homicide or suicide. A gun in the home doubles the likelihood of a lethal suicide attempt. Although handguns are often kept in homes for protection, a gun is more likely to kill a family member or a friend than an intruder. Adolescents with a history of depression or violence are at higher risk with a gun in the home. The most effective way to prevent firearm injuries is to remove guns from the home. Families who keep firearms at home should lock them in a cabinet or drawer and store ammunition in a separate locked location.

E. Drowning and Near Drowning

Drowning is the second leading cause of injury-related death in children, and those aged 1-3 years have the highest rate of drowning. For every death by drowning, six children are hospitalized for near drowning, and up to 10% of survivors experience severe brain damage. Children younger than 1 year are most likely to drown in the bathtub. Buckets filled with water also present a risk of drowning to the older infant or toddler. For children aged 1-4 years, drowning or near drowning occurs most often in home swimming pools; and for school-aged children and teens, drowning occurs most often in large bodies of water (eg, swimming pools or open water). Parents should be cautioned that inflatable swimming devices are not a substitution for approved live vests or close supervision and can give a false sense of security. School-aged children should be taught to swim, and recreational swimming should always be supervised. Home pools must be fenced securely, and parents should know how to perform cardiopulmonary resuscitation.

F. Fire and Burn Injuries

Fires and burns are the leading cause of injury-related deaths in the home. Categories of burn injury include smoke inhalation; flame contact; scalding; and electrical, chemical, and ultraviolet burns. Scalding is the most common type of burn in children. Most scalds involve foods and beverages, but nearly one-fourth of scalds are with tap water, and for that reason it is recommended that hot water heaters be set to a maximum of 120°F. Most fire-related deaths result from smoke inhalation. Smoke detectors can prevent 85% of the injuries and deaths caused by fires in the home. Families should discuss a fire plan with children and practice emergency evacuation from the home.

Sunburn is a common thermal injury and often is not recognized because symptoms of excessive sun exposure usually do not begin until after the skin has been damaged. Repeated sunburn and excessive sun exposure are associated with skin cancers. Prevention of sunburn is best achieved by sun avoidance, particularly during the midday hours of 10 am to 4 pm. A sunscreen with a minimum sun protection factor (SPF) of 30 that protects against both UVA and UVB rays should be used on sunny and cloudy days to help protect against sunburn. Hats, sunglasses, and long-sleeved swim shirts are also important aspects of safe sun exposure. The safety of sunscreen is not established for infants younger than 6 months; thus sun avoidance, appropriate clothing, and hats are recommended for this age group. In extreme circumstances in which shade is not available, a minimal amount of sunscreen can be applied to small areas, including the face and back of the hands.

G. Choking

Choking is a leading cause of injury and death in young children. Choking hazards include food and small objects. Children younger than 3 are particularly at risk because they do not have fully coordinated chewing and swallowing, and they are more apt to put small objects in their mouths. Foods that are commonly associated with choking include hot dogs, hard candy, nuts, popcorn, raw vegetables, and chunks of meat, fruit, or cheese. Common nonfood items that pose a risk for choking include coins, latex balloons, button batteries, marbles, small toys, and small toy parts. While being mindful of choking hazards is important, accidents can still occur. Again, parents and caregivers should be trained in CPR and choking first aid.

NUTRITION COUNSELING

Screening for nutritional problems and guidance for ageappropriate dietary choices should be part of every health supervision visit. Overnutrition, undernutrition, and eating

CHAPTER 9

disorders can be detected by a careful analysis of dietary and activity patterns interpreted in the context of a child's growth pattern.

Human milk feeding is species specific and is the preferred method for infant feeding for the first year of life. Pediatricians should assist mother-infant dyads with latch and help manage breast-feeding difficulties in the early newborn period. For exclusively and partially breast-fed infants, vitamin D supplementation should be given. Ironfortified formula should be used in situations when breastfeeding is contraindicated such as HIV, active untreated TB, galactosemia, and certain medications. As noted in Chapter 11 (Normal Childhood Nutrition & Its Disorders), the positive benefits of continued breast-feeding and breast milk by mothers who have used illicit drugs should be balanced in individual cases against the risk of transmission of such drugs to the infant via the milk. After the first year, breast-feeding may continue or whole cow's milk can be given because of continued rapid growth and high energy needs. After 2 years of life, milk with 2% fat or lower may be offered. Baby foods and appropriately prepared table foods should be introduced between 4 and 6 months of age and self-feeding with finger foods encouraged by 7-8 months of age.

When obtaining a dietary history, it is helpful to assess the following: who purchases and prepares food; who feeds the child; whether meals and snacks occur at consistent times and in a consistent setting; whether children are allowed to snack or "graze" between meals; the types and portion sizes of food and drinks provided; the frequency of eating meals in restaurants or eating take-out food; and whether the child eats while watching television.

For children 2 years of age and older, a prudent diet consists of diverse food sources, encourages high-fiber foods (eg, fruits, vegetables, grain products), and limits sodium and fat intake. Since obesity is becoming increasingly prevalent, foods to be avoided or limited include processed foods, sugar-sweetened drinks or soda, and candy. Parents should be gently reminded that they are modeling for a lifetime of eating behaviors in their children, both in terms of the types of foods they provide and the structure of meals (eg, the importance of the family eating together). For additional information on nutritional guidelines, undernutrition, and obesity, see Chapter 11; for eating disorders, see Chapter 6; for adolescent obesity, see Chapter 4.

As of 2009, the Women, Infants, and Children (WIC) food packages reflect the recommendations above and include provision of more fruits and vegetables, whole grains, yogurt and soy products, low-fat milk, and limitations on juice. Breast-feeding mothers receive more food as part of their package, less formula supplementation, and breast-fed infants receive baby food meats as a first food (because of more iron and zinc).

COUNSELING ABOUT TELEVISION & OTHER MEDIA

Media has a significant influence on children and adolescents. The average child in the United States watches approximately 3–5 hours of television per day, and this does not include time spent watching movies, playing video games, playing on computers/tablets, accessing the Internet, or using cell phones. Taking into account these other forms of media, current estimates are around 7.5 hours of media exposure per day for average 8- to 18-year-olds. Figure 9–3 shows a breakdown of media exposure by age group.

Having a television set in the bedroom increases daily media exposure and is also associated with sleep disturbances. According to the Kaiser Family Foundation, over 70% of 8- to 19-year-olds have a television in their bedrooms.

Watching television may have both positive and negative effects. Programs directed toward early childhood may increase knowledge and imaginativeness, and may also teach empathy and acceptance of diversity. However, excessive television viewing of programs with inappropriate content has been shown to have negative effects with respect to violence, sexuality, substance abuse, nutrition, social skills, and body self-image. More recent data suggest that excessive viewing in childhood may have a long-lasting negative effect on cognitive development and academic achievement. Clinicians should assess media exposure in their patients and offer parents concrete advice. Screen time for all media, including television, movies, DVDs, video games, computer activities, computers, tablets, the Internet, and cell phones, should be limited. The AAP recommends that 18- to 24-month-old children should not have any screen time (unless it is video chatting), and that children 2-5 years be limited to 1 hours total screen time each day. The television should not be on during mealtimes, night, or naptimes. Parents should themselves watch sensibly, monitor the program content to which their children are exposed, watch programs and discuss interesting content with children, remove television sets from all bedrooms, and encourage alternative activities. Parents should be advised that research consistently shows that exposure to media violence correlates with childhood aggression.

Social networking sites are becoming increasingly popular, and clinicians need to encourage parents to monitor participation and be aware of potential problems with cyber

IMMUNIZATIONS

A child's immunization status should be assessed at every visit and every opportunity should be taken to vaccinate. Even though parents may keep an immunization record, it is critical that providers also keep an accurate record of a child's immunizations. This information should be written in a prominent location in the paper or electronic chart or kept in an immunization registry.

Despite high overall national immunization coverage levels, areas of under immunization continue to exist in the United States. An understanding of true contraindications (vs "false contraindications") and a "no missed opportunities" approach to immunization delivery has been shown to successfully increase immunization levels. Therefore, it is important that clinicians screen records and administer required immunizations at all types of visits, and administer all needed vaccinations simultaneously. Additionally, clinicians should operate reminder/recall systems, in which parents of underimmunized children are prompted by mail, telephone, and text messages (particularly with adolescents) to visit the clinic for immunization. The assessment of clinicwide immunization levels and feedback of these data to providers have also been shown to increase immunization rates.

Parent refusal of immunizations is an issue in some communities. Because a plethora of incorrect information about vaccine safety and efficacy is on the Internet, it is useful for the provider to direct parents toward reliable sources to help them make an informed decision. A wealth of information for parents and providers about immunizations is available at the National Immunization Program's Web site (www. cdc.gov/vaccines).

Other Types of General Pediatric Service

ACUTE-CARE VISITS

Acute-care visits account for 30% or more of the general pediatrician's office visits. Office personnel should determine the reason for the visit and whether it is an emergent situation, obtain a brief synopsis of the child's symptoms, carefully document vital signs, and list known drug allergies. The clinician should document the events related to the presenting problem and carefully describe them in the medical record. The record should include supporting physical examination data and a diagnosis. Treatments and follow-up instructions must be recorded, including when to return to the office if the problem is not ameliorated. Immunization status should be screened, as previously discussed. Depending on the severity of illness, this may also be an opportunity for age-appropriate health maintenance screenings and anticipatory guidance. This may be particularly true with older school-aged children or adolescents who may be seen more rarely for routine health maintenance visits.

PRENATAL VISITS

Ideally, a couple's first trip to a physician's office should take place before the birth of their baby. A prenatal visit goes a long way toward establishing trust and enables a pediatric provider to learn about a family's expectations, concerns, and fears regarding the anticipated birth. If the infant develops a problem during the newborn period, a provider who has already met the family is in a better position to maintain rapport and communication with the new parents.

In addition to helping establish a relationship between parents and pediatric providers, the prenatal visit can be used to gather information about the parents and the pregnancy, provide information and advice, and identify high-risk situations. A range of information can be provided to parents regarding feeding choices and the benefits of breast-feeding; injury prevention, including sleeping position and the appropriate use of car seats; and techniques for managing colic. Potential high-risk situations that may be identified include mental health issues in the parents, a history of domestic violence, or maternal medical problems that may affect the infant.

Serwint JR: The prenatal pediatric visit. Pediatr Rev 2003;24:31 [PMID: 12509543].

SPORTS PHYSICALS

A preparticipation physical examination (PPE) evaluation is a recommended part of every routine well-child and adolescent care visit. Physicians should be recommending exercise and activity to every child, not just those participating in organized sports.

The goal of the sports physical is to identify medical conditions that would make sports participation unsafe, screen for underlying illness through a traditional history and physical, and recognize preexisting injuries or medical problems that have affected previous sports seasons. As part of the history, the particular sport being played or specific exercise activity should be discussed. Different sports have different potentials for injury, and prevention methods will differ. All patients should be asked about previous cardiac, respiratory, musculoskeletal, or neurologic problems associated with activity. Particular attention should be drawn to any suspicion of cardiac syncope, asthma symptoms, past concussions, or history of unilateral organs, such as kidneys or testicles. Anabolic steroid and nutritional supplement discussion should be explored. Any relevant family history of cardiac death younger than age 50 should be documented.

The physical examination starts with vital signs, including accurate blood pressure screening and examination for obesity. Highlights of the examination include a careful respiratory and cardiac examination, looking for evidence of exercise-induced bronchospasm or anatomic heart disease. Electrocardiogram (ECG) or pulmonary function tests can be considered for suspected abnormalities. The skin examination should look for evidence of potentially contagious skin infections like impetigo or molluscum. The musculoskeletal examination should include all major muscle groups, as well as range of motion and stability testing of the neck, back, shoulder, hips, knees, and ankles. Any pain or limitation should prompt consideration of further investigation or therapy.

A few specific conditions bear mentioning during the counseling phase of the sports participation, including the risks and danger of concussions and performance-enhancing drugs. Appropriate protective equipment should be encouraged.

Seto CK: The preparticipation physical examination: an update. Clin Sports Med 2011 Jul;30(3):491–501. doi: 10.1016/j.csm. 2011.03.008 [PMID: 21658544].

CHRONIC DISEASE MANAGEMENT

Chronic disease in pediatrics is defined as illness that has been present for more than 3 months. Around 25% children and 35% adolescents have illnesses that meet the definition of a chronic illness. The most common chronic conditions in pediatric practice include asthma, obesity/overweight, attention-deficit/hyperactivity disorder (ADHD), and allergic diseases, but also include congenital anomalies and other conditions. Many patients with chronic conditions are cared for only by a primary care provider. However, when subspecialist care is required, the primary care provider plays an integral part of the care to deal with the complexity of these conditions, which also includes understanding the child's growth and development, routine health promotion and anticipatory guidance, evaluating for social issues, advocating for children and their families, and care coordination.

The goal of chronic disease management is to optimize quality of life while minimizing the side effects of treatment interventions. Problem lists should be used to document chronic diagnoses and monitor associated medications. The child and family's emotional responses to chronic illness should be addressed, and referrals to counselors should be offered if needed. Nutrition and the management of medical devices (eg, catheters, gastrostomy tubes) may need to be addressed, and care coordinated with appropriate specialists.

Ludder-Jackson P, Vessey JA: Primary Care of the Child with a Chronic Condition. 5th ed. Mosby-Year Book; 2010.

MEDICAL HOME

The medical home is a concept in which children and their families have an identified, easily accessible primary care provider or group of primary care providers within an office. The American Academy of Pediatrics has identified seven characteristics of a medical home. The medical home must be (1) accessible, meaning that it must be within the child's community, physically accessible, and all insurances accepted; (2) family centered, with mutual responsibility and decision making between the patient/family and medical provider, and the family is recognized as an expert of the child; (3) continuous, in that the same medical professionals provide the continuity of care; (4) comprehensive, with provisions made such that ambulatory and inpatient care are available 24 hours per day, 7 days a week, for 52 weeks of the year; (5) coordinated, with a plan of care developed by the physician and family that is communicated to other providers and agencies as needed; (6) compassionate, meaning that concern is expressed and efforts are made to understand the patient's and family's perspective; and (7) culturally effective, in that the cultural background of the patient and family is respected and incorporated into care, and services are provided in the family's primary language or through a trained medical interpreter.

All children should have a medical home, but it is particularly crucial for children with special health care needs or those with one or more chronic health condition expected to last more than a year. A primary care provider through a medical home should be available for children to assist families with the coordination of consultant recommendations and development of a care plan to implement recommendations.

MENTAL & BEHAVIORAL HEALTH

Parents frequently consult their pediatrician on a large variety of parenting and behavioral health issues. Common topics on which the pediatrician must be comfortable counseling include discipline, temper tantrums, toilet training, biting, and sleep problems.

In addition, there are mental health issues that pediatricians will commonly address in the primary care setting, including ADHD, anxiety, depression, school problems, or family stressors (such as separation, divorce, or remarriage). After assessing the situation, the primary care physician must decide whether the child's and family's needs are within his or her area of expertise or whether referral to another professional such as a psychologist or an education specialist would be appropriate.

The pediatrician should know the warning signs of childhood depression and bipolar disorder and have a low threshold for referral of these concerns to the appropriate mental health professional. Ideally, mental health services not provided by the clinician are available in the same setting where physical health services are obtained (see as follows).

Integrated Mental & Behavioral Health in the Primary Care Setting

In the United States, approximately 20% of school-age children suffer from a diagnosable emotional impairment. Prevalence is higher for children living in poor socioeconomic circumstances. About 75% of all children with psychiatric disturbances are seen in primary care settings, and half of all pediatric office visits involve behavioral, psychosocial, or educational concerns.

Child and family concerns routinely manifest in the context of visits with pediatric primary care providers. However, many pediatric providers in community settings do not feel equipped to address the growing mental health and behavioral needs of the populations they serve due to lack of training and perceived lack of support from mental health providers and systems. Parents are most likely to turn to their primary health care provider for information regarding parenting and child development than to another specialist.

Studies have shown that improved detection of mental health conditions is best done when there is a true partnership between clinical providers and families. A small number of clinic settings have moved forward with providing integrated behavior, development, and mental health training for physicians. The Healthy Steps for Young Children Program provides an example of training pediatric providers and delivering enhanced developmental services in pediatric primary care settings. Families participating in Healthy Steps received more developmental services, were more satisfied with the quality of care provided, were more likely to attend well-child visits and receive vaccinations on time, and were

American Academy of Pediatrics. The medical home. Pediatrics 2002;110:184 [PMID: 12093969].

Medical Home Resources from the American Academy of Pediatrics. https://www.aap.org/en-us/professional-resources/ practice-transformation/medicalhome/Pages/home.aspx. Accessed April 25, 2017.

less likely to use severe discipline techniques with their children. Participation in the program also increased the likelihood that mothers at risk for depression would discuss their symptoms with someone in the pediatric setting.

- American Academy of Pediatrics, Committee on Psychosocial Aspects of Child and Family Health and Task Force on Mental Health: the future of pediatrics: mental health competencies for pediatric primary care. Pediatrics 2009 Jul;124:410–421 [PMID: 19564328].
- Asarnow J, Rozenman M, Wiblin J, Zeltzer L: Integrated medicalbehavioral care compared with usual primary care for child and adolescent behavioral health: a meta-analysis. JAMA Pediatrics 2015;169(10):929–937.

TELEPHONE MANAGEMENT & WEB-BASED INFORMATION

Providing appropriate, efficient, and timely clinical advice over the telephone is a critical element of pediatric primary care in the office setting. An estimated 20%-30% of all clinical care delivered by general pediatric offices is provided by telephone. Telephone calls to and from patients occur both during regular office hours and after the office has closed (termed after-hours), and the personnel and systems in place to handle office-hours versus before- and after-hours calls may differ. In either circumstance, several principles are important: (1) advice is given only by clinicians or other staff with formal medical education (eg, nurse, medical assistant), (2) staff is given additional training in providing telephone care, (3) documentation is made of all pertinent information from calls, (4) standardized protocols covering the most common pediatric symptoms are used, and (5) a physician is always available to handle urgent or difficult calls.

During routine office hours, approximately 20%-25% of all telephone calls to pediatric offices involve clinical matters. Many of these calls, however, are routine in nature, and an experienced nurse within the office can screen calls and provide appropriate advice by telephone. Calls from inexperienced or anxious parents about simple concerns should be answered with understanding and respect. Certain types of calls received during office hours should be promptly transferred to a physician: (1) true emergencies, (2) calls regarding hospitalized patients, (3) calls from other medical professionals, and (4) calls from parents who demand to speak with a physician. Nurses should also seek help from a clinician whenever they are uncertain about how to handle a particular call. When in doubt about the diagnosis or necessary treatment, nurses giving telephone advice should err on the side of having the patient seen in the office.

After-hours telephone answering services are available to many clinicians. Pediatric call centers, although not available in all communities, have certain benefits. Calls are managed using standardized protocols, the call centers are typically staffed by nurses with abundant pediatric experience, the calls are well documented, and call centers often perform ongoing quality assurance. Extensive research on pediatric call centers has revealed a high degree of appropriate referrals to emergency departments, safety in terms of outcomes, parent satisfaction with the process, and savings to the health care system.

In general, after-hours pediatric telephone calls tend to be more serious than calls made during regular office hours. Deciding which patients need to be seen, and how urgently, is the most important aspect of these after-hours telephone "encounters." Several factors influence this final patient disposition: (1) the age of the patient, (2) the duration and type of symptom, (3) the presence of any underlying chronic condition, (4) whether the child appears "very sick" to the caller, and (5) the anxiety level of the caller. Once all the pertinent medical information is gathered, a decision is made about whether the child should be seen immediately (by ambulance vs car), seen in the office later (today vs tomorrow), or whether the illness can be safely cared for at home. At the end of the call, it should be confirmed that parents understand and feel comfortable with the plan for their child.

The Internet has become a common tool used in pediatric office settings. Information about the practice and providers, the care of common minor problems, scheduling of appointments, insurance issues, prescription refills, and laboratory test results are often available using the web. Pertinent health information, with appropriate permissions and authority, can often be provided via the Internet to other locations such as hospitals and pharmacies. A well-functioning website is now a crucial service of a pediatric practice.

ADVOCACY & COMMUNITY PEDIATRICS

Community pediatrics is "a perspective that enlarges the pediatrician's focus from one child to all children in the community." Pediatricians have historically been very involved in supporting and developing services for vulnerable children in their communities. As a group, pediatricians recognize that communities are integral determinants of a child's health and that the synthesis of public health and personal health principles and practices is important in the practice of community pediatrics. As well, pediatricians have

241

long been committed to working with other professionals in the community and advocating for the needs of all children. For example, pediatricians have been instrumental in the passage of laws requiring car seats and bicycle helmets, as well as expanded health care coverage through State Children's Health Insurance Program (SCHIP) working with legislators on both local and federal levels.

Advocacy refers to the act of representing or pleading a cause on behalf of another. Pediatricians and other providers who care for children have a responsibility to be a voice for a population who cannot vote or advocate for themselves very effectively. Advocacy can be broken down into three categories: individual (patient-based), community, and legislative (policy-based).

Pediatricians in practice are frequently instrumental in one-on-one advocacy, which may take the form of writing a letter of medical necessity or referring children and families to valuable services and resources. Pediatricians must be familiar with programs in the community. For example, children with special health care needs may be eligible for services typically funded through state health departments and through programs such as those provided based on the Individuals with Disabilities Education Act (IDEA). A variety of community-based immunization programs can provide access to needed immunizations for eligible children. Food and nutrition programs such as the federally funded WIC program provide sources of food at no cost to eligible families. Finally, subsidized preschool and child care services such as the federally funded Head Start program provide preschool programs for qualifying children.

Community advocacy goes beyond the walls of the office or hospital. Pediatricians can become involved with local organizations that help children in the community. Pediatricians and other child advocates can work with community partners to address issues that influence child health. Community advocacy might focus on a particular condition (such as obesity) or environmental factors (such as exposure to violence) or improving health prevention (such as promoting programs to incorporate oral health into well-child visits). Finally, pediatricians can learn about issues that affect children and work to affect change at a local, state, or national level. Physician advocates may write or call their legislators, educate the public and disseminate information by writing letters or opinion pieces, provide expert testimony for legislative committees, or even help draft laws.

COMMON GENERAL PEDIATRIC ISSUES

FEVER

General Considerations

Fever is one of the most common reasons for pediatric office visits, emergency department encounters, and after-hours telephone calls. Several different definitions of fever exist, but most experts define fever as a rectal temperature of 38°C (100.4°F) or above. Temperature in pediatric patients can be measured in a variety of manners: rectal (using a mercury or digital thermometer), oral (mercury or digital), axillary (mercury, digital, or liquid crystal strip), forehead (liquid crystal strip), or tympanic (using a device that measures thermal infrared energy from the tympanic membrane). Tympanic measurement of temperature is quick and requires little patient cooperation. Several cautions apply to the use of this technique: tympanic temperatures have been shown to be less accurate in infants younger than 3 months and are subject to false readings if the instrument is not positioned properly or the external ear canal is occluded by wax.

Causes

Fever occurs when there is a rise in the hypothalamic set point in response to endogenously produced pyrogens. Among the broad range of conditions that cause fever are infections, malignancies, autoimmune diseases, metabolic diseases, chronic inflammatory conditions, medications (including immunizations), CNS abnormalities, and exposure to excessive environmental heat. In most settings, the majority of fevers in pediatric patients are caused by selflimiting viral infections. Teething does not cause fever.

Clinical Findings

A. Initial Evaluation

When evaluating a child with fever, one should elicit from the parents information about the duration of fever, how the temperature was taken, the maximum height of fever documented at home, all associated symptoms, any chronic medical conditions, any medications taken, medication allergies, fluid intake, urine output, exposures and travel, and any additional features of the illness that concern the parents (Table 9-5). In the office, temperature, heart rate, respiratory rate, and blood pressure should be documented, as well as an oxygen saturation if the child has any increased work of breathing. A complete physical examination, including a neurologic examination, should then be performed, with particular attention paid to the child's degree of toxicity and hydration status. A well-appearing, well-hydrated child with evidence of a routine viral infection can be safely sent home with symptomatic treatment and careful return precautions. **CHAPTER 9**

Table 9–5. Guidelines for evaluating children with fever.

A. See immediately if:

- 1. Child is < age 3 mo with fever > $38^{\circ}C$
- 2. Fever is $> 40.6^{\circ}C$
- 3. Child is crying inconsolably or whimpering
- 4. Child is crying when moved or even touched
- 5. Child is difficult to awaken
- 6. Child's neck is stiff
- 7. Purple spots or dots are present on the skin
- 8. Child's breathing is difficult and not better after nasal passages are cleared
- 9. Child is drooling saliva and is unable to swallow anything
- 10. A convulsion has occurred
- Child has sickle cell disease, splenectomy, human immunodeficiency virus (HIV), chemotherapy, organ transplant, chronic steroids
- 12. Child acts or looks "very sick"

B. See within 24 h if:

- Child is 3–6 mo old (unless fever occurs within 48 h after a diphtheria-tetanus-pertussis vaccination and infant has no other serious symptoms)
- 2. Fever exceeds 40°C (especially if child is < age 3 y)
- 3. Burning or pain occurs with urination
- Fever has been present for > 24 h without an obvious cause or identified site of infection
- 5. Fever has subsided for > 24 h and then returned
- 6. Fever has been present > 72 h

Depending on patient age, presence of underlying conditions, type of infection, and the provider's assessment of toxicity and hydration, many children with focal bacterial infections can also be treated as outpatients, with appropriate oral antibiotics as discussed in Chapter 42.

B. Fever Without a Focus of Infection

Children who present with fever but without any symptoms or signs of a focal infection are often a diagnostic and management challenge. When assessing a child with fever but no apparent source of infection on examination, the provider needs to carefully consider the likelihood of a serious but "hidden" or occult bacterial infection. With the widespread use of effective vaccines against Haemophilus influenza type b and Streptococcus pneumoniae, two of the most common causes of invasive bacterial infections in unimmunized children, the incidence of occult bacterial infections has declined. However, vaccines are not 100% effective, and other organisms cause serious occult infections in children; therefore, febrile children will always demand careful evaluation and observation. Appropriate choices for empiric antibiotic therapy of children with fever without focus are discussed in Chapter 39.

Febrile infants 28 days old or younger, because of their likelihood of serious disease, including sepsis, should always

be treated conservatively. Hospitalization and parenteral antibiotics should be strongly considered in all circumstances. An initial diagnostic evaluation should include CBC; blood culture; urinalysis; urine culture; and Gram stain, cerebrospinal fluid protein and glucose tests, as well as culture of the cerebrospinal fluid. Consideration should also be given to the possibility of a perinatal herpes simplex virus infection (neonatal herpes is described in more detail in Chapter 40). A chest radiograph should be obtained for any febrile infant with increased work of breathing.

Infants aged 29–60 days are at risk of developing a variety of invasive bacterial infections. Febrile infants without a focus of infection can be divided into those who appear toxic versus nontoxic, and those at low risk versus higher risk of invasive bacterial disease. As with febrile neonates, toxic children in this age group should be admitted to the hospital for parenteral antibiotics and close observation. Viral illness is the most common cause of fever in this age group; if there is evidence of viral disease (upper respiratory infection, bronchiolitis), further workup may not be necessary. Urinary tract infection is the most common bacterial cause of infection in this age group. Nontoxic low-risk infants in this age group are typically treated as outpatients with close follow-up.

In an era of increasing immunization coverage against the most common invasive pneumococcal serotypes, it is difficult to estimate the risk of occult bacteremia in febrile 3- to 36-month-olds with no focus of infection. Nevertheless, when assessing children aged 3-36 months with temperatures of 39°C or higher, urine cultures should be considered in all male children younger than 6 months and in all females younger than 2 years. Chest radiographs should be performed in any child with increased work of breathing and should also be considered in children with high (20,000/mm³) WBC counts but no respiratory symptoms. Depending on the child's appearance, underlying medical condition, and height of fever, blood cultures should also be obtained. Empiric antibiotic therapy may be considered, particularly for children with temperature of 39°C and WBC count of 15,000/mm3. However, in previously healthy, wellappearing, fully immunized children with reassuring laboratory studies, observation without antibiotics is appropriate.

Treatment

Fever phobia is a term that describes parents' anxious response to the fevers that all children experience. In a recent study, 91% of caregivers thought that a fever could cause harmful effects. Around 7% of parents thought that if they did not treat the fever, it would keep going higher. Parents need to be reassured that fevers lower than 41.7° C do not cause brain damage. They should be counseled that, although fevers can occasionally cause seizures—in which case their child needs to be seen—febrile seizures are generally harmless and likewise do not cause brain damage.

242

Several safe and effective medications are available for the treatment of fever. Acetaminophen is indicated in children older than 2 months who have fever of 39°C or are uncomfortable. Acetaminophen is given in a dosage of 15 mg/kg of body weight per dose and can be given every 4 hours. The other widely used antipyretic is ibuprofen, which can be used in children 6 months and older. Ibuprofen is given in a dosage of 10 mg/kg of body weight per dose and can be given every 6 hours. Ibuprofen and acetaminophen are similar in safety and their ability to reduce fever. Aspirin should not be used for treating fever in any child or adolescent, because of its association with the development of Reye syndrome (particularly during infections with varicella and influenza). With all antipyretics, parents should be counseled to be very careful with dosing and frequency of administration as poisoning can be dangerous. Alternating acetaminophen and ibuprofen is not recommended.

GROWTH DEFICIENCY

Growth faltering or growth deficiency—formerly termed *failure to thrive*—is deceleration of growth velocity, resulting in crossing two major percentile lines on the growth chart. The diagnosis also is warranted if a child younger than 6 months has not grown for 2 consecutive months or if a child older than 6 months has not grown for 3 consecutive months. Growth deficiency occurs in about 8% of children.

Patterns of growth deficiency suggest, but are not specific for, different causes. In type I growth deficiency, the head circumference is preserved and the weight is depressed more than the height. This most common type results from inadequate caloric intake, excessive loss of calories, or inability to use calories peripherally. Most cases of type I deficiencies are the result of poverty, lack of caregiver understanding, poor caregiverchild interaction, abnormal feeding patterns, or a combination of factors. Type II growth deficiency, which is associated with genetically determined short stature, endocrinopathies, constitutional growth delay, heart or renal disease, or various forms of skeletal dysplasias, is characterized by normal head circumference and proportionate diminution of height and weight. In type III growth deficiency, all three parameters of growth-head circumference, weight, and height-are lower than normal. This pattern is associated with CNS abnormalities, chromosomal defects, and in utero or perinatal insults.

Just because an infant crosses a growth percentile does not mean an infant necessarily has a problem. Infants can cross growth curves normally, either "lagging down" or "shooting up." This crossing of growth percentiles is usually normal if it meets the following criteria: change in body weight and length are symmetrical, the size of the infant parallels the midparental weight and stature, the development remains normal, and a new growth curve is subsequently established, usually around 15 months of age; this also can be seen in the exclusively breast-fed infants at 4–6 months. WHO growth curves are now the standard and are based on children from various countries who were exclusively or primarily breast-fed in the first 4 months of life.

Clinical Findings

A. Initial Evaluation

The history and physical examination will identify the cause of growth reduction in the vast majority of cases (Table 9–6). The physical examination should focus on signs of organic disease or evidence of abuse or neglect: dysmorphic features, skin lesions, neck masses, adventitial breath sounds, heart murmurs, abdominal masses, and neuromuscular tone and strength. Throughout the evaluation, the physician should observe the caregiver-child interaction and the level of family functioning. Developmental screening and laboratory screening tests (CBC, blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture) may be useful depending on the history and examination.

B. Further Evaluation

A prospective 3-day diet record should be a standard part of the evaluation. Occasionally, an infant or child may need to be hospitalized to obtain an accurate assessment of intake.

Table 9–6. Components of initial evaluation for growth deficiency.

Birth history: newborn screening result; rule out intrauterine growth
retardation, anoxia, congenital infections
Feeding and nutrition: difficulty sucking, chewing, swallowing
Feeding patterns: intake of formula, milk, juice, solids
Stooling and voiding of urine: diarrhea, constipation, vomiting, poor urine stream
Growth pattern: several points on the growth chart are crucial
Recurrent infections
Hospitalizations
Human immunodeficiency virus (HIV) risk factors
Developmental history
Social and family factors: family composition, financial status,
supports, stresses; heritable diseases, heights and weights of
relatives
Review of system

This is useful in assessing undernutrition even when organic disease is present. The diet history is evaluated by a dietitian for calories, protein, and micronutrients as well as for the pattern of eating. Additional laboratory tests should be ordered based on the history and physical examination. For example, stool collection for fat determination is indicated if a history of diarrhea suggests malabsorption. Moderate or high amounts of proteinuria should prompt workup for nephrotic syndrome. Vomiting should suggest a gastrointestinal, metabolic, neurologic, infectious, or renal cause. The tempo of evaluation should be based on the severity of symptoms and the magnitude of growth failure.

Treatment

A successful treatment plan addresses the child's diet and eating patterns, the child's development, caregiver skills, and any organic disease. High-calorie diets in the form of highercalorie formula or liquid supplement are often required and frequent monitoring (every 1 or 2 weeks initially) is essential. Acceptable weight gain varies by age (Table 9–7).

Education in nutrition, child development, and behavioral management as well as psychosocial support of the primary caregiver is essential. If family dysfunction is mild, behavior modification and counseling will be useful. Day care may benefit the child by providing a structured environment for all activities, including eating. If family dysfunction is severe, the local department of social services can help provide structure and assistance to the family. Rarely, the child may need to be temporarily or permanently removed from the home. Hospitalization is reserved for management of dehydration, for cases in which home therapy has failed to result in expected growth, for children who show evidence of abuse or willful neglect, for management of an illness that

Immunization

Matthew F. Daley, MD Sean T. O'Leary, MD, MPH Ann-Christine Nyquist, MD, MSPH

Immunization is widely recognized as one of the greatest public health achievements of modern times. Largely as a consequence of immunization, the annual incidences of diphtheria, paralytic poliomyelitis, measles, mumps, rubella, and Haemophilus influenzae type b (Hib) in the United States have fallen by more than 99% compared with the average annual incidences of these diseases in the 20th century. Invasive pneumococcal disease in children less than 5 years has declined steeply since routine pneumococcal vaccination began in 2000. Similarly, rotavirus vaccination has been associated with substantial declines in hospitalizations and emergency department visits for diarrheal illnesses in young children. Childhood immunization has also led, through herd immunity, to significant decreases in several infectious illnesses in adults, including pneumococcal, rotavirus, and varicella disease.

Every year, more than 4 million children are born in the United States, and successful immunization of each birth cohort requires the concerted effort of health care providers, public health officials, vaccine manufacturers, and the public. Public perceptions about immunizations, particularly routine childhood immunizations, are generally positive. However, parent concerns about the safety of vaccines have risen in recent years, in part fueled by unfounded speculation about an association between various vaccines or vaccine components and autism. Modern vaccines have a high degree of safety, and serious adverse events following vaccination are rare. Nonetheless, health care providers need to be prepared to discuss the benefits and risks of vaccination with uncertain parents, providing factual information in a clear and empathic fashion.

This chapter starts with general principles regarding immunizations and the recommended pediatric and adolescent vaccination schedules, followed by a discussion of vaccine safety. Each routinely recommended vaccine is then discussed. Vaccines that are only given in special circumstances are discussed in the final section. Several acronyms that are commonly used in this and other vaccine-related publications are summarized in Table 10–1.

Because the field of immunizations is rapidly changing, it is important for health care providers to seek the most up-to-date information available. The recommendations outlined are current but will change as technology evolves and our understanding of the epidemiology of vaccinepreventable diseases changes. The most useful sources for regularly updated information about immunization are the following:

- 1. National Center for Immunization and Respiratory Diseases at the Centers for Disease Control and Prevention (CDC). It maintains a website with extensive vaccinerelated resources, including the recommendations of the Advisory Committee on Immunization Practices (ACIP), vaccination schedules, Vaccine Information Statements (VISs), information for the public and providers, and links to other vaccine materials. Available at: www.cdc.gov/vaccines.
- CDC Contact Center. The CDC-INFO contact center provides services to the public and health care professionals regarding a variety of health-related issues, including immunizations. Available at: www.cdc.gov/ cdc-info, or by phone at 1-800-232-4636 (English and Spanish).
- 3. The Red Book. Report of the Committee on Infectious Diseases. Published at 2- to 3-year intervals by the American Academy of Pediatrics (AAP). A newly revised Red Book was published in 2015. Updates are published in the journal Pediatrics and can also be accessed at redbook.solutions.aap.org/.
- 4. Immunization Action Coalition. This nonprofit organization creates and distributes educational materials for health care providers and the public related to vaccines. All materials are provided free of charge and can be accessed at www.immunize.org.

Table 10–1. Vaccine-related acronyms.

ACIP	Advisory Committee on Immunization Practices
BCG	Bacillus Calmette-Guérin vaccine against tuberculosis
CDC	Centers for Disease Control and Prevention
CI	Confidence interval
CISA	Clinical Immunization Safety Assessment Network
DT	Pediatric diphtheria and tetanus toxoids
DTaP	Pediatric diphtheria and tetanus toxoids and
	acellular pertussis vaccine
DTP	Pediatric diphtheria and tetanus toxoids and whole-cell pertussis vaccine
HBIG	Hepatitis B immune globulin
HBsAg	Hepatitis B surface antigen
НерА	Hepatitis A vaccine
НерВ	Hepatitis B vaccine
Hib	Haemophilus influenzae type b
Hib-MenCY-TT	Hib, meningococcal C and Y, tetanus toxoid
	vaccine
HIV	Human immunodeficiency virus
HPV	Human papillomavirus
HPV2	HPV vaccine, bivalent
HPV4	HPV vaccine, quadrivalent
HPV9	HPV-vaccine, nine-valent
lg	Immunoglobulin
IPV	Inactivated poliovirus vaccine
LAIV	Live attenuated influenza vaccine
MCV4	Meningococcal conjugate vaccine
MMR	Measles-mumps-rubella vaccine
MMRV	Measles-mumps-rubella-varicella vaccine
MPSV4	Meningococcal polysaccharide vaccine
OPV	Oral poliovirus vaccine
PCV	Pneumococcal conjugate vaccine
PCV7	Pneumococcal conjugate vaccine, 7-valent
PCV13	Pneumococcal conjugate vaccine, 13-valent
PPSV23	Pneumococcal polysaccharide vaccine, 23-valent
PRISM	Post-Licensure Rapid Immunization Safety Monitoring
RV1	Rotavirus vaccine, monovalent
RV5	Rotavirus vaccine, pentavalent
ТВ	Tuberculosis
Td	Adult tetanus and diphtheria toxoid
Tdap	Tetanus and reduced diphtheria and acellular pertussis vaccine for adolescents and adults
VAERS	Vaccine Adverse Events Reporting System
VariZIG	Varicella-zoster immune globulin
VIS	Vaccine Information Statement
VSD	Vaccine Safety Datalink
VZV	Varicella-zoster virus

STANDARDS FOR PEDIATRIC IMMUNIZATION PRACTICES

In the United States, every infant requires more than 25 doses of vaccine by age 18 months to be protected against 14 or more childhood diseases. In 2015, immunization coverage rates for children aged 19-35 months were more than 90% for poliovirus, measles-mumps-rubella, varicella, and hepatitis B vaccines, and were steadily increasing for more recently recommended vaccines such as rotavirus and hepatitis A vaccines. CDC recommends the following specific proven strategies to increase vaccination coverage rates: (1) assessing and providing feedback on practice/provider immunization rates; (2) keeping accurate immunization records; (3) recommending vaccination to parents, and reinforcing when to return for vaccination; (4) sending reminder messages to parents; (5) sending reminder messages to providers; (6) reducing missed opportunities to vaccinate; and (7) reducing barriers to immunize within the practice.

The National Childhood Vaccine Injury Act of 1986 requires that for each vaccine covered under the Vaccine Injury Compensation Program, parents should be advised about the risks and benefits of vaccination in a standard manner, using VIS forms produced by CDC. Each time a Vaccine Injury Compensation Program–covered vaccine is administered, the current version of the VIS must be provided to the non-minor patient or legal guardian. Vaccination documentation that is required in the medical record includes the vaccine manufacturer, lot number, and administration date, and expiration date. The VIS version and date, and site and route of administration should also be recorded.

Needles used for vaccination should be sterile and disposable to minimize contamination. A 70% solution of alcohol is appropriate for disinfecting the stopper of the vaccine container and the skin at the injection site. A 5% topical emulsion of lidocaine-prilocaine applied to the site of vaccination for 30–60 minutes prior to the injection minimizes pain, especially when multiple vaccines are administered.

Compliance with the manufacturer's recommendations for route and site of administration of injectable vaccines are critical for safety and efficacy. With few exceptions (intradermal influenza vaccine and Bacillus Calmette-Guérin [BCG] vaccine), all vaccines are given either intramuscularly or subcutaneously. All vaccines containing an adjuvant must be administered intramuscularly to avoid local irritation or granuloma formation. Intramuscular injections are given at a 90-degree angle to the skin, using a needle that is sufficiently long to reach the muscle tissue, but not so long as to injure underlying nerves, blood vessels, or bones. The anterolateral thigh is the preferred site of vaccination in newborns and children up to 2 years of age, and the deltoid muscle is the preferred site for children aged 3-18 years, although the anterolateral thigh is an acceptable site. Needle length and location should be: 5% inch in newborn infants (thigh); 1 inch in infants 1- to 12-month-olds (thigh), 1–1¼ inches in 1- to 18-year-olds (thigh), and $\frac{5}{4}$ –1 inch in 1- to 18-year-olds (deltoid). Subcutaneous injections should be administered at a 45-degree angle into the anterolateral aspect of the thigh (for infants < 12 months) or the upper outer triceps area (for children 12 months and older) using a 23- or 25-gauge, $\frac{5}{4}$ -inch needle. Pulling back on the syringe prior to vaccine injection (aspiration) is not recommended. A separate syringe and needle should be used for each vaccine.

Many combinations of vaccines can be administered simultaneously without increasing the risk of adverse effects or compromising immune response. Inactivated vaccines can be given simultaneously with, or at any time after, a different vaccine. Injectable or intranasal live-virus vaccines (eg, measles-mumps-rubella [MMR], varicella [VAR], or live attenuated influenza [LAIV]), if not administered on the same day, should be given at least 4 weeks apart. Depending on the combination vaccine used, children may receive an "extra" dose of hepatitis B (HepB) or Hib; these additional doses are not harmful. If an immunoglobulin (Ig) or blood product has been administered, live-virus vaccination should be delayed 3–11 months, depending on the dose of Ig given, to avoid interference with the immune response.

With the large number of vaccine preparations available, interchangeability of vaccines is an issue. All brands of Hib conjugate, hepatitis B (HepB), and hepatitis A (HepA) vaccines are interchangeable. For vaccines containing acellular pertussis antigens, it is recommended that the same brand be used, but when the brand is unknown or the same brand is unavailable, any vaccine with diphtheria and tetanus toxoids and acellular pertussis should be used to continue vaccination. Exceptions to this rule are the recently licensed serogroup B meningococcal [MenB] vaccines, which are not interchangeable under any circumstance. Extending recommended intervals between vaccinations does not alter final antibody titers, and lapsed schedules do not require restarting the series.

The numerous vaccines and other immunologic products used in routine practice vary in the storage temperatures required. The majority of vaccines should never be subjected to freezing temperatures, except varicella-containing vaccines (MMRV, VAR, and herpes zoster) which should be stored frozen. Product package inserts should be consulted for detailed information on vaccine storage conditions and shelf life.

Vaccines very rarely (about 1 case per million doses) cause acute anaphylactic-type reactions. All vaccine providers should have the equipment, medications, staff, established protocols, and training to manage emergencies that may occur following vaccination.

ROUTINE CHILDHOOD & ADOLESCENT IMMUNIZATION SCHEDULES

Each year, CDC recommends immunization schedules for children and adolescents, which are an important guide for vaccination providers. Vaccines in the schedules are roughly ordered by the age at which the vaccines are first given. Table 10–2 is the 2017 schedule of routine immunizations for normal infants, children, and adolescents from birth through 18 years of age. Table 10–3 is the 2017 schedule for persons aged 4 months through 18 years who start vaccination late or are more than 1 month behind the routine immunization schedule. Updated immunization schedules are available at www.cdc.gov/vaccines.

Combination vaccines address the problem of large numbers of injections during a clinic visit. Currently available combination vaccines include MMR, MMRV, and various combinations of Hib, HepB, IPV, and DTaP, including DTaP-HepB-IPV and DTaP-IPV-Hib. Through a unique collaboration between competing manufacturers, an application has been submitted to the FDA for a hexavalent vaccine that includes DTaP-IPV-Hib-HepB. Separate vaccines should not be combined into one syringe by the provider unless approved by the Food and Drug Administration (FDA), because this could decrease the efficacy of vaccine components.

VACCINE SAFETY

Vaccine Safety Monitoring

The United States has a sophisticated, multifaceted system to monitor the safety of licensed vaccines. The Vaccine Adverse Event Reporting System (VAERS), the Vaccine Safety Datalink (VSD), the Post-Licensure Rapid Immunization Safety Monitoring (PRISM), and the Clinical Immunization Safety Assessment (CISA) system each provide distinct contributions to monitoring of vaccine safety. VAERS is a national passive surveillance system administered jointly by the FDA and CDC to accept reports from health care providers and the public about possible vaccine-related adverse events. Reports of adverse events possibly related to vaccination can be made via the Internet (vaers.hhs.gov) or by telephone (1-800-822-7967). As a passive surveillance system, VAERS is subject to limitations, including underreporting, overreporting, the reporting of events that are temporally but not causally related to vaccination, the lack of denominator data, and the lack of a comparison group. The VSD and PRISM, in

Table 10–2. Recommended Immunization Schedule for Children and Adolescents Aged 18 Years or Younger, United States, 2017.

(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE Table 10-3.

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Table 10–2. To determine minimum intervals between doses, see the catch-up schedule (Table 10-3). School entry and adolescent vaccine age groups are shaded in gray.

Measles, mumps, rubella ⁸	N/A	4 weeks			
Varicella ⁹	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

Footnotes—Recommended Immunization Schedule for Children and Adolescents Aged 18 Years or Younger, UNITED STATES, 2017

For further guidance on the use of the vaccines mentioned below, see: www.cdc.gov/vaccines/hcp/acip-recs/index.html.

For vaccine recommendations for persons 19 years of age and older, see the Adult Immunization Schedule.

This schedule includes recommendations in effect as of January 1, 2017. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (www.cdc.gov/vaccines/hcp/admin/contraindications.html) or by telephone (800-CDC-INFO [800-232-4636]).

The Recommended Immunization Schedule for Children and Adolescents Aged 18 Years or Younger are approved by the Advisory Committee on Immunization Practices (www. cdc.gov/vaccines/acip), the American Academy of Pediatrics (www.aap.org), the American Academy of Family Physicians (www.aafp.org), and the American College of Obstetricians and Gynecologists (www.acog.org)

Additional information

- For information on contraindications and precautions for the use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the ACIP General Recommendations on Immunization and the relevant ACIP statement, available online at www.cdc.gov/ vaccines/hcp/acip-recs/index.html.
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered ≤4 days before the minimum interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see Table 1, Recommended and minimum ages and intervals between vaccine doses, in MMWR, General Recommendations on Immunization and Reports / Vol. 60 / No. 2, available online at www.cdc.gov/mmwr/pdf/rr/ rr6002.pdf.
- Information on travel vaccine requirements and recommendations is available at wwwnc.cdc.gov/travel/.

- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, Vaccination of persons with primary and secondary immunodeficiencies, in General Recommendations on Immunization (ACIP), available at www.cdc.gov/mmwr/pdf/rr/r6002.pdf; and Immunization in Special Clinical Circumstances, (American Academy of Pedatrics). In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. Red Book: 2015 report of the Committee on Infectious Diseases. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2015:68-107.
- The National Vaccine Injury Compensation Program (VICP) is a no-fault alternative to the traditional legal system for resolving vaccine injury petitions. Created by the National Childhood Vaccine Injury Act of 1986, it provides compensation to people found to be injured by certain vaccines. All vaccines within the recommended childhood immunization schedule are covered by VICP except for pneumococcal polysaccharide vaccine (PPSV23). For more information; see www.hrsa.aov/vaccinecompensation/index.html.

1. Hepatitis B (HepB) vaccine. (Minimum age: birth) Routine vaccination:

At birth:

- Administer monovalent HepB vaccine to all newborns within 24 hours of birth.
- For infants born to hepatitis B surface antigen (HBsAg)positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) at age 9 through 12 months (preferably at the next well-child visit) or 1 to 2 months after completion of the HepB series if the series was delayed.
- If mother's HBsAg status is unknown, within 12 hours of birth, administer HepB vaccine regardless of birth weight.
 For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth.
 Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG to infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.

Doses following the birth dose:

- The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
- Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months, starting as soon as feasible (see figure 2).
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the first dose. The final (third or fourth) dose in the HepB vaccine series should be administered no earlier than age 24 weeks.
- Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.

Catch-up vaccination:

- Unvaccinated persons should complete a 3-dose series.
- A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
- For other catch-up guidance, see Figure 2.

Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq]) Routine vaccination:

Administer a series of RV vaccine to all infants as follows:

- 1. If Rotarix is used, administer a 2-dose series at ages 2 and 4 months.
- 2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
- 3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

Catch-up vaccination:

- The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days, or older.
- The maximum age for the final dose in the series is 8 months, 0 days.
- For other catch-up guidance, see Figure 2.
- Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks. Exception: DTaP-IPV [Kinrix, Quadrace]: 4 years) Routine vaccination:
 - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
 - Inadvertent administration of fourth DTaP dose early: If the fourth dose of DTaP was administered at least 4 months after the third dose of DTaP and the child was 12 months of age or older, it does not need to be repeated.

Catch-up vaccination:

- The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
- For other catch-up guidance, see Figure 2.
- Haemophilus influenzae type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ActHIB, DTaP-IPV/Hib (Pentacel), Hiberix, and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB]) Routine vaccination:
 - Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4, depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
 - The primary series with ActHIB, MenHibrix, Hiberix, or Pentacel consists of 3 doses and should be administered at ages 2, 4, and 6 months. The primary series with PedvaxHIB consists of 2 doses and should be administered at ages 2 and 4 months; a dose at age 6 months is not indicated.
 - One booster dose (dose 3 or 4, depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months.

n, diabetes have not PCV13 has e adminisministered le cell disfunctional mcies; HIV come: dis-

IMMUNIZATION

 For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, refer to the meningococcal vaccine footnotes and also to MMWR February 28, 2014/63(RR01):1-13, available at www.cdc.gov/ mmwr/PDF/rr/rr6301.pdf.

Catch-up vaccination:

- If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
- If both doses were PRP-OMP (PedvaxHIB or COMVAX) and were administered before the first birthday, the third (and final) dose should be administered at age 12 through 59 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
- If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be administered 8 weeks later.
- For unvaccinated children aged 15–59 months, administer only 1 dose.
- For other catch-up guidance, see Figure 2. For catch-up guidance related to MenHibrix, see the meningococcal vaccine footnotes and also MMWR February 28, 2014/ 63(RR01):1-13, available at www.cdc.gov/mmwr/PDF/rr/ rr6301.pdf.

Vaccination of persons with high-risk conditions:

Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before age 12 months, should receive 2 additional doses of Hib vaccine, 8 weeks apart; children who received 2 or more doses of Hib vaccine before age 12 months should receive 1 additional dose.

- For patients younger than age 5 years undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
- Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
- A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.

 Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unimmunized* persons 5 through 18 years of age with HIV infection.

* Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

5. Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)

Routine vaccination with PCV13:

• Administer a 4-dose series of PCV13 at ages 2, 4, and 6 months and at age 12 through 15 months.

Catch-up vaccination with PCV13:

- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions with PCV13 and PPSV23:

- All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
- For children aged 2 through 5 years with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; solid organ transplantation; or congenital immunodeficiency:
 - 1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV13 was received previously.
 - Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV13 was received previously.
 - 3. The minimum interval between doses of PCV13 is 8 weeks.
 - For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.
- For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma:

- 1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.
- 2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.
- If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.
- For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.
- A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma.
- 6. Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)

Routine vaccination:

 Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:

- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- If both oral polio vaccine (OPV) and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. If only OPV was administered, and all doses were given prior to age 4 years, 1 dose of IPV should be given at 4 years or older, at least 4 weeks after the last OPV dose.
- IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up guidance, see Figure 2.

7. Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 18 years for recombinant influenza vaccine [RIV])

Routine vaccination:

 Administer influenza vaccine annually to all children beginning at age 6 months. For the 2016–17 season, use of live attenuated influenza vaccine (LAIV) is not recommended.

For children aged 6 months through 8 years:

- For the 2016–17 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time or who have not previously received ≥2 doses of trivalent or quadrivalent influenza vaccine before July 1, 2016. For additional guidance, follow dosing guidelines in the 2016–17 ACIP influenza vaccine recommendations (see MMWR August 26, 2016;65(5):1-54, available at www.cdc.qov/mwmr/volumes/65/rr/pdfs/rr6505.pdf).
- For the 2017–18 season, follow dosing guidelines in the 2017–18 ACIP influenza vaccine recommendations.

For persons aged 9 years and older:

Administer 1 dose.

Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination) Routine vaccination:

- Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

Catch-up vaccination:

• Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

9. Varicella (VAR) vaccine. (Minimum age: 12 months) Routine vaccination:

 Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

Catch-up vaccination:

 Ensure that all persons aged 7 through 18 years without evidence of immunity (see MMWR 2007;56[No. RR-4], available at www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

10. Hepatitis A (HepA) vaccine. (Minimum age: 12 months) Routine vaccination:

- Initiate the 2-dose HepA vaccine series at ages 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

Catch-up vaccination:

- The minimum interval between the 2 doses is 6 months. Special populations:
- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children. or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close, personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally, 2 or more weeks before the arrival of the adoptee.

Meningococcal vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 2 months for MenACWY-CRM [Menveo], 9 months for MenACWY-D [Menactra], 10 years for serogroup B meningococcal [MenB] vaccines: MenB-4C [Bexsero] and MenB-FHbp [Trumenba]) Routine vaccination:

- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- For children aged 2 months through 18 years with highrisk conditions, see "Meningococcal conjugate ACWY vaccination of persons with high-risk conditions and other persons at increased risk" and "Meningococcal B vaccination of persons with high-risk conditions and other persons at increased risk of disease" below.

Catch-up vaccination:

- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years,

a booster dose should be administered at age 16 through 18 years, with a minimum interval of at least 8 weeks between doses.

- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Figure 2.

Clinical discretion:

- Young adults aged 16 through 23 years (preferred age range is 16 through 18 years) who are not at increased risk for meningococcal disease may be vaccinated with a 2-dose series of either Bexsero (0, ≥1 month) or Trumenba (0, 6 months) vaccine to provide short-term protection against most strains of serogroup B meningococcal disease. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.
- If the second dose of Trumenba is given at an interval of <6 months, a third dose should be given at least 6 months after the first dose; the minimum interval between the second and third doses is 4 weeks.

Meningococcal conjugate ACWY vaccination of persons with high-risk conditions and other persons at increased risk: <u>Children with anatomic or functional asplenia (including</u> sickle cell disease), children with HIV infection, or children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in <u>C3</u>, C5-9, properdin, factor D, factor H, or taking eculizumab [Soliris]):

Menveo

- Children who initiate vaccination at 8 weeks. Administer doses at ages 2, 4, 6, and 12 months.
- Unvaccinated children who initiate vaccination at 7 through 23 months. Administer 2 primary doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
- Children 24 months and older who have not received a complete series. Administer 2 primary doses at least 8 weeks apart.

MenHibrix

- Children who initiate vaccination at 6 weeks. Administer doses at ages 2, 4, 6, and 12 through 15 months.
- If the first dose of MenHibrix is given at or after age 12 months, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.

Menactra

• <u>Children with anatomic or functional asplenia or</u> <u>HIV infection</u>

— Children 24 months and older who have not received a complete series. Administer 2 primary doses at least 8 weeks apart. If Menactra is administered to a child with asplenia (including sickle cell disease) or HIV infection, do not administer Menactra until age 2 years and at least 4 weeks after the completion of all PCV13 doses.

- <u>Children with persistent complement component</u> <u>deficiency</u>

 - Children 24 months and older who have not received a complete series. Administer 2 primary doses at least 8 weeks apart.
- ° All high-risk children
 - If Menactra is to be administered to a child at high risk for meningococcal disease, it is recommended that Menactra be given either before or at the same time as DTaP.

Meningococcal B vaccination of persons with high-risk conditions and other persons at increased risk of disease: Children with anatomic or functional asplenia (including sickle cell disease) or children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in C3, C5-9, properdin, factor D, factor H, or taking eculizumab [Soliris]):

- Bexsero or Trumenba
- Persons 10 years or older who have not received a complete series. Administer a 2-dose series of Bexsero, with doses at least 1 month apart, or a 3-dose series of Trumenba, with the second dose at least 1–2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj:

 Administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.

For children at risk during an outbreak attributable to a vaccine serogroup:

- For serogroup A, C, W, or Y: Administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo.
- For serogroup B: Administer a 2-dose series of Bexsero, with doses at least 1 month apart, or a 3-dose series of Trumenba, with the second dose at least 1-2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

For MenACWY booster doses among persons with high-risk conditions, refer to *MMWR* 2013;62(RR02):1-22, at *www.cdc.* gov/mmwr/preiew/mmwrhtml/rr6202a1.htm, *MMWR* June 20, 2014/63(24):527-530, at *www.cdc.gov/mmwr/pdf/wk/mm6324.* pdf, and *MMWR* November 4, 2016/65(43):1189-1194, at *www.* cdc.gov/mmwr/volumes/65/wr/pdfs/mm6543a3.pdf.

For other catch-up recommendations for these persons and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see meningococcal *MMWR* publications, available at: www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/ mening.html.

12. Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Boostrix and Adacel)

Routine vaccination:

- Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
- Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
- Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferably during the early part of gestational weeks 27 through 36), regardless of time since prior Td or Tdap vaccination.

Catch-up vaccination:

- Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 dose (preferably the first) in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years may be administered.
- Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose, followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
- · Inadvertent doses of DTaP vaccine:
- If administered inadvertently to a child aged 7 through 10 years, the dose may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child may receive a Tdap booster dose at age 11 through 12 years.
- If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
- For other catch-up guidance, see Figure 2.

Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for 4vHPV [Gardasil] and 9vHPV [Gardasil 9]) Routine and catch-up vaccination:

- Administer a 2-dose series of HPV vaccine on a schedule of 0, 6-12 months to all adolescents aged 11 or 12 years. The vaccination series can start at age 9 years.
- Administer HPV vaccine to all adolescents through age 18 years who were not previously adequately vaccinated. The number of recommended doses is based on age at administration of the first dose.
- For persons initiating vaccination before age 15, the recommended immunization schedule is 2 doses of HPV vaccine at 0, 6-12 months.
- For persons initiating vaccination at age 15 years or older, the recommended immunization schedule is 3 doses of HPV vaccine at 0, 1–2, 6 months.
- A vaccine dose administered at a shorter interval should be readministered at the recommended interval.
- In a 2-dose schedule of HPV vaccine, the minimum interval is 5 months between the first and second dose. If the second dose is administered at a shorter interval, a third dose should be administered a minimum of 12 weeks after the second dose and a minimum of 5 months after the first dose.
- In a 3-dose schedule of HPV vaccine, the minimum intervals are 4 weeks between the first and second dose, 12 weeks between the second and third dose, and 5 months between the first and third dose. If a vaccine dose is administered at a shorter interval, it should be readministered after another minimum interval has been met since the most recent dose.

Special populations:

- For children with history of sexual abuse or assault, administer HPV vaccine beginning at age 9 years.
- Immunocompromised persons*, including those with human immunodeficiency virus (HIV) infection, should receive a 3-dose series at 0, 1–2, and 6 months, regardless of age at vaccine initiation.
- Note: HPV vaccination is not recommended during pregnancy, although there is no evidence that the vaccine poses harm. If a woman is found to be pregnant after initiating the vaccination series, no intervention is needed; the remaining vaccine doses should be delayed until after the pregnancy. Pregnancy testing is not needed before HPV vaccination.

comparison, are active surveillance systems with continuous safety monitoring of vaccines in defined patient populations. The VSD and PRISM can conduct timely investigations of newly licensed vaccines or emerging vaccine safety concerns. The CISA system is designed to develop protocols for the evaluation, diagnosis, and treatment of adverse events following immunization. Patients with rare and serious adverse events following immunization can be referred to CISA for evaluation.

Vaccine Contraindications & Precautions

All vaccines have certain contraindications and precautions that guide their administration. A contraindication indicates that the potential vaccine recipient is at increased risk of a serious adverse event. A vaccine should not be given when a contraindication to that vaccine is present, whereas a precaution indicates a circumstance that might increase the risk of adverse events or diminish the effectiveness of the vaccine. In the setting of precautions, the risks and benefits of vaccination must be carefully weighed prior to a decision regarding vaccination. Precautions are often temporary, in which case vaccination can resume once the precaution no longer applies. Contraindications and precautions are listed with each vaccine. Additional, more detailed, information is available from the CDC (www.cdc.gov/vaccines), in the AAP's *Red Book*, and in vaccine package inserts.

VACCINATION IN SPECIAL CIRCUMSTANCES

Minor Acute Illnesses

Minor acute illnesses, with or without low-grade fever, are not contraindications to vaccination, because there is no evidence that vaccination under these conditions increases the rate of adverse effects or decreases efficacy. A moderate to severe febrile illness may be a reason to postpone vaccination. Routine physical examination and temperature assessment are not necessary before vaccinating healthy infants and children.

Children With Chronic Illnesses

Most chronic diseases are not contraindications to vaccination; in fact, children with chronic diseases may be at greater risk of complications from vaccine-preventable diseases, such as influenza and pneumococcal infections. Premature infants are a good example. They should be immunized according to their chronologic, not gestational, age. Vaccine doses should not be reduced for preterm or low-birth-weight infants. One exception is children with progressive central nervous system disorders. Vaccination with DTaP should be deferred until the neurologic condition has been clarified and is stable.

Immunodeficient Children

Congenitally immunodeficient children should not be immunized with live-virus vaccines (oral polio vaccine [OPV, available only in developing countries], rotavirus, MMR, VAR, MMRV, yellow fever, or LAIV) or live-bacteria vaccines (BCG or live typhoid fever vaccine). Depending on the nature of the immunodeficiency, other vaccines are safe, but may fail to evoke an immune response. Children with cancer and children receiving high-dose corticosteroids or other immunosuppressive agents should not be vaccinated with live-virus or live-bacteria vaccines. This contraindication does not apply if the malignancy is in remission and chemotherapy has not been administered for at least 90 days. Live-virus vaccines may also be administered to previously healthy children receiving low to moderate doses of corticosteroids (defined as up to 2 mg/kg/day of prednisone or prednisone equivalent, with a 20 mg/day maximum) for less than 14 days; children without other immunodeficiency receiving short-acting alternate-day corticosteroids; children being maintained on physiologic corticosteroid therapy; and children receiving only topical, inhaled, or intra-articular corticosteroids.

Contraindication of live-pathogen vaccines also applies to children with HIV infection who are severely immunosuppressed. Those who receive MMR should have at least 15% CD4 cells, a CD4 lymphocyte count equivalent to CDC immunologic class 2, and be asymptomatic from their HIV. MMR for these children is recommended at 12 months of age (after 6 months of age during an epidemic); some experts suggest delaying MMR vaccination in HIV-infected children until they have received antiretroviral therapy for 3 months. For HIV-infected children, a booster MMR dose may be given at least 1 month after the initial dose; in fact, giving this booster dose earlier than at 4-6 years of age is often encouraged. Doses given before 1 year of age should not be considered part of a complete series. VAR vaccination is also recommended for HIV-infected children with CD4 cells preserved as listed earlier. The ACIP recommends only IPV vaccination for children. Thus, immunodeficient children should no longer be exposed to OPV through household contacts. MMR and VAR are not contraindicated in household contacts of immunocompromised children. HIV-infected children who were vaccinated before their HIV was treated should be reimmunized to ensure adequate protection. The recommended immunization schedule for immunocompromised children is available at http://www .cdc.gov/vaccines/pubs/pinkbook/index.html.

Allergic or Hypersensitive Children

Severe hypersensitivity reactions are rare following vaccination (1.53 cases per 1 million doses). They are generally attributable to a trace component of the vaccine other than to the antigen; for example, MMR, IPV, and VAR contain microgram quantities of neomycin, and IPV also contains trace amounts of streptomycin and polymyxin B. Children with known anaphylactic responses to these antibiotics should not be given these vaccines. Trace quantities of egg antigens may be present in both inactivated and live influenza and yellow fever vaccines. Guidelines for influenza vaccination in children with egg allergies have recently changed. Children with only urticaria following exposure to egg can be vaccinated, as long as injectable influenza vaccine is used as opposed to LAIV; vaccination is by a health care provider experienced in recognizing allergic reactions; and the child is observed for 30 minutes following vaccination. Children with more serious allergic reactions to egg, such as angioedema, respiratory symptoms, or anaphylaxis, may be eligible for injectable influenza vaccine, but should be referred to an allergist for an assessment of vaccination risk. Some vaccines (MMR, MMRV, and VAR) contain gelatin. For any persons with a history of anaphylactic reaction to gelatin or any component contained in a vaccine, the vaccine package insert should be reviewed and additional consultation sought, such as from a pediatric allergist. Some tips and rubber plungers of vaccine syringes contain latex. These vaccines should not be administered to individuals with a history of severe anaphylactic allergy to latex, but may be administered to people with less severe allergies. Thimerosal is an organic mercurial compound used as a preservative in vaccines since the 1930s. While there is no evidence that thimerosal has caused serious allergic reactions or autism, all routinely recommended vaccines for infants have been manufactured without thimerosal since mid-2001. Thimerosal-free formulations of injectable influenza vaccine are available, and LAIV does not contain thimerosal.

Other Special Circumstances

Detailed recommendations for preterm low-birth-weight infants; pediatric transplant recipients; Alaskan Natives/ American Indians; children in residential institutions or military communities; or refugees, new immigrants, or travelers are available from the CDC (at http://www.cdc.gov/ vaccines) and from the AAP's *Red Book*.

Communicating With Parents About Vaccines

Most parents in the United States choose to vaccinate their children. In 2013, less than 1% of young children had received no vaccines. However, parental concern about vaccines are on the rise, and an increasing number of parents are choosing to delay or decline vaccination for their children. While there are myriad reasons given for not vaccinating, several themes recur. Some parents do not believe their children are at risk for diseases such as poliomyelitis, measles, and tetanus. Other parents do not believe that certain vaccine-preventable diseases, such as varicella and pertussis, are particularly serious. There are also widespread concerns about the safety of vaccines. Health care providers have a critically important role in discussing the known risks and benefits of vaccination with parents. In this context, it is important that providers recognize that parent decisions are often based on inaccurate information about vaccine risk provided by the media or Internet sources.

AAP, CDC, and others have developed resources to guide providers on how best to communicate with parents about vaccines. A presumptive recommendation ("We have three shots to do today") is likely more effective than a participatory approach ("Have you thought about the shots he is due for today?"). For parents who resist or have questions about vaccines, some will agree to be vaccinated after simply receiving the necessary knowledge. For many, however, simply correcting misinformation is not enough, and may increase resistance to vaccination. For these parents, it is best to avoid arguments or rebuttals, and some have suggested the use of motivational interviewing or other conversational techniques in these situations. Other promising techniques include pivoting away from discussions of vaccine side effects to emphasize the importance of the vaccine for disease prevention, personal recommendations ("I vaccinate my own children according to the recommended schedule"), promotion of social norms ("Almost all of our patients are fully vaccinated"), or highlighting circumstances which increase risk ("These infectious diseases are just a plane flight away.").

Parents with questions about vaccine safety may be directed to trusted websites, such as those of the AAP (www. aap.org), CDC (www.cdc.gov/vaccines), and the Immunization Action Coalition (www.immunize.org).

HEPATITIS B VACCINATION

Reported cases of acute hepatitis B has declined dramatically in the United States, largely attributable to vaccination. Based on surveillance data from 2015, acute hepatitis B
CHAPTER 10

incidence has declined by at least 87% since 1985. The greatest declines are in children younger than 15 years, in whom rates have decreased by 98%.

Success in reducing hepatitis B in the United States is due, in large part, to a comprehensive hepatitis B prevention strategy initiated in 1991. The four central elements of this approach are (1) immunization of all infants beginning at birth; (2) routine screening of all pregnant women for hepatitis B infection, and provision of hepatitis B immunoglobulin (HBIg) to all infants born to infected mothers; (3) routine vaccination of previously unvaccinated children and adolescents; and (4) vaccination of adults at increased risk of hepatitis B infection.

While high immunization rates have been achieved in young children (more than 92% were fully immunized in 2015), there has been less success in identifying hepatitis B-infected mothers and at immunizing high-risk adults. Of the estimated 23,000 mothers who deliver each year who are hepatitis B surface antigen (HBsAg) positive, only 9000 are identified through prenatal screening. While there is an average of 90 cases of perinatally acquired hepatitis B infection reported to the CDC every year, the actual number of perinatal HBV infections is estimated to be 10-20 times higher than the number currently detected and reported. This circumstance represents a significant missed opportunity for prevention in exposed infants, given that administration of hepatitis B vaccine (HepB) in conjunction with HBIg is 95% effective at preventing mother-to-infant transmission of the virus. Further, many hospitals do not routinely offer HepB to all newborns, despite ACIP recommendations for universal newborn HepB vaccination. Similarly, while HepB alone is 90%-95% effective at preventing hepatitis B infection, only 45% of high-risk adults have been vaccinated.

All pregnant women should be routinely screened for HBsAg. Infants born to HBsAg-positive mothers should receive both HepB and HBIg immediately after birth. Infants for whom the maternal HBsAg status is unknown should receive vaccine (but not HBIg) within 12 hours of birth. In such circumstances, the mother's HBsAg status should be determined as soon as possible during her hospitalization, and the infant given HBIg if the mother is found to be HBsAg positive. For all infants, the hepatitis B immunization series should be started at birth, with the first dose given prior to 24 hours of age without exception. The ACIP has recommended that any decision to defer the birth dose require an explanation in the medical record, accompanied by a copy of the mother's negative HBsAg test during the current pregnancy. In 2015, 72% of infants nationally received HepB within 3 days after birth, with wide variation by state (49%-88%).

Routine immunization with three doses of HepB is recommended for all infants and all previously unvaccinated children aged 0–18 years. A two-dose schedule is available for adolescents. Screening for markers of past infection before vaccinating is not indicated for children and adolescents, but may be considered for high-risk adults. Because HepB vaccines consist of an inactivated subunit of the virus, they are not infectious and not contraindicated in immunosuppressed individuals or pregnant women.

Vaccines Available

- 1. Hepatitis B vaccine (Recombivax HB, Merck) contains recombinant HepB only.
- 2. Hepatitis B vaccine (Engerix-B, GlaxoSmithKline) contains recombinant HepB only.
- 3. DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains vaccines against diphtheria, tetanus, pertussis, hepatitis B, and poliovirus.

Only the noncombination vaccines (Recombivax HB and Engerix-B) can be given between birth and 6 weeks of age. Any single or combination vaccine listed above can be used to complete the hepatitis B vaccination series. A combination vaccine against hepatitis A and hepatitis B (Twinrix, GlaxoSmithKline) is available, but is only licensed in the United States for persons 18 years and older.

Dosage Schedule of Administration

HepB is recommended for all infants and children in the United States. Table 10–4 presents the vaccination schedule for newborn infants, dependent on maternal HBsAg status. Infants born to mothers with positive or unknown HBsAg status should receive HepB vaccine within 12 hours of birth. Infants born to HBsAg-negative mothers should receive the vaccine prior to 24 hours of age.

For children younger than 11 years not previously immunized, three intramuscular doses of HepB are needed. Adolescents aged 11-15 years have two options: the standard pediatric three-dose schedule or two doses of adult Recombivax HB (1.0 mL dose), with the second dose administered 4-6 months after the first dose. Certain patients may have reduced immune response to HepB vaccination, including preterm infants weighing less than 2000 g at birth, the elderly, immunosuppressed patients, and those receiving dialysis. Preterm infants whose mothers are HBsAg-positive or with unknown HBsAg status should receive both HepB and HBIg within 12 hours of birth. For preterm infants whose mothers are known to be HBsAg-negative, initiation of the vaccination series should be delayed until 30 days of age if the infant is medically stable, or prior to hospital discharge if the infant is discharged before 30 days of age. Pediatric hemodialysis patients and immunocompromised persons may require larger doses or an increased number of doses, with dose amounts and schedules available in the most recent CDC hepatitis B recommendations (see references).

	Single Antigen Vaccine		Single Antig	en Followed by Combination Vaccine
Maternal HBsAg Status	Dose	Age	Dose	Age
Positive ^b	1 ^c	Birth (≤ 12 h)	1c	Birth (≤ 12 h)
	HBIg ^d	Birth (≤ 12 h)	HBIg	Birth (≤ 12 h)
	2	1–2 mo	2	2 mo
			3	4 mo
	3 ^e	6 mo	4 ^e	6 mo (Pediarix) or 12–15 mo (Comvax)
Unknown ^f	1 ^c	Birth (\leq 12 h)	1 ^c	Birth (\leq 12 h)
	2	1–2 mo	2	2 mo
			3	4 mo
	3 ^e	6 mo	4 ^e	6 mo (Pediarix) or 12–15 mo (Comvax)
Negative	1 ^{c,g}	Birth (< 24 h)	1 ^{c,g}	Birth (< 24 h)
	2	1–2 mo	2	2 mo
			3	4 mo
	3 ^e	6–18 mo	4 ^e	6 mo (Pediarix) or 12–15 mo (Comvax)

Table 10-4. Hepatitis B vaccine schedules for newborn infants, by maternal hepatitis B surface antigen (HBsAg) status.⁸

^aSee text for vaccination of preterm infants weighing less than 2000 g.

^bInfants born to HBsAg-positive mothers should be tested at one year after completion of the immunization series for anti-HBs and HBsAg. ^cRecombivax HB or Engerix-B should be used for the birth dose. Comvax and Pediarix cannot be administered at birth or before age 6 weeks. ^dHepatitis B immune globulin (HBIg) (0.5 mL) administered intramuscularly in a separate anatomic site from vaccine.

^eThe final dose in the vaccine series should not be administered before age 24 weeks (164 days).

Mothers should have blood drawn and tested for HBsAg as soon as possible after admission for delivery; if the mother is found to be HBsAgpositive, the infant should receive HBIg as soon as possible, but no later than age 7 days.

⁹On a case-by-case basis and only in rare circumstances, the first dose may be delayed until after hospital discharge for an infant who weighs ≥ 2000 g and whose mother is HBsAg negative, but only if a physician's order to withhold the birth dose and a copy of the mother's original HBsAg-negative laboratory report are documented in the infant's medical record.

Reproduced with permission from Mast EE, Margolis HS, Fiore AE, et al: A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP) Part 1: Immunization of infants, children, and adolescents. MMWR Recomm Rep 2005 Dec 23;54(RR-16):1–31.

Contraindications & Precautions

HepB should not be given to persons with a serious allergic reaction to yeast or to any vaccine components. Individuals with a history of serious adverse events, such as anaphylaxis, after receiving HepB should not receive additional doses. Vaccination is not contraindicated in persons with a history of Guillain-Barré syndrome, multiple sclerosis, autoimmune disease, other chronic conditions, or in pregnancy.

Adverse Effects

The overall rate of adverse events following vaccination is low. Those reported are minor, including fever (1%-6%)and pain at the injection site (3%-29%). There is no evidence of an association between vaccination and sudden infant death syndrome, multiple sclerosis, autoimmune disease, or chronic fatigue syndrome.

Postexposure Prophylaxis

Postexposure prophylaxis is indicated for unvaccinated persons with perinatal, sexual, household, percutaneous, or mucosal exposure to hepatitis B virus. When prophylaxis is indicated, unvaccinated individuals should receive HBIg (0.06 mL/kg) and the first dose of HepB at a separate anatomic site. Sexual and household contacts of someone with chronic (as opposed to acute) infection should receive HepB only. All vaccinated persons not previously tested for antibody should be tested for anti-HBs after exposure to hepatitis B. If antibody levels are adequate (≥10 mIU/mL), no treatment is necessary. If levels are inadequate (<10 mIU/mL) and the exposure was to HBsAg-positive blood, HBIg and vaccination are required. For non-vaccinated individuals with percutaneous or permucosal exposure to blood, HepB should be given, and HBIg considered depending on the HBsAg status of the person who was the source of the blood exposure.

Antibody Preparations

HBIg is prepared from HIV-negative and hepatitis C virusnegative donors with high titers of hepatitis B surface antibody. The process used to prepare this product inactivates or eliminates any undetected HIV and hepatitis C virus.

ROTAVIRUS VACCINATION

Rotavirus is the leading cause of hospitalization and death from acute gastroenteritis in young children worldwide. The burden of rotavirus is particularly severe in the developing world, where as many as 500,000 children die each year from rotavirus-associated dehydration and other complications. While deaths from rotavirus were uncommon in the United States (20–60 deaths per year), prior to the introduction of rotavirus vaccine, rotavirus infections caused substantial morbidity annually with an estimated 2.7 million diarrheal illnesses, 410,000 office visits, and 55,000–70,000 hospitalizations.

Rotavirus vaccination has been routinely recommended in the United States since 2006. Two rotavirus vaccines are currently available, a pentavalent rotavirus vaccine (RV5; RotaTeq) and a monovalent rotavirus vaccine (RV1; Rotarix). Hospitalizations and outpatient visits for rotavirus disease have fallen significantly among vaccinated infants in the United States, and disease has also declined among unimmunized older children and adults.

Rotavirus vaccination has also reduced morbidity and mortality from rotavirus disease worldwide. While effectiveness of rotavirus vaccines is somewhat lower in developing countries, disease burden is so high that the public health impact of rotavirus vaccination is substantial in developing countries which have introduced these vaccines. Extensive efforts are underway to develop more effective, lower cost, heat-stable (ie, not requiring refrigeration) rotavirus vaccines for use in the developing world.

RV5 and RV1 are known to cause intussusception, although rarely. Intussusception risk has been estimated at 1.5 excess cases per 100,000 recipients after the first dose for RV5, and 5.3 excess cases per 100,000 recipients after

2 doses of RV1. At this level of risk, the benefits of vaccination against rotavirus disease continue to greatly outweigh the risks in the United States and globally.

Vaccines Available

- 1. RV5 (Rotateq, Merck) is a pentavalent, live, oral, humanbovine reassortant rotavirus vaccine. The vaccine is a liquid, does not require any reconstitution, and does not contain any preservatives. The dosing tube is latex-free.
- RV1 (Rotarix, GlaxoSmithKline) is a monovalent, live, oral, attenuated human rotavirus vaccine. The vaccine needs to be reconstituted with 1 mL of diluent using a prefilled oral applicator. The vaccine does not contain any preservatives. The oral applicator contains latex.

Dosage & Schedule of Administration

Either RV5 or RV1 can be used to prevent rotavirus gastroenteritis. RV5 should be administered orally, as a three-dose series, at 2, 4, and 6 months of age. RV1 should be administered orally, as a two-dose series, at 2 and 4 months of age. For both rotavirus vaccines, the minimum age for dose 1 is 6 weeks, and the maximum age for dose 1 is 14 weeks and 6 days. The vaccination series should not be started at 15 weeks of age or older, because of the lack of safety data around administering dose 1 to older infants. The minimum interval between doses is 4 weeks. All doses should be administered by 8 months and 0 days of age. While the ACIP recommends that the vaccine series be completed with the same product (RV5 or RV1) used for the initial dose, if this is not possible, providers should complete the series with whichever product is available.

Either rotavirus vaccine can be given simultaneously with all other recommended infant vaccines. No restrictions are placed on infant breast or formula feeding before or after receiving rotavirus vaccine. Infants readily swallow the vaccine in most circumstances; however, if an infant spits up or vomits after a dose is administered, the dose should not be readministered; the infant can receive the remaining doses at the normal intervals.

Contraindications & Precautions

Rotavirus vaccine should not be given to infants with a severe hypersensitivity to any components of the vaccine, to infants who had a serious allergic reaction to a previous dose of the vaccine, or to infants with a history of intussusception from any cause. RV1 should not be given to infants with a severe latex allergy. Both vaccines are contraindicated in infants with severe combined immunodeficiency (SCID). Vaccination should be deferred in infants with acute moderate or severe gastroenteritis. Limited data suggest that rotavirus vaccination is safe and effective in premature infants. Small trials in Africa demonstrated that RV1 and RV5 were well tolerated and immunogenic in HIV-infected children. However, vaccine safety and efficacy in infants with immunocompromising conditions other than SCID, preexisting chronic gastrointestinal conditions (eg, Hirschsprung disease or short-gut syndrome), or a prior episode of intussusception, has not been established. Clinicians should weigh the potential risks and benefits of vaccination in such circumstances. Infants living in households with pregnant women or immunocompromised persons can be vaccinated.

Adverse Effects

In addition to the aforementioned slightly increased risk of intussusception, in prelicensure trials, RV5 was associated with a very small but statistically significant increased risk of vomiting and diarrhea, and RV1 with a similarly small but significant increased risk of cough or runny nose.

DIPHTHERIA-TETANUS-ACELLULAR PERTUSSIS VACCINATION

Diphtheria, tetanus, and pertussis vaccines have been given in a combined vaccine for many decades, and have dramatically reduced each of these diseases. The efficacy with antigens in the combined vaccine is similar to that with antigens in single component vaccines. DTP vaccines containing whole-cell pertussis antigens are used widely in the world, but have been entirely replaced in the United States with DTaP vaccines, which contain purified, inactivated components of the pertussis bacterium.

Diphtheria is caused by a gram-positive bacillus, *Cory-nebacterium diphtheriae*. It is a toxin-mediated disease, with diphtheria toxin causing local tissue destruction, as in pharyngeal and tonsillar diphtheria, as well as systemic disease, particularly myocarditis and neuritis. The overall case fatality rate is between 5% and 10%, with higher death rates in persons younger than 5 years, or older than 40 years. Largely because of successful vaccination programs, only six cases of diphtheria have been reported in the United States since 2000. The majority of the rare cases of diphtheria in the United States have been in unimmunized or inadequately immunized persons. The clinical efficacy of diphtheria vaccine is estimated to be greater than 95%.

The anaerobic gram-positive rod Clostridium tetani causes tetanus, usually through infection of a contaminated wound. When C tetani colonizes devitalized tissue, the exotoxin tetanospasmin is disseminated to inhibitory motor neurons, resulting in generalized rigidity and spasms of skeletal muscles. Tetanus-prone wounds include (1) puncture wounds, including those acquired due to body piercing, tattooing, and intravenous drug abuse; (2) animal bites; (3) lacerations and abrasions; and (4) wounds resulting from nonsterile neonatal delivery and umbilical cord care (neonatal tetanus). In persons who have completed the primary vaccination series and have received a booster dose within the past 10 years, vaccination is virtually 100% protective. In 2014, 25 cases of tetanus occurred in the United States, almost all in persons who have had inadequate, distant (> 10 years) or no tetanus immunization.

Pertussis is also primarily a toxin-mediated disease caused by Bordetella pertussis, which is called "whooping cough" because of the high-pitched inspiratory whoop that can follow intense paroxysms of cough. Pertussis complications include death, often from associated pneumonia, seizures, and encephalopathy. Pertussis incidence in the United States declined dramatically between the 1940s and 1980s, but beginning in the early 1980s, incidence has been slowly increasing, with adolescents and adults accounting for a greater proportion of reported cases. Reasons for increased incidence include improved detection of cases with better laboratory testing methodology (polymerase chain reaction), increased recognition of cases in adolescents and adults, and waning protection from childhood vaccination or prior infection. Infants less than 6 months old have the highest rate of pertussis infection (143 cases per 100,000); greater than 90% of pertussis deaths occur in neonates and infants less than 3 months.

In 2015, 20,762 cases of pertussis were reported in the United States with many localized outbreaks necessitating enhanced vaccination programs. A single booster dose of a different formulation, Tdap, is now recommended for all adolescents and adults, and pregnant women with each pregnancy. Providing a booster dose of pertussis-containing vaccine may prevent adolescent and adult pertussis cases, and also has the potential to reduce the spread of pertussis to infants, who are most susceptible to pertussis complications.

Vaccines Available

Diphtheria, Tetanus, and Acellular Pertussis Combinations

 DTaP (Daptacel, sanofi pasteur; Infanrix, GlaxoSmith-Kline) contains tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine. DTaP is licensed for ages 6 weeks through 6 years and can be used for doses 1 through 5.

Cortese MM, Parashar UD: CDC: Prevention of rotavirus gastroenteritis among infants and children: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2009;58(RR-2):1 [PMID: 19194371].

CHAPTER 10

- 2. Tdap (Boostrix, GlaxoSmithKline) is a tetanus-reduced dose diphtheria-acellular pertussis vaccine formulated for persons 10 years of age and older, including adults and the elderly.
- 3. Tdap (Adacel, sanofi pasteur) is a tetanus-diphtheriaacellular pertussis vaccine approved for persons 11 through 64 years of age.

DTaP Combined With Other Vaccines

- DTaP-IPV-Hepatitis B (Pediarix, GlaxoSmithKline) contains DTaP combined with poliovirus and HepB vaccines. It is approved for the first three doses of the DTaP and IPV series, given at 2, 4, and 6 months of age. Although it is approved for use through age 6 years, it is not licensed for booster doses. It cannot be used, for example, as the fourth dose of DTaP (typically given at 15–18 months of age).
- 2. DTaP-IPV-Hib (Pentacel, sanofi pasteur) contains DTaP, IPV, and Hib vaccines. The Hib component is Hib capsular polysaccharide bound to tetanus toxoid. This vaccine is approved for use as doses 1 through 4 of the DTaP series among children 6 weeks to 4 years of age. It is typically given at 2, 4, 6, and 15–18 months of age, and should not be used as the fifth dose in the DTaP series.
- DTaP-IPV (Kinrix, GlaxoSmithKline) contains DTaP and IPV vaccines. The vaccine is licensed for children 4–6 years of age, for use as the fifth dose of the DTaP vaccine series and the fourth dose of the IPV series. Using this vaccine would reduce by one the number of injections a 4- to 6-year-old child would receive.

Diphtheria and Tetanus Combinations

- 1. DT (generic, sanofi pasteur) contains tetanus toxoid and diphtheria toxoid to be used only in children younger than age 7 years with a contraindication to pertussis vaccination.
- 2. Td (Decavac, sanofi pasteur; generic, Massachusetts Biological Labs) contains tetanus toxoid and a reduced quantity of diphtheria toxoid, which is typically used for adults requiring tetanus prophylaxis.

Tetanus Only

TT (generic, sanofi pasteur) contains tetanus toxoid only, and can be used for adults or children. However, the use of this single-antigen vaccine is generally not recommended, because of the need for periodic boosting for both diphtheria and tetanus.

Dosage & Schedule of Administration

Although several different vaccines are available, a few general considerations can guide their use in specific circumstances. DTaP (alone or combined with other vaccines) is used for infants and children between 6 weeks and 6 years of age. Children 7–10 years of age not fully immunized against pertussis (meaning those who have not received five prior doses of DTaP, or four doses of DTaP if the fourth dose was given on or after the fourth birthday), who have no contraindications to pertussis immunization, should receive a single dose of Tdap for pertussis protection. For adolescents and adults, a single dose of Tdap is used, followed by booster doses of Td every 10 years; a detailed description of Tdap use is provided later in this chapter.

The primary series of DTaP vaccination should consist of four doses, given at 2, 4, 6, and 15–18 months of age. The fourth dose may be given as early as 12 months of age if 6 months have elapsed since the third dose. Giving the fourth dose between 12 and 15 months of age is indicated if the provider thinks the child is unlikely to return for a clinic visit between 15 and 18 months of age. Children should receive a fifth dose of DTaP at 4–6 years of age. However, a fifth dose of DTaP is not needed if the fourth dose was given after the child's fourth birthday. The same brand of DTaP should be used for all doses if feasible.

Contraindications & Precautions

DTaP vaccines should not be used in individuals who have had an anaphylactic-type reaction to a previous vaccine dose or to a vaccine component. DTaP should not be given to children who developed encephalopathy, not attributable to another identified cause, within 7 days of a previous dose of DTaP or DTP. DTaP vaccination should also be deferred in individuals with progressive neurologic disorders, such as infantile spasms, uncontrolled epilepsy, or progressive encephalopathy, until their neurologic status is clarified and stabilized.

Precautions to DTaP vaccination include: high fever (\geq 40.5°F), persistent inconsolable crying, or shock-like state within 48 hours of a previous dose of DTP or DTaP; seizures within 3 days of a previous dose of DTP or DTaP; Guillain-Barré syndrome less than 6 weeks after a previous tetanus-containing vaccine; or incident moderate or severe acute illness with or without a fever.

Adverse Effects

Local reactions, fever, and other mild systemic effects occur with acellular pertussis vaccines at one-fourth to two-thirds the frequency noted following whole-cell DTP vaccination. Moderate to severe systemic effects, including fever of 40.5°C, persistent inconsolable crying lasting 3 hours or more, and hypotonic-hyporesponsive episodes, are *much* less frequent than with whole-cell DTP. These are without sequelae. Severe neurologic effects have not been temporally associated with DTaP vaccines in use in the United States. Data are limited regarding differences in reactogenicity among currently licensed DTaP vaccines. More severe local reactions at injection sites appear to occur with increasing dose number (including swelling of the thigh or entire upper arm) after receipt of the fourth and fifth doses for all currently licensed DTaP vaccines.

Diphtheria Antibody Preparations

Diphtheria antitoxin is manufactured in horses. Sensitivity to diphtheria antitoxin must be tested before it is given. Dosage depends on the size and location of the diphtheritic membrane and an estimate of the patient's level of intoxication. Consultation on the use of diphtheria antitoxin is available from the CDC's National Center for Immunization and Respiratory Diseases. Diphtheria antitoxin is not commercially available in the United States and must be obtained from the CDC.

Tetanus Antibody Preparations

Human tetanus immune globulin (TIg) is indicated in the management of tetanus-prone wounds in individuals who have had an uncertain number or fewer than three tetanus immunizations. Persons fully immunized with at least three doses do not require TIg, regardless of the nature of their wounds (Table 10–5). The optimal dose of TIg has not been established, but some sources recommend 3000–6000 units as a single dose, with part of the dose infiltrated around the wound.

Table 10–5. Guide to tetanus prophylaxis in routine wound management.

HAEMOPHILUS INFLUENZAE TYPE B VACCINATION

H influenzae type b (Hib) causes a wide spectrum of serious bacterial illnesses, particularly in young children, including meningitis, epiglottitis, pneumonia, septic arthritis, and cellulitis. Before the introduction of effective vaccines, Hib was the leading cause of invasive bacterial disease in children younger than 5 years in the United States with two-thirds of cases occurring in children younger than 18 months.

Hib is surrounded by a polysaccharide capsule (polyribosylribitol phosphate [PRP]) that contributes to virulence. Antibodies to this polysaccharide confer immunity to the disease. When Hib polysaccharide is chemically bonded (conjugated) to certain protein carriers, the conjugate vaccine induces long-term T-cell dependent immune memory that is highly effective in young children. Importantly, polysaccharide-protein conjugate vaccines also prevent carriage of the bacterium, and therefore limit spread from asymptomatic carriers to others in the community. All Hib vaccines are polysaccharide-protein conjugates.

Bacterial serotyping is required to differentiate Hib caused infections from those caused by other encapsulated and nonencapsulated *H influenzae* species. In the early 1980s, roughly 20,000 cases of invasive Hib disease occurred each year in the United States. Because of the introduction of protein conjugate Hib vaccines, only 40 cases of invasive Hib disease occurred in children younger than age 5 years in 2014. An additional 432 cases were caused by *H influenzae* species, which were not serotype b or the serotype was not reported.

History of Adsorbod Totopus	Clean, Minor Wounds		All Other Wounds ^a

Tdap indicates booster tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; DTaP, diphtheria and tetanus toxoids an acellular pertussis vaccine; Td, adult-type diphtheria and tetanus toxoids vaccine; tig, tetanus immune globulin (human).

^aSuch as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^bDTaP is used for children younger than 7 years. Tdap is preferred over Td for underimmunized children 7 years of age and older who have not received Tdap previously.

^cImmune globulin intravenous should be used when TIG is not available.

^dMore frequent boosters are not needed and can accentuate adverse effects.

Reproduced with permission from Centers for Disease Control and Prevention (CDC).

Vaccines Available

Four vaccines against Hib disease are available in the United States; three are Hib-only vaccines, and one is a combination vaccines. Each vaccine contains Hib polysaccharide conjugated to a protein carrier, but different protein carriers are used. The Hib conjugate vaccine that uses a meningococcal outer membrane protein carrier is abbreviated PRP-OMP; and PRP-T vaccine uses a tetanus toxoid carrier.

Hib-Only Vaccines

- 1. Hib (PedvaxHIB, Merck, uses PRP-OMP), for use at 2, 4, and 12–15 months of age.
- 2. Hib (ActHIB, sanofi pasteur, uses PRP-T), for use at 2, 4, 6, and 12–15 months of age.
- Hib (Hiberix, GlaxoSmithKline, uses PRP-T), for use as the booster (final) dose in the Hib vaccine series for children 15 months of age and older; it is not licensed for the primary series.

Hib Combined With Other Vaccines

1. DTaP-IPV-Hib (Pentacel, sanofi pasteur, uses PRP-T) contains DTaP, IPV, and Hib vaccines. This vaccine is approved for use in children 6 weeks to 4 years of age.

Dosage & Schedule of Administration

Hib vaccination is recommended for all infants in the United States. The vaccine dose is 0.5 mL given intramuscularly. Vaccines containing PRP-OMP (PedvaxHib) are given at 2, 4, and 12–15 months of age; vaccines containing PRP-T (ActHib, Pentacel) are given at 2, 4, 6, and 12–15 months of age. The recommended interval between doses in the primary series is 8 weeks, but a minimal interval of 4 weeks is permitted. For infants who missed the primary vaccination series, a catch-up schedule is used (see Table 10–3). Hib vaccine is not generally recommended for children 5 years of age or older.

Contraindications & Precautions

Hib vaccine should not be given to anyone who has had a severe allergic reaction to a prior Hib vaccine dose or to any vaccine components. Hib vaccine should not be given to infants before 6 weeks of age.

Adverse Effects

Adverse reactions following Hib vaccination are uncommon. Between 5% and 30% of vaccine recipients experience swelling, redness, or pain at the vaccination site. Systemic reactions such as fever and irritability are rare. Briere EC, Rubin L, Moro PL, Cohn A, Clark T, Messonnier N: Division of Bacterial Diseases; National Center for Immunization and Respiratory Diseases; CDC: Prevention and control of *Haemophilus influenzae* type b disease: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2014;63(RR-01):1 [PMID: 24572654].

PNEUMOCOCCAL VACCINATION

Before the routine use of pneumococcal conjugate vaccines in infants, *Streptococcus pneumoniae* (pneumococcus) was the leading cause of invasive bacterial disease in children. Pneumococcus remains a leading cause of febrile bacteremia, bacterial sepsis, meningitis, and pneumonia in children and adults in the United States and worldwide. It is also a common cause of otitis media and sinusitis. At least 90 different serotypes of pneumococcus have been identified, and immunity to one serotype does not confer immunity to other serotypes.

A conjugate vaccine against seven pneumococcal serotypes (PCV7) was first licensed in the United States in 2000. The routine use of PCV7 led to a dramatic decrease in pneumococcal disease. However, as disease from PCV7 serotypes declined, disease caused by pneumococcal serotypes not included in PCV7 increased. In 2010, a 13-valent pneumococcal conjugate vaccine (PCV13) was licensed for use in the United States. This vaccine contains the serotypes in PCV7 and an additional six pneumococcal serotypes, with the capsular polysaccharide antigens of the 13 serotypes individually conjugated to a diphtheria carrier protein.

A 23-valent pneumococcal nonconjugated polysaccharide vaccine (PPSV23) is available in the United States, but its use in children is limited to those with certain chronic medical conditions. PPSV23 protects against 23 serotypes, and provides protection against the approximately 25% of pneumococcal infections not prevented by PCV13. However, it does not produce a long-lasting immune response and does not reduce nasopharyngeal carriage.

While all children and adults are at risk of pneumococcal disease, certain children are at particularly high risk of invasive pneumococcal disease (Table 10–6). These children need enhanced protection against pneumococcal disease, which includes the use of PPSV23.

Vaccines Available

- 1. PCV13 (Prevnar13, Wyeth). The vaccine contains an aluminum phosphate adjuvant, and does not contain thimerosal preservative. It is licensed for use in children 6 weeks of age and older and for adults.
- PPSV23 (Pneumovax23, Merck). The vaccine contains the capsular polysaccharide antigens of 23 pneumococcal serotypes. It contains phenol as a preservative. It is licensed for children 2 years of age and older and for adults.

Table 10–6. Medical conditions or other indications for administration of PCV13^a, and indications for PPSV23^b administration and revaccination for children aged 6–18 years.^c

^a13-valent pneumococcal conjugate vaccine.

^b23-valent pneumococcal polysaccharide vaccine.

^cChildren aged 2–5 years with chronic conditions (eg, heart disease or diabetes), immunocompromising conditions (eg, human immunodeficiency virus), functional or anatomic asplenia (including sickle cell disease), cerebrospinal fluid leaks, or cochlear implants, and who have not previously received PCV13, have been recommended to receive PCV13 since 2010.

^dIncluding congestive heart failure and cardiomyopathies.

^eIncluding chronic obstructive pulmonary disease, emphysema, and asthma.

^fIncludes B-(humoral) or T-lymphocyte deficiency, complement deficiencies (particularly C1, C2, C3, and C4 deficiencies), and phagocytic disorders (excluding chronic granulomatous disease).

⁹Diseases requiring treatment with immunosuppressive drugs, including long-term systemic corticosteroids and radiation therapy.

Reproduced with permission from Centers for Disease Control and Prevention (CDC): Use of 13-valent pneumococcal conjugate vaccine and 23-valent pneumococcal polysaccharide vaccine among children aged 6–18 years with immunocompromising conditions: recommendations of the Advisory Committee on Immunization Practices (ACIP), MMWR Morb Mortal Wkly Rep. 2013 Jun 28;62(25):521-524.

Dosage & Schedule of Administration

PCV13 is given as a 0.5-mL intramuscular dose. PPSV23 is given as a 0.5-mL dose by either the intramuscular or subcutaneous route.

PCV13 is routinely recommended for infants at 2, 4, 6, and 12-15 months of age. For healthy children 24-59 months

of age, if they are unvaccinated or did not complete the four-dose PCV13 series, they should receive a single dose of PCV13. Children 24-59 months of age and at high risk of pneumococcal disease (see Table 10-6) should receive two doses of PCV13 (if they previously received fewer than three doses) or one dose of PCV13 (if they previously received three doses). Higher risk children 24–59 months of age should also receive a dose of PPSV23, at least 8 weeks after their final dose of PCV13. If not previously vaccinated against pneumococcus, higher risk children 6 through 18 years of age should receive one dose of PCV13, followed at least 8 weeks later by PPSV23. Updated and detailed schedule information is available from the CDC (at http://www.cdc. gov/vaccines) and the Immunization Action Coalition (at www.immunize.org).

The rationale for using both PCV13 and PPSV23 in some high-risk children is that, while less immunogenic than PCV13, PPSV23 covers additional serotypes that may cause disease. Table 10–6 also includes the indications for revaccination with PPSV23.

Contraindications & Precautions

For both PCV13 and PPSV23, vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. PCV13 and PPV23 vaccination should be deferred during moderate or severe acute illness, with or without fever.

Adverse Effects

The most common adverse effects associated with PCV13 administration are fever, injection site reactions, irritability, and increased or decreased sleep. Although not definitely proven, PCV13 administered simultaneously with inactivated influenza vaccine may lead to a small increased risk of febrile seizures. With PPSV23, 50% of vaccine recipients develop pain and redness at the injection site. Fewer than 1% develop systemic side effects such as fever and myalgia. Anaphylaxis is rare. PPSV23 appears to be safe and immunogenic during pregnancy, although safety data are lacking regarding vaccination during the first trimester of pregnancy.

POLIOMYELITIS VACCINATION

Polioviruses are highly infectious, spread primarily by fecaloral and oral–oral routes, and cause acute flaccid paralysis via destruction of motor neurons. There are three polio serotypes; immunity to one serotype does not confer immunity to the others. Poliomyelitis can be prevented by vaccination, and type 2 poliovirus has been eradicated from the globe. While the goal of polio eradication has not yet been achieved, the global incidence of polio has decreased from roughly 350,000 cases annually in the prevaccination era, to 37 polio cases detected in 2016. Polio remains endemic in Afghanistan, Nigeria, and Pakistan.

Although extraordinary progress has been made toward the goal of global polio eradication, complex challenges remain. Armed conflict and civil strife continue to impede access to vulnerable populations, and vaccinators have been the target of violence. Also, the attenuated vaccine strains used in trivalent OPV can rarely mutate into pathogenic strains and cause polio disease. To address this issue, while maintaining population immunity to all three poliovirus strains, several steps have been necessary: (1) introduction of IPV into all countries using OPV; (2) switch from trivalent OPV to a more immunogenic bivalent form of OPV; and (3) eventually stopping routine use of OPV altogether. This massive global public health transition occurred during 2015 and 2016, and has largely been successful. However, an IPV vaccine shortage has resulted, and strategies are in place to prioritize IPV use and significantly increase vaccine production. Despite set-backs, a polio-free world is achievable. Timely updates on the worldwide polio eradication program can be found at www.polioeradication.org.

IPV, a trivalent inactivated vaccine, is the only vaccine against poliomyelitis available in the United States. IPV cannot cause polio.

Vaccines Available

- 1. IPV (IPOL, sanofi pasteur) is given intramuscularly or subcutaneously.
- DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains diphtheria and tetanus toxoids and acellular pertussis adsorbed, hepatitis B, and inactivated poliovirus vaccines. Approved for use at 2, 4, and 6 months of age; not approved for use as the fourth dose of IPV or the fourth or fifth doses of DTaP; given intramuscularly.
- DTaP-IPV-Hib (Pentacel, sanofi pasteur) contains DTaP, IPV, and Hib vaccines. Approved for use at 2, 4, 6, and 15–18 months of age; not approved for use at 4–6 years of age as the final booster dose of IPV; given intramuscularly.
- DTaP-IPV (Kinrix, GlaxoSmithKline) contains DTaP and IPV vaccines. Licensed for children 4–6 years of age, for use as a final booster dose of IPV; given intramuscularly.

Dosage & Schedule of Administration

In the United States, all children without contraindications should receive an IPV-containing vaccine at 2, 4, 6–18 months, and 4–6 years of age. A dose of IPV should be given at 4 years of age or older, regardless of the number of prior doses of IPV. Completely immunized adult visitors to areas of continuing wild-type poliovirus circulation should receive a booster dose of IPV. Unimmunized or incompletely immunized adults and children should have received at least two (preferably three) doses of IPV prior to travel.

Contraindications & Precautions

IPV vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. IPV vaccination should be deferred during moderate or severe acute illness with or without fever. Pregnancy is also a precaution to IPV vaccination. Receipt of previous doses of OPV is not a contraindication to IPV.

Adverse Effects

Minor local reactions, such as pain or redness at the injection site, may occur following IPV vaccination. No serious adverse reactions following IPV vaccination have been described.

INFLUENZA VACCINATION

Influenza occurs each winter-early spring period, often associated with significant morbidity and mortality in certain high-risk persons. Up to 36,000 deaths per year in the United States are attributable to influenza, and global epidemics (pandemics) can occur. The recent pandemic H1N1 strain is now incorporated into the seasonal vaccine. Each year, recommendations are formulated in the spring regarding the constituents of influenza vaccine for the coming season. Influenza vaccines contain either three strains (two influenza A strains and one of two influenza B lineages), or all four strains, including two influenza A and two influenza B lineages. It is difficult to predict which influenza B lineages (or both) will predominate in any given influenza season. Children at high risk of seasonal influenza-related complications include those with hemoglobinopathies or with chronic cardiac, pulmonary (including asthma), metabolic, renal, and immunosuppressive diseases (including immunosuppression caused by medications or by HIV); and those with any condition (eg, cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function or the handling of respiratory secretions, or that can increase the risk of aspiration. Children and adolescents receiving long-term aspirin therapy are also at risk of influenza-related Reye syndrome. Healthy children aged 6-23 months are at substantially increased risk of influenza-related hospitalizations, and children aged 24-59 months (ie, 2-4 years) remain at increased risk of influenza-related clinic and emergency department visits and hospitalizations, but less so than younger children.

Annual influenza vaccination is routinely recommended for all persons older than 6 months of age. In a number of prior influenza seasons, LAIV was more effective than inactivated influenza vaccine in children. However, in the 2014–2015 influenza season, this was not the case, and the ACIP made an interim recommendation that LAIV should not be used. Physicians should identify high-risk children in their practices and encourage parents to seek influenza vaccination for their children and themselves as soon as influenza vaccine is available. Influenza prevention will help prevent lower respiratory tract disease or other secondary complications in high-risk groups, thereby decreasing hospitalizations and deaths.

Vaccines Available

The inactivated influenza vaccine virus is grown in eggs, formalin inactivated, and may contain trace quantities of thimerosal as a preservative. Only split-virus or purified viral antigens are available in the United States. Fluzone (sanofi pasteur) is approved for children 6 months and older; Fluvirin (Novartis) is approved only for children 4 years and older, Fluarix (GlaxoSmithKline) is approved for children 3 years and older, and Afluria (CSL Biotherapies) is recommended for children 9 years and older. There are a number of additional influenza vaccines licensed for adults but not for children, including a high-dose vaccine, a cell culture-based vaccine, and a recombinant vaccine. Intranasal live attenuated influenza vaccine (LAIV [FluMist, MedImmune) is still licensed in the United States, although it is not currently recommended for use.

Dosage & Schedule of Administration Inactivated Influenza Virus Vaccine

Because influenza can circulate from November through early March in the US states, the optimal time to initiate vaccination is as soon as vaccine is available in the early fall. However, providers should continue vaccinating individuals as long as vaccine is available and there is influenza activity in the community. Children younger than age 6 months should not be immunized. Two doses are recommended for children younger than age 9 years who did not receive two vaccine doses in the past. Older children receiving vaccine for the first time require only a single dose. The dose for children aged 6–35 months is 0.25 mL given intramuscularly; for older children the dose is 0.5 mL. Pregnancy is not a contraindication to use of inactivated vaccine, and vaccine is recommended for all pregnant women and those contemplating pregnancy during the influenza season. Simultaneous administration with other routine vaccines is acceptable.

Live Attenuated Influenza Virus Vaccine

LAIV is not currently recommended in the United States. However, LAIV continues to be used in Canada, Europe, and elsewhere in the world.

Contraindications & Precautions

Inactivated Influenza Virus Vaccine

Inactivated influenza vaccine is contraindicated in individuals with a severe allergic reaction, such as anaphylaxis, to a previous dose of an inactivated influenza vaccine component. However, guidelines for influenza vaccination in children with egg allergies have recently changed. Children with only urticaria following exposure to egg can be vaccinated. Children with more serious allergic reactions to egg, such as angioedema, respiratory symptoms, or anaphylaxis, may be eligible for inactivated influenza vaccine but should be referred to an allergist for an assessment of vaccination risk and should receive vaccine in an inpatient or outpatient medical setting and by a health care provider who is able to recognize and manage severe allergic conditions.

Adverse Effects

Inactivated Influenza Virus Vaccine

Injection site reactions are the most common adverse events after inactivated influenza vaccine administration. A small proportion of children will experience some systemic toxicity, consisting of fever, malaise, and myalgias. These symptoms generally begin 6–12 hours after vaccination and may last 24–48 hours. Cases of Guillain-Barré syndrome followed the swine influenza vaccination program in 1976–1977, but careful study by the Institute of Medicine showed no association with that vaccine in children and young adults—nor in any age group that received vaccines in subsequent years.

- CDC: Prevention and control of influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices, United States, 2016–2017 Influenza Season. MMWR 2015;65:5 [PMID: 27560619].

MEASLES, MUMPS, & RUBELLA VACCINATION

Due to an effective vaccination program beginning in 1963, measles was declared eliminated from the US states in 2000. Until 2008, there were sporadic importations of measles from countries with lower vaccination rates, but since then there have been numerous outbreaks of measles, primarily from viral transmission within the United States after initial exposure to imported cases. In 2016, there were 70 confirmed measles cases in the United States. In 2015, there was a large multistate outbreak of measles, linked to a theme park in California. In outbreaks such as this, the majority of people who developed measles were unvaccinated.

In the United States, after adding mumps vaccine to the childhood schedule in 1977, there was a 99% decline in mumps to fewer than 300 cases each year between 2001 and 2003. However, since then, there have been several large outbreaks, the largest of which occurred in 2009–2010, in which about 3000 people, mostly high school students from an insular religious community in New York City, were diagnosed with mumps. In 2016, there were more than 5000 reported cases of mumps. Risk factors for outbreaks include lack of immunization; close contact, such as in a school setting; two doses of MMR vaccine is only 88% effective in preventing mumps; and waning immunity, which may occur in young adults who had their last dose of a mumps-containing vaccine a decade or more in the past.

The rubella vaccine is primarily intended to prevent the serious consequences of rubella infection in pregnant women: miscarriage, fetal demise, and congenital rubella syndrome. In the United States and elsewhere, the approach has been to vaccinate young children. Over time, this approach has led to most women being rubella immune by the time they reach child-bearing age; herd immunity also reduces transmission to susceptible women. With the use of rubella vaccines, rubella and congenital rubella syndrome were declared eliminated in the United States in 2004. There are now fewer than 10 rubella cases per year, and all recent cases were infected while living or traveling outside the country. There were only four cases of congenital rubella syndrome in the United States between 2010 and 2015.

Despite many reports in the lay press and on the Internet of a link between MMR and autism, there is overwhelming scientific evidence that there is no causal association between the two. There is also no evidence that separation of MMR into its individual component vaccines lessens the risk of any vaccine adverse event, and such practice is not recommended.

Vaccines Available

- Measles-mumps-rubella (MMR II, Merck): MMR II is a lyophilized preparation of measles, mumps, and rubella vaccines. The measles and mumps portions are prepared using chick embryo tissue cultures and rubella is grown in human diploid cells. There is no adjuvant and no preservative. It contains small amounts of gelatin, sorbitol, and neomycin. The individual components of MMR II are no longer available.
- 2. MMRV: A combined live attenuated measles, mumps, rubella, and varicella vaccine (ProQuad, Merck) is licensed for use in children 1–12 years of age. The measles, mumps, and rubella components are identical to MMR II. The varicella component has a higher varicella zoster virus titer than the varicella-only (VAR) vaccine.

Dosage & Schedule of Administration

Routine Vaccination

Measles, mumps, and rubella vaccinations should be given as MMR or MMRV at 12-15 months and again at 4-6 years of age. Both MMR and MMRV can cause febrile seizures, although uncommonly. Because febrile seizures following MMRV occur at a rate twice that of MMR, the ACIP recommends that after a discussion of the benefits and risks of both vaccination options with the parents or caregivers, either MMR or MMRV may be given at 12-15 months of age. MMRV is the preferred vaccine at 4-6 years of age if available; no excess risk of febrile seizures following MMRV vaccination has been observed at 4-6 years of age. A personal or family history of febrile seizures in an infant is considered a precaution for the use of MMRV, and MMR and VAR given separately is preferred. A dose of 0.5 mL should be given subcutaneously. The second dose of MMR or MMRV is recommended at school entry to help prevent school-based measles and mumps outbreaks. Children not reimmunized at school entry should receive their second dose by age 11-12 years. If an infant receives MMR before 12 months of age (such as for travel), two additional doses are required to complete the series, the first after 12 months of age and the second at least 1 month later. Ig interferes with the immune response to the attenuated vaccine strains of MMR and MMRV. Therefore, MMR and MMRV immunization should be deferred by 3-11 months after Ig administration, depending on the type of Ig product received. Consult the AAP's *Red Book* for specific recommendations.

For measles, mumps, and rubella, most persons can be considered immune if they were fully vaccinated at appropriate intervals, or were born before 1957, or if there is laboratory evidence of serologic immunity or disease. However, special considerations apply to health care workers: for those born before 1957, laboratory confirmation of immunity or disease should be performed, and nonimmune healthcare workers should be vaccinated. A clinical diagnosis of any of these diseases is not acceptable evidence of immunity. For rubella, susceptible pubertal girls and postpubertal women identified by prenatal screening should be immunized after delivery. Whenever rubella vaccination is offered to a woman of childbearing age, pregnancy should be ruled out and the woman advised to prevent conception for 3 months following vaccination. If a pregnant woman is vaccinated or becomes pregnant within 3 weeks of vaccination, she should be counseled regarding the risk to her fetus, although no cases of rubella-vaccine-related fetal anomalies have been reported. The risk of congenital rubella syndrome after wildtype maternal infection in the first trimester of pregnancy is 20%-85%. All susceptible adults in institutional settings (including colleges), day care center personnel, military personnel, and hospital and health care personnel should be immunized.

Vaccination of Travelers

People traveling abroad should be immune to measles, mumps, and rubella. Infants 6–11 months of age traveling to high-risk areas should receive one dose of MMR prior to travel followed by either MMR or MMRV at 12–15 months of age (given at least 4 weeks after the initial dose) and either MMR or MMRV at 4–6 years of age to complete the series. Children over 12 months of age who are traveling to highrisk areas should receive two doses separated by at least 4 weeks. Children traveling internationally to lower-risk areas should be immunized as soon as possible after their first birthday and complete the series at 4–6 years of age in the usual fashion.

Revaccination Under Other Circumstances

Persons entering college and other institutions for education beyond high school, medical personnel beginning employment, and persons traveling abroad should have documentation of immunity to measles and mumps, defined as receipt of two doses of measles vaccine after their first birthday, birth before 1957, or a laboratory documented measles or mumps history.

Outbreak Control of Measles

A community outbreak is defined as a single documented case of measles. Control depends on immediate protection of all susceptible persons (defined as persons who have no documented immunity to measles in the affected community). In the case of unvaccinated individuals, the following recommendations hold: (1) age 6-11 months, give MMR if cases are occurring in children younger than age 1 year, followed by a dose of MMR or MMRV at age 12-15 months and again at age 4-6 years; and (2) age 12 months or older, give MMR or MMRV followed by revaccination at age 4-6 years. A child with an unclear or unknown vaccination history should be reimmunized with MMR or MMRV. Anyone with a known exposure who is not certain of having previously received two doses of MMR should receive an additional dose. Unimmunized persons who are not immunized within 72 hours of exposure, which is the acceptable interval for active postexposure prophylaxis, should be excluded from contact with potentially infected persons until at least 2 weeks after the onset of rash of the last case of measles.

Contraindications & Precautions

MMR and MMRV vaccines are contraindicated in pregnant women, women intending to become pregnant within the next 28 days, immunocompromised persons, and persons with an anaphylactic reaction to a prior dose or vaccine component. It is also contraindicated in children receiving high-dose corticosteroid therapy (> 2 mg/kg/day, or 20 mg/day total, for longer than 14 days) with the exception of those receiving physiologic replacement doses. In these patients, an interval of 1 month between cessation of steroid therapy and vaccination is sufficient. Leukemic patients who have been in remission and off chemotherapy for at least 3 months can receive MMR and MMRV safely. Persons with HIV infection should receive two doses of MMR vaccine according to the recommended schedule if they do not have evidence of current severe immunosuppression (for persons aged \leq 5 years, they must have CD4 percentages \geq 15% for \geq 6 months; and for persons aged > 5 years, they must have CD4 percentages \geq 15% and CD4 \geq 200 lymphocytes/mm³ for \geq 6 months). MMRV is contraindicated in HIV-positive individuals. Children with minor acute illnesses (including febrile illnesses), egg allergy, or a history of tuberculosis should be immunized. MMR and MMRV may be safely administered simultaneously with other routine pediatric immunizations.

Adverse Effects

Between 5% and 15% of individuals receiving MMR become febrile to 39.5°C or higher about 6–12 days following vaccination, lasting approximately 1–2 days, and 5% may develop a transient morbilliform rash. MMR and MMRV vaccines can cause febrile seizures, typically 8 to 14 days after vaccination; these febrile seizures have not been associated with any long-term complications. Other serious adverse events following vaccination are rare, and include anaphylaxis, transient thrombocytopenia (1 per 40,000 vaccine recipients), arthralgias (more common in adults than children), and measles inclusion body encephalitis (which is very rare, and occurs only among persons with specific immunodeficiencies).

Antibody Preparations Against Measles

Ig is effective at preventing measles, if given to a nonimmune person within 6 days of exposure to measles. However, the immunity conferred by Ig should be considered temporary. Infants less than 12 months of age who have been exposed to measles should receive 0.5 mL/kg of Ig, given intramuscularly. MMR vaccine should also be used, as appropriate, for infants aged 6–11 months. Pregnant women without evidence of measles immunity and severely immune-compromised persons (regardless of evidence of measles immunity) who are exposed to measles should receive 400 mg/kg of Ig given intravenously. Ig given intramuscularly (0.5 mL/kg, maximum dose, 15 mL) may be given to more immune-competent exposed persons without evidence of immunity, with priority for those with the most intense contact with a case.

VARICELLA VACCINATION

Prior to the availability of vaccine, about 4 million cases of varicella-zoster virus (VZV) infection occurred as chickenpox annually in the United States, mostly in children younger than 10 years old. This resulted in 11,000 hospitalizations and 100 deaths per year due to severe complications such as secondary bacterial infections, pneumonia, encephalitis, hepatitis, and Reye syndrome.

A live, attenuated varicella vaccine (VAR) was licensed in the United States in 1995 and routine immunization of children 12 months of age and older was instituted. The vaccine is almost 100% effective at preventing severe disease. The incidence, morbidity, mortality, and medical costs associated with varicella infection have significantly declined since VAR was licensed. Vaccination prevents an estimated 3.5 million cases of varicella, 9000 hospitalizations, and 100 deaths from varicella in the United States each year. Once the routine use of VAR was achieved, it became apparent that there is "breakthrough" (usually very mild) varicella occurring in about 15% of immunized patients. Outbreaks of wild-type infectious VZV have been reported in schools with high one-dose VAR vaccination coverage (96%–100%). Varicella attack rates among these children varied between 11% and 17% and thus, it was concluded that a single VAR dose could not prevent endemic varicella.

A second dose of VAR in children, when given 3 months or 4–6 years after the initial dose, greatly increased the magnitude of the anti-VZV antibody response, which is a correlate of vaccine efficacy. A combination MMRV vaccine has also been shown to be immunologically noninferior to the MMR and VAR components administered separately. MMRV is effective as primary immunization or as a booster administered to children age 4–6 years. The two-dose regimen is almost 100% effective against severe varicella, and the risk of breakthrough varicella is threefold less than the risk with a one-dose regimen. Therefore, ACIP and the AAP recommend two doses of VAR for children older than 12 months of age, and for adolescents and adults without evidence of immunity.

The vaccine is also effective in preventing or modifying VZV severity in susceptible individuals exposed to VZV if used within 3 days (and possibly up to 5 days) of exposure, with an efficacy of 95% for preventing any postexposure disease and 100% for preventing moderate or severe disease. There is no evidence that postexposure prophylaxis increases the risk of vaccine-related adverse events or interferes with development of immunity.

Vaccines Available

- 1. A cell-free preparation of Oka strain VZV is produced and marketed in the United States as Varivax (Merck). Each dose of VAR contains not less than 1350 plaque-forming units of VZV and trace amounts of neomycin, fetal bovine serum, and gelatin. There is no preservative.
- MMRV (measles-mumps-rubella-varicella, ProQuad, Merck) is licensed for use in children 1–12 years of age. MMRV is well tolerated and provides adequate immune response to all of the antigens it contains. In MMRV, the varicella component is present in higher titer than in VAR. Concomitant administration of MMRV with DTaP, Hib, and HepB vaccines is acceptable.

Dosage & Schedule of Administration

Two doses (0.5 mL) of VAR are recommended for immunization of healthy children aged 12 months and older, and for adolescents and adults without evidence of immunity. For children aged 12 months to 12 years the immunization interval is 3 months, and for persons 13 years or older it is 4 weeks. MMRV is approved only for healthy children aged 12 months to 12 years. A second dose of catch-up vaccination is required for children, adolescents, and adults who previously received one dose of VAR vaccine. All children should have received two doses of VAR before prekindergarten or school. HIV-infected children ($\geq 15\%$ CD4⁺ cells) should receive two doses of the single-antigen vaccine (with a 3-month interval between doses).

VAR may be given simultaneously with MMR at separate sites. If not given simultaneously, the interval between administration of VAR and MMR must be greater than 28 days. Simultaneous VAR administration does not appear to affect the immune response to other childhood vaccines. VAR should be delayed 5 months after receiving intravenous immune globulin, blood, or plasma. In addition, persons who received VAR should not be administered an antibodycontaining product for at least 2 weeks or an antiviral medication active against varicella for at least 3 weeks. If this occurs, the individual may need to be tested for immunity or revaccinated. After a discussion of the benefits and risks of both vaccination options with the parents or caregivers (see section "Adverse Effects"), either MMR or MMRV may be given at 12-15 months. MMRV is the preferred vaccine if available at 4-6 years of age.

Contraindications & Precautions

Contraindications to VAR vaccination include a severe allergic reaction after a previous vaccine dose or to a vaccine component. Because VAR and MMRV are live-virus vaccines, they are also contraindicated in children who have acquired treatment-related cellular immunodeficiencies or congenital T-cell abnormalities. The exception to this rule is the recommendation that VAR be administered to HIVinfected children who are not severely immunosuppressed. Household contacts of immunodeficient patients should be immunized. VAR should not be given to pregnant women; however, the presence of a pregnant mother in the household is not a contraindication to immunization of a child within that household. A personal or family history of febrile seizures in an infant is considered a precaution for the use of MMRV; administration of MMR and VAR separately is preferred for the first dose.

Adverse Events

The most commonly recognized adverse reactions, occurring in approximately 20% of vaccines, are minor injection site reactions. Additionally, 3%–5% of patients will develop a rash at the injection site, and an additional 3%–5% will develop a sparse varicelliform rash outside of the injection site. These rashes typically consist of two to five lesions and may appear 5–26 days after immunization. The two-dose vaccine regimen is generally well tolerated with a safety profile comparable to that of the one-dose regimen. The incidence of fever and varicelliform rash is lower after the second dose than the first. Although VAR is contraindicated in pregnancy, there have been hundreds of inadvertent administrations of vaccine to pregnant women tracked by the "Pregnancy Registry for Varivax" with no known cases of congenital varicella syndrome or increases in fetal abnormalities.

Studies comparing MMRV to MMR and VAR administered concomitantly showed more systemic adverse events following MMRV (fever 21.5% vs 14.9% and measles-like rash 3% vs 2.1%, respectively). The risk of febrile seizures in children 12–23 months old with the MMRV preparation is twice that of MMR and VAR given separately, resulting in one additional febrile seizure per 2300–2600 children vaccinated with MMRV.

Transmission of vaccine virus from healthy vaccines to other healthy persons is very rare; has never been documented in the absence of a rash in the index case; and has only resulted in mild disease. Herpes zoster infection has occurred in recipients of VAR in immunocompetent and immunocompromised persons within 25–722 days after immunization. Many of these cases were found to be caused by unappreciated latent wild-type virus. Vaccine-strain varicella does cause herpes zoster in children, but the agespecific risk of herpes zoster infection seems much lower in children following VAR immunization than after natural infection, and it also tends to be milder.

Antibody Preparations

In the event of an exposure to varicella, there are currently two antibody preparations potentially available in the United States for postexposure prophylaxis, VariZIG (Cangene Corporation) and intravenous Ig. Exposure is defined as a household contact or playmate contact (> 1 h/day), hospital contact (in the same or contiguous room or ward), intimate contact with a person with herpes zoster deemed contagious, or a newborn contact. Susceptibility is defined as the absence of a reliable history of varicella or varicella vaccination. Uncertainty in this designation can be resolved with an appropriate test for anti-VZV antibody.

VariZIG should be administered as soon as possible after exposure, ideally within 96 hours, but may be given within 10 days postexposure. If VariZig is not available, it is recommended that intravenous Ig be used in its place. The dose is 400 mg/kg administered once. A subsequent exposure does not require additional prophylaxis if this occurs within 3 weeks of intravenous Ig administration.

HEPATITIS A VACCINATION

The incidence of hepatitis A in the United States has decreased dramatically from an average of 28,000 cases reported annually in the years prior to availability of a hepatitis A vaccine to 1390 cases reported in 2015.

Initial vaccination recommendations for hepatitis A targeted high-risk individuals, primarily adults. However, children, who are more likely than adults to be asymptomatic while infected, usually contribute to the spread of hepatitis A through households and communities. Therefore, since 2006 hepatitis A vaccination has been routinely recommended for children 12–23 months of age. As a consequence of vaccination, the epidemiology of hepatitis A infection has changed substantially. In a recent investigation, more than 40% of reported cases were associated with international travel, often in foreign-born persons returning to their countries of origin.

In addition to routine immunization of all children 12–23 months of age, hepatitis A vaccination is indicated for the following groups: (1) travelers to countries with moderate to high rates of hepatitis A, (2) children with chronic hepatitis B or hepatitis C infections or other chronic liver disease, (3) children with clotting factor disorders, (4) adolescent and adult males who have sex with men, (5) persons with an occupational exposure to hepatitis A, (6) illegal drug users, and (7) all previously unvaccinated persons who anticipate close personal contact with an international adoptee from countries with moderate to high rates of hepatitis A. Vaccination should also be considered in previously unimmunized children 2–18 years old, even if none of the above risk factors are present.

Vaccines Available

- 1. HepA (Havrix, GlaxoSmithKline): An inactivated vaccine against hepatitis A. Approved for use in children 12 months of age and older, and adults.
- HepA (Vaqta, Merck): An inactivated vaccine against hepatitis A. Approved for use in children 12 months of age and older, and adults.
- HepA-HepB (Twinrix, GlaxoSmithKline): A combined inactivated vaccine against hepatitis A and hepatitis B. Approved for use in adults 18 years of age and older.

Dosage & Schedule of Administration

The two HepA vaccines given in childhood (Havrix and Vaqta) are given as a two-dose series. The first dose is recommended at 12–23 months of age; the second dose is

recommended 6–18 months later. For individuals 12 months through 18 years of age, these vaccines are administered intramuscularly in a dose of 0.5 mL. Adults 19 years of age and older can receive Havrix (two doses of 1.0 mL each, separated by at least 6 months), Vaqta (two doses of 1.0 mL each, separated by at least 6 months), or Twinrix (for adults 18 years and older, 1.0 mL per dose, in a three-dose series). If needed, such as for imminent travel, Twinrix can be given on an accelerated four-dose schedule, with doses on days 1, 7, and 21–30, with a booster dose given 12 months after the first dose.

Contraindications & Precautions

Hepatitis A vaccine should not be given to anyone with a prior severe allergic reaction, such as anaphylaxis, after a previous vaccine dose or to a vaccine component. Precautions to vaccination include pregnancy and moderate or severe acute illness.

Adverse Effects

Adverse reactions, which are uncommon and mild, consist of pain, swelling, and induration at the injection site (10%–15%), headache, and loss of appetite. There have been no reports of serious adverse events attributed definitively to hepatitis A vaccine.

Postexposure Prophylaxis

Postexposure prophylaxis is recommended for household or sexual contacts of persons with serologically confirmed hepatitis A, and for day care staff and attendees in outbreak situations. Postexposure prophylaxis may also be recommended in food-borne outbreaks, depending on the extent and timing of exposure. Postexposure prophylaxis of unimmunized persons who are exposed to hepatitis A should consist of either a single dose of hepatitis A vaccine or Ig (0.02 mL/kg), given as soon as possible after exposure. The efficacy of Ig when given more than 2 weeks after exposure has not been established. For healthy people 12 months through 40 years of age, hepatitis A vaccine is preferred to Ig for postexposure prophylaxis because of the advantages of vaccination, including long-term protection and ease of administration. For those older than 40 years of age, Ig is preferred, although the vaccine should be used if Ig is not available. Ig should also be used for children less than 12 months of age, immunocompromised persons, those with chronic liver disease, and anyone for whom vaccination is contraindicated. People who are given Ig, and for whom hepatitis A vaccine is recommended for other reasons, should receive a dose of vaccine simultaneously with Ig. If given at the same time, the vaccine and Ig should be administered at different injection sites.

Antibody Preparations

Ig can be used as preexposure as well as postexposure prophylaxis. Ig is indicated as preexposure prophylaxis in children younger than age 12 months at increased risk of hepatitis A infection (eg, those traveling to endemic areas, or those with clotting factor disorders). For preexposure prophylaxis, recommended dosages are 0.02 mL/kg in a single intramuscular dose if the duration of exposure is likely to be less than 3 months and 0.06 mL/kg if exposure is likely to be more than 3 months. For long-term prophylaxis of persons not eligible for vaccination, prophylactic doses can be repeated every 5 months.

CDC (hepatitis A information): www.cdc.gov/hepatitis/HAV. Accessed November 5, 2017.

CDC: Prevention of hepatitis A through active or passive immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2006;55(RR-7):1 [PMID: 16708058].

MENINGOCOCCAL VACCINATION

Infections with *Neisseria meningitidis* cause significant morbidity and mortality, with an estimated 800–1200 cases occurring in the United States annually. Even with appropriate treatment, meningococcal disease has an estimated case-fatality rate of 10%–14%, and up to 19% of survivors are left with serious disabilities, including neurologic deficits, hearing loss, and loss of limbs. Five serogroups of meningococcus (A, B, C, W, and Y) cause nearly all serious disease worldwide; serogroups B, C, and Y predominate in the United States, while serogroups A and C cause most disease in developing countries. Serogroup B is responsible for more than 50% of cases in children younger than 1 year of age in the United States; it is also responsible for several recent outbreaks on college campuses.

Six different meningococcal vaccines are available in the United States. Vaccination recommendations are somewhat complex, because disease rates vary substantially by age and depending on whether or not a chronic condition increasing meningococcal disease risk is present. Updated, detailed vaccination recommendations are available at https://www.cdc .gov/vaccines/vpd/mening/.

Two quadrivalent meningococcal polysaccharide-protein conjugate vaccines are available (MCV4; tradenames Menactra and Menveo), providing protection against serogroups A, C, W, and Y. Menactra is licensed for persons 9 months through 55 years of age; Menveo is licensed for 2 months through 55 years of age. Two doses of either Menactra or Menveo are recommended for all adolescents in the United States, with a first dose at 11–12 years of age, and a second dose at 16 years of age.

Also licensed in the United States is a quadrivalent polysaccharide vaccine against serogroups A, C, W, and Y

(MPSV4, tradename Menomune). However, the vaccine is less immunogenic than either Menactra or Menveo, and so is used infrequently. It is used for persons older than 55 years of age needing meningococcal vaccination, and can be used for individuals 2 through 55 years of age if Menactra or Menveo are not available.

Two vaccines are available that protect against serogroup B disease (MenB), Bexsero and Trumenba, licensed for use at 10 years of age and older. For healthy young adults who do not have a chronic health condition predisposing to meningococcal disease, Bexsero and Trumenba are not recommended for universal use. However, these vaccines may be used with clinical discretion to reduce the risk of serogroup B meningococcal disease. These two vaccines are not interchangeable, so the same vaccine product must be used for all doses in the series.

Meningococcal disease risk is significantly higher among children with certain chronic conditions, including anatomic or functional asplenia (including children with sickle cell disease), children with HIV infection, and children with complement component deficiencies. In these circumstances, Menveo may be given as a four-dose series beginning at 2 months of age. Additionally, MenHibrix is a vaccine protecting against Hib as well as meningococcal serogroups C and Y, and can be given as a four-dose series beginning at 6 weeks of age. Alternatively, Menactra may be given to children with anatomic or functional asplenia, or HIV infection, beginning at 2 years of age, or to children with complement deficiencies beginning at 9 months of age.

Children with anatomic or functional asplenia (including those with sickle cell disease) or children with complement deficiencies are also at increased risk of meningococcal serogroup B disease, and should receive Bexsero or Trumenba starting at 10 years of age. Additionally, individuals traveling abroad to areas with endemic serogroups A and W meningococcal disease should be vaccinated with Menactra or Menveo. Finally, meningococcal disease outbreaks occasionally occur in the United States, and vaccination may be recommended against the serogroups causing the outbreak.

Vaccines Available

- MCV4 (Menactra, sanofi pasteur): A single 0.5-mL dose contains capsular polysaccharide from serogroups A, C, Y, and W conjugated to diphtheria toxoid.
- MCV4 (Menveo, Novartis): A single 0.5-mL dose contains serogroups A, C, Y, and W capsular polysaccharide, all of which is conjugated to CRM₁₉₇, a nontoxic mutant of diphtheria toxoid.
- Hib-MenCY-TT (MenHibrix, GlaxoSmithKline Biologicals): A single 0.5-mL dose contains serogroups C and Y capsular polysaccharide conjugated to tetanus toxoid, and Hib capsular polysaccharide conjugated to tetanus toxoid.

- 4. MPSV4 (Menomune-A/C/Y/W, sanofi pasteur): Each dose consists of 50 mcg each of the four bacterial capsular polysaccharides.
- MenB (Trumenba, Pfizer): A single 0.5-mL dose contains 120 mcg of recombinant lipidated factor H binding protein (fHBP) variants from *N meningitidis* serogroup B, 0.018 mg of polysorbate 80, and 0.25 mg of aluminum phosphate as an adjuvant.
- MenB (Bexsero, Novartis): A single 0.5-mL dose contains 50 mcg each of recombinant *N meningitidis* serogroup B proteins: Neisserial adhesin A (NadA), Neisserial Heparin Binding Antigen (NHBA), and factor H binding protein (fHbp); and 25 mcg of outer membrane vesicles (OMV).

Dosage & Schedule of Administration

MCV4 is given as a single intramuscular dose of 0.5 mL. If a dose is inadvertently administered subcutaneously, it does not need to be repeated. Hib-MenCY-TT is given as a single intramuscular dose of 0.5 mL; MPSV4 as a single subcutaneous dose of 0.5 mL; MenB as a single intramuscular dose of 0.5 mL in a prefilled syringe. These vaccines can be given at the same time as other vaccines, at a different anatomic site. If a four-dose schedule of Hib-MenCY-TT is given, no additional Hib doses are needed. Protective antibody levels are typically achieved within 10 days of vaccination. The schedule of administration of MCV4, Hib-MenCY-TT, and MPSV4 are described previously. MenB vaccines are licensed for use in persons aged 10-25 years. Trumenba is a three-dose series given at 0, 2, and 6 months, and Bexsero is a two-dose series given at least 1 month apart. MenB should be given to persons age ≥ 10 years at increased risk of meningococcal disease (complement deficiencies, asplenia, microbiologists, or serogroup B outbreaks).

Contraindications & Precautions

MCV4 and MPSV4 are contraindicated in anyone with a known severe allergic reaction to any component of the vaccine, including diphtheria toxoid (for MCV4) and rubber latex. Although MCV4 vaccination is not contraindicated in someone with a prior history of Guillain-Barré syndrome, providers should discuss the possible risks and benefits of vaccination in anyone with this history. Both MCV4 and MPSV4 can be given to individuals who are immunosuppressed. MPSV4 is thought to be safe during pregnancy; no information is available regarding the safety of MCV4 during pregnancy.

Adverse Effects

Both MCV4 products and MPSV4 are generally well tolerated in adolescent patients. Local vaccination reactions (redness, swelling, or induration) occur in 11%–16% of

persons 11–18 years old receiving MCV4 and in 4%–6% of persons of the same age receiving MPSV4. The most common solicited complaints among children aged 2–10 years were injection site pain and irritability. More severe systemic reactions (presence of any of the following: fever of 39.5°C or above; headache, fatigue, malaise, chills, or arthralgias requiring bed rest; anorexia; multiple episodes of vomiting or diarrhea; rash; or seizures) occur in 4.3% of MCV4 recipients and 2.6% of MPSV4 recipients. Although cases of Guillain-Barré syndrome have been reported after MCV4, the current data does not suggest that the rate is above that which would be expected in the absence of vaccination.

TETANUS-REDUCED DIPHTHERIA-ACELLULAR PERTUSSIS VACCINATION (ADOLESCENTS & ADULTS)

Pertussis is increasingly recognized as a disease affecting older children and adults, including fully vaccinated persons with waning immunity. In the United States, the most dramatic increases in pertussis incidence are among adolescents and young adults, prompting development of booster pertussis vaccines for this population. FDA approval in 2005 of the tetanus-reduced dose diphtheria-acellular pertussis (Tdap) vaccine was based on comparable seroresponse to pertussis antigens and a safety profile similar to control Td. Adolescent, adult, and elderly immunization not only has the capacity to protect adolescents from pertussis, but also should limit spread of pertussis from adults to infants and decrease overall pertussis endemicity.

Vaccines Available

- Tdap (Boostrix, GlaxoSmithKline) contains tetanus toxoid, diphtheria toxoid, and three acellular pertussis antigens (detoxified pertussis toxin [PT], filamentous hemagglutinin [FHA], and pertactin) and is licensed for use in persons aged 10 years and older; this vaccine can be used in adults and the elderly.
- Tdap (Adacel, sanofi pasteur) contains tetanus toxoid, diphtheria toxoid, and five acellular pertussis antigens (PT, FHA, pertactin, and fimbriae types 2 and 3) and is licensed for use in persons aged 11–64 years.

Dosage & Schedule of Administration

Adolescents 11-18 years of age should receive a 0.5-mL dose of Tdap intramuscularly in the deltoid, instead of the tetanus and diphtheria toxoids (Td) vaccine for booster immunization. The preferred age for Tdap immunization is 11-12 years. Adults 19-64 years of age should receive a single dose of Tdap. Adults 65 years of age and older should receive a single dose of Tdap if they have not previously received Tdap and if they anticipate close contact with an infant less than 12 months. Women who are pregnant should receive a Tdap booster with each pregnancy, ideally during the third trimester. Tdap can be administered regardless of the interval since the last tetanus- or diphtheria-toxoid containing vaccine. Tdap and MCV4 should be administered during the same visit if both vaccines are indicated. If not administered at the same time, a minimum interval of 1 month between vaccines is suggested.

Contraindications & Precautions

Contraindications to Tdap include severe allergic reaction to any vaccine component and encephalopathy (eg, coma, prolonged seizures) not attributable to an identifiable cause within 7 days of administration of a vaccine with pertussis components. Precautions for Tdap administration include Guillain-Barré syndrome occurring within 6 weeks of a previous dose of a tetanus toxoid-containing vaccine, a progressive neurologic disorder, uncontrolled epilepsy, or progressive encephalopathy until the condition has stabilized.

Adverse Effects

Pain at the injection site was the most frequently reported local adverse event among adolescents. Headache and fatigue were the most frequently reported systemic adverse events.

- CDC: Updated recommendations for use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) in pregnant women, Advisory Committee on Immunization Practices (ACIP), 2012. MMWR Morb Mortal Wkly Rep 2013;62:131 [PMID: 23425962].

HUMAN PAPILLOMAVIRUS VACCINATION

Genital human papillomavirus (HPV) is the most common sexually transmitted infection in the United States and worldwide. Most of the estimated 14 million persons newly infected every year in the United States have no symptoms. Up to 75% of new infections occur among persons 15–24 years of age. Approximately 70% of cervical cancers and 80% of all HPV-associated cancers (also includes oral, vaginal, anal) are caused by the high cancer risk types 16 and 18. Over 90% of genital warts are caused by low cancer risk types 6 and 11.

Three HPV vaccines are licensed in the United States. Bivalent HPV vaccine (2vHPV) contains types 16 and 18 (Cervarix, GlaxoSmithKline) and is approved for females. Quadrivalent HPV vaccine (4vHPV) contains types 6, 11, 16, and 18 (Gardasil, Merck) and is approved for females and males. Nine-valent HPV vaccine adds types HPV 31, 33, 45, 52, and 58 to 4vHPV and is approved for females and males. The added serotypes provide protection against an additional 12% of HPV-related cancers. Routine HPV vaccination is recommended for females and males aged 11-12 years and may be given as early as age 9. Catch-up vaccination is recommended for females aged 13-26 years and males aged 13-21 years who were not previously vaccinated or have not completed the full vaccine series. HPV vaccination is also recommended through age 26 years for men who have sex with men, and for men with immunocompromising conditions (including HIV infection), if they were not previously vaccinated or had not completed the vaccine series. Females who might have been exposed to HPV, test positive for a high-risk HPV types, or have an abnormal Pap test are still likely to benefit from HPV vaccine by avoiding infection with other HPV types.

Vaccines Available

- 1. Quadrivalent HPV vaccine (Gardasil, Merck), a nonlive vaccine; a 0.5-mL dose contains HPV-6, 11, 16, and 18 L1 proteins.
- Nine-valent HPV vaccine (Gardasil 9, Merck), a nonlive vaccine; a 0.5-mL dose contains HPV-6, 11, 16, 18, 31, 33, 45, 52, and 58 L1 proteins.
- Bivalent HPV vaccine (Cervarix, GlaxoSmithKline), a nonlive vaccine is a 0.5-mL dose that contains HPV-16 and HPV-18 L1 protein and the adjuvant AS04. Licensed for use in females only.

Dosage & Schedule of Administration

HPV vaccine is administered intramuscularly as two or three separate 0.5-mL doses depending on age at initial vaccination. For healthy adolescents initiating the series prior to their 15th birthday, two doses separated by 6–12 months are recommended (minimum interval 5 months). Three doses are recommended for those initiating vaccination on or after the 15th birthday or for persons with certain immunocompromising conditions. The second dose should be administered 1–2 months after the first dose and the third dose 6 months after the first dose. The minimum interval between the first and second dose is 4 weeks; the minimum recommended interval between the second and third doses of vaccine is 12 weeks. HPV vaccine may be administered with other vaccines. If the vaccine schedule is interrupted, the series need not be restarted. When feasible, the same HPV vaccine should be used for the complete series. However, if the HPV vaccine previously administered is unknown or not available, any HPV vaccine can be used to complete the series to protect against HPV types 16 and 18. There is currently no recommendation for repeat vaccination with 9vHPV for persons who have completed a vaccination series with 2vHPV or 4vHPV; the most current recommendations can be found at www.cdc.gov/vaccines.

Contraindications & Precautions

HPV vaccine is contraindicated in persons with a history of anaphylaxis to any vaccine component. HPV vaccine is not recommended for use in pregnancy. The vaccine can be administered to persons with minor acute illnesses and to immunocompromised persons.

Adverse Effects

Injection site pain (83.9%) and mild to moderate swelling and erythema were the most common adverse events reported by vaccine recipients. Fever (10.3%), nausea (4.2%), and dizziness (2.8%) were reported as systemic adverse events. Postmarketing reports of syncope, which were reported after vaccination with HPV vaccine, may follow any vaccination, so vaccine recipients should be observed for 15 minutes after vaccination.

VACCINATIONS FOR SPECIAL SITUATIONS

RABIES VACCINATION

After symptoms of infection develop, rabies is almost invariably fatal in humans. While sylvan animal and bat rabies in the United States is common, the incidence of human rabies is very low, with fewer than three cases per year. Although dogs represent the most important vector for human rabies worldwide, in the United States because of widespread vaccination of dogs and cats, the most common rabies virus variants responsible for human rabies are bat-related. Rabies is also common in skunks, raccoons, and foxes; it is uncommon in rodents.

Human rabies is preventable with appropriate and timely postexposure prophylaxis. Postexposure care consists of local wound care, passive immunization, and active immunization. Immediately after an animal bite, all wounds should be flushed and aggressively cleaned with soap and water. If possible, the wound should not be sutured. Passive immunization after high-risk exposure consists of the injection of human rabies immune globulin (RIG) near the wound. Active immunization is accomplished by completing a schedule of immunization with one of the two available rabies vaccines licensed in the United States. Because bites from bats are often unrecognized, prophylaxis should be given if a bat is found indoors even if there is no history of contact, especially if found in the same room with a sleeping or unattended child or with an intoxicated or otherwise incapacitated individual.

Local public health officials should be consulted before postexposure rabies prophylaxis is started to avoid unnecessary vaccination and to assist in the proper handling of the animal (if confinement or testing of the animal is appropriate). To facilitate consultation, the health care provider should know the species of animal, its availability for testing or confinement, the nature of the attack (provoked or unprovoked), and the nature of the exposure (bite, scratch, lick, or aerosol of saliva). Rabies immunization should also be considered for children traveling to countries where rabies is endemic.

Vaccines Available

Rabies vaccines stimulate immunity after 7–10 days, and the immunity persists for 2 years or more. Two inactivated preparations are licensed in the United States.

- Imovax Rabies (sanofi pasteur) human diploid cell vaccine (HDCV)
- RabAvert (Novartis) purified chick embryo cell vaccine (PCEC)

Dosage & Schedule of Administration

These two rabies vaccines are equally safe and effective for both preexposure and postexposure prophylaxis. For each vaccine, 1 mL is given intramuscularly in the deltoid (for adults and older children) or anterolateral thigh (for infants and young children). The volume of the dose is not reduced for children. Vaccine should not be given in the gluteal region.

Primary Preexposure Vaccination

Preexposure rabies immunization should be considered for individuals at high risk of exposure to rabies (eg, veterinarians, animal handlers, spelunkers, and people moving to or extensively traveling in areas with endemic rabies). Three intramuscular injections of any vaccine are given on days 0, 7, and 21 or 28.

Postexposure Prophylaxis

After an individual has possibly been exposed to rabies, decisions about whether to initiate postexposure prophylaxis need to be made urgently, in consultation with local public health officials.

In previously unvaccinated individuals—After prompt and thorough wound cleansing, an individual exposed to rabies should receive rabies vaccination and RIG. Vaccination is given on the day of exposure (day 0) and on days 3, 7, and 14 following exposure. Immune suppressed individuals should receive an additional dose on day 28. RIG should also be given as soon as possible after exposure, ideally on the day of exposure, in a recommended dose of 20 IU/kg. If anatomically possible, the entire dose of RIG should be infiltrated into and around the wound. Any remaining RIG should be administered intramuscularly at an anatomic site distant from the location used for rabies vaccination. If RIG was not administered when vaccination was begun, it can be administered up to 7 days after the first dose of vaccine. Postexposure failures have occurred only when some deviation from the approved protocol occurred (eg, no cleansing of the wound, less than usual amount of RIG, no RIG at the wound site, or vaccination in the gluteal area).

In previously vaccinated individuals—RIG should not be administered, and only two doses of vaccine on days 0 and 3 after exposure are needed.

Booster Vaccination

Previously vaccinated individuals with potential continued exposure to rabies should have a serum sample tested for rabies antibody every 2 years. If the titer is less than 1:5 for virus neutralization, a booster dose of rabies vaccine should be administered.

Adverse Effects

The rabies vaccines are relatively free of serious reactions. Local reactions at the injection site such as pain, swelling, induration, or erythema range in frequency from 11% to 89% of vaccine recipients. Mild systemic reactions, such as headache, nausea, muscle aches, and dizziness, occur in 6% to 55% of vaccine recipients. An immune complex-like reaction occurs in about 6% of adults 2–21 days after receiving

booster doses of rabies vaccine; symptoms may include generalized urticaria, arthralgias, arthritis, and angioedema.

Travelers to countries where rabies is endemic may need immediate postexposure prophylaxis and may have to use locally available vaccines and RIG. In many developing countries, the only vaccines readily available may be nerve tissue vaccines derived from the brains of adult animals or suckling mice, and the RIG may be of equine origin. Although adverse reactions to RIG are uncommon and typically mild, the nervous tissue vaccines may induce neuroparalytic reactions in 1:200–1:8000 vaccines; this is a significant risk and is another justification for preexposure vaccination prior to travel in areas where exposure to potentially rabid animals is likely.

Antibody Preparations

In the United States, RIG is prepared from the plasma of human volunteers hyperimmunized with rabies vaccine. The recommended dose is 20 IU/kg body weight. The rabiesneutralizing antibody content is 150 IU/mL, supplied in 2- or 10-mL vials.

TYPHOID FEVER VACCINATION

Typhoid fever causes an estimated 21 million illnesses and 200,000 deaths each year worldwide; in the United States an estimated 5700 cases occur each year, predominantly from traveling outside the United States.

Two vaccines against *Salmonella enterica typhi*, the bacterium that causes typhoid fever, are available in the United States: a live attenuated vaccine given orally (Ty21a), and an inactivated vaccine composed of purified capsular polysaccharide (ViCPS) given parenterally. Both vaccines protect 50%–80% of vaccine recipients. The oral vaccine is most commonly used because of its ease of administration. However, noncompliance with the oral vaccine dosing schedule occurs frequently, and correct usage should be stressed or the parenteral ViCPS vaccine used.

Routine typhoid vaccination is recommended only for children who are traveling to typhoid-endemic areas or who reside in households with a documented typhoid carrier. While CDC recommendations emphasize typhoid vaccination for travelers expected to have long-term exposure to potentially contaminated food and drink, vaccination should also be considered for short-term travel to high-risk countries. Although typhoid fever occurs throughout the world, areas of highest incidence include southern Asia and southern Africa. Travelers should be advised that because the typhoid vaccines are not fully protective, and because of the potential for other food- and waterborne illnesses, careful selection of food and drink and appropriate hygiene remain necessary when traveling internationally.

Vaccines Available

- 1. Parenteral ViCPS (Typhim Vi, sanofi pasteur) is for intramuscular use.
- Oral live attenuated Ty21a vaccine (Vivotif Berna Vaccine, Swiss Serum and Vaccine Institute) is supplied as enteric-coated capsules.

Dosage & Schedule of Administration

ViCPS is administered as a single intramuscular dose (0.5 mL) in the deltoid muscle, with boosters needed every 2 years if exposure continues. It is approved for children aged 2 years and older.

The dose of the oral vaccine (Ty21a) is one capsule every other day for a total of four capsules, taken 1 hour before meals. The capsules should be taken with cool liquids and should be kept refrigerated. A full course of four capsules is recommended every 5 years if exposure continues. Mefloquine and chloroquine may be given at the same time as the oral vaccine; however if mefloquine is administered, immunization with Ty21a should be delayed for 24 hours. Proguanil should be administered only if 10 days have lapsed since the last dose of oral vaccine. This vaccine is not approved for children younger than age 6 years. As with all live attenuated vaccines, Ty21a should not be given to immunocompromised patients.

Adverse Reactions

Both the oral and parenteral vaccines are well tolerated, and adverse reactions are uncommon and usually self-limited. The oral vaccine can cause gastroenteritis-like illness, fatigue, and myalgia, whereas the parenteral vaccine can cause injection site pain, abdominal pain, dizziness, and pruritus.

CHOLERA VACCINATION

Cholera is caused by toxigenic *Vibrio cholera* bacteria of serogroup O1 (> 99% of global cases) or O139. The illness manifests as watery diarrhea that can be severe and rapidly fatal without prompt fluid rehydration. Annually in the United States less than 25 cases are reported and most occur among travelers to countries where cholera is endemic or epidemic.

A single dose, live-attenuated monovalent oral vaccine, CVD103-HgR (Vaxchora) is approved by the FDA and available in the United States for use for travelers, age 18–64 years, who are traveling to areas of the world with active cholera transmission. The vaccine has 90% efficacy against severe diarrhea at 10 days after vaccination and 80% efficacy 3 months post-vaccination. CVD103-HgR should not be given to patients who have received antibiotics within the preceding 14 days. CVD103-HgR is an oral live attenuated vaccine that can be shed in the stool and potentially transmitted to close contacts. Additional cholera vaccines are available in countries outside the United States. Vaccinated travelers should continue to utilize careful selection of food and drink and use appropriate hygiene when traveling internationally.

Vaccine Available

1. CVD 103-HgR (Vaxchora, PaxVax, Redwood City, California) is a live-attenuated monovalent oral vaccine that is FDA approved and available in the United States.

CDC. Recommendations of the Advisory Committee on immunization practices for use of cholera vaccine. MMWR Morb Mortal Wkly Rep 2017;66:482 [PMID: 28493859].

JAPANESE ENCEPHALITIS VACCINATION

Japanese encephalitis virus (JE) is a mosquito-borne flavivirus that carries a high morbidity and mortality for those infected. It is endemic in parts of Asia, although the risk to most travelers to Asia is low. Travel to rural areas and extended travel in endemic areas may increase the risk. One safe and effective vaccine is available in the United States. Travelers to IE-endemic countries should be advised of risks of IE and the importance of measures to reduce mosquito bites. Vaccination is not recommended for short-term travelers whose visit will be restricted to urban areas or outside of a well-defined JE transmission season, but vaccination is recommended for travelers who plan to spend more than 1 month in endemic areas during the JE transmission season. Vaccination should be considered for short-term travelers to endemic areas during the JE transmission season if they will travel outside of an urban area and their activities will increase the risk of JE exposure and should also be considered for travelers to an area with an ongoing JE outbreak. If the primary series of JE-VC was administered more than 1 year previously, a booster dose may be given before potential JE virus exposure.

Vaccines Available and Schedule of Administration

Ixiaro (JE-VC) (Novartis) is an inactivated Vero cell-derived JE vaccine. It contains aluminum hydroxide as an adjuvant and has no preservative. It is given intramuscularly in a two-dose series at 0 and 28 days. It is licensed for persons aged 2 months and older. For adults and children aged more than or equal to 3 years, each dose is 0.5 mL. For children aged 2 months through 2 years, each dose is 0.25 mL.

TUBERCULOSIS VACCINATION

Approximately one-third of the world's population is infected with Mycobacterium tuberculosis, which is a leading cause of death in low- and middle-income nations, killing approximately 1.5 million people annually. It is relatively uncommon in the United States, and most cases occur in persons born abroad or their close contacts. Bacille Calmette-Guérin vaccine (BCG) consists of live attenuated Mycobacterium bovis. BCG is the most widely used vaccine in the world and has been administered to over 3 billion people, with a low incidence of adverse events following immunization. BCG vaccine is inexpensive, can be given any time after birth, sensitizes the vaccinated individual for 5-50 years, and stimulates both B-cell and T-cell immune responses. BCG reduces the risk of tuberculous meningitis and disseminated TB in pediatric populations by 50%-100% when administered in the first month of life. Efficacy against pulmonary tuberculosis has been variable (0%-80%) depending on the study setting and other factors.

BCG vaccination should be considered only in children with a negative TB skin test who are not infected with HIV and who are continually exposed to TB without the possibility of being separated from the infected adult. This is essential if the adult is untreated and the child cannot be given preventive treatment. BCG is not recommended for travel.

The two licensed BCG vaccines in the United States are produced by Organon Teknika Corporation (Tice BCG) and sanofi pasteur (Mycobax). They are given intradermally in a dose of 0.05 mL for newborns and 0.1 mL for all other children. Adverse effects occur in 1%–10% of healthy individuals, including local ulceration, regional lymph node enlargement, and very rarely lupus vulgaris. The vaccine is contraindicated in pregnant women and in immunocompromised individuals, including those with HIV infection, because it has caused extensive local adenitis and disseminated or fatal infection.

BCG almost invariably causes its recipients to be tuberculin-positive (5–7 mm), but the reaction often becomes negative after 3–5 years. Thus, a positive TST test in a child with a history of BCG vaccination who is being investigated for TB as a case contact should be interpreted as indicating infection with *M tuberculosis*. This is discussed in Chapter 42.

YELLOW FEVER VACCINATION

A live, attenuated vaccine against yellow fever is available in the United States, but is available only at official yellow fever vaccination locations (typically public health departments), and should only be given after consultation with travel medicine specialists or public health officials. Immunization against yellow fever is indicated for children age 9 months and older traveling to endemic areas. Proof of vaccination against yellow fever may be required for travel to certain countries. Yellow fever vaccine is made from the 17D yellow fever attenuated virus strain grown in chick embryos. It is contraindicated in infants younger than age 6 months due to an increased risk of vaccine-associated encephalitis, in persons with anaphylactic egg allergy, and in immunocompromised individuals or individuals with a history of thymus disease. In children 6-8 months of age, the vaccine risks and benefits should be weighed on an individual basis. When yellow fever vaccine is indicated, a subcutaneous injection of 0.5 mL is administered. Immunity following vaccination appears to be long-lasting and booster doses are no longer recommended for most travelers. Adverse reactions are generally mild, consisting of low-grade fever, mild headache, and myalgia 5-10 days after vaccination, occurring in fewer than 25% of vaccines. Although very uncommon, several types of severe adverse reactions can occur following vaccination. Serious allergic reactions occur in roughly 1 case per every 55,000 vaccine recipients. The risk of vaccineassociated neurotropic disease within 30 days following vaccination has been estimated to be 1 case per every 125,000 vaccine recipients. The risk of severe multiple organ system failure following vaccination has been estimated at 1 case per every 250,000 vaccine recipients. Health care providers should administer yellow fever vaccine only to persons truly at risk of exposure to yellow fever. There is no contraindication to giving other live-virus vaccines simultaneously with vellow fever vaccine.

PASSIVE PROPHYLAXIS

1. Intramuscular & Specific Intravenous Immune Globulin

Ig may prevent or modify infection with hepatitis A virus if administered in a dose of 0.02 mL/kg within 14 days after exposure. Measles infection may be prevented or modified in a susceptible person if Ig is given in a dose of 0.5 mL/kg within 6 days after exposure. Pathogen-specific preparations of Ig include tetanus Ig (TIg), hepatitis B Ig (HBIg), rabies Ig (RIg), CMV Ig (IV), botulism Ig (IV), and varicella-zoster Ig (VariZig). These are obtained from donors known to have high titers of antibody against the organism in question. Ig must be given only by the route (IV or IM) for which it is recommended. The dose varies depending on the clinical indication. Adverse reactions include pain at the injection site, headache, chills, dyspnea, nausea, and anaphylaxis, although all but the first are rare.

Palivizumab (Synagis, MedImmune) is a humanized monoclonal antibody against RSV that is used to prevent RSV infection in high-risk populations with monthly doses during RSV season. Palivizumab is administered in a dose of 15 mg/kg once a month beginning with the onset of the RSV season and continuing until the end of the season. Prophylaxis should be discontinued in any child who experiences a breakthrough hospitalization.

The maximum number of doses recommended in any one season is five. Palivizumab is packaged in 50- and 100-mg vials. Palivizumab does not interfere with response to routine childhood vaccinations. Eligibility Criteria for Palivizumab Prophylaxis of High-Risk Infants and Young Children based on AAP Policy Statement:

- Infants born before 29 weeks, 0 days, who are younger than 12 months at the start of RSV season
- Infants less than 12 months with chronic lung disease (CLD) of prematurity, defined as gestational age less than 32 weeks, 0 days, and requiring more than 21% oxygen for at least the first 28 days after birth; for the second year of life in children with a history of CLD, consideration of prophylaxis is recommended only for infants who continue to require medical support (chronic corticosteroids, diuretics, or supplemental oxygen) in the 6 months prior to the start of RSV season
- Certain children less than 12 months of age with significant congenital heart disease (acyanotic heart disease on medication to control heart failure and will require cardiac surgical procedures, infants with moderate to severe pulmonary hypertension)
- Infants with a neuromuscular disease or congenital anomaly that impairs the ability to clear respiratory secretions
- Infants younger than 24 months who are profoundly immunocompromised at the start of RSV season
- Infants younger than 24 months with severe cystic fibrosis (respiratory hospitalizations or weight for length < 10th percentile)

2. Intravenous Immune Globulin

The primary indications for IVIg are for replacement therapy in antibody-deficient individuals; for the treatment of Kawasaki disease, immune thrombocytopenic purpura or hemolytic anemia, Guillain-Barré syndrome and other autoimmune diseases; and replacement therapy in chronic B-cell lymphocytic leukemia. IVIg may be beneficial in some children with toxic shock syndrome, and for anemia caused by parvovirus B19. It may also be used as postexposure prophylaxis for varicella in at-risk persons when VariZIG is not available.

Normal Childhood Nutrition & Its Disorders

Matthew A. Haemer, MD, MPH Laura E. Primak, RD, CNSD Nancy F. Krebs, MD, MS

NUTRITIONAL REQUIREMENTS

NUTRITION & GROWTH

The nutrient requirements of children are influenced by (1) growth rate, (2) body composition, and (3) composition of new growth. These factors vary with age and are especially important during early postnatal life. Growth rates are higher in early infancy than at any other period of life (Table 11–1). Growth rates normally decline rapidly starting in the second month of postnatal life (proportionately later in the preterm infant).

Nutrient requirements also depend on body composition. In the adult, the brain, which accounts for only 2% of body weight, contributes 19% to the total basal energy expenditure. In contrast, in a full-term neonate, the brain accounts for 10% of body weight and for 44% of total energy needs under basal conditions. Thus, in the young infant, total basal energy expenditure and the energy requirement of the brain are relatively high.

Composition of new tissue is a third factor influencing nutrient requirements. For example, fat should account for about 40% of weight gain between birth and 4 months but for only 3% between 24 and 36 months. The corresponding figures for protein are 11% and 21%; for water, 45% and 68%. The high rate of fat deposition in early infancy impacts not only for energy requirements but also the optimal composition of infant feedings.

Because of the high nutrient requirements for growth and the body composition, the young infant is especially vulnerable to undernutrition. Slowed physical growth is an early and prominent sign of undernutrition in the young infant. The limited fat stores of the very young infant mean that energy reserves are modest. The relatively large size and continued growth of the brain render the central nervous system (CNS) especially vulnerable to the effects of malnutrition in early postnatal life.

ENERGY

The major determinants of energy expenditure are (1) basal metabolism, (2) physical activity, (3) growth, and (4) metabolic response to food. The efficiency of energy use may be a significant factor, and thermoregulation may contribute in extremes of ambient temperature if the body is inadequately clothed. Because adequate data on requirements for physical activity in infants and children are unavailable and because individual growth requirements vary, recommendations have been based on calculations of actual intakes by healthy subjects. Suggested guidelines for energy intake of infants and young children are given in Table 11–2. Also included in this table are calculated energy intakes of infants who are exclusively breast-fed. Growth velocity of breast-fed infants during the first 3 months equals and may exceed that of formula-fed infants, but from 6 to 12 months breast-fed infants typically weigh less than formula-fed babies and may show a decrease in growth velocity. The World Health Organization developed, and the United States has adopted, growth standards derived from an international sample of healthy breast-fed infants and young children raised in environments that do not constrain growth. These are considered to represent physiologic growth for infants and young children. (See also section Pediatric Undernutrition.)

After the first 4 years, energy requirements expressed on a body weight basis decline progressively. The estimated daily energy requirement is about 40 kcal/kg/day at the end of adolescence. Approximate daily energy requirements can be calculated by adding 100 kcal/y to the base of 1000 kcal/day at age 1 year. Appetite and growth are reliable indices of caloric needs in most healthy children, but intake also depends to some extent on the energy density of the food offered. Individual energy requirements of healthy infants and children vary considerably, and malnutrition

	(Growth Rate (g/day) Body Composition (%)			%)		
Age (mo)	Male	Both	Female	Growth (kcal/kg/day)	Water	Protein	Fat
0–0.25		0 ^a			75	11.5	11
0.25-1	40		35	50

Table 11–1. Changes in growth rate, energy required for growth, and body composition in infants and young children.

^aBirth weight is regained by 10 days. Weight loss of more than 10% of birth weight indicates dehydration or malnutrition; this applies to both formula- and breast-fed infants.

Data from Fomon SJ: Infant Nutrition, 2nd ed. Philadelphia: WB Saunders; 1974.

and disease increase the variability. Preterm infant energy requirements can exceed 120 kcal/kg/day, especially during illness or when catch-up growth is desired.

One method of calculating requirements for malnourished patients is to base the calculations on the ideal body weight (ie, 50th percentile weight-for-length, or weight determined from current height and the 50th percentile body mass index [BMI] for age), rather than actual weight. World Health Organization: Report of a Joint FAO/WHO/UNO Expert Consultation: Energy and Protein Requirements. WHO Tech Rep Ser No. 724, 1985;724.

PROTEIN

Only amino acids and ammonium compounds are usable as sources of nitrogen in humans. Amino acids are provided through the digestion of dietary protein. Nitrogen is

	Energy (kcal/kg/day)			Protein (g/kg/day)

3–5 у	—	—	90	—	1.1	

Table 11–2. Recommendations for energy and protein intake.

Data from Krebs NF et al: Growth and intakes of energy and zinc in infants fed human milk. J Pediatr 1994;124:32; Garza C, Butte NF: Energy intakes of human milk-fed infants during the first year. J Pediatr 1990;117:S124.

absorbed from the intestine as amino acids and short peptides. Absorption of nitrogen is more efficient from synthetic diets that contain peptides in addition to amino acids. Some intact proteins are absorbed in early postnatal life, a process that may be important in the development of protein tolerance or allergy.

Because there are no major stores of body protein, a regular dietary supply of protein is essential. In infants and children, optimal growth depends on an adequate dietary protein supply. Relatively subtle effects of protein deficiency are now recognized, especially those affecting tissues with rapid protein turnover rates, such as the immune system and the gastrointestinal (GI) mucosa.

Relative to body weight, rates of protein synthesis and turnover and accretion of body protein are exceptionally high in the infant, especially the preterm infant. Eighty percent of the dietary protein requirement of a premature infant is used for growth, compared with only 20% in a 1-year-old child. Protein requirements per unit of body weight decline rapidly during infancy as growth velocity decreases. The recommendations in Table 11-2 are derived chiefly from the Joint FAO/WHO/UNO Expert Committee and are similar to the Recommended Dietary Allowances (RDAs). They deliver a protein intake above the quantity provided in breast milk. The protein intake required to achieve protein deposition equivalent to the in utero rate in very low-birth-weight infants is 3.7-4.0 g/kg/day simultaneously with adequate energy intake. Protein requirements increase in the presence of skin or gut losses, burns, trauma, and infection. Requirements also increase during times of catch-up growth accompanying recovery from malnutrition (~0.2 g of protein per gram of new tissue deposited). Young infants experiencing rapid recovery may need as much as 1-2 g/kg/day of extra protein. By age 1 year, the extra protein requirement is unlikely to be more than 0.5 g/kg/day.

The quality of protein depends on its amino acid composition. Infants require 43% of protein as essential amino acids, and children require 36%. Adults cannot synthesize nine essential amino acids: histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Cysteine and tyrosine are considered partially essential because their rates of synthesis from methionine and phenylalanine, respectively, are limited and may be inadequate in infants, the elderly, and those with malabsorption. In young infants, synthetic rates for cysteine, tyrosine, and, perhaps, taurine are insufficient for needs. Taurine, an amino acid used to conjugate bile acids, may also be conditionally essential in infancy. Lack of an essential amino acid leads to weight loss within 1-2 weeks. Wheat and rice are low in lysine, and legumes are low in methionine. Appropriate mixtures of vegetable protein are therefore necessary to achieve high protein quality.

Because the mechanisms for removal of excess nitrogen are efficient, moderate excesses of protein are not harmful and may help to ensure an adequate supply of certain micronutrients. Adverse effects of excessive protein intake may include increased calcium losses in urine and, over a life span, increased loss of renal mass. Excessive protein intake of more than 4 g/kg/day in older children and adolescents may also cause elevated blood urea nitrogen, acidosis, hyperammonemia, and, in the preterm infant more than 6 g/kg/day has caused failure to thrive, lethargy, and fever. Impaired capacity to deaminate proteins from liver insufficiency or to excrete excess nitrogen as urea from renal insufficiency can further limit tolerable protein intake.

Ziegler EE. Nutrient needs for catch-up growth in low-birth weight infants. Nestle Nutr Inst Workshop Ser 2015;81:135–143. doi: 10.1159/000365902 [PMID: 26111570].

LIPIDS

Fats are the main dietary energy source for infants and account for up to 50% of the energy in human milk. Over 98% of breast milk fat is triglyceride (TG), which has an energy density of 9 kcal/g. Fats can be stored efficiently in adipose tissue with a minimal energy cost of storage. This is especially important in the young infant. Fats are required for the absorption of fat-soluble vitamins and for myelination of the CNS. Fat also provides essential fatty acids (EFAs) necessary for brain development, for phospholipids in cell membranes, and for the synthesis of prostaglandins and leukotrienes. The EFAs are polyunsaturated fatty acids, linoleic acid (18:2w6), and linolenic acid (18:3w3). Arachidonic acid $(20:4\omega 6)$ is derived from dietary linoleic acid and is present primarily in membrane phospholipids. Important derivatives of linolenic acid are eicosapentaenoic acid (20:6w3) and docosahexaenoic acid (DHA, 22:6ω3) found in human milk and brain lipids. Visual acuity and possibly psychomotor development of formula-fed premature infants is improved in formulas supplemented with DHA (22:6w3) and ARA (20:4w6). The benefits of long-chain polyunsaturated fatty acid supplementation in formulas for healthy term infants are unclear (though safety has been established).

Clinical features of EFA omega-6 deficiency include growth failure, erythematous and scaly dermatitis, capillary fragility, increased fragility of erythrocytes, thrombocytopenia, poor wound healing, and susceptibility to infection. The clinical features of deficiency of omega-3 fatty acids are less well defined, but dermatitis and neurologic abnormalities including blurred vision, peripheral neuropathy, and weakness have been reported. Fatty fish are the best dietary source of omega-3 fatty acids. A high intake of fatty fish is associated with decreased platelet adhesiveness and decreased inflammatory response.

Up to 5%–10% of fatty acids in human milk are polyunsaturated, with the specific fatty acid profile reflective of maternal dietary intake. Most of these are omega-6 series with smaller amounts of long-chain omega-3 fatty acids. About 40% of breast milk fatty acids are monounsaturates, primarily oleic acid (18:1), and up to 10% of total fatty acids are medium-chain triglycerides (MCTs) (C₈ and C₁₀) with a calorie density of 7.6 kcal/g. In general, the percentage of calories derived from fat is a little lower in infant formulas than in human milk.

The American Academy of Pediatrics recommends that infants receive at least 30% of calories from fat, with at least 2.7% of total fat as linoleic acid, and 1.75% of total fatty acids as linolenic. During at least the first year of life 40%–50% of energy requirements should be provided as fat. Children older than 2 years should be switched gradually to a diet containing approximately 30% of total calories from fat, with no more than 10% of calories from saturated fats.

 β -Oxidation of fatty acids occurs in the mitochondria of muscle and liver. Carnitine is necessary for oxidation of the fatty acids, which must cross the mitochondrial membranes as acylcarnitine. Carnitine is synthesized in the human liver and kidneys from lysine and methionine. Carnitine needs of infants are met by breast milk or infant formulas. In the liver, substantial quantities of fatty acids are converted to ketone bodies, which are then released into the circulation as an important fuel for the brain of the young infant.

MCTs are sufficiently soluble that micelle formation is not required for transport across the intestinal mucosa. They are transported directly to the liver via the portal circulation. MCTs are rapidly metabolized in the liver, undergoing β -oxidation or ketogenesis. They do not require carnitine to enter the mitochondria. MCTs are useful for patients with luminal phase defects, absorptive defects, and chronic inflammatory bowel disease. The potential side effects of MCT administration include diarrhea when given in large quantities; high octanoic acid levels in patients with cirrhosis; and, if they are the only source of lipids, deficiency of EFA.

Radmacher PG, Adamkin DH. Fortification of human milk for preterm infants. Semin Fetal Neonatal Med Feb2017;22(1):30–35. doi: 10.1016/j.siny.2016.08.004 [PMID: 27593561].

CARBOHYDRATES

The energy density of carbohydrate is 4 kcal/g. Approximately 40% of caloric intake in human milk is in the form of lactose, or milk sugar. Lactose supplies 20% of the total energy in cow's milk. The percent of total energy in infant formulas from carbohydrate is similar to that of human milk.

The rate at which lactase hydrolyzes lactose to glucose and galactose in the intestinal brush border determines how quickly milk carbohydrates are absorbed. Lactase levels are highest in young infants, and decline with age depending on genetic factors. About 20% of nonwhite Hispanic and black children younger than 5 years have lactase deficiency. White children typically do not develop symptoms of lactose intolerance until they are at least 4 or 5 years of age, while nonwhite Hispanic, Asian American, and black children may develop these symptoms by 2 or 3 years of age. Lactoseintolerant children have varying symptoms depending on the specific activity of their intestinal lactase and the amount of lactose consumed. Galactose is preferentially converted to glycogen in the liver prior to conversion to glucose for subsequent oxidation. Infants with galactosenia, an inborn metabolic disease caused by deficient galactose-1-phosphate uridyltransferase, require a lactose-free diet starting in the neonatal period.

After the first 2 years of life, 50%–60% of energy requirements should be derived from carbohydrates, with no more than 10% from simple sugars as recommended by the World Health Organization, or less than 25 g of sugar added to foods per day as recommended by the American Heart Association in 2016. These dietary guidelines are, unfortunately, not reflected in the diets of North American children, who typically derive 25% of their energy intake from sucrose and less than 20% from complex carbohydrates.

Children and adolescents in North America often consume large quantities of sucrose and high-fructose corn syrup in soft drinks and other sweetened beverages, candy, syrups, sweetened breakfast cereals, and a variety of processed foods. A high intake of these sugars, especially in the form of sweetened beverages, may predispose to obesity and insulin resistance, is a major risk factor for dental caries, and may be associated with an overall poorer quality diet, including high intake of saturated fat. Sucrase hydrolyzes sucrose to glucose and fructose in the brush border of the small intestine. Fructose absorption through facilitated diffusion occurs more slowly than glucose absorption through active transport. Fructose does not stimulate insulin secretion or enhance leptin production. Since both insulin and leptin play a role in regulation of food intake, consumption of fructose (eg, as high-fructose corn syrup) may contribute to increased energy intake and weight gain. Fructose is also easily converted to hepatic TGs, which may be undesirable in patients with insulin resistance/metabolic syndrome and cardiovascular disease risk.

Dietary fiber can be classified in two major types: nondigested carbohydrate (β 1–4 linkages) and noncarbohydrate (lignin). Insoluble fibers (cellulose, hemicellulose, and lignin) increase stool bulk and water content and decrease gut transit time. Soluble fibers (pectins, mucilages, oat bran) bind bile acids and reduce lipid and cholesterol absorption. Pectins also slow gastric emptying and the rate of nutrient absorption. Few data regarding the fiber needs of children are available. The Dietary Reference Intakes recommend 14 g of fiber per 1000 kcal consumed. The American Academy of Pediatrics recommends that children older than 2 years consume in grams per day an amount of fiber equal to 5 plus the age in years. Fiber intakes are often low in North America. Children who have higher dietary fiber intakes have been found to consume more nutrient-dense diets than children with low-fiber intakes. In general, higher fiber diets are associated with lower risk of chronic diseases such as obesity, cardiovascular disease, and diabetes.

Cantoral A et al: Early introduction and cumulative consumption of sugar-sweetened beverages during the pre-school period and risk of obesity at 8-14 years of age. Pediatr Obes Feb 2016; 11(1):68–74. doi: 10.1111/ijpo.12023 [PMID: 25891908].

Vos MB et al: Added sugars and cardiovascular disease risk in children: a scientific statement from the American Heart Association. Circulation Aug 22, 2016. doi: 10.1161/ CIR.000000000000439 [PMID: 27550974].

MAJOR MINERALS

Dietary sources, absorption, metabolism, and deficiency of the major minerals are summarized in Table 11–3. Recommended intakes are provided in Table 11–4.

TRACE ELEMENTS

Trace elements with a recognized role in human nutrition are iron, iodine, zinc, copper, selenium, manganese, molybdenum, chromium, cobalt (as a component of vitamin B_{12}), and fluoride. Information on food sources, functions, and deficiencies of the trace elements is summarized in Table 11–5. Supplemental fluoride recommendations are listed in Table 11–6. Dietary Reference Intakes of trace elements are summarized in Table 11–4. Iron deficiency is discussed in Chapter 30.

- King JC et al: Biomarkers of nutrition for development (BOND)-Zinc Review. J Nutr Mar 9, 2016. doi: 10.3945/jn.115.220079 [PMID: 26962190].
- Tang M et al: Effect of Vitamin E with therapeutic iron supplementation on iron repletion and gut microbiome in US iron deficient infants and toddlers. J Pediatr Gastroenterol Nutr Sep 2016;63(3):379–385. doi: 10.1097/MPG.000000000001154 [PMID: 27548249].

VITAMINS

In general, highly restrictive diets (eg, those in which entire food groups are absent) should prompt consideration of vitamin deficiencies. For example, numerous cases of scurvy have been reported in children with autism who have had markedly constrained diets. Untreated fat-malabsorption syndromes (eg, cystic fibrosis, celiac disease, short gut syndrome) are associated with deficiencies of fat-soluble vitamins. See Table 11–7 for other general circumstances that should prompt assessment for vitamin deficiencies.

Fat-Soluble Vitamins

Because they are insoluble in water, the fat-soluble vitamins require digestion and absorption of dietary fat and a carrier system for transport in the blood. Deficiencies of these vitamins develop more slowly than deficiencies of watersoluble vitamins because the body accumulates stores of the fat-soluble vitamins. Prematurity and some childhood conditions (especially those with fat malabsorption) place children at risk (see Table 11–7). Excessive intakes carry potential for toxicity (Table 11–8). A summary of reference intakes is found in Table 11–9. Dietary sources of fat-soluble vitamins, their absorption/metabolism, and causes and clinical features of deficiency are summarized in Table 11–10. Vitamin deficiency and related diagnostic laboratory findings and treatment are detailed in Table 11–11.

Recent recognition of low levels of 25-OH-vitamin D in a relatively large percentage of the population and the broad range of functions beyond calcium absorption have led many experts including the American Academy of Pediatrics to recommend a daily intake of at least 400 IU (10 mcg)/day for all infants, including those who are breast-fed, beginning shortly after birth.

- Golden NH, Carey DE: Vitamin D in health and disease in adolescents: when to screen, whom to treat, and how to treat. Adolesc Med State Art Rev Spring 2016;27(1):125–139 [PMID: 27363237].
- Weaver CM et al: The National Osteoporosis Foundation's position statement on peak bone mass development and lifestyle factors: a systematic review and implementation recommendations. Osteoporos Int Apr 2016;27(4):1281–1386. doi: 10.1007/ s00198-015-3440-3 [PMID: 26856587].

Water-Soluble Vitamins

Deficiencies of water-soluble vitamins are generally uncommon in the United States because of the abundant food supply and fortification of prepared foods. Cases of deficiencies (eg, scurvy) in children with special needs (eg, autism) have been reported in the context of sharply restricted diets. Most bread and wheat products are fortified with B vitamins, including the mandatory addition of folic acid to enriched grain products since 1998. Folic acid supplements (400 mcg/day) during the periconceptional period protect against neural tube defects. Dietary intakes of folic acid from natural foods and enriched products also are protective. Biological roles of water-soluble vitamins are listed in Table 11-12. The risk of toxicity from watersoluble vitamins is not as great as that associated with fat-soluble vitamins because excesses are excreted in the urine. However, deficiencies of these vitamins develop more quickly than fat-soluble vitamins because of limited stores,

I able I I	- J. Jui	TITLATY OF	IIIajui	IIIIIIeiais

		Deficiency		
Mineral	Absorption/Metabolism	Causes	Clinical Features	
Calcium Dietary sources: dairy products, legumes, broccoli, green leafy vegetables.	20%–30% from diet; 60% from HM. Enhanced by lactose, glucose, protein; impaired by phytate, fiber, oxalate, unabsorbed fat. Absorption is regulated by serum calcitriol, which increases when PTH is secreted in response to low plasma-ionized calcium. PTH also promotes release of calcium from bone. Renal excretion.	Can occur in preterm infants without adequate supplementation and in lactating adolescents with limited calcium intake or in patients with steatorrhea.	Osteopenia or osteoporosis, tetany.	
Phosphorus Dietary sources: meats, eggs, dairy products, grains, legumes, and nuts; high in processed foods and sodas.	80% from diet. PTH decreases tubular resorption of phosphorus in kidneys; homeostasis is maintained by GI tract and kidneys.	Rare, but can occur in preterm infants fed unfortified HM (results in osteoporosis and rickets, sometimes hypercalcemia). Also seen in patients with protein-energy malnutrition and may occur with refeeding.	Muscle weakness, bone pain, rhabdomyolysis, osteomalacia, and respiratory insufficiency.	
Magnesium Dietary sources: vegetables, cereals, nuts.	Kidneys regulate homeostasis by decreasing excretion when intake is low.	Occurs as part of refeeding syndrome with protein-energy malnutrition. Renal disease, malabsorption, or magnesium wasting medications may lead to depletion. May cause secondary hypocalcemia.	Neuromuscular excitability, muscle fasciculation, neurologic abnormalities, ECG changes.	
Sodium Dietary sources: processed foods, table salt.	Hypo- and hypernatremic dehydration are discussed in Chapter 23. Kidneys are primary site of homeostatic regulation.	Results from excess losses associated with diarrhea and vomiting.	Anorexia, vomiting, hypotension, and mental apathy. Severe malnutrition, stress, and hypermetabolism may lead to excess intracellular sodium, affecting cellular metabolism.	
Chloride Dietary sources: table salt or sea salt, seaweed, many vegetables.	Homeostasis is closely linked to sodium. Plays an important role in physiologic mechanisms of kidneys and gut.	Can occur in infants fed low chloride- containing diets, or in children with cystic fibrosis, vomiting, diarrhea, chronic diuretic therapy, or Bartter syndrome.	Associated with failure to thrive and especially poor head growth; anorexia, lethargy, muscle weakness, vomiting, dehydration, hypovolemia. <i>Laboratory findings</i> : may include hypochloremia, hypokalemia, metabolic alkalosis, hyperreninemia.	
Potassium Dietary sources: nuts, whole grains, meats, fish, beans, fruits and vegetables, especially bananas, orange juice.	Kidneys control potassium homeostasis via the aldosterone renin-angiotensin endocrine system. Amount of total body potassium depends on lean body mass.	Occurs in protein-energy malnutrition (eg, total body depletion + refeeding syndrome) and can cause cardiac failure and sudden death if not treated proactively. With loss of lean body mass, excessive potassium is excreted in urine in any catabolic state. Can also occur during acidosis, from diarrhea, and from diuretic use. Hyperkalemia may result from renal insufficiency.	Muscle weakness, mental confusion, arrhythmias.	

ECG, electrocardiogram; Gl, gastrointestinal; HM, human milk; PTH, parathyroid hormone.

Table 11–4. Summary of dietary reference intakes for selected minerals and trace elements.

^aAdequate Intakes (AI). All other values represent the Recommended Dietary Allowances (RDAs). Both the RDA and AI may be used as goals for individual intakes.

Table 11–5. Summary of trace elements.

	De		
Mineral	Causes	Clinical Features	Treatment
Zinc Dietary sources: meats, shellfish, legumes, nuts, and whole-grain cereals. Functions: component of many enzymes and gene transcription factors; plays critical roles in nucleic acid metabolism, protein synthesis, and gene expression; supports membrane structure and function.	Diets low in available zinc (high phytate), unfortified synthetic diets; malabsorptive diseases (enteritis, celiac disease, cystic fibrosis); excessive losses (chronic diarrhea); inborn errors of zinc metabolism (acrodermatitis enteropathica, mammary gland zinc secretion defect). Inadequate intake in breast-fed infants after age 6 mo. Preterm birth and low birth weight are risk factors.	Mild: impaired growth, poor appetite, impaired immunity. Moderate to severe: mood changes, irritability, lethargy, impaired immune function, increased susceptibility to infection; acro- orificial skin rash, diarrhea, alopecia. Response to zinc supplement is gold standard for diagnosis of deficiency; plasma zinc levels are lowered by acute phase response.	1 mg/kg/day of elemental zinc for 2–3 mo (eg, 4.5 mg/kg/day of zinc sulfate salt), given separately from meals and iron supplements. With acrodermatitis enteropathica, 30–50 mg Zn ²⁺ /day (or more) sustains remission.
Copper Dietary sources: meats, shellfish, legumes, nuts, and whole-grain cereals. Functions: vital component of several oxidative enzymes: cytochrome c oxidase (elec- tron transport chain), cytosolic and mitochondrial superoxide dismutase (free radical defense), lysyl oxidase (cross-linking of elastin and collagen), ferroxidase (oxidation of ferrous storage iron prior to transport to bone marrow).	Generalized malnutrition, prolonged PN without supplemental copper, malabsorption, or prolonged diarrhea. Prematurity is a risk factor.	Osteoporosis, enlargement of costochondral cartilages, cupping and flaring of long bone metaphyses, spontaneous rib fractures. Neutropenia and hypochromic anemia resistant to iron therapy. Defect of copper metabolism (Menkes kinky hair syndrome) results in severe CNS disease. Low plasma levels help to confirm deficiency; levels are normally very low in young infants. Age-matched normal data are necessary for comparison. Plasma levels are raised by acute phase response.	1% copper sulfate solution (2 mg of salt) or 500 mcg/day elemental copper for infants.

Table 11–5.	Summary of trace elements.	(Continued)
-------------	----------------------------	-------------

	De		
Mineral	Causes	Clinical Features	Treatment
Selenium Dietary sources: seafood, meats, garlic (geochemical distribution affects levels in foods). Function: essential component of glutathione peroxidase.	Inadequate dietary intake; can occur with selenium-deficient PN. Renal disease. Prematurity	Skeletal muscle pain and tenderness, macrocytosis, loss of hair pigment. Keshan disease, an often fatal cardiomyopathy in infants and children.	Minimum recommended selenium content for full-term infant formulas is 1.5 mcg/100 kcal, and for preterm formulas, 1.8 mcg/100 kcal. PN should be supplemented.
Iodine Dietary source: iodized salt. Typical fortification provides 225 mcg/5 g. Functions: essential component of thyroid hormones; regulates metabolism, growth, and neural development.	Inadequate dietary intake. Maternal iodine deficiency causes endemic neonatal hypothyroidism in 5%–16% of neonates who may have goiter at birth.	Neurologic endemic cretinism (severe mental retardation, deaf mutism, spastic diplegia, and strabismus) occurs with severe deficiency. Myxedematous endemic cretinism occurs in some central African countries where signs of congenital hypothyroidism are present.	Use of iodized salt is effective in preventing goiter. Injections of iodized oil can also be used for prevention.
Fluoride Function: incorporated into the hydroxyapatite matrix of dentin.	Inadequate intake (unfluoridated water supply).	Low intake increases incidence of dental caries.	See Table 11–6 for supplementation guidelines. Excess fluoride intake results in fluorosis.

CNS, central nervous system; PN, parenteral nutrition.

with the exception of vitamin B12. Major dietary sources of the water-soluble vitamins are listed in Table 11–13. Additional salient details are summarized in Tables 11–7, 11–14, and 11–15.

Carnitine is synthesized in the liver and kidneys from lysine and methionine. In certain circumstances (see Table 11–14), synthesis is inadequate, and carnitine can then be considered a vitamin. A dietary supply of other organic compounds, such as inositol, may also be required in certain circumstances.

 Table 11–6.
 Supplemental fluoride recommendations (mg/day).

	Concentration of Fluoride in Drinking Water

^cVegan mother or maternal pernicious anemia.

 $^{\rm d}{\rm lnfant}$ not exposed to sunlight and mother's vitamin D status suboptimal.

^eProphylaxis omitted.

Table 11–8. Effects of vitamin toxicity.

Pyridoxine

Sensory neuropathy at doses > 500 mg/day Niacin

Histamine release → cutaneous vasodilation; cardiac arrhythmias; cholestatic jaundice; gastrointestinal disturbance; hyperuricemia; glucose intolerance

Folic acid

May mask B₁₂ deficiency, hypersensitivity Vitamin C

Diarrhea; increased oxalic acid excretion; renal stones

Vitamin A

(> 20,000 IU/day): Vomiting, increased intracranial pressure (pseudotumor cerebri); irritability; headaches; insomnia; emotional lability; dry, desquamating skin; myalgia and arthralgia; abdominal pain; hepatosplenomegaly; cortical thickening of bones of hands and feet

Vitamin D

(> 50,000 IU/day): Hypercalcemia; vomiting; constipation; nephrocalcinosis

Vitamin E

(> 25–100 mg/kg/day intravenously): Necrotizing enterocolitis and liver toxicity (but probably due to polysorbate 80 used as a solubilizer)

Vitamin K

Lipid-soluble vitamin K: Very low order of toxicity Water-soluble, synthetic vitamin K: Vomiting; porphyrinuria; albuminuria; hemolytic anemia; hemoglobinuria; hyperbilirubinemia (do not give to neonates)

INFANT FEEDING

BREAST-FEEDING

Breast-feeding provides optimal nutrition for the normal infant during the early months of life. The World Health Organization recommends exclusive breast-feeding for approximately the first 6 months of life, with continued breast-feeding along with appropriate complementary foods through the first 2 years of life. Numerous immunologic factors in breast milk (including secretory immunoglobulin A [IgA], lysozyme, lactoferrin, bifidus factor, oligosaccharides, and macrophages) provide protection against GI and upper respiratory infections.

In developing countries, lack of refrigeration and contaminated water supplies make formula feeding hazardous. Although formulas are made to resemble breast milk as closely as possible, they cannot fully replicate the nutritional or immune composition of human milk. Additional differences of physiologic importance continue to be identified. Furthermore, the relationship developed through breastfeeding can be an important part of maternal interactions and provides a source of security and comfort to the infant. Breast-feeding has been reestablished as the predominant initial mode of feeding young infants in the United States. Unfortunately, breast-feeding rates remain low among several subpopulations, including low-income, minority, and young mothers. Many mothers face obstacles in maintaining lactation once they return to work, and rates of breast-feeding at 6 months are considerably less than the goal of 50%. Use of an electric breast pump can help to maintain lactation when mothers and infants are separated for extended periods.

Absolute contraindications to breast-feeding are rare. They include active tuberculosis (in the mother) and galactosemia (in the infant). Breast-feeding is associated with maternal-to-child transmission of human immunodeficiency virus (HIV), but the risk is influenced by duration and pattern of breast-feeding and maternal factors, including immunologic status and presence of mastitis. Complete avoidance of breast-feeding by HIV-infected women is presently the only mechanism to prevent maternal-infant transmission. HIV-infected mothers in developed countries are recommended to refrain from breast-feeding if safe alternatives are available. In developing countries, the use of antiretroviral therapy (ART) and exclusive breastfeeding is encouraged; if ART is not available, avoidance of breast-feeding may be considered. The protection of the child against diarrheal illness and malnutrition may outweigh the risk of HIV transmission via breast milk. In such circumstances, HIV-infected women should be encouraged to exclusively breast-feed for 6 months. Mixed feeding should be avoided because of the increased risk of HIV transmission.

In newborns less than 1750 g, human milk should be fortified to increase protein, calcium, phosphorus, and micronutrient content, as well as caloric density. Breastfed infants with cystic fibrosis can be breast-fed successfully if exogenous pancreatic enzymes are provided. All infants with cystic fibrosis should receive supplemental vitamins A, D, E, K, and sodium chloride. Those with growth faltering should receive caloric supplementation.

American Academy of Pediatrics: In: Schanler RJ, Krebs NF, Mass SB (eds): Breastfeeding Handbook for Physicians. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2014.

Carling SJ et al: Breastfeeding duration and weight gain trajectory in infancy. Pediatrics 2015 Jan;135(1):111–119 [PMID: 25554813].

Support of Breast-Feeding

In developed countries, health professionals play a significant role in supporting and promoting breastfeeding. Perinatal hospital routines and early pediatric care have a great influence on the successful initiation of breast-feeding by promoting prenatal and postpartum education, frequent mother-baby contact after delivery,

Table 11–10.	Summary	of fat-soluble vitamins
	Summary	of fat-soluble vitamins.

		Deficiency		
Vitamin	Absorption/Metabolism	Causes	Clinical Features	
Vitamin A Dietary sources: dairy products, eggs, liver, meats, fish oils. Precursor β-carotene is abundant in yellow and green vegetables. Functions: has critical role in vision, help- ing to form photosensitive pigment rhodopsin; modifies differentiation and proliferation of epithelial cells in respiratory tract; and is needed for glycoprotein synthesis.	Retinol is stored in liver and from there is exported, attached to RBP and prealbumin. RBP may be decreased in liver disease or in protein energy malnutrition. Circulating RBP may be increased in renal failure.	Occurs in premature infants, in association with inadequately supplemented PN; protein-energy malnutrition (deficiency worsened by measles); dietary insufficiency and fat malabsorption.	Night blindness, xerosis, xerophthalmia, Bitot spots, keratomalacia, ulceration and perforation of cornea, prolapse of lens and iris, and blindness; follicular hyperkeratosis; pruritus; growth retardation; increased susceptibility to infection.	
Vitamin K Dietary sources: leafy vegetables, fruits, seeds; synthesized by intestinal bacteria. Functions: necessary for the maintenance of normal plasma levels of coagulation factors II, VII, IX, and X; essential for maintenance of normal levels of the anticoagulation protein C; essential for osteoblastic activity.	Absorbed in proximal small intestine in micelles with bile salts; circulates with VLDL.	Occurs in newborns, especially those who are breast-fed and who have not received vitamin K prophylaxis at delivery; in fat malabsorption syndromes; and with use of unabsorbed antibiotics and anticoagulant drugs (warfarin).	Bruising or bleeding in Gl tract, genitourinary tract, gingiva, lungs, joints, and brain.	

CHAPTER 11

Table 11–10. Summary of fat-soluble vitamins. (Continued)

		Deficiency		
Vitamin	Absorption/Metabolism	Causes	Clinical Features	
Vitamin E Dietary sources: vegetable oils, some cereals, dairy, wheat germ, eggs. Functions: free-radical scavenger, stops oxidation reactions. Located at specific sites in cell membrane to protect polyunsaturated fatty acids in membrane from peroxidation and thiol groups and nucleic acids; also acts as cell membrane stabilizer; may function in electron transport chain; may modu- late chromosomal expression.	Emulsified in intestinal lumen with bile salts; absorbed via passive diffusion; transported by chylomicrons and VLDL.	May occur with preterm birth, cholestatic liver disease, pancreatic insufficiency, abetalipoproteinemia, and short bowel syndrome. Isolated inborn error of vitamin E metabolism. May result from increased consumption during oxidant stress.	Hemolytic anemia; progressive neurologic disorder with loss of deep tendon reflexes, loss of coordination, vibratory and position sensation, nystagmus, weakness, scoliosis, and retinal degeneration.	
 Vitamin D Dietary sources: fortified milk and formulas, egg yolk, fatty fish. Functions: calcitriol, the biologically active form of vitamin D, stimulates intestinal absorption of calcium and phosphate, renal reabsorption of filtered calcium, and mobilization of calcium and phosphorus from bone. 	Normally obtained primarily from cholecalciferol (D_3) produced by UV radiation of dehydrocholesterol in skin. Ergocalciferol (D_2) is derived from UV irradiation of ergosterol in skin. Vitamin D is transported from skin to liver, attached to a specific carrier protein.	Results from a combination of inadequate sunlight exposure, dark skin pigmentation, and low dietary intake. Breast-fed infants are at risk because of low vitamin D content of human milk. Cow's milk and infant formulas are routinely supplemented with vitamin D. Deficiency also occurs in fat malabsorption syndromes. Hydroxylated vitamin D may be decreased by CYP-450– stimulating drugs, hepatic or renal disease, and inborn errors of metabolism.	Osteomalacia (adults) or rickets (children), in which osteoid with reduced calcification accumulates in bone. <i>Clinical findings</i> : craniotabes, rachitic rosary, pigeon breast, bowed legs, delayed eruption of teeth and enamel defects, Harrison groove, scoliosis, kyphosis, dwarfism, painful bones, fractures, anorexia, and weakness. <i>Radiographic findings</i> : cupping, fraying, flaring of metaphyses.	

CYP, cytochrome P; GI, gastrointestinal; PN, parenteral nutrition; PTH, parathyroid hormone; RBP, retinol-binding protein; UV, ultraviolet; VLDL, very low-density lipoproteins.

one-on-one advice about breast-feeding technique, demand feeding, rooming-in, avoidance of bottle supplements, early follow-up after delivery, maternal confidence, family support, adequate maternity leave, and advice about common problems such as sore nipples. Medical providers can modify their own practice patterns and advocate for hospital policies that support breast-feeding.

Very few women are physically unable to nurse their babies, but both maternal and/or infant factors can adversely impact successful initiation of nursing and lactogenesis. The newborn is generally fed ad libitum every 2–3 hours, with longer intervals (4–5 hours) at night. Thus, a newborn infant nurses at least 8–10 times a day, stimulating a generous milk supply. This frequency is not an indication of inadequate lactation. In neonates, a loose stool is often passed with each feeding; later (at age 3–4 months), there may be an interval of several days between stools. Failure to pass several stools a day in the early weeks of breast-feeding suggests inadequate milk intake. Expressing milk using an electric breast pump may be indicated if the mother returns to work or if the infant is preterm, cannot suck adequately, or is hospitalized.

McFadden A et al: Support for healthy breastfeeding mothers with healthy term babies. Cochrane Database Syst Rev Feb 28, 2017;2:CD001141. doi: 10.1002/14651858.CD001141. pub5 [PMID: 28244064].

Technique of Breast-Feeding

Breast-feeding can be started as soon as both mother and baby are stable after delivery, ideally within the first 30–60 minutes (the "golden hour"). Correct positioning and
 Table 11–11.
 Evaluation and treatment of deficiencies of fat-soluble vitamins.

Vitamin Deficiency	Diagnostic Laboratory Findings and Treatment
Vitamin A	<i>Laboratory findings</i> : serum retinol < 20 mcg/dL; molar ratio of retinol:RBP < 0.7 is also diagnostic. <i>Treatment</i> : xerophthalmia requires 5000–10,000 IU/kg/day for 5 day PO or IM; with fat malabsorption, standard dose is 2500–5000 IU. Toxicity effects are listed in Table 11–8.
Vitamin K	<i>Laboratory findings</i> : assess plasma levels of PIVKA or PT. <i>Treatment</i> : Oral: 2.5–5.0 mg/day or IM/IV: 1–2 mg/ dose as single dose.
Vitamin E	Laboratory findings: normal serum level is 3–15 mg/mL for children. Ratio of serum vitamin E to total serum lipid is normally \geq 0.8 mg/g. <i>Treatment</i> : large oral doses (up to 100 IU/kg/day) correct deficiency from malabsorption; for abetalipoproteinemia, 100–200 IU/kg/day are needed.
Vitamin D	Laboratory findings: low serum phosphorus and calcium, high alkaline phosphatase, high serum PTH, low 25-OH-cholecalciferol. American Academy of Pediatrics recommends supplementation, as follows: 400 IU/day for all breast-fed infants, beginning in first 2 mo of life and continuing until infant is receiving \ge 500 mL/day of vitamin D-fortified formula or cow's milk. <i>Treatment</i> : 1600–5000 IU/day of vitamin D ₃ for rickets. If poorly absorbed, give 0.05–0.2 mcg/kg/day of calcitriol.

IM, intramuscular, IV, intravenous; PIVKA, protein-induced vitamin K absence; PO, by mouth; PT, prothrombin time; PTH, parathyroid hormone; RBP, retinol-binding protein.

breast-feeding technique are necessary to ensure effective nipple stimulation and optimal breast emptying with minimal nipple discomfort.

If the mother wishes to nurse while sitting, the infant should be elevated to the height of the breast and turned completely to face the mother, so that their abdomens touch. The mother's arms supporting the infant should be held tightly at her side, bringing the baby's head in line with her breast. The breast should be supported by the lower fingers of her free hand, with the nipple compressed between the thumb and index fingers to make it more protractile. When the infant opens its mouth, the mother should quickly insert as much nipple and areola as possible.

The most common early cause of poor weight gain in breast-fed infants is poorly managed mammary engorgement, which rapidly decreases milk supply. Unrelieved engorgement can result from long intervals between feeding,
 Table 11–12.
 Summary of biologic roles of water-soluble vitamins.

B vitamins involved in production of energy Thiamin (B.)			
Thiamin pyrophosphate is a coenzyme in oxidative decarboxylation (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and transketolase).			
 Riboflavin (B₂) Coenzyme of several flavoproteins (eg, flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]) involved in oxidative/electron transfer enzyme systems. 			
Niacin			
Hydrogen-carrying coenzymes: nicotinamide-adenine dinucleotide (NAD), nicotinamide-adenine dinucleo- tide phosphate (NADP); decisive role in intermediary metabolism.			
Pantothenic acid			
Major component of coenzyme A.			
Biotin			
Component of several carboxylase enzymes involved in			
fat and carbohydrate metabolism.			
Hematopoietic B vitamins			
Folic acid			
Tetrahydrofolate has essential role in one-carbon transfers.			
Essential role in purine and pyrimidine synthesis;			
deficiency \rightarrow arrest of cell division (especially bone			
marrow and intestine).			
Copalamin (B_{12})			
with simultaneous synthesis of tetrahydrofelate (roason			
for megaloblastic anomia in B deficiency). Adenosyl			
cohalamin (mitochondria) is connyme for mutases and			
dehydratases			
Other B vitamins			
Pyridovine (B.)			
Prosthetic group of transaminases, etc. involved in amino			
acid interconversions; prostaglandin and heme synthesis;			
central nervous system function; carbohydrate metabo-			
lism; immune development.			
Other water-soluble vitamins			
I-Ascorbic acid (C)			
Strong reducing agent—probably involved in all			
hydroxylations. Roles include collagen synthesis;			
phenylalanine $ ightarrow$ tyrosine; tryptophan $ ightarrow$			
5-hydroxytryptophan; dopamine \rightarrow norepinephrine; Fe ³⁺ ;			
folic acid \rightarrow folinic acid; cholesterol \rightarrow bile acids; leukocyte			
function; interferon production; carnitine synthesis. Copper			
metabolism; reduces oxidized vitamin E.			

improper infant suckling, a nondemanding infant, sore nipples, maternal or infant illness, nursing from only one breast, and latching difficulties. Poor technique, maternal dehydration, or excessive fatigue can contribute. Some infants may need waking to feed at night. Primary lactation failure occurs in less than 5% of women.
Table 11–13.
 Major dietary sources of water-soluble vitamins.

Thiamin (B₁)

Whole and enriched grains, lean pork, legumes

Riboflavin (B₂)

Dairy products, meat, poultry, wheat germ, leafy vegetables

Niacin (B₃)

Meats, poultry, fish, legumes, wheat, all foods except fats; synthesized in body from tryptophan

Pyridoxine (B₆)

Animal products, vegetables, whole grains

Pantothenic acid

Ubiquitous

Biotin

Yeast, liver, kidneys, legumes, nuts, egg yolks (synthesized by intestinal bacteria)

Folic acid

Leafy vegetables (easily destroyed in cooking), fruits, whole grains, wheat germ, beans, nuts

Cobalamin (B₁₂)

Eggs, dairy products, liver, meats; none in plants

Vitamin C

Fruits and vegetables

Carnitine

Meats, dairy products; none in plants

A sensible guideline for duration of feeding is 5 minutes per breast at each feeding the first day, 10 minutes on each side at each feeding the second day, and 10–15 minutes per side thereafter. A vigorous infant can obtain most of the available milk in 5–7 minutes, but additional sucking time ensures breast emptying, promotes milk production, and satisfies the infant's sucking urge. The side on which feeding is commenced should be alternated. The mother may break suction gently after nursing by inserting her finger between the baby's gums.

Follow-up

Assessment before discharge should identify dyads needing additional support. All mother-infant pairs require early follow-up. The second through fourth days postpartum when milk secretion becomes copious is a critical time. Failure to empty the breasts during this time can cause engorgement, which quickly leads to diminished milk production.

Common Problems

Nipple tenderness requires attention to proper positioning of the infant and correct latch-on. Nursing for shorter periods, beginning feedings on the less sore side, air drying the nipples well after nursing, and use of lanolin cream may provide relief.

Table 11–14. Causes of deficiencies in water-soluble vitamins.

Thiamin

Beriberi: in infants breast-fed by mothers with history of alcoholism
or poor diet; has been described as complication of parenteral
nutrition (PN); protein-energy malnutrition; following bariatric
surgery of all types—reported in adults and adolescents;
endemic deficiency in mothers and infants reported in Asia
where unfortified, refined rice is major food staple
Riboflavin
General undernutrition: inactivation in total parenteral nutrition
(TPN) solutions exposed to light
Niacin
Maize- or millet-based diets (high-leucine and low-tryptophan
intakes); carcinoid tumors
Pyridoxine
Prematurity (these infants may not convert pyridoxine to
pyridoxal-5-P); B _e dependency syndromes; drugs (isoniazid)
Biotin
Suppressed intestinal flora and impaired intestinal absorption;
regular intake of raw egg whites
Folic acid
Breast-fed infants whose mothers are folate-deficient; term
infants fed unsupplemented processed cow's milk or goat's
milk; kwashiorkor; chronic overcooking of food sources;
malabsorption of folate because of a congenital defect; celiac
disease; drugs (phenytoin)
Increased requirements: chronic hemolytic anemias, diarrhea,
malignancies, extensive skin disease, cirrhosis, pregnancy
Cobalamin (B ₁₂)
Breast-fed infants of mothers with latent pernicious anemia
or who are on an unsupplemented vegan diet; absence of
luminal proteases; short gut syndrome (absence of stomach
or ileum); congenital malabsorption of B ₁₂
Vitamin C
Maternal megadoses during pregnancy \rightarrow deficiency in infants
(rebound); diet without fruits or vegetables; seen in infants
fed formula based on pasteurized cow's milk (historical)
Carnitine
Premature infants fed unsupplemented formula or fed
intravenously; dialysis; inherited deficits in carnitine synthesis;
organic acidemias; infants receiving valproic acid

Severe nipple pain and cracking usually indicate improper latch. Temporary pumping may be needed.

Breast-feeding jaundice is exaggerated physiologic jaundice associated with low intake of breast milk, infrequent stooling, and poor weight gain. (See Chapter 2.) If possible, the jaundice should be managed by increasing the frequency of nursing and, if necessary, augmenting the infant's sucking with regular breast pumping. Supplemental feedings may be necessary, but care should be taken not to decrease breast milk production further.

In a small percentage of breast-fed infants, hyperbilirubinemia with jaundice is caused by an unidentified property **Table 11–15.** Clinical features of deficiencies in water-soluble vitamins.

Thiamin (B₁)

- "Dry" Beriberi (paralytic or nervous): peripheral neuropathy, with impairment of sensory, motor, and reflex functions, ophthalmoplegia, vomiting
- "Wet" Beriberi: high output congestive heart failure $\pm\mbox{ signs of }$ dry beriberi
- Cerebral Beriberi: ophthalmoplegia, ataxia, mental confusion, memory loss

Riboflavin

Cheilosis; angular stomatitis; glossitis; soreness and burning of lips and mouth; dermatitis of nasolabial fold and genitals; ± ocular signs (photophobia → indistinct vision)

Niacin

Pellagra (dermatitis, especially on sun-exposed areas; diarrhea; dementia)

Pyridoxine (B₆)

Listlessness; irritability; seizures; anemia; cheilosis; glossitis Biotin

BIOTIN

Scaly dermatitis; alopecia; irritability; lethargy

Folic acid

Megaloblastic anemia; neutropenia; growth retardation; delayed maturation of central nervous system in infants; diarrhea (mucosal ulcerations); glossitis; neural tube defects

Cobalamin (B₁₂)

Megaloblastic anemia; hypersegmented neutrophils; neurologic degeneration: paresthesias, gait problems, depression

Ascorbic acid (C)

Irritability, apathy, pallor; increased susceptibility to infections; hemorrhages under skin, petechiae in mucous membranes, in joints and under periosteum; long bone tenderness; costochondral beading; often presents with refusal to walk secondary to joint pain

Carnitine

Increased serum triglycerides and free fatty acids; decreased ketones; fatty liver; hypoglycemia; progressive muscle weakness, cardiomyopathy, hypoglycemia

of the milk that inhibits conjugation of bilirubin. In severe cases, interruption of breast-feeding for 24–36 hours may be necessary. The mother's breast should be emptied with an electric breast pump during this period.

The symptoms of mastitis include flulike symptoms with breast tenderness, firmness, and erythema. Antibiotic therapy covering β -lactamase–producing organisms should be given for 10 days. Analgesics may be necessary, but breast-feeding should be continued. Breast pumping may be helpful adjunctive therapy.

Maternal Drug Use

Factors playing a role in the transmission of drugs in breast milk include the route of administration, dosage, molecular weight, pH, and protein binding. Generally, any drug prescribed to a newborn can be consumed by the breast-feeding mother without ill effect. Very few drugs are absolutely contraindicated in breast-feeding mothers; these include radioactive compounds, antimetabolites, lithium, diazepam, chloramphenicol, antithyroid drugs, and tetracycline. For up-to-date information, a regional drug center should be consulted.

Maternal use of illicit or recreational drugs may be a contraindication to breast-feeding, but the risks to the infant should be balanced by the benefits of milk and breast-feeding. Expression of milk for a feeding or two after use of a drug is not an acceptable compromise. The breast-fed infants of mothers taking methadone alone as part of a treatment program have generally not experienced ill effects when the dose is less than 40 mg/day.

United States National Library of Medicine Drugs and Lactation Database (Lactmed): http://toxnet.nlm.nih.gov/newtoxnet/ lactmed.htm.

Nutrient Composition

The nutrient composition of human milk is compared to that of cow's milk and formulas in Table 11–16. Outstanding characteristics include (1) relatively low but highly bioavailable protein content, which is adequate for the normal infant; (2) generous quantity of EFAs; (3) longchain polyunsaturated fatty acids, of which DHA is thought to be especially important; (4) relatively low sodium and solute load; and (5) lower concentration of highly bioavailable minerals, which are adequate for the needs of normal breast-fed infants for approximately 6 months.

Complementary Feeding

The AAP and the WHO recommend the introduction of solid foods in normal infants at about 6 months of age. Fortified cereals, fruits, vegetables, and meats should complement the breast milk diet. Meats are an important source of iron and zinc, both of which are low in human milk by 6 months. Pureed meats may be introduced as an early complementary food. Single-ingredient complementary foods are introduced one at a time at 3- to 4-day intervals before a new food is given. Fruit juice should not be introduced until after 6 months; should only be offered in a cup; and the amount should be limited to 4 oz/day. Delaying the introduction of complementary foods beyond 6 months has not been shown to prevent atopic disease. Whole cow's milk can be introduced after the first year of life. Breast-feeding should ideally continue for at least 12 months.

Khan J et al: Timing of breastfeeding initiation and exclusivity of breastfeeding during the first month of life: effects on neonatal mortality and morbidity—a systematic review and meta-analysis. Matern Child Health J 2015 Mar;19(3):468–479 [PMID: 24894730].

^aCommittee on Nutrition, American Academy of Pediatrics.

^bProtein of nutritional quality equal to casein.

^cIncludes 300 mg of essential fatty acids.

While breast milk, dairy, soy, legume, and other vegetable sources of protein can provide adequate protein for growth, vegetarian foods are impractical as sources of iron or zinc. Breast-fed infants or toddlers on a vegetarian diet are at particular risk for inadequate intake of iron and zinc because of relatively high requirements during rapid growth and because animal-based foods are best sources. To meet requirements, infants and toddlers consuming vegetarian diets should be offered fortified foods including cereals and formula or daily supplementation of iron and zinc. A vegan diet that omits all animal protein sources will require supplementation of vitamin B_{12} as well. Guidance from a pediatric registered dietitian is suggested for families seeking for their infant or toddler to follow a vegetarian or vegan diet to ensure adequate protein, calorie, vitamin, and micronutrient intakes.

Results of recent large-scale randomized controlled trials have shifted recommended practice around peanut consumption in infancy by the AAP and National Institute of Allergy and Infectious Diseases (NIAID). For infants with severe eczema or egg allergy but without evidence of active peanut sensitization by skin prick test or specific peanut IgE, introduction of 6–7 g/wk of peanut protein served as a puree is recommended beginning at 4–6 months to reduce the risk of peanut allergy. Infants with less severe eczema are recommended to start consuming peanut purees around 6 months. Furthermore, it was the expert opinion of the NIAID panel that infants without risk factors for food allergy should have age appropriate peanut containing products introduced freely into the diet with other purees and solid foods in a manner consistent with familial and cultural norms.

- Alkis T et al: Addendum guidelines for the prevention of peanut allergy in the United States: Report of the National Institute of Allergy and Infectious Diseases–sponsored expert panel Annals of Allergy, Asthma & Immunology, ePub Dec 2016, [PMID: 28065802].

SPECIAL DIETARY PRODUCTS FOR INFANTS

Soy Protein Formulas

Historically, a common rationale for the use of soy protein formulas was the transient lactose intolerance after acute gastroenteritis. Lactose-free cow's milk protein-based formulas are also now available. The medical indications for soy formulas are rare: galactosemia and hereditary lactase deficiency. Soy formulas provide an option when a vegetarian diet is preferred. Soy protein formulas are often used in cases of suspected intolerance to cow's milk protein, though cow's milk hydrolysate formulas are preferred because 30%–40% of infants intolerant to cow's milk protein will also react to soy protein. In contrast to this T-cell-mediated protein intolerance, those infants with less commonly documented IgE-mediated allergy to cow's milk protein do not typically cross-react to soy formula. The estrogenic properties of isoflavones from soy had raised concern about potential reproductive system effects, but an Expert Committee of the National Toxicology program found minimal concern for potential harm in their 2011 report.

Boyle RJ et al: Hydrolysed formula and risk of allergic or autoimmune disease: systematic review and meta-analysis. BMJ Mar 8, 2016;352:i974 [PMID: 26956579].

Semielemental & Elemental Formulas

Semielemental formulas include protein hydrolysate formulas. The major nitrogen source of most of these products is casein hydrolysate, supplemented with selected amino acids, but partial hydrolysates of whey are also available. These formulas contain an abundance of EFA from vegetable oil; certain brands also provide substantial amounts of MCTs. Elemental formulas are available with free amino acids and varying levels and types of fat components.

Semielemental and elemental formulas are invaluable for infants with a wide variety of malabsorption syndromes. They are also effective in infants who cannot tolerate cow's milk and soy protein. Controlled trials suggest that for infants with a family history of atopic disease, partial hydrolysate formulas may delay or prevent atopic disease compared to standard cow milk protein-based formula.

Goldsmith AJ et al: Formula and breast-feeding in infant food allergy: a population-based study. J Paediatr Child Health Apr 2016;52(4):377–384. doi: 10.1111/jpc.13109 [PMID: 27145499].

Formula Additives

Occasionally, it may be necessary to increase the caloric density of an infant feeding to provide more calories or to restrict fluid intake. Concentrating formula to 24–26 kcal/oz is usually well tolerated, delivers an acceptable renal solute load, and increases the density of all the nutrients. Beyond this, individual macronutrient additives (Table 11–17) are usually employed to achieve the desired caloric density (up to 30 kcal/oz) based on the infant's needs and underlying condition(s). A pediatric dietitian can provide guidance in formulating calorically dense infant formula feedings. The caloric density of breast milk can be increased by adding infant formula. Because of their specialized nutrient composition, human milk fortifiers are generally used only for preterm infants.

Additive	Kcal/g	Kcal/Tbsp	Kcal/mL	Comments
Dry rice cereal	3.75	15	_	Thickens formula but not breast milk
Benecalorie (Nestle)	7.3	110	7.3	High-calorie liquid supplement; calcium caseinate, high oleic sunflower oil, mono- and di-glycerides
MCT oil (Mead Johnson)	8.3	116	7.7	Not a source of essential fatty acids
Microlipid (Nestle)	9	68.5	4.5	Safflower oil emulsion with 0.4 g linoleic acid/mL; mixes easily with enteral formulas
Vegetable oil	9	124	8.3	Does not mix well
Beneprotein (Nestle)	3.6	16.7 (4 g protein);	_	Whey protein, soy lecithin (25 kcal/scoop); 1 scoop = 7 g
Duocal (Nutricia)	4.9	42	—	Protein-free mix of hydrolyzed corn starch (60% kcal) and fat (35% MCT)

 Table 11–17.
 Common infant formula additives.

MCT, medium-chain triglyceride.

Special Formulas

Special formulas are those in which one component, often an amino acid, is reduced in concentration or removed for the dietary management of a specific inborn metabolic disease. Also included under this heading are formulas designed for specific disease states, such as hepatic failure, pulmonary failure with chronic carbon dioxide retention, and renal failure. These condition-specific formulas were formulated primarily for critically ill adults and are used sparingly in those populations; thus, they should be used in pediatrics only with clear indication and caution.

Complete information regarding the composition of formulas can be found in reference texts and in the manufacturers' literature.

American Academy of Pediatrics Committee on Nutrition: In: Kleinman RE, Greer FR (eds): *Pediatric Nutrition*. 7th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2014.

NUTRITION FOR CHILDREN 2 YEARS & OLDER

Because diet impacts the development of chronic diseases such as diabetes, obesity, and cardiovascular disease, learning healthy eating behaviors at a young age is an important preventative measure.

Salient features of the diet for children older than 2 years include the following:

- 1. Three regular meals per day, and one or two healthful snacks.
- 2. *A variety of foods*: diet should be nutritionally complete and promote optimal growth and activity.

- 3. Fat less than 35% of total calories (severe fat restriction < 10% may result in an energy deficit and growth failure). Saturated fats should provide less than 10% of total calories. Monounsaturated fats should provide 10% or more of caloric intake. Trans-fatty acids should provide less than 1% of total calories.
- 4. Cholesterol intake less than 100 mg/1000 kcal/day, to a maximum of 300 mg/day.
- 5. Carbohydrates should provide 45%–65% of daily caloric intake, less than 10% in the form of simple sugars. A high-fiber, whole-grain–based diet is recommended.
- 6. Limitation of grazing behavior, eating while watching television, and the consumption of soft drinks and other sweetened beverages.
- 7. Limitation of sodium intake by limiting processed foods and added salt.
- 8. Consumption of lean cuts of meats, poultry, and fish should be encouraged. Skim or low-fat milk, and vegetable oils (especially canola or olive oil) should be used. Plentiful amounts of fruits and vegetables are recommended. The consumption of processed foods, sugar-sweetened drinks, desserts, and candy should be limited. The American Academy of Pediatrics has endorsed use of low-fat milk in children after 12 months of age.

Lifestyle counseling for children should also include maintenance of a BMI in the healthy range; regular physical activity, limiting sedentary behaviors; avoidance of smoking; and screening for hypertension at age 3 years. Current recommendations from the National Heart Lung and Blood Institute are to routinely screen all children for familial hyperlipidemia using a fasting or nonfasting lipid panel once at age 9–11, and to consider screening children at younger ages who have additional risk factors (obesity, diabetes, family history of premature cardiovascular disease). The preferred time for screening occurs before puberty, a period in which hormonal changes render lipids unreliable in predicting levels in adulthood.

PEDIATRIC UNDERNUTRITION

- Poor weight gain or weight loss.
- Loss of subcutaneous fat, temporal wasting.
- Most commonly related to inadequate caloric intake.
- In toddlers, often associated with low iron and zinc status.

General Considerations

Pediatric undernutrition is usually multifactorial in origin, and successful treatment depends on accurate identification and management of those factors. The terms "organic" and "nonorganic" failure to thrive, though still used by many medical professionals, are not helpful because any systemic illness or chronic condition can cause growth impairment and yet may also be compounded by psychosocial problems.

Clinical Findings

A. Definitions

Failure to thrive is an imprecise term used to describe growth faltering in infants and young children whose weight curve has fallen by two major percentile channels from a previously established rate of growth, or whose weight for length falls below the 5th percentile. (See Chapter 9.) The World Health Organization growth charts (http://www.who .int/childgrowth/en/) should be used for all infants, as these charts reflect the slower velocity of weight gain for healthy breast-fed infants without formula supplementation. Differences in weight gain are particularly notable after 6 months of age. The acute loss of weight, or failure to gain weight at the expected rate, produces a condition of reduced weight for height known as *wasting*. The reduction in height for age, as is seen with more chronic malnutrition, is termed *stunting*.

The typical pattern for mild pediatric undernutrition is decreased weight, with normal height and head circumference. In more chronic malnutrition, linear growth will slow relative to the standard for age, although this should also prompt consideration of nonnutritional etiologies. Significant calorie deprivation produces severe wasting, called *marasmus* (< 3 SD weight for height). The term **severe acute malnutrition (SAM)** has generally replaced the term protein energy malnutrition. Significant protein deprivation in the face of adequate energy intake, possibly with additional insults such as infection, may produce edematous malnutrition called *kwashiorkor*.

B. Risk Factors

Multiple medical conditions can cause pediatric undernutrition, and a thorough discussion is beyond the scope of this chapter. However, the most common cause is inadequate dietary intake. In young infants, a weak or uncoordinated suck may be the causative factor. Congenital heart disease, breathing problems (eg, laryngomalacia), and other physical problems that may interfere with normal feeding. Inappropriate formula mixing or a family's dietary beliefs may lead to hypocaloric or unbalanced dietary intakes. Diets restricted because of suspected food allergies or intolerances may result in inadequate intake of calories, protein, or specific micronutrients. Deficiencies of iron or zinc occur in older breast-fed infants whose diets are low in meats or fortified foods, and in toddlers not taking fortified formula or not consuming good dietary sources. Cases of severe malnutrition and kwashiorkor have occurred in infants of parents who substitute milk alternatives (eg, rice, hemp or almond milk or unfortified soy milk) for infant formula. Such plant source "milks" are hypocaloric, provide an incomplete protein source (ie, low in quality and quantity of protein), and are not adequately fortified with all essential micronutrients to meet infant requirements.

C. Assessment

- Measurement of weight for age; length/height for age; occipital frontal circumference (OFC) for age (for < 2 years age), weight for length; and calculation of percent ideal body weight (current weight/median weight [50th percentile] for current length). Assess for downward crossing of growth percentiles (acute malnutrition) and for linear growth stunting (chronic malnutrition).
- History should include details of diet intake and feeding patterns (including restrictive intake, grazing feeding pattern, inappropriate foods for age and development, excessive juice, sugar-sweetened beverages, or

CHAPTER 11

water intake); past medical history, including birth and developmental history; family history; social history; and review of systems.

- 3. Physical examination should include careful examination of skin (for rashes), mouth, eyes, nails, and hair for signs of micronutrient and protein deficiencies, as well as for abnormal neurologic function (eg, loss of deep tendon reflexes, abnormal strength and tone).
- 4. Laboratory studies are generally of low yield for diagnosis for growth faltering in the absence of other findings, and should be reserved for moderately severe cases of malnutrition. In such cases, risk of and suspicion for nutrient deficiencies and systemic pathology should guide studies ordered. Typical screening laboratories include chemistry panel; complete blood count; and iron panel, including ferritin (and marker of inflammation, eg, CRP or ESR). Thyroid function testing is indicated with linear growth faltering. Serology for celiac disease may also be warranted for toddlers, especially with short stature or linear growth faltering. Guidelines for screening for inborn errors of metabolism are available.
- Some infants are naturally small and have weight for 5. age percentile values below the 5th percentile and may have length and head circumferences at higher percentiles. Such infants are often called "constitutionally small," as their thinness was present from birth, there was no evidence of intrauterine growth restriction, their mothers had small stature and usually thinness, and the family growth pattern is similar. Mothers of such normally small children should not be discouraged from breast-feeding and should not be counseled to prematurely add food supplements. Workup for failure to thrive is not indicated in these infants and evaluations or referrals for growth failure or child neglect from underfeeding are not warranted.

When providing nutritional rehabilitation to infants/ children with severe malnutrition, refeeding syndrome may occur. Monitoring for hypophosphatemia, hypokalemia, hypomagnesemia, and hyperglycemia is prudent for the first ~3 days of nutritional rehabilitation (until stable), and calorie intake should be slowly increased to avoid metabolic instability.

Treatment

Poor eating is often a learned behavior. Families should be counseled regarding choices of foods that are appropriate for the age and developmental level of the child. Increasing the caloric density of foods is associated with increased daily caloric intake and improved weight gain. Food sources should contain both fat and protein to achieve repletion of both lean body mass and fat stores. Micronutrient deficiencies should be corrected. For repletion of iron, 3-6 mg/kg/day, divided BID, can be initiated if acute inflammation has been excluded. Acute inflammation should be allowed to resolve prior to initiating iron supplementation. For zinc, 1 mg/kg/day for 1-2 months, ideally administered several hours apart from iron supplement, is typically adequate. Children should have structured meal times (eg, three meals and two to three snacks during the day), ideally at the same time other family members eat. Consultation with a pediatric dietitian can be helpful for educating the families. Poor feeding may be related to family dysfunction. Children whose households are chaotic and children who are abused, neglected, or exposed to poorly controlled mental illness may be described as poor eaters, and may fail to gain. Careful assessment of the social environment of such children is critical, and disposition options may include support services, close medical follow-up visits, family counseling, and even foster placement while a parent receives therapy.

Kerzner B et al: A practical approach to classifying and managing feeding difficulties. Pediatrics 2015 Feb;135(2):344–353 [PMID: 25560449].

PEDIATRIC OVERWEIGHT & OBESITY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Excessive rate of weight gain; upward change in BMI percentiles (See also Chapter 3 for obesity in adolescents).
- BMI for age between the 85th and 95th percentiles indicates overweight.
- BMI for age greater than 95th percentile indicates obesity and is associated with increased risk of secondary complications.
- BMI for age greater than 99th percentile, or a BMI that exceeds 120% of the 95th percentile, indicates severe obesity and a higher risk of complications.

General Considerations

The prevalence of childhood and adolescent obesity has increased rapidly in the United States and many other parts of the world. Currently in the United States, approximately 17% of 6- to 19-year-olds are obese, with even higher rates among subpopulations of minority and economically disadvantaged children. The increasing prevalence of

Bouma S: Diagnosing pediatric malnutrition. Nutr Clin Pract Feb 2017;32(1):52–67. doi: 10.1177/0884533616671861 [PMID: 27765878].

childhood obesity is related to a complex combination of socioeconomic, genetic, and biologic factors.

Childhood obesity, especially when severe, is associated with significant comorbidities. The probability of obesity persisting into adulthood has been estimated to increase from 20% at 4 years to 80% by adolescence. Rates of persistence from early childhood are much higher when one or both parents are obese. Obesity is associated with cardiovascular and endocrine abnormalities (eg, dyslipidemia, insulin resistance, and type 2 diabetes), orthopedic problems, pulmonary complications (eg, obstructive sleep apnea), and mental health problems (Table 11–18).

Kumar S et al: Review of childhood obesity: from epidemiology, etiology, and comorbidities to clinical assessment and treatment. Mayo Clin Proc Feb 2017;92(2):251–265. doi: 10.1016/j. mayocp.2016.09.017 [PMID: 28065514].

Clinical Findings

A. Definitions

BMI is the standard measure of obesity in adults and children. BMI is correlated with more accurate measures of body fatness and is calculated with readily available information: weight and height (kg/m²). Routine plotting of the BMI on age- and gender-appropriate charts (http:// www.cdc.gov/growthcharts) can identify those with excess weight. BMI between the 85th and 95th percentiles for age and sex identifies those who are overweight. Obese is defined as BMI at or above 95% and is associated with increased risk of secondary complications. Severe obesity is characterized by BMI for age and sex at or above the 99th percentile and is associated with greatly increased risk of comorbidity. An alternate definition of severe obesity recommended by the American Heart Association numerically approximates the 99th percentile, but provides a framework for clinicians to better gauge progress numerically for children with severe obesity. This standard defines severe obesity class 2 as above 120% of the 95th percentile for a given age and gender, and severe obesity class 3 as above 140% of the 95th percentile. The degree of obesity as a percent of the 95th percentile can be tracked on special growth charts created for this purpose, which offer an advantage for tracking progress over percentiles that are constrained by the 100th percentile. An upward change in BMI percentiles in any range should prompt evaluation and possible treatment. For children younger than 2 years, weight for length greater than 95th percentile indicates overweight and warrants further assessment, especially of energy intake and feeding behaviors.

B. Risk Factors

There are multiple risk factors for developing obesity, reflecting the complex relationships between genetic and

environmental factors. Family history is a strong risk factor. Parental obesity, especially in both parents, strongly increases the odds of a child becoming an obese adult.

Risk factors in the home environment offer targets for intervention. Consumption of sugar-sweetened beverages, lack of family meals, large portion sizes, foods prepared outside the home, television viewing, video gaming, poor sleep, and lack of activity are all associated with risk of excessive weight gain.

C. Assessment

Early recognition of rapid weight gain or high-risk behaviors is important. Anticipatory guidance or intervention earlier in childhood and before weight gain becomes severe is more likely to be successful than delayed intervention. Routine evaluation at well-child visits should include:

- Measurement of weight and height, calculation of BMI, and plotting all three parameters on age- and sex-appropriate growth charts (http://www.cdc.gov/ growthcharts). Evaluate for upward crossing of BMI percentile channels.
- 2. History regarding diet and activity patterns (Table 11–19); family history, and review of systems. Physical examination should include blood pressure measurement, distribution of adiposity (central vs generalized); markers of comorbidities, such as acanthosis nigricans, hirsutism, hepatomegaly, orthopedic abnormalities; and physical stigmata of genetic syndromes (eg, Prader-Willi syndrome).
- 3. Laboratory studies are recommended as follows for children beginning by age 10 years or at onset of puberty. Consider testing at younger ages with severe obesity but not younger than 2 years:
 - Overweight with personal or family history of heart disease risk factors—fasting lipid profile, fasting glucose and/or hemoglobin A_{1c}, alanine aminotransferase (ALT).
 - Obese—fasting lipid profile, fasting glucose and/or hemoglobin A_{1c}, ALT.
 - Other studies should be guided by findings in the history and physical.

Treatment

Treatment should be based on risk factors, including age, severity of obesity, and comorbidities, as well as family history. For children with uncomplicated obesity, the primary goal is to achieve healthy eating and activity patterns, not necessarily to achieve ideal body weight. For children with a secondary complication, improvement of the complication is an important goal. In general, weight goals for obese children range from weight maintenance up to

Table 11–18. S	Selected complications	of childhood obesity.
----------------	------------------------	-----------------------

System	Condition	Note	Review of Systems
Pulmonary	Obstructive sleep apnea	13%–33% of obese youth	Snoring, apnea, poor sleep, nocturnal enuresis, AM headaches, fatigue, poor school performance
	Obesity-hypoventilation syndrome	Severe obesity, restrictive lung disease, may lead to right heart failure	Dyspnea, edema, somnolence
Cardiovascular	Hypertension	3 occasions > 95th percentile on NHLBI tables for gender, age, and height	
	Lipid abnormalities	Total cholesterol 170–199 borderline, > 200 high LDL 110–129 borderline, > 130 high HDL < 40 low	
		TG > 150 high	Assess for pancreatitis if TG > 400, nausea, vomiting, abdominal pain
GI	NAFLD	10%–25% of obese youth; elevated ALT; rule out other liver disease; steatohepatitis may progress to fibrosis, cirrhosis	Commonly asymptomatic; rarely abdominal pain: vague, recurrent,
	GERD	Increased abdominal pressure	Abdominal pain: heartburn
	Gallstones	Associated with rapid weight loss	Abdominal pain: right upper or epigastric
	Constipation	Associated with inactivity, r/o encopresis	Abdominal pain: distension, hard infrequent stools, soiling/incontinence
Endocrine	Impaired glucose metabolism	Elevated fasting glucose = 100–125	Acanthosis nigricans
		Impaired glucose tolerance = 2-h OGTT 140–199	
	Type 2 diabetes (T2DM)	Random glucose > 200 with symptoms; Fasting glucose > 126, 2-h OGTT > 200, HgA _{1c} > 6.5	Polyuria and polydipsia, unintentional weight loss
	Polycystic ovarian syndrome (PCOS)	 Two of three: Hyperandrogenism Oligomenorrhea Polycystic ovaries; insulin resistance; risk of infertility and endometrial cancer 	Oligomenorrhea (> 9 menses/y), hyperandrogenism: hirsutism, acne
	Hypothyroid	Associated with poor linear growth	Asymptomatic until uncompensated: linear growth failure, cold intolerance, decline in school performance, coarse features, thin hair
Neurology/ ophthalmology	Pseudotumor cerebri	Papilledema, vision loss possible, consult neuro/ophthalmology	Headaches (severe, recurrent), often worse in AM
Orthopedic	Blount disease	Stress injury to medial tibial growth plate, often painless	Bowed legs, \pm knee pain
	SCFE	More likely to progress to bilateral disease in obese	Hip, groin, or knee pain; limp with leg held in external rotation
Dermatology	Acanthosis nigricans	Secondary effect of elevated insulin	Darkening of skin on neck, axillae, groin, \pm skin tags
	Intertrigo/furunculosis/ panniculitis	Examine skin folds, pannus; bacteria, and/or yeast	Rash/infection in skin folds, inflammatory papules
	Hydradenitis suppurativa	Draining cysts in axillae or groin	Rash/infection in skin folds, blocked glands, recurrent and unrelenting

ALT, alanine aminotransferase; GERD, gastroesophageal reflux disease; GI, gastrointestinal; HDL, high-density lipoprotein; HgA_{1c}, hemoglobin A_{1c}. LDL, low-density lipoprotein; NAFLD, nonalcoholic fatty liver disease; NHLBI, National Heart, Lung, and Blood Institute; OGTT, oral glucose tolerance test; SCFE, slipped capital femoral epiphysis; T2DM, type 2 diabetes mellitus; TG, triglycerides.

1 lb/mo weight loss for those younger than 12 years up to 2 lb/wk for those older than 12 years. More rapid weight loss should be monitored for pathologic causes that may be associated with nutrient deficiencies and linear growth stunting (Table 11–20).

Treatment focused on behavior changes in the context of family involvement has been associated with sustained weight loss and decreases in BMI. Clinicians should assess the family's readiness to take action. Motivational interviewing techniques can be helpful with resistant or ambivalent families to promote readiness. These techniques include open-ended questioning, exploring and resolving the family's ambivalence toward changes, and accepting the family's resistance nonjudgmentally. Providers should engage the family in collaborative decision making about which behavior change goals will be targeted. Improving dietary habits and activity levels concurrently is desirable for successful weight management. The entire family should adopt healthy eating patterns, with parents modeling healthy

 Table 11–19.
 Suggested areas for assessment of diet and activity patterns.

n	F	ot
υ	L	eι

- Portion sizes: adult portions for young children
- Frequency of meals away from home (restaurants or takeout)
- Frequency/amounts of sugar-sweetened beverages (soda, juice drinks)
- Meal and snack pattern: structured vs grazing, skipping meals
- Frequency of eating fruits and vegetables
- Frequency of family meals
- Television viewing while eating

Activity

- Time spent in sedentary activity: television, video games, computer
- Time spent in vigorous activity: organized sports, physical education, free play
- Activities of daily living: walking to school, chores, yard work
- Sleep duration: risk of obesity is increased with inadequate sleep

food choices, controlling foods brought into the home, and guiding appropriate portion sizes. The American Academy of Pediatrics recommends no television for children younger than 2 years, a maximum of 2 h/day of television and video games for older children, with lower levels recommended for children during attempts at BMI reduction.

A "staged approach" for treatment has been proposed, with the initial level depending on the severity of overweight, the age of the child, the readiness of the family to implement changes, the preferences of the parents and child, and the skills of the health care provider.

- 1. *Prevention plus*: Counseling regarding problem areas identified by screening questions (see Table 11–19); emphasis on lifestyle changes, including healthy eating and physical activity patterns.
- 2. *Structured weight management*: Provides more specific and structured dietary pattern, such as meal planning, exercise prescription, and behavior change goals. This

Age (y)	BMI	Weight Change Goal to Achieve BMI < 85%
2–5	85%-94%	Maintain weight
	95%–98%	Maintain weight, or if complications lose 1 lb/mo
	99%	Lose 1 lb/mo
6–11	85%-94%	Maintain weight
	95%–98%	Lose 1 lb/mo
	99%	Lose 2 lb/wk
12–18	85%-95%	Maintain weight
	95%-98%	Lose 2 lb/wk
	99%	Lose 2 lb/wk

Table 11–20. Weight management goals.

BMI, body mass index.

CHAPTER 11

may be done in the primary care setting. Generally referral to at least one ancillary health professional will be required: dietitian, behavior specialist, and/or physical therapist. Monitoring is monthly or tailored to patient and family's needs.

- 3. *Comprehensive multidisciplinary*: This level further increases the structure of therapeutic interventions and support, employs a multidisciplinary team, and may involve weekly group meetings.
- 4. Tertiary care intervention: This level is for patients who have not been successful at the other intervention levels or who are severely obese. Interventions are prescribed by a multidisciplinary team, and may include intensive behavior therapy, specialized diets, medications, and surgery.

Pharmacotherapy can be an adjunct to dietary, activity, and behavioral treatment, but by itself it is unlikely to result in significant or sustained weight loss. Only one medication is approved for obesity treatment in adolescents: orlistat, a lipase inhibitor, is approved for patients older than 12 years. For severely obese adolescents, particularly with comorbidities, bariatric surgery is performed in some centers. In carefully selected and closely monitored patients, surgery can result in significant weight loss with a reduction in comorbidities.

Desai NK et al: Update on Adolescent Bariatric Surgery. Endocrinol Metab Clin North Am Sep2016;45(3):667–676. doi: 10.1016/j.ecl.2016.04.015 [PMID: 27519138].

NUTRITION SUPPORT

ENTERAL

Indications

Enteral nutrition support is indicated when a patient cannot adequately meet nutritional needs by oral intake alone and has a functioning GI tract. This method of support can be used for short- and long-term delivery of nutrition. Even when the gut cannot absorb 100% of nutritional needs, some enteral feedings should be attempted. Enteral nutrition, full or partial, has many benefits:

- 1. Maintaining gut mucosal integrity
- 2. Preserving gut-associated lymphoid tissue
- 3. Stimulating gut hormones and bile flow

Access Devices

Nasogastric feeding tubes can be used for supplemental enteral feedings, but generally are not used for more than 6 months because of the complications of otitis media and sinusitis. Initiation of nasogastric feeding usually requires a brief hospital stay to ensure tolerance to feedings and to allow for parental instruction in tube placement and feeding administration.

If long-term feeding support is anticipated, a more permanent feeding device, such as a gastrostomy tube, may be considered. Referral to a home care company is necessary for equipment and other services such as nursing visits and dietitian follow-up.

Table 11–21 suggests appropriate timing for initiation and advancement of drip and bolus feedings, according to a child's age. Clinical status and tolerance to feedings should ultimately guide their advancement.

Monitoring

Monitoring the adequacy of enteral feeding depends on nutritional goals. For critically ill patients in the intensive care unit, provision of enteral nutrition in the first 48 hours is associated with lower mortality. Even when calorie and protein goals cannot be met, provision of more than 60% protein goals enterally is associated with lower odds of mortality in mechanically ventilated children. Evaluating normal growth parameters in critically ill infants and children can be skewed by fluid status changes and loss of muscle mass. While weight and linear growth must still be followed,

Table 11–21. Guidelines for the initiation and advancement of tube feedings.

	Drip Feeds Age Initiation Advancement		Bolus Feeds	
Age			Initiation (mL)	Advancement
Preterm	1–2 mL/kg/h	5–10 mL/kg q8–12 h over 5–7 day as tolerated	10–20 mL/kg	20–30 mL/kg/day as tolerated
Birth–12 mo	5–10 mL/h	5–10 mL q2–8 h	10–60	20–40 mL q3–4 h
1–6 у	10–15 mL/h	10–15 mL q2–8 h	30–90	30–60 mL q feed
6–14 y	15–20 mL/h	10–20 mL q2–8 h	60–120	60–90 mL q feed
> 14 y	20–30 mL/h	20–30 mL q2–8 h	60–120	60–120 mL q feed

other measures such as mid-arm muscle circumference may provide another measure to assess nutritional adequacy. Frequent assessment of anthropometrics, medical status changes, biochemical indices, and tolerance to enteral feeds with documentation of delivered nutrition intake versus goal intake is essential in managing this nutritionally challenging population.

For more stable hospitalized young infants and malnourished children, growth data should be regularly obtained and evaluated based on age appropriate growth charts. Hydration status should be assessed carefully at the initiation of enteral feeding and regularly thereafter. Either constipation or diarrhea can be problems, and attention to stool frequency, volume, and consistency can help guide management. When diarrhea occurs, factors such as infection, hypertonic enteral medications, antibiotic use, and alteration in normal gut flora should be addressed.

In medically stable patients, the enteral feeding schedule should be developmentally appropriate (eg, 5–6 small feedings/day for a toddler). When night drip feedings are used in conjunction with daytime feeds, it is suggested that less than 50% of goal calories be delivered at night so as to maintain a daytime sense of hunger and satiety. This will be especially important once a transition to oral intake begins.

Mehta NM et al: Adequate enteral protein intake is inversely associated with 60-d mortality in critically ill children: a multicenter, prospective, cohort study. Am J Clin Nutr Jul 2015;102(1): 199–206. doi: 10.3945/ajcn.114.104893 [PMID: 25971721].
Mikhailov TA et al: Early enteral nutrition is associated with lower mortality in critically ill children. JPEN J Parenter Enteral Nutr 2014 May;38(4):459–466 [PMID: 24403379].

PARENTERAL NUTRITION

Indications

A. Peripheral Parenteral Nutrition

Peripheral parenteral nutrition is indicated when complete enteral feeding is temporarily impossible or undesirable. Short-term partial intravenous (IV) nutrition via a peripheral vein is a preferred alternative to administration of dextrose and electrolyte solutions alone. Because of the osmolality of the solutions required, it is usually impossible to achieve total calorie and protein needs with parenteral nutrition via a peripheral vein.

B. Total Parenteral Nutrition

Total parenteral nutrition (TPN) should be provided only when clearly indicated. Apart from the expense, numerous risks are associated with this method of feeding (see the section Complications). Even when TPN is indicated, every effort should be made to provide at least a minimum of nutrients enterally to help preserve the integrity of the GI mucosa and of GI function.

The primary indication for TPN is the loss of function of the GI tract that prohibits the provision of required nutrients by the enteral route. Important examples include short bowel syndrome, some congenital defects of the GI tract, and prematurity.

In recent years, a number of injectable essential nutrients have been in short supply in the US pharmaceutical market. Shortages have included IV lipids, multivitamins mixtures, and trace minerals. Deficiencies of these micronutrients have led to significant medical morbidity. Nutrition support teams should develop clinical guidelines to ensure injectable micronutrients are available for those patients who have the greatest need, for example, preterm infants and children with long-term dependence upon TPN. Policies to promote use of enteral micronutrient preparations can also help to reduce the reliance on parenteral supplies.

Fivez T et al: Evidence for the use of parenteral nutrition in the pediatric intensive care unit. Clin Nutr Feb 2017;36(1):218–223. doi: 10.1016/j.clnu.2015.11.004 [PMID: 26646358].

Catheter Selection & Position

An indwelling central venous catheter is preferred for long-term IV nutrition. For periods of up to 3–4 weeks, a percutaneous central venous catheter threaded into the superior vena cava from a peripheral vein can be used. For the infusion of dextrose concentrations higher than 12.5%, the tip of the catheter should be located in the superior vena cava. Catheter positioning in the right atrium has been associated with complications, including arrhythmias and thrombus. After placement, a chest radiograph must be obtained to check catheter position. If the catheter is to be used for nutrition and medications, a double-lumen catheter is preferred.

Complications

A. Mechanical Complications

- 1. Related to catheter insertion or to erosion of catheter through a major blood vessel: Complications include trauma to adjacent tissues and organs, damage to the brachial plexus, hydrothorax, pericardial effusion with potential cardiac tamponade, pneumothorax, hemothorax, and cerebrospinal fluid penetration. The catheter may slip during dressing or tubing changes, or the patient may manipulate the line.
- Clotting of the catheter: Addition of heparin (1000 U/L) to the solution is an effective means of preventing this complication. If an occluded catheter does not respond to heparin flushing, recombinant tissue plasminogen activator may be effective.

CHAPTER 11

3. Related to composition of infusate: Calcium phosphate precipitation may occur if excess amounts of calcium or phosphorus are administered. Factors that increase the risk of calcium phosphate precipitation include increased pH and decreased concentrations of amino acids. Precipitation of medications incompatible with TPN or lipids can also cause clotting.

B. Septic Complications

Septic complications are the most common cause of nonelective catheter removal, but strict use of aseptic technique and limiting entry into the catheter can reduce the rates of line sepsis. Fever over 38–38.5°C in a patient with a central catheter should be considered a line infection until proved otherwise. Cultures should be obtained and IV antibiotics empirically initiated. Removing the catheter may be necessary with certain infections (eg, fungal), and catheter replacement may be deferred until infection is treated.

C. Metabolic Complications

Many of the metabolic complications of IV nutrition are related to deficiencies or excesses of nutrients in administered fluids, whereas uncommon, specific deficiencies still occur, especially in the preterm infant. Safe and effective IV nourishment requires attention to the nutrient balance, electrolyte composition, and delivery rate of the infusate and careful monitoring, especially when the composition or delivery rate is changed. The most challenging metabolic complication is cholestasis, particularly common in preterm infants of very low birth weight with prolonged feeding intolerance, infants with congenital gut disorders requiring surgery, such as those with gastroschisis, and infants with short gut syndrome following surgical resections for disorders such as necrotizing enterocolitis. See discussion on parenteral nutrition-associated cholestasis (PNAC) in Chapter 22 for details.

Fivez T et al: Early versus late parenteral nutrition in critically ill children. N Engl J Med Mar 24, 2016;374(12):1111–1122. doi: 10.1056/NEJMoa1514762 [PMID: 26975590].

NUTRIENT REQUIREMENTS & DELIVERY

Energy

When patients are fed intravenously, no fat and carbohydrate intakes are unabsorbed, and no energy is used in nutrient absorption. These factors account for at least 7% of energy in the diet of the enterally fed patient. The intravenously fed patient usually expends less energy in physical activity. Average energy requirements may therefore be lower in children fed intravenously, by a total of 10%–15%. Caloric guidelines for the IV feeding of infants and young children are outlined below.

The guidelines are averages, and individuals vary considerably. Factors significantly increasing the energy requirement estimates include exposure to cold environment, fever, sepsis, burns, trauma, cardiac or pulmonary disease, and catch-up growth after malnutrition.

With few exceptions, such as some cases of respiratory insufficiency, at least 50%–60% of energy requirements are provided as glucose. Up to 40% of calories may be provided by IV fat emulsions.

Dextrose

The energy density of IV dextrose (monohydrate) is 3.4 kcal/g. Dextrose is the main energy source provided by total IV feeding. IV dextrose suppresses gluconeogenesis and can be oxidized directly, especially by the brain, red and white blood cells, and wounds. Because of the high osmolality, concentrations of dextrose greater than 10%–12.5% cannot be delivered via a peripheral vein or improperly positioned central line.

Dosing guidelines: The standard initial quantity of dextrose administered will vary by age (Table 11–22). Tolerance to IV dextrose normally increases rapidly due to suppression of hepatic glucose production. Dextrose can be increased by 2.5 g/kg/day, by 2.5%–5%/day, or by 2–3 mg/kg/min/day if there is no glucosuria or hyperglycemia. Standard final infusates for infants via a properly positioned central venous line usually range from 15% to 25% dextrose, though concentrations of up to 30% dextrose may be used at low flow rates. Tolerance to IV dextrose loads is markedly diminished in the preterm neonate and in hypermetabolic states.

Problems associated with IV dextrose administration include hyperglycemia, hyperosmolality, and glucosuria (with osmotic diuresis and dehydration). Possible causes of hyperglycemia include the following: (1) inadvertent infusion of higher dextrose rates than ordered and achieving higher glucose concentrations than desired, (2) uneven flow rate, (3) sepsis, (4) a stress situation (including administration of catecholamines or corticosteroids), and (5) pancreatitis. If these causes have been addressed and severe hyperglycemia persists, use of insulin may be considered. IV insulin reduces hyperglycemia by suppressing hepatic glucose production and increasing glucose uptake by muscle and fat tissues. It usually increases plasma lactate concentrations, but does not necessarily increase glucose oxidation rates; it may also decrease the oxidation of fatty acids, resulting in less energy for metabolism. Use of IV insulin also increases the risk of hypoglycemia. Hence, insulin should be used very cautiously. A standard IV dose is 1 U/4 g of carbohydrate, but much smaller quantities may be adequate and, usually, one starts with 0.2-0.3 U/4 g of carbohvdrate.

	Dextrose		Amino Acids	Lipids
	mg/kg/min	g/kg/day	g/kg/day	g/kg/day
Age	50%-6	0% kcal	10%–20% kcal	30%–40% kcal
Preterm	Initial 5–8	Initial 7–11	Initial 1.5–2	Initial 0.5–1
	Max 11–12.5	Max 16–18	Max 3–4	Max 2.5–3.5
Birth–12 mo	Initial 6–8	Initial 9–11	Initial 1.5–2	Initial 1
	Max 11–15	Max 16–21.5	Max 3	Max 2.5–3.5
1–6 у	Initial 6–7	Initial 8–10	Initial 1–1.5	Initial 1
	Max 10–12	Max 14–17	Max 2–2.5	Max 2.5–3.5
> 6 y	Initial 5–7	Initial 8–10	Initial 1	Initial 1
	Max 9	Max 13	Max 1.5–2	Max 3
> 10 y	Initial 4–5	Initial 5–7	Initial 1	Initial 1
	Max 6–7	Max 8–10	Max 1.5–2	Max 2–3
Adolescents	Initial 2–3	Initial 3–4	Initial 1	Initial 0.5–1
	Max 5–6	Max 7–8	Max 1.5–2	Max 2

--	--------------	-------------------------	----------------------	-----------------------

Hypoglycemia may occur after an abrupt decrease in or cessation of IV glucose. When cyclic IV nutrition is provided, the IV glucose load should be decreased steadily for 1–2 hours prior to discontinuing the infusate. If the central line must be removed, the IV dextrose should be tapered gradually over several hours.

Oxidation rates for infused dextrose decrease with age. It is important to note that the ranges for dextrose administration provided in Table 11–22 are guidelines and that individual patients may require either less or more dextrose. Quantities of dextrose in excess of maximal glucose oxidation rates are used initially to replace depleted glycogen stores; hepatic lipogenesis occurs thereafter. Excess hepatic lipogenesis may lead to a fatty liver (steatosis). Lipogenesis produces carbon dioxide, as does glucose oxidation. Thus, excess dextrose may elevate the Paco₂ and aggravate respiratory insufficiency or impede weaning from a respirator.

Lipids

The energy density of 20% lipid emulsions is 10 kcal/g of lipid or 2 kcal/mL. The lipids are derived from either soybean or safflower oil. All commonly available formulations consist of more than 50% linoleic acid and 4%–9% linolenic acid. This high level of linoleic acid is not ideal due to the proinflammatory potential of omega-6 fatty acids, except when small quantities of lipid are being given to prevent an EFA deficiency. Because 10% and 20% lipid emulsions

contain the same concentrations of phospholipids, a 10% solution delivers more phospholipid per gram of lipid than a 20% solution. Twenty percent lipid emulsions are preferred. IV lipid is often used to provide 30%–40% of calorie needs for infants and up to 30% of calorie needs in older children and teens.

Lipoprotein lipase (LPL) activity is the rate-limiting factor in the metabolism and clearance of fat emulsions from the circulation. LPL activity is inhibited or decreased by malnutrition, leukotrienes, immaturity, growth hormone, hypercholesterolemia, hyperphospholipidemia, and theophylline. LPL activity is enhanced by glucose, insulin, lipid, catecholamines, and exercise. Heparin releases LPL from the endothelium into the circulation and enhances the rate of hydrolysis and clearance of TGs. In small premature infants, low dose heparin infusions may increase tolerance to IV lipid emulsion.

In general, adverse effects of IV lipid can be avoided by starting with modest quantities and advancing cautiously in light of results of TG monitoring and clinical circumstances. Monitoring TGs is particularly important in cases of severe sepsis. It should continue periodically with long-term use.

IV lipid dosing guidelines: Check serum TGs before starting and after increasing the dose. Commence with 1 g/kg/day, given over 12–20 hours or 24 hours in small preterm infants. Advance by 0.5–1.0 g/kg/day, every 1–2 days, up to goal (see Table 11–22). As a general rule, do not increase the dose if the serum TG level is above 400 mg/dL during

infusion or if the level is greater than 250 mg/dL 6-12 hours after cessation of the lipid infusion.

Serum TG levels above 400–600 mg/dL may precipitate pancreatitis. In patients for whom normal amounts of IV lipid are contraindicated, 4%–8% of calories as IV lipid should be provided to prevent EFA deficiency. Neonates and malnourished pediatric patients receiving lipid-free parenteral nutrition are at high risk for EFA deficiency.

Finn KL et al. Impact of providing a combination lipid emulsion compared with a standard soybean oil emulsion in children receiving parenteral nutrition: a systematic review and metaanalysis. JPEN J Parenter Enteral Nutr 2015 Aug;39(6):656667 [PMID: 25057053].

Nitrogen

One gram of nitrogen is produced by 6.25 g of protein (1 g of protein contains 16% nitrogen). Caloric density of protein is equal to 4 kcal/g.

A. Protein Requirements

Protein requirements for IV feeding are the same as those for normal oral feeding (see Table 11–2).

B. Intravenous Amino Acid Solutions

Nitrogen requirements can be met by commercially available amino acid solutions. For infants, including premature infants, accumulating evidence suggests that the use of TrophAmine (McGaw) is associated with a more normal plasma amino acid profile, superior nitrogen retention, and a lower incidence of cholestasis. TrophAmine contains 60% essential amino acids, is relatively high in branched-chain amino acids, contains taurine, and is compatible with the addition of cysteine within 24–48 hours after administration. The dose of added cysteine is 40 mg/g of TrophAmine. The relatively low pH of TrophAmine enhances solubility of calcium and phosphorus.

C. Dosing Guidelines

Amino acids can be started at 1–2 g/kg/day in most patients (see Table 11–22). In severely malnourished infants, the initial amount should be 1 g/kg/day. In infants of very low birth weight, there is evidence that higher initial amounts of amino acids are tolerated with little indication of protein "toxicity." Larger quantities of amino acids in relation to calories can minimize a negative nitrogen balance even when the infusate is hypocaloric. Amino acid intake can be advanced by 0.5–1.0 g/kg/day toward the goal. Normally the final infusate will contain 2%–3% amino acids, depending on the rate of infusion. Concentration should not be advanced beyond 2% in peripheral vein infusates due to osmolality.

D. Monitoring

Monitoring for tolerance of the IV amino acid solutions should include blood urea nitrogen. Serum alkaline phosphatase, γ -glutamyltransferase, and bilirubin should be monitored to detect the onset of cholestatic liver disease.

Minerals & Electrolytes

A. Calcium, Phosphorus, and Magnesium

Intravenously fed premature and full-term infants should be given relatively high amounts of calcium and phosphorus. Current recommendations are as follows: calcium, 500-600 mg/L; phosphorus, 400-450 mg/L; and magnesium, 50-70 mg/L. After 1 year of age, the recommendations are as follows: calcium, 200-400 mg/L; phosphorus, 150-300 mg/L; and magnesium, 20-40 mg/L. The ratio of calcium to phosphorous should be 1.3:1.0 by weight or 1:1 by molar ratio. These recommendations are deliberately presented as milligrams per liter of infusate to avoid inadvertent administration of concentrations of calcium and phosphorus that are high enough to precipitate in the tubing. During periods of fluid restriction, care must be taken not to inadvertently increase the concentration of calcium and phosphorus in the infusate. These recommendations assume an average fluid intake of 120-150 mL/kg/day and an infusate of 25 g of amino acid per liter. With lower amino acid concentrations, the concentrations of calcium and phosphorus should be decreased.

B. Electrolytes

Standard recommendations are given in Table 11–23. After chloride requirements are met, the remainder of the anion required to balance the cation should be given as acetate to avoid the possibility of acidosis resulting from excessive chloride. Electrolyte concentrations should be modified based on the flow rate and if indications dictate for the individual patient. IV sodium should be administered sparingly in the severely malnourished patient because of impaired membrane function and high intracellular sodium levels. Conversely, generous quantities of potassium and phosphorus may be needed.

Table 11–23.	Electrolyte requirements for parenteral
nutrition.	

Electrolyte	Preterm Infant (mEq/kg)	Full-Term Infant (mEq/kg)	Child (mEq/kg)	Adolescent (mEq/kg)
Sodium	2–5	2–3	2–3	60–150
Chloride	2–5	2–3	2–3	60–150
Potassium	2–3	2–3	2–3	70–180

C. Trace Elements

Recommended IV intakes of trace elements are as follows: zinc 100 mcg/kg, copper 20 mcg/kg, manganese 1 mcg/kg, chromium 0.2 mcg/kg, selenium 2 mcg/kg, and iodide 1 mcg/kg. Of note, IV zinc requirements may be as high as 400 mcg/kg for premature infants and can be up to 250 mcg/kg for infants with short bowel syndrome and significant GI losses of zinc. When IV nutrition is supplemental or limited to fewer than 2 weeks, and preexisting nutritional deficiencies are absent, only zinc need routinely be added.

IV copper requirements are relatively low in the young infant because of the presence of hepatic copper stores. These are significant even in the 28-week fetus. Circulating levels of copper and manganese should be monitored in the presence of cholestatic liver disease. If monitoring is not feasible, temporary withdrawal of added copper and manganese is advisable in cholestasis.

Copper and manganese are excreted primarily in the bile, but selenium, chromium, and molybdenum are excreted primarily in the urine. These trace elements, therefore, should be administered with caution in the presence of renal failure.

Vitamins

Two vitamin formulations are available for use in pediatric parenteral nutrition: MVI Pediatric and MVI-12 (Astra-Zeneca). MVI Pediatric contains the following: vitamin A, 0.7 mg; vitamin D, 400 IU; vitamin E, 7 mg; vitamin K, 200 mcg; ascorbic acid, 80 mg; thiamin, 1.2 mg; riboflavin, 1.4 mg; niacinamide, 17 mg; pyridoxine, 1 mg; vitamin B₁₂, 1 mcg; folic acid, 140 mcg; pantothenate, 5 mg; and biotin, 20 mcg. Recommended dosing is as follows: 5 mL for children weighing more than 3 kg, 3.25 mL for infants 1-3 kg, and 1.5 mL for infants weighing less than 1 kg. Children older than 11 years can receive 10 mL of the adult formulation, MVI-12, which contains the following: vitamin A, 1 mg; vitamin D, 200 IU; vitamin E, 10 mg; ascorbic acid, 100 mg; thiamin, 3 mg; riboflavin, 3.6 mg; niacinamide, 40 mg; pyridoxine, 4 mg; vitamin B₁₂, 5 mcg; folic acid, 400 mcg; pantothenate, 15 mg; and biotin, 60 mcg. MVI-12 contains no vitamin K.

IV lipid preparations contain enough tocopherol to affect total blood tocopherol levels. The majority of tocopherol in soybean oil emulsion is α -tocopherol, which has substantially less biologic activity than the α -tocopherol present in safflower oil emulsions.

Table 11–24. Summary	y of suggested	monitoring for	parenteral	nutrition.
----------------------	----------------	----------------	------------	------------

Variables	Acute Stage	Long-Term ^b
Growth	Daily	Weekly
Weight	Weekly	
Length	Weekly	
Head circumference		
Urine		
Glucose (dipstick)	With each void	With changes in intake or status
Specific gravity	Void	
Volume	Daily	
Blood		
Glucose	4 h after changes, a then daily \times 2 day	Weekly
Na ⁺ , K ⁺ , Cl, CO ₂ , blood urea nitrogen	Daily for 2 days after changes, ^a then twice weekly	Weekly
Ca ²⁺ , Mg ²⁺ , P	Initially, then twice weekly	Weekly
Total protein, albumin, bilirubin, aspartate trans- aminase, and alkaline phosphatase	Initially, then weekly	Every other week
Zinc and copper	Initially according to clinical indications	Monthly
Triglycerides	Initially, 1 day after changes, ^a then weekly	Weekly
Compete blood count	Initially, then twice weekly; according to clinical indications (see text)	Twice weekly

^aChanges include alterations in concentration or flow rate.

^bLong-term monitoring can be tapered to monthly or less often, depending on age, diagnosis, and clinical status of patient.

A dose of 40 IU/kg/day of vitamin D (maximum 400 IU/day) is adequate for both full-term and preterm infants.

Mertallo JM: Perspectives on parenteral micronutrient shortages. Nutr Clin Pract 2015 Feb 30(1):86–91 [PMID: 25520411].

Fluid Requirements

The initial fluid volume and subsequent increments in flow rate are determined by basic fluid requirements, the patient's clinical status, and the extent to which additional fluid administration can be tolerated and may be required to achieve adequate nutrient intake. Calculation of initial fluid volumes to be administered should be based on standard pediatric practice. If replacement fluids are required for ongoing abnormal losses, these should be administered via a separate line.

Monitoring

Vital signs should be checked on each shift. With a central catheter in situ, a fever of more than 38.5°C requires peripheral and central-line blood cultures, urine culture, complete physical examination, and examination of the IV entry point. Instability of vital signs, elevated white blood cell count with left shift, and glycosuria suggest sepsis. Removal of the central venous catheter should be considered if the patient is toxic or unresponsive to antibiotics.

A. Physical Examination

Monitor especially for hepatomegaly (differential diagnoses include fluid overload, congestive heart failure, steatosis, and hepatitis) and edema (differential diagnoses include fluid overload, congestive heart failure, hypoalbuminemia, and thrombosis of superior vena cava).

B. Intake and Output Record

Calories and volume delivered should be calculated from the previous day's intake and output records (that which was delivered rather than that which was ordered). The following entries should be noted on flow sheets: IV, enteral, and total fluid (mL/kg/day); dextrose (g/kg/day or mg/kg/min); protein (g/kg/day); lipids (g/kg/day); energy (kcal/kg/day); and percent of energy from enteral nutrition.

C. Growth, Urine, and Blood

Routine monitoring guidelines are given in Table 11–24. These are minimum requirements, except in the very long-term stable patient. Individual variables should be monitored more frequently as indicated, as should additional variables or clinical indications. For example, a blood ammonia analysis should be ordered for an infant with lethargy, pallor, poor growth, acidosis, azotemia, or abnormal liver test results.

Kevin P. Carney, MD Kelley Roswell, MD

INTRODUCTION TO PEDIATRIC EMERGENCIES & INJURIES

Of the approximately 130 million annual emergency department (ED) visits in the United States, over 25 million (20%) are children younger than 18 years. Injuries and poisonings are the leading cause of all pediatric ED visits (30%), with respiratory disorders (27%) also accounting for a significant percentage. Though the vast majority (93%) of children presenting for ED evaluation are discharged home, over 1 million each year require hospital admission from the ED and, sadly, nearly 8000 children die every year in US EDs.

This chapter begins with the initial approach to the acutely ill pediatric patient, discusses the differentiation and initial management of shock, presents the general approach to the evaluation of pediatric trauma patients, summarizes commonly used emergency drugs, and concludes with the management of a number of common clinical scenarios in pediatric emergency medicine.

INITIAL APPROACH TO THE ACUTELY ILL INFANT OR CHILD

- Most causes of pediatric cardiac arrest are due to hypoxia from respiratory failure.
- Hypotension is a *late* finding in pediatric shock; early signs may include tachycardia, capillary refill > 2 seconds, skin mottling, and decreased mental status.

A pediatric patient in serious distress may present with a known diagnosis or in cardiorespiratory failure of unknown cause. The initial approach must be simple and consistent in order to rapidly identify physiologic derangements and injuries, prioritize management, and reverse life-threatening conditions immediately. Once stabilized following interventions, the provider must then carefully consider the underlying cause, focusing on those that are treatable or reversible. Specific diagnoses can then be made, and targeted therapy initiated.

Pediatric cardiac arrest most commonly results from progressive respiratory deterioration or shock as opposed to a primary cardiac etiology. Unrecognized deterioration may lead to bradycardia, agonal breathing, hypotension, and ultimately asystole. Resulting hypoxic and ischemic insult to the brain and other vital organs make neurologic recovery extremely unlikely, even in the doubtful event that the child survives the arrest. When cardiopulmonary arrest does occur, survival is rare and most often associated with significant neurological impairment. Current data reflect a 6% survival rate for out-of-hospital cardiac arrest, 8% for those who receive prehospital intervention, and 27% survival rate for in-hospital arrest. Children who respond to rapid intervention with ventilation and oxygenation alone or to less than 5 minutes of advanced life support are much more likely to survive neurologically intact. In fact, more than 70% of children with respiratory arrest who receive rapid and effective bystander resuscitation survive with good neurologic outcomes. Therefore, it is essential to recognize the child who is at risk for progressing to cardiopulmonary arrest and to provide aggressive intervention before asystole occurs.

Please see the selected references at the end of this section for more information on the specifics of the American Heart Association's Pediatric Advanced Life Support (PALS) guidelines, most recently updated in 2015. The importance of quality Compressions is emphasized in both pediatric and adult cardiopulmonary resuscitation (CPR), with followup close attention paid to Airway and Breathing (acronym "C-A-B"). Please do not confuse this acronym with the "ABCs of resuscitation" approach described later as the following discussion details care of the critically ill pediatric patient who does not require CPR.

Of note, "compressions only" CPR has been touted as a way to encourage bystander CPR and increase survival rates of out-of-hospital cardiac arrests. In the pediatric population, however, conventional CPR (rescue breaths and chest compressions) is still emphasized and should be provided for infants and children in cardiac arrest. This is due to the asphyxial nature of most pediatric cardiac arrests which necessitates ventilation as part of effective CPR, whereas the majority of most adult cardiac arrest is due to a primary cardiac cause which may be more responsive to compressionsonly CPR.

THE ABCS OF RESUSCITATION

A severely ill child should be rapidly evaluated in a deliberate sequence known as the *ABCs*: Airway patency, *B*reathing adequacy, and Circulation integrity. If a potentially life-threatening problem is detected during the evaluation, it must be corrected before proceeding to the next step. Age-appropriate equipment (including laryngoscope blade, endotracheal tubes, nasogastric or orogastric tubes, IV lines, and an indwelling urinary catheter) and monitors (cardiorespiratory monitor, pulse oximeter, and appropriate blood pressure cuff) should be assembled and readily available.

Table 12–1. Equipment sizes and estimated weight by age

Use a length-based emergency tape if available. See Table 12–1 for endotracheal tube and laryngeal mask airways (LMA) sizes. Cuffed endotracheal tubes are acceptable for children and infants beyond the newborn period. Cuff inflation pressures must be carefully monitored and maintained below 20 cm H_2O . In certain circumstances, such as poor lung compliance or high airway resistance, the use of cuffed tubes may be preferable in controlled settings.

Airway

In all children, look for evidence of spontaneous breathing. Breath sounds such as stridor, stertor, or gurgling, or increased work of breathing without air movement are suggestive of airway obstruction. Significant airway obstruction often is associated with altered level of consciousness, including agitation or lethargy. During the airway assessment, if the patient is noted to be apneic or producing only gasping (agonal) breaths, chest compressions should be initiated immediately in accordance with PALS guidelines.

If concerned for obstruction, the airway is managed initially by noninvasive means such as oxygen administration, chin lift, jaw thrust, suctioning, or bag-valve mask ventilation (BMV). Invasive maneuvers such as endotracheal intubation, laryngeal mask insertion, or rarely, cricothyroidotomy are required if the aforementioned maneuvers are unsuccessful. The following discussion assumes that basic life support has been instituted.

Age (y)	Weight (kg)	Laryngeal Mask Airway (LMA) Size	Endotracheal Tube Size (mm) ^{a,b}	Laryngoscope Blade Size	Chest Tube (Fr)	Foley (Fr)	
Premature	1–2.5	1	2.5 (uncuffed only)	0	8	5	
Term newborn	3	1	3.0 (uncuffed only)	0-1	10	8	
1	10	1.5	3.5-4.0	1	18	8	
2	12	2	4.5	1	18	10	
3	14	2	4.5	1	20	10	
4	16	2	5.0	2	22	10	
5	18	2	5.0-5.5	2	24	10	
6	20	2–2.5	5.5	2	26	12	
7	22	2.5	5.5-6.0	2	26	12	
8	24	3	6.0	2	28	14	
10	32	4	6.0–6.5	2–3	30	14	
Adolescent	50	4	7.0	3	36	14	
Adult	70		8.0	3	40	14	

^aInternal diameter.

^bDecrease tube size by 0.5 mm if using a cuffed tube.

Knowledge of pediatric anatomy is important for airway management. Children's tongues are large relative to their oral cavities, and the larynx is high and anteriorly located. Infants are obligate nasal breathers; therefore, secretions, blood, or foreign bodies in the nasopharynx can cause significant distress.

- 1. Place the head in the sniffing position. In the patient without concern for cervical spine injury, the neck should be flexed slightly and the head extended. This position aligns the oral, pharyngeal, and tracheal planes. In infants and children younger than about 8 years, the relatively large occiput causes significant neck flexion and poor airway positioning. This is relieved by placing a towel roll under the shoulders, thus returning the child to a neutral position (Figure 12–1). In an older child, slightly more head extension is necessary. Avoid hyperextension of the neck, especially in infants.
- 2. Perform the head tilt/chin lift or jaw thrust maneuver (Figure 12–2). Lift the chin upward while avoiding pressure on the submental triangle, or lift the jaw by traction upward on the angle of the jaw. Important: head tilt/chin lift must not be done if cervical spine injury is possible. (See section Approach to the Pediatric Trauma Patient, later.)
- 3. Assess airway for foreign material. Suction the mouth; use Magill forceps to remove visible foreign bodies. If needed, visualize with a laryngoscope. Do *not* perform blind finger sweeps.
- 4. If airway obstruction persists, first attempt to reposition the head, then proceed with insertion of an airway

▲ Figure 12–1. Correct positioning of the child younger than 8 years for optimal airway alignment: a folded sheet or towel is placed beneath the shoulders to accommodate the occiput and align the oral, pharyngeal, and tracheal airways.

Α

▲ Figure 12–2. A: Opening the airway with the head tilt and chin lift in patients without concern for spinal trauma: gently lift the chin with one hand and push down on the forehead with the other hand. B: Opening the airway with jaw thrust in patients with concern for spinal trauma: lift the angles of the mandible; this moves the jaw and tongue forward and opens the airway without bending the neck.

adjunct, such as the oropharyngeal or nasopharyngeal airway (Figure 12–3). Such adjuncts relieve upper airway obstruction due to prolapse of the tongue into the posterior pharynx, the most common cause of airway obstruction in unconscious children. The correct size for an oropharyngeal airway is obtained by measuring from the upper central gumline to the angle of the jaw (Figure 12–4) and should be used only in the

▲ Figure 12–3. A: Oropharyngeal airways of various sizes. B: Nasopharyngeal airways of different sizes.

unconscious victim. Proper sizing is paramount, as an oropharyngeal airway that is too small will push the tongue further into the airway while one that is too large will obstruct the airway. Nasopharyngeal airways should fit snugly within the nares and should be equal in length to the distance from the nares to the tragus (Figure 12–5). This airway adjunct should be avoided in children with significant injuries to the midface due to the risk of intracranial perforation through a damaged cribriform plate.

Breathing

Assessment of respiratory status beings with inspection. *Look* for adequate and symmetric chest rise and fall, rate and work of breathing (eg, accessory muscle use, retractions, flaring, and grunting), skin color, and tracheal deviation. Pulse oximetry measurement and end-tidal CO_2 determination are highly desirable. *Listen* for adventitious breath sounds such as wheezing. Auscultate for air entry, symmetry of breath sounds, and rales. *Feel* for subcutaneous crepitus.

▲ Figure 12–4. Size selection for the oropharyngeal airway: hold the airway next to the child's face and estimate proper size by measuring from the upper central gumline to the angle of the jaw.

▲ Figure 12–5. Size selection for the nasopharyngeal airway: hold the airway next to the child's face and estimate proper size by measuring from the nares to the tragus.

If spontaneous breathing is inadequate, initiate positivepressure ventilation with BMV and 100% oxygen. Assisted ventilations should be coordinated with the patient's efforts, if present. Effective BMV is a difficult skill that requires training and practice. To begin, ensure a proper seal by choosing a mask that encompasses the area from the bridge of the nose to the cleft of the chin. Form an E-C clamp around the mask to seal the mask tightly to the child's face. The thumb and index finger form the "C" surrounding the mask, while the middle, ring, and small fingers lift the jaw into the mask (Figure 12-6). Use only enough force and volume to make the chest rise visibly. In the patient with a pulse, administer one breath every 3-5 seconds (12-20 breaths/min). This may be done using the timing mnemonic "squeeze-release-release" in a normal speaking voice. Two-person ventilation is optimal. When proper technique is used, BMV is effective in the vast majority of cases.

Adequacy of BMV is reflected with appropriate chest rise and auscultation of bilateral air entry. Avoid hyperventilation, as it may lead to barotrauma, increased risk of aspiration, and a decreased likelihood that return of spontaneous circulation will be achieved during cardiac arrest. If the chest does not rise and fall easily with bagging, reposition the airway and assess for foreign material as previously described. The presence of asymmetrical breath sounds in a child in shock or in severe distress suggests pneumothorax and is an indication for needle thoracostomy. In small children, the transmission of breath sounds throughout the chest may impair the ability to auscultate the presence of a pneumothorax. **Note:** Effective oxygenation and ventilation are the keys to successful resuscitation.

Cricoid pressure (Sellick maneuver) during positivepressure ventilation may decrease gastric inflation; however, it has not been shown to reduce the risk of aspiration and is no longer recommended by the American Heart Association during CPR.

Circulation

The methodical assessment of blood circulation is critical to the diagnosis of shock, defined as the inadequate perfusion of vital organs. Circulation may be assessed in the following ways:

A. Pulses

Check adequacy of peripheral pulses and compare with central pulses. In the infant, central pulses should be checked at the brachial artery.

B. Heart Rate

Compare with age-specific norms. Tachycardia can be a nonspecific sign of distress; bradycardia for age is a sign of imminent arrest and necessitates aggressive resuscitation.

Α

В

▲ Figure 12–6. A: Bag-valve-mask ventilation, one-person technique: the thumb and index finger form the "C" surrounding the mask, while the middle, ring, and little fingers lift the jaw into the mask. B: Bag-valve-mask ventilation, two-person technique: the first rescuer forms the "C" and "E" clamps with both hands; the second rescuer provides ventilation.

C. Blood Pressure

It is vital to understand that shock may be present even with a normal blood pressure. As intravascular volume falls, peripheral vascular resistance increases. Blood pressure is maintained until there is 35%–40% depletion of blood volume, followed by precipitous and often irreversible deterioration. **Compensated** shock occurs where there is normal blood pressure but signs of decreased organ perfusion. When blood pressure also falls, **decompensated (hypotensive)** shock is present. Blood pressure determination should be performed manually using an appropriately sized cuff, because automated machines can give erroneous readings in children.

D. Extremities

As shock progresses, extremities become cooler from distally to proximal. A child whose extremities are cool distal to the elbows and knees is in severe shock.

E. Capillary Refill Time

When fingertip pressure is applied to a patient's distal extremity and released, blood should refill the area in less than 2 seconds. A prolonged capillary refill time in the setting of other signs of shock indicates a compensated shock state. It is important to recognize that capillary refill time is influenced by ambient temperature, limb position, site, age of the patient, and room lighting.

F. Mental Status

Assess the patient's mental status, as hypoxia, hypercapnia, poor cerebral perfusion, or ischemia will result in altered mental status.

G. Skin Color

Skin that is pale, gray, sallow, mottled, or ashen may indicate compromised circulatory status.

MANAGEMENT OF SHOCK

Intravenous (IV) access is essential but can be difficult to establish in children with shock. Peripheral access, especially via the antecubital veins, should be attempted first. Use short, wide-bore catheters to allow maximal flow rates. Two IVs should be started in severely ill children. Intraosseous (IO) needle placement is an acceptable alternative in any severely ill child when venous access cannot be established rapidly (within 90 seconds) (Figure 12–7). Both manual and automated insertion devices are available for pediatric patients. Increasing evidence suggests that automated devices result in faster, more successful IO placement compared to manual devices. Decisions on more invasive access

should be based on individual expertise as well as urgency of obtaining access. Options include percutaneous cannulation of femoral, subclavian, or internal or external jugular veins; cutdown at antecubital, femoral, or saphenous sites. In newborns, the umbilical veins may be cannulated. Consider arterial access if beat-to-beat monitoring or frequent laboratory tests will be needed.

Differentiation of Shock States & Initial Therapy

Therapy for inadequate circulation is determined by the cause of circulatory failure.

314

A. Hypovolemic Shock

The most common type of shock in the pediatric population is hypovolemia. Frequent causes include dehydration, diabetes, heat illness, and hemorrhage. Normal saline or lactated Ringer's solution (isotonic crystalloid) is given as initial therapy in shock and should be initiated even in normotensive patients. There is no advantage to the early administration of colloid (albumin). Give 20 mL/kg body weight (maximum 1 L bolus) and repeat as necessary, until perfusion normalizes. Typically no more than 60 mL/kg is needed in hypovolemic shock, but more may be required if ongoing losses are severe. Appropriate monitoring and frequent reassessment will guide your therapy. Packed red blood cell transfusion is indicated in trauma patients not responding to initial crystalloid bolus fluid replacement; however, there is insufficient evidence to determine the volume required. Pressors are not required in simple hypovolemic states.

B. Distributive Shock

Distributive shock results from increased vascular capacitance with normal circulating volume. Examples are sepsis, anaphylaxis, and spinal cord injury. Initial therapy is isotonic volume replacement with crystalloid, but pressors may be required if perfusion does not normalize after delivery of two or three 20 mL/kg boluses of crystalloid (total of 40-60 mL/kg). Outcomes improve when threshold heart rates, normalized blood pressure, and a capillary refill in less than 2 seconds are achieved within the first hour of symptom onset. Early identification of septic shock and rapid delivery of goal-directed therapies as fluids, antibiotics, and inotropes within the first hour of presentation to the ED can reduce mortality and neurologic morbidity risks twofold. Recently updated recommendations from the American College of Critical Care Medicine (reference at end of section) stress the importance of aggressively managing hypotension in the pediatric population and recommend no patient be hypotensive for more than 1 hour without starting vasopressor medications. Depending on the clinical scenario, epinephrine, dopamine, norepinephrine or dobutamine may be used safely in children, though it is important to note that central venous access is required for epinephrine and norepinephrine drips. Thus dopamine may be a preferred agent to be given peripherally until central access can be established.

C. Cardiogenic Shock

Cardiogenic shock can occur as a complication of congenital heart disease, myocarditis, dysrhythmias, ingestions (eg, clonidine, cyclic antidepressants), or as a complication of prolonged shock due to any cause. The diagnosis is suggested by any of the following signs: abnormal cardiac rhythm, distended neck veins, rales, abnormal heart sounds such as an S_3 or S_4 , friction rub, narrow pulse pressure, rales, or hepatomegaly. Chest radiographs may show cardiomegaly and pulmonary edema. An initial bolus of crystalloid may be given, but pressors, and possibly afterload reducers, are necessary to improve perfusion. Giving multiple boluses of fluid is deleterious. Comprehensive cardiopulmonary monitoring is essential.

D. Obstructive Shock

Obstructive shock is rare in the pediatric population and involves extracardiac obstruction of blood flow and/or obstruction of adequate diastolic filling. Examples include cardiac tamponade, tension pneumothorax, massive pulmonary embolism, or a critical coarctation of the aorta after closure of the ductus arteriosus. Management is directed toward resolution of the obstruction. In the case of a critical coarctation, management should include emergent prostaglandin initiation to reopen the ductus arteriosus while awaiting surgical repair.

Observation & Further Management

Clinically reassess physiologic response to each fluid bolus to determine additional needs. Serial central venous pressure determinations or a chest radiograph may help determine volume status. Place an indwelling urinary catheter to monitor urine output.

Caution must be exercised with volume replacement if intracranial pressure (ICP) is potentially elevated, as in severe head injury, diabetic ketoacidosis, or meningitis. Even in such situations, however, normal intravascular volume must be restored in order to achieve adequate mean arterial pressure and thus cerebral perfusion pressure.

SUMMARY OF INITIAL APPROACH TO THE ACUTELY ILL INFANT OR CHILD

Assess the ABCs in sequential fashion and, before assessing the next system, immediately intervene if physiologic derangement is detected. It is essential that each system be reassessed after each intervention to ensure improvement and prevent failure to recognize clinical deterioration.

EMERGENCY PEDIATRIC DRUGS

Although careful attention to airway and breathing remains the mainstay of pediatric resuscitation, medications are often needed. Rapid delivery to the central circulation, which can be via peripheral IV catheter, is essential. Infuse medications close to the catheter's hub and flush with saline to achieve the most rapid systemic effects. In the rare instance that no IV or IO access is achievable, important emergency resuscitation drugs such as epinephrine, atropine, and naloxone may be given endotracheally (see dosing in Table 12-2). However, the dose, absorption, and effectiveness of drugs given via this route are either unknown or controversial. The use of length-based emergency measuring tapes that contain preprinted drug dosages, equipment sizes, and IV fluid amounts (Broselow tapes) or preprinted resuscitation drug charts is much more accurate than estimation formulas and helps minimize dosing errors. Selected emergency drugs used in pediatrics are summarized in Table 12-2.

APPROACH TO THE PEDIATRIC TRAUMA PATIENT

Traumatic injuries, including motor vehicle crashes, falls, burns, and immersions, account for the greatest number of deaths among children older than 1 year; injury exceeds all other causes of death combined with motor vehicle accidents accounting for the majority of deaths. Blunt trauma is most common, with penetrating trauma occurring in only 10% of cases. Head and abdominal injuries are particularly common and important.

A coordinated team approach to the severely injured child will optimize outcomes. A calm atmosphere in the receiving area will contribute to thoughtful care. Parents are often anxious, angry, or guilty, requiring ongoing support from staff, social workers, or child life workers (therapists knowledgeable about child development).

To provide optimal multidisciplinary care, regional pediatric trauma centers provide dedicated teams of pediatric

Drug	Indications	Decade and Poute	Comment
Drug	indications	bosage and koute	comment
Epinephrine	 Bradycardia, especially hypoxic-ischemic Hypotension (by infusion) Asystole Fine ventricular fibrillation refractory to initial defibrillation Pulseless electrical activity Anaphylaxis (IM) 	Bradycardia and cardiac arrest: 0.01 mg/kg of 1:10,000 solution IV/IO: 0.1 mg/kg of 1:1000 solution ET Anaphylaxis: 0.01 mg/kg of 1:1000 solution SC/IM Maximum dose: 0.3 mg. May repeat every 3–5 min. Constant infusion by IV drip: 0.1–1 mcg/kg/min.	Epinephrine is the single most important drug in pediatric resuscitation. Recent pediatric studies have shown no added advantage to high-dose epinephrine in terms of survival to discharge or neurologic outcome. Because other studies have indicated adverse effects, including increased myocardial oxygen consumption during resuscitation and worsened postarrest myocardial dysfunction, high-dose epinephrine is no longer recommended.
Glucose	 Hypoglycemia Altered mental status (empirical) With insulin, for hyperkalemia 	0.5–1 g/kg IV/IO. Continuous infusion may be necessary.	2–4 mL/kg D ₁₀ W, 1–2 mL/kg D ₂₅ W.
Naloxone	 Opioid overdose Altered mental status (empirical) 	0.1 mg/kg IV/IO/ET; maximum single dose, 2 mg. May repeat as necessary.	Side effects are few. A dose of 2 mg may be given in children \ge 5 years or $>$ 20 kg. Repeat as necessary, or give as constant infusion in opioid overdoses.
Sodium bicarbonate	 Documented metabolic acidosis Hyperkalemia 	1 mEq/kg IV or IO; by arterial blood gas: $0.3 \times kg \times base$ deficit. May repeat every 5 min.	Infuse slowly. Sodium bicarbonate will be effective only if the patient is adequately oxygenated, ventilated, and perfused. Some adverse side effects.
Calcium chloride 10%	 Documented hypocalcemia Calcium channel blocker overdose Hyperkalemia, hypermagnesemia 	20 mg/kg slowly IV, preferably centrally, or IO with caution. Maximum single dose 2 g.	Calcium is no longer indicated for asystole. Potent tissue necrosis results if infiltration occurs. Use with caution and infuse slowly.

 $D_{5}W$ would be 10 mL/kg; $D_{50}W$ would be 1 mL/kg; $D_{10}W/D_{25}W$, 10%/25% glucose in water; ET, endotracheally; IO, intraosseously; IV, intravenously; SC, subcutaneously. $D_{50}W$ is not recommended PIV and use caution with D_{25} . D_{10} is preferred for neonates (newborn –1 month of age).

Table 12–2. Important emergency pediatric drugs.

specialists in emergency pediatrics, trauma surgery, orthopedics, neurosurgery, and critical care. However, most children with severe injuries are not seen in these centers. Primary care providers must be able to provide initial assessment and stabilization of the child with life-threatening injuries before transport to a verified pediatric trauma center.

MECHANISM OF INJURY

Document the time of occurrence, the type of energy transfer (eg, hit by a car, fall from playground), secondary impacts (if the child was thrown by the initial impact), appearance of the child at the scene, interventions performed, and clinical condition during transport. The report of emergency service personnel is invaluable. Forward all of this information with the patient to the referral facility if secondary transport occurs.

INITIAL ASSESSMENT & MANAGEMENT

The vast majority of children who reach a hospital alive survive to discharge. As most deaths from trauma in children are due to head injuries, cerebral resuscitation must be the foremost consideration when treating children with serious injuries. Strict attention to the ABCs (see the previous section) ensures optimal oxygenation, ventilation, and perfusion, and ultimately, cerebral perfusion.

The primary and secondary survey is a method for evaluating and treating injured patients in a systematic way that provides a rapid assessment and stabilization phase, followed by a head-to-toe examination and definitive care phase.

PRIMARY SURVEY

The primary survey is designed to immediately identify and treat all physiologic derangements resulting from trauma. The mnemonic, *ABCDE*, is a simple way to remember the general steps of the primary survey: Airway, with cervical spine control; *Breathing*; Circulation, with hemorrhage control; *Disability* (neurologic deficit); *Exposure* (maintain a warm *Environment*, undress the patient completely, and *Examine*)

If the patient is apneic or has agonal breaths, the sequence becomes the *CABs* (chest compressions, open the *a*irway, provide two rescue *b*reaths). Please refer to PALS guidelines for further information. Refer to preceding discussion regarding details of the ABC assessment. Modifications in the trauma setting are added as follows:

Airway

Failure to manage the airway appropriately is the most common cause of preventable morbidity and death. Administer 100% high-flow oxygen to all patients. Initially, provide cervical spine protection by manual inline immobilization, not traction. A hard cervical spine collar is applied after the primary survey.

Breathing

Most ventilation problems are resolved adequately by the airway maneuvers described earlier and by positive-pressure ventilation. Sources of traumatic pulmonary compromise include pneumothorax, hemothorax, pulmonary contusion, flail chest, and central nervous system (CNS) depression. Asymmetric breath sounds, particularly with concurrent tracheal deviation, cyanosis, or bradycardia, suggest pneumothorax, possibly under tension. To evacuate a tension pneumothorax, insert a large-bore catheter-over-needle assembly attached to a syringe through the second intercostal space in the midclavicular line into the pleural cavity and withdraw air. If a pneumothorax or hemothorax is present, place a chest tube in the fourth or fifth intercostal space in the anterior axillary line. Connect to water seal. Insertion should be over the rib to avoid the neurovascular bundle that runs below the rib margin. Open pneumothoraces can be treated temporarily by taping petrolatum-impregnated gauze on three sides over the wound, creating a flap valve.

A child with a depressed level of consciousness (Glasgow Coma Scale [GCS] score < 9), a need for prolonged ventilation, severe head trauma, or an impending operative intervention requires endotracheal intubation after bagmask preoxygenation. Orotracheal intubation is the route of choice and is possible without cervical spine manipulation. Nasotracheal intubation may be possible in children 12 years of age or older who have spontaneous respirations, if not contraindicated by midfacial injury.

Supraglottic devices, such as the laryngeal mask airway (LMA), are being used with increasing frequency, in both the prehospital and hospital settings. The device consists of a flexible tube attached to an inflatable rubber mask (Figure 12-8). The LMA is inserted blindly into the hypopharynx and is seated over the larynx, occluding the esophagus. Advantages to its use include ease of insertion, lower potential for airway trauma, and higher success rates. Patients remain at higher risk for aspiration with LMA use compared with orotracheal intubation; therefore, the LMA should not be used for prolonged, definitive airway management. Rarely, if tracheal intubation cannot be accomplished, particularly in the setting of massive facial trauma, cricothyroidotomy may be necessary. Needle cricothyroidotomy using a large-bore catheter through the cricothyroid membrane is the procedure of choice in patients younger than 12 years.

Circulation

Evaluation for ongoing external or internal hemorrhage is important in the trauma evaluation. Large-bore IV access CHAPTER 12

▲ Figure 12–8. Laryngeal mask airways of various sizes.

should be obtained early during the assessment, preferably at two sites. If peripheral access is not readily available, a central line, cutdown, or IO line is established. Determine hematocrit and urinalysis in all patients. Blood type and cross-match should be obtained in the hypotensive child unresponsive to isotonic fluid boluses or with known hemorrhage. Consider coagulation studies, chemistry panel, liver transaminases, amylase, and toxicologic screening as clinically indicated.

External hemorrhage can be controlled by direct pressure. To avoid damage to adjacent neurovascular structures, avoid placing hemostats on vessels, except in the scalp. Determination of the site of internal hemorrhage can be challenging. Sites include the chest, abdomen, retroperitoneum, pelvis, and thighs. Bleeding into the intracranial vault rarely causes shock in children except in infants. Evaluation by an experienced clinician with adjunctive computed tomography (CT) or ultrasound will localize the site of internal bleeding.

Suspect cardiac tamponade after penetrating or blunt injuries to the chest if shock, pulseless electrical activity, narrowed pulse pressure, distended neck veins, hepatomegaly, or muffled heart sounds are present. Ultrasound may be diagnostic if readily available. Diagnose and treat with pericardiocentesis and rapid volume infusion.

Treat signs of poor perfusion vigorously: A tachycardic child with a capillary refill time of 3 seconds, or other evidence of diminished perfusion, is in *shock* and is sustaining vital organ insults. Recall that hypotension is a late finding. Volume replacement is accomplished initially by rapid infusion of normal saline or lactated Ringer solution at 20 mL/kg of body weight. If perfusion does not normalize after two crystalloid bolus infusions, 10 mL/kg of packed red blood cells is infused. Rapid reassessment must follow each bolus. If clinical signs of perfusion have not normalized, repeat the bolus. Lack of response or later or recurring signs of hypovolemia suggest the need for blood transfusion and possible surgical exploration.

A common problem is the brain-injured child who is at risk for intracranial hypertension and who is also hypovolemic. In such cases, circulating volume must be restored to ensure adequate cerebral perfusion; therefore, fluid replacement is required until perfusion normalizes. Thereafter provide maintenance fluids with careful serial reassessments. Do not restrict fluids for children with head injuries.

Disability-Neurologic Deficit

Assess pupillary size and reaction to light and the level of consciousness. The level of consciousness can be reproducibly characterized by the AVPU (alert, voice, pain, unresponsive) system (Table 12–3). Pediatric GCS assessments can be done as part of the secondary survey (Table 12–4).

Exposure & Environment

Significant injuries can be missed unless the child is completely undressed and examined fully, front and back. Any patient transported on a backboard should be removed as soon as possible, as pressure sores may develop on the buttocks and heels of an immobilized patient within hours.

Because of their high ratio of surface area to body mass, infants and children cool rapidly. Hypothermia compromises outcome except with isolated head injuries; therefore, continuously monitor the body temperature and use warming techniques as necessary. Hyperthermia can adversely affect outcomes in children with acute brain injuries, so maintain normal body temperatures.

Table 12–3. AVPU system for evaluation of level of consciousness.

A Alert

V Responsive to Voice

P Responsive to Pain

U Unresponsive

^aThe appropriate number from each section is added to total between 3 and 15. A score less than 8 usually indicates CNS depression requiring positive-pressure ventilation.

^bIf no modification is listed, the same response applies for both infants and children.

Monitoring

Cardiopulmonary monitors, pulse oximetry, and end-tidal CO_2 monitors should be put in place immediately. At the completion of the primary survey, additional "tubes" may be needed to be placed. See Table 12–1 for age/weight-appropriate equipment sizes.

A. Nasogastric or Orogastric Tube

Children's stomachs should be assumed to be full. Gastric distention from positive-pressure ventilation increases the chance of vomiting and aspiration. The nasogastric route should be avoided in patients with significant midface trauma.

B. Urinary Catheter

An indwelling urinary bladder catheter should be considered to monitor urine output. Contraindications are based on

the risk of urethral transection; signs include blood at the meatus or in the scrotum or a displaced prostate detected on rectal examination. Urine should be tested for blood. After the initial flow of urine with catheter placement, the urine output should exceed 1 mL/kg/h.

SECONDARY SURVEY

After the Primary Survey and resuscitation phase, a focused history and a head-to-toe examination should be performed to reveal all injuries and determine priorities for definitive care.

History

Obtain a rapid, focused history from the patient (if possible), available family members or prehospital personnel. The AMPLE mnemonic is frequently used:

- A—Allergies
- M—Medications
- P—Past medical history/pregnancy
- L—Last meal
- E-Events/environment leading to the injury

Physical Examination

Skin

Search for lacerations, hematomas, burns, swelling, and abrasions. Remove superficial foreign material and cleanse as necessary. Cutaneous findings may indicate underlying pathology (eg, a flank hematoma overlying a renal contusion), although surface signs may be absent even with significant internal injury. Do not remove penetrating foreign objects as vital respiratory, vascular or organs may be involved and require removal in a controlled environment by a surgeon. Make certain that the child's tetanus immunization status is current. Consider tetanus immune globulin for incompletely immunized children.

Head

Check for hemotympanum and for clear or bloody cerebrospinal fluid leak from the nares. Battle sign (hematoma over the mastoid) and raccoon eyes are late signs of basilar skull fracture. Explore wounds, evaluating for foreign bodies and defects in galea or skull. CT scan of the head is an integral part of evaluation for altered level of consciousness, posttraumatic seizure, or focal neurologic findings (see section Head Injury, later). Pneumococcal vaccine may be considered for basilar skull fractures.

Spine

Cervical spine injury must be excluded in all children. This can be done clinically in children older than 4 or 5 years with

normal neurologic findings on examination who are able to deny midline neck pain or midline tenderness on palpation of the neck and who have no other painful distracting injuries that might obscure the pain of a cervical spine injury. If radiographs are indicated, a cross-table lateral neck view is obtained initially followed by anteroposterior, odontoid, and, in some cases, oblique views. Normal studies do not exclude significant injury, either bony or ligamentous, or involving the spinal cord itself. Therefore, an obtunded child should be maintained in cervical spine immobilization until the child has awakened and an appropriate neurologic examination can be performed. The entire thoracolumbar spine must be palpated and areas of pain or tenderness examined by radiography.

Chest

Children may sustain significant internal injury without outward signs of trauma. The most common type of injuries sustained from blust chest trauma are pulmonary contusions which may lead to hypoxemia. Pneumothoraces are detected and decompressed during the primary survey. Hemothoraces can occur with rib fractures or with injury to intercostal vessels, large pulmonary vessels, or lung parenchyma. Tracheobronchial disruption is suggested by large continued air leak despite chest tube decompression. Myocardial contusions and aortic injuries are unusual in children.

Abdomen

Blunt abdominal injury is common in multisystem injuries. Significant injury may exist without cutaneous signs or instability of vital signs. Abdominal pain and tenderness coupled with a linear contusion across the abdomen ("seat belt sign") increases the risk of intra-abdominal injury threefold. Tenderness, guarding, distention, diminished or absent bowel sounds, or poor perfusion mandate immediate evaluation by a pediatric trauma surgeon. Injury to solid viscera frequently can be managed nonoperatively in stable patients; however, intestinal perforation or hypotension necessitates operative treatment. Intra-abdominal injury is highly likely if the AST is less than 200 U/L or the ALT greater than 125 U/L; however, elevated levels that are below these thresholds do not exclude significant injury if a significant mechanism has occurred. When measured serially, a hematocrit of less than 30% also may suggest intra-abdominal injury in blunt trauma patients. Coagulation studies are rarely beneficial if no concomitant head injury is present. Obtaining a serum amylase immediately post-injury is controversial, as there is variable correlation between elevated levels and pancreatic injury.

Trauma ultrasonography, or the FAST (focused assessment with sonography for trauma), is routinely used in the adult trauma population. The purpose of the four-view examination (Morison pouch, splenorenal pouch, pelvic retrovesical space, and subcostal view of the heart) is to detect free fluid or blood in dependent spaces. In adults, such detection indicates clinically significant injury likely to require surgery. Accuracy and indications in children are much less clear. Solid-organ injuries are more frequently missed and much of the pediatric trauma management is nonoperative. As a result, detection of free fluid by ultrasound in children is less likely to lead to surgery or result in a change in management. At least one recent study showed no change in the rate of pediatric patients eventually undergoing abdominal CT regardless of FAST findings.

Pelvis

Pelvic fractures are classically manifested by pain, crepitus, and abnormal motion. Significant blood loss into the pelvis may occur due to vascular injury, thus have a sign index of suspicion in the setting of unexplained tachycardia or hypotension. Pelvic fracture is a relative contraindication to urethral catheter insertion. Many providers perform a rectal examination, noting tone, tenderness, and in boys, prostate position. If this is done, stool should be tested for blood.

Genitourinary System

If urethral transection is suspected, perform a retrograde urethrogram before catheter placement. Diagnostic imaging of the child with hematuria less than 50 red blood cells per high-power (hpf) field often includes CT scan or occasionally, IV urograms. Management of kidney injury is largely nonoperative except for renal pedicle injuries.

Extremities

Long bone fractures are common but rarely life threatening. Test for pulses, perfusion, and sensation. Neurovascular compromise requires immediate orthopedic consultation. Treatment of open fractures includes antibiotics, tetanus prophylaxis, and orthopedic consultation.

Central Nervous System

Most deaths in children with multisystem trauma are from head injuries, so optimal neurointensive care is important. Significant injuries include diffuse axonal injury; cerebral edema; subdural, subarachnoid, and epidural hematomas; and parenchymal hemorrhages. Spinal cord injury occurs less commonly. Level of consciousness should be assessed serially. A full sensorimotor examination should be performed. Deficits require immediate neurosurgical consultation and should be considered for a patient with a GCS less than 12. Extensor or flexor posturing represents intracranial hypertension until proven otherwise. If accompanied by a fixed, dilated pupil, such posturing indicates that a herniation syndrome is present, and mannitol or 3% hypertonic saline should be given if perfusion is normal (see further

discussion in next section). Treatment goals include aggressively treating hypotension to optimize cerebral perfusion, providing supplemental oxygen to keep saturations above 90%, achieving eucapnia (end-tidal CO₂ 35-40 mm Hg), avoiding hyperthermia, and minimizing painful stimuli. Early rapid sequence intubation, sedation, and paralysis should be considered. Mild prophylactic hyperventilation is no longer recommended, although brief periods of hyperventilation are still indicated in the setting of acute herniation. Seizure activity warrants exclusion of significant intracranial injury. In the trauma setting, seizures are frequently treated with fosphenytoin or levetiracetam. The use of high-dose corticosteroids for suspected spinal cord injury has not been prospectively evaluated in children and is not considered standard of care. Corticosteroids are not indicated for head trauma.

HEAD INJURY

Closed-head injuries range in severity from minor asymptomatic trauma without sequelae to fatal injuries. Even after minor closed-head injury, long-term disability and neuropsychiatric sequelae can occur.

- Traumatic brain injury (TBI) is the most common injury in children.
- Rapid acceleration-deceleration forces (eg, the shaken infant) as well as direct trauma to the head can result in brain injury.
- Rapid assessment can be made by evaluating mental status with the GCS score and assessing pupillary light response.
- All head injuries require a screening evaluation with symptom inventory and complete neurologic examination.

Prevention

Wearing helmets while riding wheeled recreational devices, playing contact sports, and participating in snowsports is a simple strategy in preventing head injuries. Over 50% of children fail to wear helmets when riding bicycles; rates are lower with other wheeled devices. Adolescents are less likely to use protective equipment and warrant special attention when discussing helmet use. More stringent helmet use while playing contact sports and return to play recommendations are now in place in child and high school sports programs. Toppled televisions, dressers and other unsecured furniture can also result in mild to severe head injuries in young children; anticipatory guidance regarding properly securing furniture should be provided to parents.

Clinical Findings

A. Signs and Symptoms

Head injury symptoms are nonspecific and may include headache, dizziness, nausea/vomiting, disorientation, amnesia, slowed thinking, and perseveration. Loss of consciousness is not necessary to diagnose a concussion (see Chapter 27 for more on concussion). Worsening symptoms in the first 24 hours may indicate more severe TBI. Obtain vital signs and assess the child's level of consciousness by the AVPU system (see Table 12-3) or GCS (see Table 12-4), noting irritability or lethargy and pupillary equality, size, and light reaction. Perform a physical examination, including a detailed neurologic examination, being mindful of the mechanism of injury. Cerebrospinal fluid or blood from the ears or nose, hemotympanum, or the later appearance of periorbital hematomas (raccoon eyes) or Battle sign imply a basilar skull fracture. Evaluate for associated injuries, paying special attention to the cervical spine. Consider child abuse; injuries observed should be consistent with the history, the child's developmental stage, and the injury mechanism.

B. Imaging Studies

CT may be indicated. However, observation may be appropriate management and reduces the use of CT. A 2009 multicenter investigation of head-injured patients presenting to the ED derived and validated a decision rule for identifying those children at very low risk of clinically important traumatic brain injuries (Figure 12–9). Plain films are not generally indicated. In infants, a normal neurologic examination does not exclude significant intracranial hemorrhage. Consider imaging if large scalp hematomas or concerns of nonaccidental trauma are present in younger children.

Differential Diagnosis

CNS infection, toxicological ingestions, or other medical causes of altered mental status may present similarly to head injuries which often have no external signs of injury. In young infants when no history is available, one must also consider sepsis and inborn errors of metabolism.

Complications

Central Nervous System Infection

Open-head injuries (fractures with overlying lacerations) pose an infection risk due to direct contamination. Basilar skull fractures that involve the cribriform plate or middle

CHAPTER 12

ciTBI = clinically important traumatic brain injury. GCS = Glasgow Coma Scale. LOC = loss of consciousness. [†]Other signs of altered mental status: agitation, somnolence repetitive questioning, or slow response to verbal communication.

¹Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by motorized vehicle; falls of more than 3 ft (or more than 5 ft for panel B); or head struck by a high-impact object.

[§]Patients with certain isolated findings (ie, with no other findings suggestive of traumatic brain injury), such as isolated LOC, isolated headache, isolated vomiting, and certain type of isolated scalp hematomas in infants older than 3 mo, have a risk of ciTBI substantially lower than 1%.

¹Risk of ciTBI exceedingly low, generally lower than risk of CT-induced malignancies. Therefore, CT scans are not indicated for most patients in this group.

▲ Figure 12–9. Suggested CT algorithm for children younger than 2 years (A) and for those aged 2 years and older (B) with GCS scores 14–15 after head trauma. (Adapted with permission from Kuppermann N et al: Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study. Lancet 2009 Oct 3;374(9696):1160–1170.)

ear cavity may allow a portal of entry for *Streptococcus pneumoniae*. Pneumococcal vaccination is considered for such cases.

Acute Intracranial Hypertension

Close observation will detect early signs and symptoms of elevated increased ICP. Early recognition is essential to avoid disastrous outcomes. Symptoms include altered mental status, headache, vision changes, vomiting, gait difficulties, and pupillary abnormalities. Papilledema is a cardinal sign of increased ICP. Other signs may include stiff neck, cranial nerve palsies, and hemiparesis. Cushing triad (bradycardia, hypertension, and irregular respirations) is a late and ominous finding. Consider CT scan before lumbar puncture if there is concern for elevated ICP because of the risk of herniation. Lumbar puncture should be deferred in the unstable patient.

Treatment-Therapy for elevated ICP must be swift and aggressive. Maintenance of adequate oxygenation, ventilation, and perfusion is paramount. Rapid sequence intubation is often necessary to protect the airway using a sedative and paralytic to decrease the ICP elevation accompanying intubation. Lidocaine is a controversial adjunct pretreatment medication (administered 2-3 minutes prior to attempt) during RSI and is thought to blunt increases in ICP during intubation by suppressing cough and gag reflexes and protect cerebral perfusion. Avoid hypoperfusion and hypoxemia, as both are associated with increased risk of morbidity and mortality. Hyperventilation (goal PCO, 30-35 mm Hg) is reserved for acute herniation; otherwise, maintain PCO₂ between 35 and 40 mm Hg. Mannitol (0.5-1 g/kg IV), an osmotic diuretic, will reduce brain water during acute herniation and hypertonic saline (3%; 4-6 mL/kg bolus doses or 1-2 mL/kg/h infusion) also may be used. Adjunctive measures to decreased ICP include elevating the head of the bed 30 degrees, maintaining the head in a midline position and treating hyperpyrexia (fever) and pain. Obtain immediate neurosurgical consultation. Further details about management of intracranial hypertension (cerebral edema) are presented in Chapter 14.

Prognosis

Children with concussion should not return to sports on the day of injury. Return to sport usually begins when symptomfree at rest and during exercise without medication use, followed by a graduated return-to-play protocol. All states now have a concussion law and most require a physician's note to return to play. In addition to sport limitations, patients may require a modified academic schedule and additional academic accommodations, including shorter days, longer testing periods, and decreased amounts of homework. Patients should only return to sports after a complete return to other school activities. Most children recover fully within 1–2 weeks. Acute symptoms seen in the ED do not correlate with long-term outcome, and therefore it is crucial for all patients to have follow-up management by their primary physician. Persistent symptoms indicate the need for rehabilitation and/or neuropsychological referral. The CDC's Heads Up program has accessible concussion and return to play information online and is a good resource for parents, coaches, and health care providers.

The prognosis for children with moderate to severe injuries depends on many factors including severity of initial injury, presence of hypoxia or ischemia, development and subsequent management of intracranial hypertension, and associated injuries.

BURNS

THERMAL BURNS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Burn patterns can distinguish accidental burns from inflicted burns.
- Burns are categorized into three classes based on skin layer involved: superficial, partial thickness, and full thickness.
- Burns of the hands, feet, face, eyes, ears, and perineum are always considered to be major burns.

Burns are a common cause of accidental death and disfigurement in children. Common causes include hot water or food, appliances, flames, grills, vehicle-related burns, and curling irons. Burns occur commonly in toddlers—in boys more frequently than in girls. The association with child abuse and the preventable nature of burns constitute an area of major concern in pediatrics.

Prevention

Hot liquids should be placed as far as possible from counter edges. While cooking, panhandles should be turned away from stove edge. Water heater thermostats should be turned to less than 120°F (49°C). Irons and electrical cords should be kept out of reach of children. Barriers around fireplaces are crucial. Infant and young children should wear protective clothing including hats when outdoors. Infant approved sunscreen should be applied to children 6 months and older, and also in younger infants in long periods of sun exposure outdoors.

Clinical Findings

A. Signs and Symptoms

Superficial-thickness burns are painful, dry, red, and hypersensitive. Sunburn is an example. Partial-thickness burns are subgrouped as superficial or deep, depending on appearance. Superficial partial-thickness burns are red and often blister. Deep partial-thickness burns are pale, edematous, blanch with pressure, and they display decreased sensitivity to pain. Full-thickness burns affect all epidermal and dermal elements. A full-thickness wound is white or black, dry, depressed, leathery in appearance, and insensate. Deep full-thickness burns are the most severe, extending through all layers of skin as well as into the underlying fascia, muscle, and possibly bone. Singing of nasal or facial hair, carbonaceous material in the nose and mouth, and stridor indicate inhalational burns and may herald critical airway obstruction. Up to 25% of burns in children may be due to child physical abuse. Burn patterns can help distinguish inflicted from accidental causes. If the burn pattern does not fit the mechanism, consider child abuse.

B. Laboratory Findings

Laboratory evaluation is rarely indicated. With extensive partial- and full-thickness burns, baseline complete blood cell count (CBC), basic metabolic panel, and creatine kinase are helpful for tracking infectious or renal complications. Consider carbon monoxide poisoning after inhalational injury: obtain an arterial blood gas and carboxyhemoglobin levels.

C. Imaging Studies

Imaging studies are rarely indicated. Neck x-rays should not delay intubation when inhalational injury is suspected.

Differential Diagnosis

The differential diagnosis of burns is limited when a history is provided. In the preverbal child when no history is available, the primary alternate consideration is cellulitis.

Complications

Superficial- and superficial partial-thickness burns typically heal well. Deep partial- and full-thickness burns are at risk of scarring. Loss of barrier function predisposes to infection. Damage to deeper tissues in full-thickness burns may result in loss of function, contractures, and in the case of circumferential burns, compartment syndrome. Renal failure secondary to myoglobinuria from rhabdomyolysis is also a concern with more severe burns.

Treatment

Burn extent can be classified as major or minor. Minor burns are less than 10% of the body surface area (BSA) for partialthickness burns, or less than 2% for full-thickness burns. **Superficial thickness burns are not counted when assessing** % **BSA**. Partial- or full-thickness burns of the hands, feet, face, eyes, ears, and perineum are considered major.

A. Superficial- and Partial-Thickness Burns

These burns generally can be treated in the outpatient setting. Wounds with a potential to cause disfigurement or functional impairment-especially wounds of the face, hands, feet, digits, or perineum-should be referred promptly to a burn surgeon. Analgesia is paramount. After parenteral narcotic administration, initial treatment of partial-thickness burns with blisters consists of saline irrigation followed by application of clear antibiotic ointment and a nonadherent dressing (eg, petroleum gauze). Digits should be individually dressed to prevent adhesions. Because of the pain associated with aggressive debridement and the ability to provide an infectious barrier, smaller blisters may be left intact under the dressing. Larger bullae may either be drained or left in place. Protect the wound with a bulky dressing, reexamine within 48 hours and serially thereafter. Treatment at home with cool compresses and hydrocodone or oxycodone is preferred.

B. Full-Thickness, Deep or Extensive Partial-Thickness, and Subdermal Burns

Major burns require particular attention to the ABCs of trauma management. Early establishment of an artificial airway is critical with oral or nasal burns because of their association with inhalation injuries and critical airway obstruction. If singing of the oro or nasopharynx is noted on initial exam, immediate intubation is recommended. Perform a primary survey (see earlier discussion). Consider toxicity from carbon monoxide, cyanide, or other combustion products. Place a nasogastric tube and bladder catheter. The secondary survey identifies associated injuries, including those suggestive of abuse.

Fluid losses can be substantial. Initial fluid resuscitation should restore adequate circulating volume. Subsequent fluid administration must account for increased losses. Fluid needs are based on weight and percentage of BSA with partial- and full-thickness burns. Figure 12–10 shows percentages of BSA by region in infants and children. The Parkland formula for fluid therapy is 4 mL/kg/% BSA burned for the first 24 hours, with half administered in the first 8 hours, in addition to maintenance rates. Use of burn tables improves calculation of appropriate fluids. Goal urine output is 1–2 mL/kg/h.

Children with burns greater than 10% BSA in a circumferential pattern, who are suspicious for abuse, or with burns associated with inhalational injury, explosions or fractures, should be admitted. Additionally, admission is warranted for adequate pain control in a patient requiring parenteral analgesia. Burns greater than 20% BSA or full-thickness burns greater than 2% BSA should be admitted to a children's hospital or burn center. Children with subdermal burns require immediate hospitalization at a burn center under the care of a burn specialist.

Prognosis

Outcome depends on many factors. Healing occurs with minimal damage to epidermis in superficial burns. In contrast, full-thickness burns will be hard, uneven, and fibrotic unless skin grafting is provided. In general, the greater the surface area and depth of burn injury, the greater the risk of long-term morbidity and mortality.

ELECTRICAL BURNS

Brief contact with a high-voltage source results in a contact burn and is treated accordingly. Infants and toddlers may bite electric cords, resulting in burns to the commissure of the lips. A late complication is labial artery hemorrhage. Children electrocuted with household current who are awake and alert at the time of medical evaluation are unlikely to have significant injury. An electrocardiogram (ECG) is not necessary but urinalysis should be considered for severe electrical injury as rhabdomyolysis may result. If current passes through the body, the pattern of the injury depends on the path of the current. Exposure to high-voltage current often induces a "locking-on" effect due to alternating current causing tetany. Extensive nerve and muscle injury, fractures, and cardiac arrhythmias in addition to dermal burns are possible. Lightning strikes are more likely to induce asystole

DISORDERS DUE TO EXTREMES OF ENVIRONMENT

HEAT-RELATED ILLNESSES & HEAT STROKE

- Heat illness is a spectrum ranging from heat cramps to life-threatening heat stroke.
- A high index of suspicion is required to make the diagnosis given the lack of specific symptoms and a usually normal or only slightly elevated temperature.

Prevention

Avoid exposure to extremes of temperature for extended periods. Plan athletic activities for early morning or late afternoon and evening. Acclimatization, adequate water, shade, and rest periods can prevent heat-related illness.

Clinical Findings

Heat cramps are brief, severe cramps of skeletal or abdominal muscles following exertion. Core body temperature is normal or slightly elevated. Electrolyte disturbance is rare and mild: laboratory evaluation is not indicated.

Heat exhaustion includes multiple, vague constitutional symptoms following heat exposure. Patients continue to sweat and have varying degrees of sodium and water depletion. Core temperature should be monitored frequently but is often normal or slightly increased. Symptoms and signs include weakness, fatigue, headache, disorientation, pallor, thirst, nausea with or without vomiting, and occasionally muscle cramps without CNS dysfunction. Shock may be present.

Heat stroke is a life-threatening failure of thermoregulation. Diagnosis is based on a rectal temperature above 40.6°C with associated neurologic dysfunction in a patient with an exposure history. Lack of sweating is **not** a necessary criterion. Symptoms are similar to those of heat exhaustion, but severe CNS dysfunction is a hallmark. Patients may be incoherent or combative. In severe cases, vomiting, shivering, coma, seizures, nuchal rigidity, and posturing may be present. Cardiac output may be high, low, or normal. Cellular hypoxia, enzyme dysfunction, and disrupted cell membranes lead to global end-organ derangements and patients may develop rhabdomyolysis, myocardial necrosis, electrolyte abnormalities, acute tubular necrosis and renal failure, hepatic degeneration, acute respiratory distress syndrome (ARDS), and disseminated intravascular coagulation (DIC).

Differential Diagnosis

Viral gastroenteritis, sepsis and other infectious processes, neuroleptic malignant syndrome, malignant hyperthermia, and anticholinergic poisoning may present similarly.

Treatment

Removal from the offending environment and removal of clothing are the first steps in managing any heat-related illness. **Heat cramps** typically respond to rest and rehydration with electrolyte solutions. Severe cramping and **heat exhaustion** should prompt evaluation of electrolytes to guide IV fluid rehydration.

Heat Stroke Management

- 1. Address the ABCs and administer 100% oxygen.
- 2. Place monitors, rectal temperature probe, Foley catheter and nasogastric tube
- Administer IV fluids: isotonic crystalloid for hypotension; cooled fluids are acceptable. Consider central venous pressure monitoring. Consider providing diazepam for patient comfort.
- Once resuscitative efforts have begun, initiate active cooling: fanning/misting with cool water; ice application at neck, groin, and axillae. Discontinue active cooling measures once core temperature reaches 39°C to prevent shivering.
- Order laboratory tests: CBC; electrolytes; glucose; creatinine; prothrombin time and partial thromboplastin time; creatine kinase; liver function tests; arterial blood gases; urinalysis; and serum calcium, magnesium, and phosphate.
- 6. Admit to the pediatric intensive care unit.

Prognosis

Full recovery is the rule for heat cramps and heat exhaustion. Patients with heat stroke are at risk of end-organ damage due to volume depletion, rhabdomyolysis, direct renal injury, hepatocellular injury, and DIC; however, even in this critically ill population, some children recover fully with intensive management.

HYPOTHERMIA

- ► Hypothermia is defined as a core temperature of less than 35°C.
- Children are at increased risk due to a greater BSAweight ratio.

 In children, hypothermia is most commonly associated with water submersion.

Prevention

Given the high association with submersion injuries, children should be carefully monitored around water. Proper use of life vests is critical.

Clinical Findings

A. Signs and Symptoms

Hypothermia is defined as a core temperature of less than 35°C. In an attempt to maintain core temperature, peripheral vasoconstriction leads to cool mottled skin. Shivering increases heat production to two to four times the basal levels. As temperature falls, heart rate slows and mental status declines. Severe cases (< 28°C) mimic death: patients are pale or cyanotic, pupils may be fixed and dilated, muscles are rigid, and there may be no palpable pulses. Heart rates as low as 4-6 beats/min may provide adequate perfusion, due to lowered metabolic needs in severe hypothermia. Besides cold exposure, disorders that cause incidental hypothermia include sepsis, metabolic derangements, ingestions, CNS disorders, and endocrinopathies. Neonates, trauma victims, intoxicated patients, and the chronically disabled are particularly at risk. Because hypothermia may be confused with postmortem changes, death is not pronounced until the patient has been rewarmed and remains unresponsive to resuscitative efforts.

B. Laboratory Findings

Standard evaluation includes CBC, electrolytes, creatinine, coagulation studies, and glucose and blood gas studies. Coagulopathy, hypoglycemia, and acidosis are common. However, correction of derangements is accomplished by rewarming and resuscitating the patient. Also consider toxicology screen depending on the clinical scenario.

C. Imaging Studies

Submersion is the most common cause of hypothermia. Chest x-ray should be performed to assess for pulmonary edema and/or aspiration. Other radiographic studies should be performed according to the history with special attention to potential head or skeletal trauma.

Treatment

A. General Supportive Measures

Management of hypothermia is largely supportive. Administer warmed and humidified 100% oxygen. Continuously monitor core body temperature using a low-reading indwelling rectal thermometer. Handle patients gently as the hypothermic myocardium is exquisitely prone to arrhythmias. Ventricular fibrillation may occur spontaneously or as a result of minor handling or invasive procedures. If asystole or ventricular fibrillation is present on the cardiac monitor, perform chest compressions and use standard pediatric advanced life support techniques as indicated. Defibrillation and pharmacologic therapy (eg, epinephrine) are unlikely to be successful until core rewarming has occurred. Hypoglycemia should be corrected. Spontaneous reversion to sinus rhythm at 28–30°C may take place as rewarming proceeds.

B. Rewarming

Remove wet clothing immediately. Rewarming techniques are categorized as passive external, active external, or active core rewarming. Passive rewarming, such as covering with blankets, is appropriate only for mild cases (33–35°C). Active external rewarming methods include warming lights, thermal mattresses or electric warming blanket, and warm bath immersion. Be aware of potential core temperature depression after rewarming has begun when vasodilation allows cooler peripheral blood to be distributed to the core circulation. This phenomenon is called *afterdrop*.

Active core rewarming techniques supplement active external warming for moderate to severe hypothermia. The techniques include warmed, humidified oxygen, warmed (to 40°C) crystalloid IV fluids, and warm peritoneal and pleural lavage. Bladder and bowel irrigation are not generally effective because of low surface areas for temperature exchange. ECMO achieves controlled core rewarming, can stabilize volume and electrolyte disturbances, and is maximally effective.

Prognosis

Recovery of the hypothermic victim is multifactorial. If associated with submersion injury (see next), CNS anoxic injuries and lung injury play a major role. Mortality rates are high and are related to the presence of underlying disorders and injuries. Children with a core temperature as low as 19°C have survived without neurologic compromise.

SUBMERSION INJURIES

- CNS and pulmonary injuries account for major morbidity.
- Child may appear well at presentation, but late CNS and pulmonary changes can occur hours later.
- Minimum observation period is 12–24 hours.
CHAPTER 12

Prevention

The World Health Organization defines *drowning* as the process of experiencing respiratory impairment from submersion/immersion in liquid. The terms *wet* or *drydrowning*, *near-drowning*, and others are no longer used; nonfatal drowning describes survivors. Water hazards are ubiquitous; even toilets, buckets, and washing machines pose a threat. Risk factors include epilepsy, alcohol, and lack of supervision. Males predominate in submersion deaths. Prevention strategies include protective fencing around public and private pools, use of life vests, avoiding swimming alone, and adequate supervision. Swim lessons may have a role in a comprehensive prevention strategy, even for children 1–4 years of age.

Clinical Findings

A. Signs and Symptoms

Depending on the duration of submersion and any protective hypothermia effects, children may appear clinically dead or completely normal. Major morbidity stems from CNS and pulmonary insult. Cough, nasal flaring, grunting, retractions, wheezes or other lung sounds, and cyanosis are common. A child rewarmed to 33°C but who remains apneic and pulseless is unlikely to survive to discharge or will have severe neurologic deficits. Until a determination of brain death can be made, however, aggressive resuscitation should continue in a patient with return of circulation. Cardiovascular changes include myocardial depression and arrhythmias. Children may develop ARDS.

B. Laboratory Findings

Electrolyte alterations are generally negligible. Unless hemolysis occurs, hemoglobin concentrations change only slightly. Blood gas will show hypoxemia and acidosis.

C. Imaging Studies

Chest radiographs may be normal or may show signs of pulmonary edema. CT of the brain is warranted when the patient is comatose or believed to have suffered prolonged asphyxia or blunt head trauma. Consider cervical spine injury in teens where diving or intoxication may be involved.

Treatment

Care is supportive. Correct hypothermia and treat symptomatically. For children who appear well initially, observe for 12–24 hours for late pulmonary or neurologic compromise. Respiratory distress, an abnormal chest radiograph, abnormal arterial blood gases, or hypoxemia by pulse oximetry require maximal supplemental oxygen, cardiopulmonary monitoring, and frequent reassessment. There is little evidence for use of surfactant following drowning.

Prognosis

Anoxia from laryngospasm or aspiration leads to irreversible CNS damage after only 4–6 minutes. A child must fall through ice or directly into icy water for cerebral metabolism to be slowed sufficiently by hypothermia to provide protection from anoxia. Survival of the drowning victim depends on the duration of anoxia and the degree of lung injury. Children experiencing brief submersion with effective, high-quality resuscitation are likely to recover without sequelae. Children presenting asystolic are unlikely to survive.

LACERATIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- The basic objectives of wound management are to stop bleeding, prevent infection, and ensure wound healing that achieves optimal functional and cosmetic outcomes.
- Options for wound closure include staples, sutures, and tissue adhesives.

Lacerations are a common reason to visit an ED. Lacerations can range from minor cuts that require no repair to complex lacerations that may require surgical consultation for adequate repair. The goals of laceration repair are to stop ongoing bleeding, prevent infection, and ensure wound healing that achieves optimal functional and cosmetic outcomes. Technical instruction of laceration repair is beyond the scope of this text as we present the basics of laceration wound care.

Clinical Findings

A. Signs and Symptoms

Lacerations present in a variety of shapes and sizes and occur over all parts of the body. Patients may present immediately after the injury or several days later. Wounds may contain foreign material, involve muscular, vascular, bony, tendon/ ligamentous structures, or extend into joint spaces. Options for wound repair include staples, suture material (both absorbable and nonabsorbable), and tissue adhesives. Tissue adhesives should *never* be used for highly contaminated wounds (eg, bites).

B. Imaging Studies

Imaging is usually not indicated for simple lacerations; however, plain x-rays may be indicated in certain situations. Lacerations caused by penetrating or crush injury may be associated with fractures. Lacerations may involve joint spaces. Foreign bodies may be present in wounds.

Treatment

Obtain information regarding mechanism and age of the injury. Assess extent of the wound with identification of foreign bodies, neurovascular compromise, tendon/ligament damage, muscle, or joint involvement. Obtain appropriate surgical consultations as needed.

Provide adequate analgesia or anesthesia, using topical or injectable methods prior to wound care. Irrigate the wound using normal saline (tap water is an appropriate alternative) with high pressure (5–8 psi [pounds per square inch]). Debride devitalized tissue, remove foreign material, and then close wound using staples, sutures, or tissue adhesive. Antibiotic ointment may be applied after wound repair. Consider tetanus prophylaxis depending on immunization status. Patients should return as instructed to have suture material removed if needed (Table 12–5).

Prognosis

Functional and aesthetically pleasing cosmetics is generally achieved with initial repair. Complex lacerations may involve multiple visits with surgical service for wound reconstruction.

Table 12-5. Timing of suture removal.

Area of Body	Number of Days
Face	3–4
Neck	5–6
Scalp	6–7
Chest or abdomen	7
Arms and backs of hands	7
Legs and tops of feet	10
Back	10
Palms of hands or soles of feet	14

- Weiss EA et al: Water is a safe and effective alternative to sterile normal saline for wound irrigation prior to suturing, a prospective, double-blind, randomized, controlled clinical trial. BMJ Open 2013;16:3(1) [PMID: 23325896].

ANIMAL & HUMAN BITES

Bites account for a large number of visits to the ED. Most fatalities are due to dog bites. Human and cat bites cause the majority of infected bite wounds.

DOG BITES

Prevention

Boys are bitten more often than girls. The dog is known by the victim in most cases. Younger children have a higher incidence of head and neck wounds, whereas school-age children are bitten most often on the upper extremities. Children should be taught to not taunt dogs or approach dogs that are eating, sleeping, or are unknown to them.

Clinical Findings

A. Signs and Symptoms

Dogs may cause abrasions, lacerations, and puncture wounds. Larger dogs may tear skin, subcutaneous tissue, and muscle, or even cause fractures. Other signs and symptoms are related to the structures injured.

B. Imaging Studies

Bites caused by large dogs associated with significant crush injury may be associated with fractures. Dislodged teeth may also be present in the wound. Plain x-rays may be indicated.

Treatment

Provide appropriate analgesia or anesthesia before starting wound care. Debride any devitalized tissue and remove foreign matter. Irrigate using normal saline with high pressure (> 5 psi) and volume (> 1 L). Consider tetanus prophylaxis depending on immunization status. Rabies risk is low among dogs in developed countries; prophylaxis is rarely indicated. Suture wounds only if necessary for cosmesis as closure increases the risk of infection. **Do not use tissue adhesives due to risk of infection.** Prophylactic antibiotics do not decrease infection rates in low-risk dog bites, except those involving the hands and feet. Bites involving a tendon, joint, periosteum, or associated with fracture require prompt orthopedic surgery consultation. *Pasteurella canis* and *Pasteurella multocida*, streptococci, staphylococci, and anaerobes may infect dog bites. Broad-spectrum coverage with amoxicillin and clavulanic acid is first-line therapy.

Complications

Complications of dog bites include scarring, skin infections, CNS infections, septic arthritis, osteomyelitis, endocarditis, sepsis, and posttraumatic stress.

CAT BITES

Prevention

Cat-inflicted wounds occur more frequently in girls. The principal complication is infection, and the risk is higher compared to dog bites as cat bites produce a puncture wound. Children should be observed closely when playing with kittens or cats.

Clinical Findings

A. Signs and Symptoms

Cat bites typically result in abrasions and puncture wounds. Within 12 hours, untreated bites may result in cellulitis or, when involving the hand, tenosynovitis and septic arthritis. Other signs and symptoms are related to the structures injured. Cat scratch disease (CSD) can occur after bites or scratches especially from kittens. Local findings include a papule, vesicle, or pustule at the site of inoculation. The hallmark of CSD is regional lymphadenitis. See Chapter 42 for a detailed discussion of CSD.

B. Laboratory Findings

Serologic tests for *Bartonella henselae* are available when cat scratch is suspected. C-reactive protein and erythrocyte sedimentation rate may be useful to monitor treatment response in infected cat bites.

Complications

Cellulitis, tenosynovitis, and septic arthritis are important potential complications of cat bites. Systemic illness is rare.

Treatment

Management is similar to that for dog bites. Provide appropriate analgesia or anesthesia before starting wound care. Debride any devitalized tissue and remove foreign matter. With isolated puncture wounds, high-pressure irrigation is contraindicated as it may force bacteria deeper into the tissue. Although controversial, soaking puncture wounds in an antiseptic solution (eg, dilute povidone-iodine) solution for 15 minutes is an accepted method to cleanse puncture wounds. Some experts recommend the practice to promote wound healing while others report delayed wound healing.

Alternatively, the wound may be soaked in dilute povidone-iodine solution for 15 minutes. Consider tetanus prophylaxis in the under- or unimmunized. As with dogs, rabies risk is low in developed countries and prophylaxis is rarely indicated. Cat bites should *not* be closed except when absolutely necessary for cosmesis.

P multocida is the most common pathogen. Prophylactic antibiotics are recommended. First-line treatment is amoxicillin and clavulanic acid. The dosage of the amoxicillin component should be 80 mg/kg/24 h in three divided doses. The maximum dosage is 2 g/24 h. Strongly consider admission and parenteral antibiotics for infected wounds on the hands and feet.

HUMAN BITES

Most infected human bites occur during fights when a clenched fist strikes bared teeth. Pathogens most commonly include streptococci, staphylococci, anaerobes, and *Eikenella corrodens*. Hand wounds and deep wounds should be treated with antibiotic prophylaxis against *E corrodens* and grampositive pathogens with a penicillinase-resistant antibiotic (amoxicillin with clavulanic acid). Wound management is the same as for dog bites. Only severe lacerations involving the face should be sutured. Other wounds can be managed by delayed primary closure or healing by secondary intention. A major complication of human bite wounds is infection of the metacarpophalangeal joints. A hand surgeon should evaluate clenched-fist injuries from human bites if extensor tendon injury is identified or joint involvement is suspected.

Halaas GW: Management of foreign bodies in the skin. Am Fam Physician 2007:76(5):683 [PMID: 17894138].

PAIN MANAGEMENT & PROCEDURAL SEDATION

Relief of pain and anxiety is paramount in providing care to pediatric patients and should be assessed and managed at all times. Parenteral agents are effective, safe, and produce few side effects if used judiciously. Intranasal administration of several sedative and narcotic medications is now an accepted route of administration and may omit the need for IV placement. Many agents also have amnestic properties. Refer to Chapter 32 for more information on typical analgesic medications used in pediatric emergency care.

Procedures such as fracture reduction, laceration repair, burn care, sexual assault examinations, abscess incision and drainage, lumbar puncture, and diagnostic procedures such as CT and magnetic resonance imaging may all be performed more effectively and compassionately if effective analgesia, anxiolysis or sedation is used. The clinician should decide whether procedures will require analgesia, anxiolysis, sedation, or a combination of methods.

Safe and effective sedation requires thorough knowledge of the selected agent and its side effects, as well as suitable monitoring devices, resuscitative medications, equipment, and personnel. The decision to perform procedural sedation and analgesia (PSA) must be patient-oriented and tailored to specific procedural needs, while ensuring the child's safety throughout the procedure. In order to successfully complete this task, a thorough pre-procedural assessment should be completed, including a directed history and physical examination. Risks, benefits, and limitations of the procedure should be discussed with the parent or guardian and informed; verbal consent must be obtained PSA goals in the ED setting usually involve minimal or moderate sedation. Minimal sedation is a state in which the patient's sensorium is dulled, but he or she is still responsive to verbal stimuli. Moderate sedation is a depression of consciousness in which the child responds to tactile stimuli. In both cases, airway reflexes are preserved. It is important to remember that sedation is a continuum and the child may drift to deeper, unintended levels of sedation. Ensure appropriate resuscitative equipment and personnel are readily available when providing analgesia, anxiolysis and sedation.

Poisoning

Richard C. Dart, MD, PhD Barry H. Rumack, MD George Sam Wang, MD

INTRODUCTION

Accidental and intentional exposures to toxic substances occur in children of all ages. Children younger than 6 years are primarily involved in accidental exposures, with the peak incidence in 2-year-olds. Of the more than 2 million exposures reported by the American Association of Poison Control Centers' National Poison Data System in 2015, a total of 61% of exposures occurred in those younger than 20 years: 48% in children aged 5 years and younger, 6% aged 6-12 years, and 7% aged 13-19 years. Young children's exposures are typically unintentional low dose/volume exposures, but are occasionally exposed to intentional poisoning through the actions of parents or caregivers. Involvement of child abuse specialists is very helpful in these cases (see Chapter 8). Substance abuse and intentional ingestions account for most exposures in the adolescent population. In some locales, small-scale industrial or manufacturing processes may be associated with homes and farms, and exposures to hazardous substances should be considered in the history. Methamphetamine and hash oil production is extremely hazardous and can cause injury to children from inhalation and burns.

Pediatric patients also have special considerations pertaining to nonpharmaceutical toxicologic exposures. Their shorter stature places them lower to the ground as well as the fact that many are crawling, and some gas and vapor exposures will gather closer to the ground. They may have a greater inhalational exposure due to their higher minute ventilation. At their younger age, they may not be physically mature enough to remove themselves from exposures. They also have a large body surface area to weight ratio making them vulnerable to topical exposures and hypothermia.

Mowry JB et al: 2015 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS): 33rd Annual Report. Clin Toxicol (Phila) Dec 2016;54(10): 924–1109. doi: 10.1080/15563650.2016.1245421.28004588.

PHARMACOLOGIC PRINCIPLES OF TOXICOLOGY

In the evaluation of the poisoned patient, it is important to compare the anticipated pharmacologic or toxic effects with the patient's clinical presentation. If the history is that the patient ingested a tranquilizer 30 minutes ago, but the clinical examination reveals dilated pupils, tachycardia, dry mouth, absent bowel sounds, and active hallucinations—clearly anticholinergic toxicity—diagnosis and therapy should proceed accordingly. In addition, standard pharmacokinetics (absorption, distribution, metabolism, and elimination) often cannot be applied in the setting of a large dose, since these parameters are extrapolated from healthy volunteers receiving therapeutic doses.

Absorption

Depending on the route, absorption rates can vary in general, intravenous/intra-arterial > inhalation > sublingual > intramuscular > subcutaneous > intranasal > oral > rectal > dermal. Large overdoses, hypotension, decreased gut mobility are factors that can delay absorption.

Elimination Half-Life

The $t_{1/2}$ of an agent must be interpreted carefully. Most published $t_{1/2}$ values are for therapeutic dosages. The $t_{1/2}$ may increase as the quantity of the ingested substance increases for many common intoxicants such as salicylates. One cannot rely on the published $t_{1/2}$ for salicylate (2 hours) to assume rapid elimination of the drug. In an acute salicylate overdose (150 mg/kg), the apparent $t_{1/2}$ is prolonged to 24–30 hours.

Volume of Distribution

The volume of distribution (Vd) of a drug is determined by dividing the amount of drug absorbed by the blood level.

With theophylline, for example, the Vd is 0.46 L/kg body weight, or 32 L in an average adult. In contrast, digoxin distributes well beyond total body water. Because the calculation produces a volume above body weight, this figure is referred to as an "apparent volume of distribution."

Body Burden

Body burden represents the total amount of drug or toxin within the body and may be useful to determine the dose absorbed from an ingestion. For example, a 20-kg child with an acetaminophen blood level reported as 200 mcg/mL (equivalent to 200 mg/L) would have a body burden of 4000 mg of acetaminophen. This is ascertained by taking the volume of distribution of 1 L times the weight of the child times the blood level in milligram per liter. This would be consistent with an overdose history of having consumed eight extrastrength 500-mg tablets but would not be consistent with a history of therapeutic administration of 15 mg/kg for four doses. Such a therapeutic administration would have a maximum administered dose of 1200 mg (20 kg times 15 mg/kg times four doses), which is well under the calculated body burden. Given metabolism of the drug with a normal half-life of 2 hours, it is apparent that much of the first doses would have been metabolized further adding to an understanding that this must not have been a therapeutic dose.

Metabolism & Excretion

The route of excretion or detoxification is important for planning treatment. Methanol, for example, is metabolized to the toxic product, formic acid. This metabolic step may be blocked by the antidote fomepizole or ethanol and patients with renal failure may not eliminate methanol as readily.

Blood Concentrations

Care of the poisoned patient should never be guided solely by laboratory measurements. Concentration results may not return in time to influence acute management. Initial treatment should be directed at symptomatic and supportive care, guided by the clinical presentation, followed by more specific therapy based on laboratory determinations. Clinical information may speed the identification of a toxic agent by the laboratory.

PREVENTING CHILDHOOD POISONINGS

Inclusion of poison prevention as part of routine well-child care should begin at the 6-month well-baby visit. The poison prevention handout included as Table 13–1 may be copied and distributed to parents. It contains poison prevention information as well as first-aid actions that should be taken in the event of an exposure. All poison control centers in the United States can be reached by dialing 1-800-222-1222; the call will be automatically routed to the correct regional center.

GENERAL TREATMENT OF POISONING

INITIAL TELEPHONE CONTACT

Basic information obtained at the first telephone contact includes the patient's name, age, weight, address, and telephone number; the agent and amount of agent ingested; location; exposure; the patient's present condition; and the time elapsed since ingestion or other exposure. An emergency exists if the ingestant is high risk (caustic solutions, hydrogen fluoride, drugs of abuse, or medications such as a calcium channel blocker, opioid, hypoglycemic agent, or antidepressant, supratherapeutic dose) or if the selfpoisoning was intentional. If immediate danger does not exist, obtain more details about the suspected toxic agent. If the child requires transport to a health facility, instruct parents that everything in the vicinity of the child that may be a cause of poisoning should be brought to the health care facility. Poison control centers (1-800-222-1222) are the source of expert telephone advice and have excellent follow-up programs to manage patients in the home as well as provide further poison prevention information.

It may be difficult to obtain an accurate history. Obtain names of drugs or ingredients, manufacturers, prescription numbers, names and phone numbers of prescribing physician and pharmacy, and any other pertinent information. Find out whether the substance was shared among several children, whether it had been recently purchased, who had last used it, how full the bottle was, and how much was spilled.

Obtaining Information About Poisons

Current data on ingredients of commercial products and medications can be obtained from a certified regional poison center. It is important to have the actual container at hand when calling. Safety data sheets (SDSs) can be helpful in providing product ingredient and concentration information. Caution: Antidote information on labels of commercial products or in the *Physicians' Desk Reference* may be incorrect or inappropriate. Many resources found on the Internet are inaccurate.

Follow-up

In over 95% of cases of ingestion of potentially toxic substances by children, a trip to the hospital is not required. In these cases, it is important to call the parent at 1 and 4 hours after ingestion. If the child has ingested an additional unknown agent and develops symptoms, a change in management may be needed, including transportation to the hospital.

Table 13–1. Poison prevention and emergency treatment handout.

Poison safety tips

If you or your child has come in contact with poison, call the Poison Center (1-800-222-1222). Nurses and pharmacists (who are poison experts) will answer your call. In most cases, they can help you take care of the problem right at home. When you need to get to the hospital, they will call ahead with detailed information to help doctors treat you or your child quickly and correctly.

How people get poisoned

People can breathe poison, eat or drink it, or get it on the skin or in the eyes. You probably know that antifreeze, bleach, and bug spray are poisonous. But did you know that vitamins, perfume, and makeup can be dangerous? Eating some plants can be toxic. Some spider bites can be dangerous. Taking medicine that is too old or not prescribed for you can make you sick. Also, mixing different kinds of medicine can be dangerous.

Poison safety "do's" and "don'ts"				
DO:	DON'T:			
1. Ask for "safety-lock" tops on all prescription drugs.	1. Don't store food and household cleaners together.			
 Keep cleaners, bug sprays, medicines, and other harmful products out of the reach and sight of children. If possible, keep the products locked up. 	2. Don't take medicine in front of children; children love to imitate "mommy" and "daddy."			
3. Store medicine in original containers.	3. Don't call medicine candy.			
 Read the label before taking medicine; don't take medicine that doesn't have a label. 	4. Don't take medicine that is not for you. Never take medicine in the dark.			
5. Follow the directions for all products.	Don't put gasoline, bug spray, antifreeze, or cleaning supplies in soft-drink bottles, cups, or bowls. Always keep them in their original containers.			
Kids can get into things at any age!				
Children aged 0–6 mo	Children aged 1–3 y			
Learn to roll over and reach for things.	Have the highest accident rate of any group.			
Learn about their environment by putting things in their mouths.	Begin to imitate parents and other adults.			
Children aged 7–12 mo	Put things in their mouths.			
Start to get curious and explore.	Start to climb on things.			
Learn to crawl, pull up to stand, and walk holding on.				
Put everything in their mouths.				
Pull things down.				
Different dangers at different times of the year				
Spring and summer dangers	Fall and winter dangers			
Pesticides	Antifreeze			
Fertilizers	Carbon monoxide			
Outdoor plants and mushrooms	Black widow spider bites			
Snake, spider, and other insect bites	Plants and autumn berries			
Bee stings	Holly, mistletoe, and other holiday decorations			
Ticks				
Charcoal lighter fluid				
Follow this checklist to make sure your home is safe				
Kitchen				
Remove products like detergent, drain cleaner, and dishwashing liquid from under the sink.				

Table 13–1. Poison	prevention and emergence	y treatment handout. (Continued)

- Remove medicines from counters, tables, refrigerator top, or window sills.
- -Put child safety latches on all drawers and cabinets that contain harmful products.

-Store harmful products away from food.

Bathroom

—Regularly clean out your medicine cabinet. Do not flush medicines down the toilet. Contact a pharmacy to see if they have a take-back program. If a take-back program is not available, securely wrap the medication bottle/package in newspaper and duct tape before disposing of in household garbage.

-Keep all medicine in original safety-top containers.

---Keep medicine, hair spray, powder, makeup, fingernail polish, hair-care products, and mouthwash out of reach.

Bedroom

-Don't keep medicine in or on dresser or bedside table.

-Keep perfume, makeup, aftershave, and other products out of reach.

Laundry area

-Keep bleach, soap, fabric softener, starch, and other supplies out of reach.

—Keep all products in their original containers.

Garage/basement

-Keep bug spray, weed killers, gasoline, oil, paint, and other supplies in locked area.

Keep all products in their original containers.

General household

—Keep beer, wine, and liquor out of reach.

—Keep ashtrays clean and out of reach.

Keep plants out of reach.

—Keep paint in good repair.

Emergency action in case your child ...

Breathes poison

Get child to fresh air right away. Open doors and windows. Always call the Poison Center.

Gets poison on the skin

Remove clothes that have poison on them. Rinse skin with lukewarm water for 10 min. Wash gently with soap and water and rinse. Always call the Poison Center.

Gets poison in the eye

Gently pour lukewarm water over the eye from a large glass 2 or 3 in from the eye. Repeat for 15 min. Have child blink as much as possible while pouring water in the eye. Do not force the eyelid open. Always call the Poison Center.

Swallows poison

Medicines: Do not give child **anything** until you talk with the poison center or your doctor.

Chemicals or household products: Unless your child has passed out or cannot swallow, give milk or water right away. Always call the Poison Center.

INITIAL EMERGENCY DEPARTMENT CONTACT

Address Initial Resuscitation Evaluation

As in all emergencies, the principles of treatment are attention to Pediatric Advance Life Support algorithms in resuscitation: circulation, airway, and breathing. The most important treatment in toxicological exposures is symptomatic and supportive care.

Treat Burns & Skin Exposures

Burns may occur following exposure to strongly acidic or strongly alkaline agents or petroleum distillates, and should be decontaminated by flooding with sterile saline solution or water. A burn unit should be consulted if more than minimal burn damage has been sustained. Skin decontamination should be performed in a patient with cutaneous exposure. Emergency department personnel in contact with a patient who has been contaminated (eg, with an organophosphate insecticide) should themselves be decontaminated if their skin or clothing becomes contaminated. Ocular exposures can initially be decontaminated at home by placing the child in the shower allowing the water to indirectly flow from the top of the head into the eyes. Otherwise, irrigation with assessment of pH should be performed in the emergency department.

Take a Pertinent History

The history should be taken from the parents and all individuals present at the scene. It may be crucial to determine all of the kinds of poisons in the home. These may include drugs used by family members and their medical histories, dietary or herbal supplements, foreign medications, chemicals associated with the hobbies or occupations of family members, or the purity of the water supply.

DEFINITIVE THERAPY OF POISONING

Prevention of Absorption

A. Emesis and Lavage

These measures are rarely used in pediatric patients and have their own associated risk. They should not be used routinely in the management of poisonings and should be performed only in consultation with a poison center or medical toxicologist.

B. Charcoal

The routine use of charcoal has decreased substantially in recent years, especially in unintentional pediatric ingestions where lick, sip, taste ingestions are rarely dangerous. Charcoal can be considered in patients who are awake, alert, and able to drink it voluntarily, but it should not be routinely administered to all poisoned patients. It should never be given to patients with altered sensorium who are unable to protect their airway due to risk of aspiration. The dose of charcoal is 1–2 g/kg (maximum, 100 g) per dose. Repeating the dose of activated charcoal may be useful for those agents that slow passage through the gastrointestinal (GI) tract, but repeated doses of sorbitol or saline cathartics must not be given. Repeated doses of cathartics may cause electrolyte imbalances and fluid loss. Charcoal dosing may be repeated every 4–6 hours until charcoal is passed through the rectum. It is not recommended in ingestions of heavy metals, hydrocarbons, caustics, and solvent ingestions.

C. Catharsis

Cathartics do not improve outcome and should be avoided.

D. Whole Bowel Lavage (or Irrigation)

Whole bowel lavage uses an orally administered, nonabsorbable hypertonic solution such as CoLyte or GoLYTELY. The effectiveness of this procedure in poisoned patients remains controversial. Preliminary recommendations for use of whole bowel irrigation include poisoning with sustained-release preparations, mechanical movement of items through the bowel (eg, cocaine packets, iron tablets, lead foreign bodies), and poisoning with substances that are poorly absorbed by charcoal (eg, lithium, iron). Underlying bowel pathology and intestinal obstruction are relative contraindications to its use. Consultation with a certified regional poison center is recommended.

Enhancement of Excretion

Excretion of certain substances can be hastened by urinary alkalinization or dialysis and is reserved for very special

circumstances. It is important to make certain that the patient is not volume depleted. Volume-depleted patients should receive a normal saline bolus of 10–20 mL/kg, followed by sufficient IV fluid administration to maintain urine output at 2–3 mL/kg/h.

A. Urinary Alkalinization

1. Alkaline diuresis—Urinary alkalinization should be chosen on the basis of the substance's pK_{a} , so that ionized drug will be trapped in the tubular lumen and not reabsorbed (see Table 13–1). Thus, if the pK_a is less than 7.5, urinary alkalinization is appropriate; if it is over 8.0, this technique is not usually beneficial. The pK_a is sometimes included along with general drug information. Alkaline diuresis is mainly used for salicylate toxicity. Urinary alkalinization is achieved with sodium bicarbonate. It is important to observe for hypokalemia, caused by the shift of potassium intracellularly. Follow serum potassium and observe for electrocardiogram (ECG) evidence of hypokalemia. If complications such as renal failure or pulmonary edema are present, hemodialysis or hemoperfusion may be required. It is most commonly used for the treatment of salicylate toxicity and to prevent methotrexate toxicity.

B. Dialysis

Hemodialysis is useful in the treatment of some poisons and in the general management of a critically ill patient. Characteristics of drugs amendable to dialysis include low molecular weight, low protein binding, and low volume of distribution. Continuous hemofiltration techniques may be used when hypotensive patients may not tolerate traditional hemodialysis; however, clearance rates will be slower. Dialysis should be considered part of supportive care if the patient satisfies any of the following criteria:

- A. Potentially life-threatening toxicity that is caused by a dialyzable drug and cannot be treated by conservative means.
- B. Renal failure or insufficiency.
- C. Marked hyperosmolality or severe acid-base or electrolyte disturbances not responding to therapy.

MANAGEMENT OF SPECIFIC COMMON POISONINGS

ACETAMINOPHEN (PARACETAMOL)

Overdosage of acetaminophen is common and can produce severe hepatotoxicity. The incidence of hepatotoxicity in adults and adolescents has been reported to be 10 times higher than in children younger than 5 years. In the latter group, less than 0.1% develop hepatotoxicity after acetaminophen overdose. In children, toxicity most commonly results from repeated overdosage arising from confusion about the age-appropriate dose, use of multiple products that contain acetaminophen, or use of adult suppositories.

Acetaminophen is normally metabolized in the liver. A small percentage of the drug goes through a pathway leading to a toxic metabolite. Normally, this electrophilic reactant is removed harmlessly by conjugation with glutathione. In overdosage, the supply of glutathione becomes exhausted, and the metabolite may bind covalently to components of liver cells to produce necrosis. Some authors have proposed that therapeutic doses of acetaminophen may be toxic to children with depleted glutathione stores. However, there is no evidence that administration of therapeutic doses can cause toxicity, and only a few inadequate case reports have been made in this regard.

Treatment

Treatment is to administer acetylcysteine. It may be administered either orally or intravenously. Consultation on difficult cases may be obtained from your regional poison control center or the Rocky Mountain Poison and Drug Center (1-800-525-6115). Blood levels should be obtained 4 hours after ingestion or as soon as possible thereafter and plotted on Figure 13–1. The nomogram is used only for acute ingestion, not repeated ingestions. Acetylcysteine is administered to patients whose acetaminophen levels plot in the toxic range on the nomogram. Acetylcysteine is effective even when given more than 24 hours after ingestion, although it is most effective when given within 8 hours postingestion.

For children weighing 40 kg or more, IV acetylcysteine should be administered as a loading dose of 150 mg/kg administered over 15–60 min; followed by a second infusion of 50 mg/kg over 4 hours, and then a third infusion of 100 mg/kg over 16 hours.

For patients weighing less than 40 kg, IV acetylcysteine must have less dilution to avoid hyponatremia (a dosage calculator is also available at http://www.acetadote.com) (Table 13–2). Patient-tailored therapy is critical when utilizing the IV "20-hour" protocol and those patients who still have acetaminophen measurable and/or elevated aspartate transaminase/alanine transaminase (AST/ALT) may need treatment beyond the 20 hours called for in the product insert.

The oral form of acetylcysteine can also be given and is equally efficacious as intravenous. Consult your regional poison center for dosing recommendations.

AST-serum glutamic oxaloacetic transaminase (AST-SGOT), ALT-serum glutamic pyruvic transaminase (ALT-SGPT), serum bilirubin, and plasma prothrombin time should be followed daily. Significant abnormalities of liver function may not peak until 72–96 hours after ingestion.

The Food and Drug Administration (FDA) has recommended the use of a single concentration of liquid

CHAPTER 13

Nomogram: Acetaminophen plasma concentration vs time after acetaminophen ingestion (adapted with permission from Rumack and Matthew. Pediatrics. 1975;55:871–876). The nomogram has been developed to estimate the probability of whether a plasma acetaminophen concentration in relation to the interval postingestion will result in hepatotoxicity and, therefore, whether acetylcysteine therapy should be administered.

Cautions for use of this chart:

- 1. Time coordinates refer to time postingestion.
- 2. Graph relates only to plasma concentrations following a single, acute overdose ingestion.
- 3. The Treatment line is plotted 25% below the Rumack-Matthew line to allow for potential errors in plasma acetaminophen assays and estimated time from ingestion of an overdose (Rumack et al. Arch Intern Med 1981;141(suppl):380–385).

▲ Figure 13–1. Semilogarithmic plot of plasma acetaminophen levels versus time. (Modified with permission from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. Pediatrics 1975 Jun;55(6):871–876.)

Body Weight		First 150 mg/kg in 5% Dextrose in 60 min		Second 50 mg/kg in 5% Dextrose in 4 h		Third 100 mg/kg in 5% Dextrose in 16 h

ALCOHOL, ETHYL (ETHANOL)

Alcoholic beverages, tinctures, cosmetics, mouthwashes, food extracts (vanilla, almond, etc.), rubbing alcohol, and hand sanitizers are common sources of poisoning in children. Alcohol is even available in powdered form for mixing and consumption. Concomitant exposure to other depressant drugs increases the seriousness of the intoxication. In most states, alcohol levels of 50–80 mg/dL are considered compatible with impaired faculties, and levels of 80–100 mg/dL are considered evidence of intoxication. (Blood levels cited here are for adults; comparable figures for children are not available.)

Recent erroneous information regarding hand sanitizers has indicated that a "lick" following application on the hand could cause toxicity in children. In fact, this is not the case, but because these hand sanitizers contain 62% ethanol, toxicity following ingestion is very possible. Potential blood ethanol concentration following consumption of a 62% solution in a 10-kg child is calculated as follows:

1 oz = 30 mL \times 62% =18.6 mL of pure ethanol 18.6 mL \times 0.79 (the specific gravity) = 14.7 g of ethanol, or 14,700 mg

In a patient weighing 10 kg, the distribution into total body water (Vd) will be 6 L—this is the amount of the body water into which the ethanol will be distributed.

14,700 mg ÷ 6 L = 2450 mg/L

2450 mg/L ÷ 10 = 245 mg/dL

Based on these calculations, a 10-kg child consuming 0.5 oz would have a concentration of 122.5 mg/dL; a 20-kg child consuming 1 oz would have a concentration of 122.5 mg/dL; a 30-kg child consuming 1 oz would have a concentration of 81.7 mg/dL; and a 70-kg adult consuming 1 oz would have a concentration of 35 mg/dL.

One "pump" from a hand sanitizer bottle dispenses approximately 2.5 mL of the product. If ingested, this amount (containing 62% ethanol) would create a blood ethanol concentration as follows:

- 1. In a 10-kg child: 23.1 mg/dL.
- 2. In a 20-kg child: 11.6 mg/dL.
- 3. In a 30-kg child: 7.7 mg/dL.

Children show a change in sensorium with blood levels as low as 10–20 mg/dL and any child displaying such changes should be seen immediately. Although a "lick" or a "drop" is unlikely to produce toxicity, the accuracy of the history should be considered when determining whether or not to see a child.

Complete absorption of alcohol requires 30 minutes to 6 hours, depending on the volume, the presence of food, and the time spent in consuming the alcohol. The rate of metabolic degradation is constant (about 20 mg/h in an adult). Absolute ethanol, 1 mL/kg, results in a peak blood level of about 100 mg/dL in 1 hour after ingestion. Acute intoxication and chronic alcoholism increase the risk of subarachnoid hemorrhage.

Treatment

Management of hypoglycemia and acidosis is usually the only measure required. Start an IV drip of D_5W or $D_{10}W$ if blood glucose is less than 60 mg/dL. Death is usually caused by respiratory failure. In severe cases, cerebral edema may occur and should be appropriately treated. Secondary evaluation for traumatic injury should also be performed.

AMPHETAMINES & RELATED DRUGS (STIMULANTS, METHAMPHETAMINE, MDMA)

Clinical Presentation

A. Acute Poisoning

Amphetamine, 3,4-methylenedioxy-*N*-methylamphetamine (MDMA), and methamphetamine poisoning is common because of the widespread availability of "diet pills" and the use of "ecstasy," "speed," "crank," "crystal," and "ice" by adolescents. (Care must be taken in the interpretation of slang terms because they have multiple meanings.) A new cause of stimulant poisoning is drugs for treating attention-deficit/hyperactivity disorder, such as methylphenidate. There are also newer designer drugs, synthetic cannabinoids ("spice, K2") and MPDV or mephedrone ("bath salts, plant food"), which cause effects similar to stimulants.

Symptoms include central nervous system (CNS) stimulation, anxiety, hyperactivity, hyperpyrexia, diaphoresis, hypertension, abdominal cramps, nausea and vomiting, and inability to void urine. MDMA has been associated with hyponatremia and seizures. Severe cases often include rhabdomyolysis. A toxic psychosis indistinguishable from paranoid schizophrenia may occur. Methamphetamine laboratories in homes are a potential cause of childhood exposure to a variety of hazardous and toxic substances. Maternal use and the effect on the fetus as well as exposures of young children are a continuing problem.

B. Chronic Poisoning

Chronic amphetamine users develop tolerance; more than 1500 mg of IV methamphetamine can be used daily. Hyperactivity, disorganization, and euphoria are followed by exhaustion, depression, and coma lasting 2–3 days. Heavy users, taking more than 100 mg/day, have restlessness, incoordination of thought, insomnia, nervousness, irritability, and visual hallucinations. Psychosis may be precipitated by the chronic administration of high doses. Chronic MDMA use can lead to serotonin depletion, which can manifest as depression, weakness, tremors, GI complaints, and suicidal thoughts.

Treatment

The treatment of choice are benzodiazepines, such as lorazepam, titrated in increments to effect. Very large total doses may be needed. In cases of extreme agitation or hallucinations, droperidol (0.1 mg/kg per dose) or haloperidol (up to 0.1 mg/kg) parenterally has been used. Hyperthermia should be aggressively controlled. Chronic users may be withdrawn rapidly from amphetamines. If amphetamine–barbiturate combination tablets have been used, the barbiturates must be withdrawn gradually to prevent withdrawal seizures. Psychiatric treatment should be provided.

ANESTHETICS, LOCAL

Intoxication from local anesthetics may be associated with CNS stimulation, acidosis, delirium, ataxia, shock, convulsions, and death. Methemoglobinemia has been reported following local mouth or dental analgesia, typically with benzocaine or prilocaine. It has also been reported with use of topical preparations in infants. The maximum recommended dose for subcutaneous (SQ) infiltration of lidocaine is 4.5 mg/kg (Table 13–3). The temptation to exceed this dose in procedures lasting a long time is great and may result in inadvertent overdosage. PO application of viscous lidocaine may produce toxicity and the FDA has published warnings against its use for teething. Hypercapnia may lower the seizure threshold to locally injected anesthetics.

	pK _a	Protein Binding (%)	Relative Potency	Duration of Action	Approximate Maximum Allowable Subcutaneous Dose (mg/kg)
Esters					
Chloroprocaine	9.3	Unknown	Intermediate	Short	10
Cocaine	8.7	92	Low	Medium	3
Procaine	9.1	5	Low	Short	10
Tetracaine	8.4	76	High	Long	3
Amides					
Bupivacaine	8.1	95	High	Long	2
Etidocaine	7.9	95	High	Long	4
Lidocaine	7.8	70	Low	Medium	4.5
Mepivacaine	7.9	75	Intermediate	Medium	4.5
Prilocaine	8.0	40	Intermediate	Medium	8
Ropivacaine	8.2	95	Intermediate	Long	3

Table 13–3. Pharmacologic properties of local anesthetics.

Reproduced with permission from Hoffman RS, Howland MA, Lewis NA: Goldfrank's Toxicologic Emergencies. 10th ed. New York: McGraw-Hill Education; 2011.

Local anesthetics used in obstetrics cross the placental barrier and are not efficiently metabolized by the fetal liver. Mepivacaine, lidocaine, and bupivacaine can cause fetal bradycardia, neonatal depression, and death. Accidental injection of mepivacaine into the head of the fetus during paracervical anesthesia has caused neonatal asphyxia, cyanosis, acidosis, bradycardia, convulsions, and death.

Treatment

If the anesthetic has been ingested, mucous membranes should be cleansed carefully, topical applications should be cleaned and irrigated. Oxygen administration is indicated, with assisted ventilation if necessary. Symptomatic methemoglobinemia is treated with methylene blue, 1%, 0.2 mL/kg (1-2 mg/kg per dose, IV) over 5-10 minutes; this should promptly relieve the cyanosis. Acidosis may be treated with sodium bicarbonate, hypotension with vasopressors, seizures with benzodiazepines, and bradycardia with atropine. In the event of cardiac arrest, 20% lipid (fat) emulsion therapy should be initiated. Initial 1.5 mL/kg bolus over 1 minute, followed by 0.25 mL/kg/min for up to 20-30 minutes until spontaneous circulation returns. Repeat bolus can be considered. Lipid emulsion therapy has been used with varying success for other pharmaceutical toxicity. Therapeutic levels of mepivacaine, lidocaine, and procaine are less than 5 mg/mL.

ANTIHISTAMINES & COUGH & COLD PREPARATIONS

The use of cough and cold preparations in young children has recently been called into question due to potential toxicity. In 2007, manufacturers voluntarily removed preparations intended for use in children younger than 4 from the market. Considerable controversy remains as to the toxicity of these medications if they are used according to labeled directions and an evaluation of the cases on file at FDA stated, "In the cases judged to be therapeutic intent or unknown intent, several factors appeared to contribute to the administration of an overdosage: administration of two medicines containing the same ingredients, failure to use a measuring device, use of wrong units (mL vs teaspoon), use of an adult product, use of the wrong product because of product misidentification, and two or more caregivers administering the same medication. In the cases of nontherapeutic intent, circumstances involved attempts at sedation and several included apparent attempts of overt child abuse and were under investigation by law enforcement authorities."

Medications included in this area are antihistamine (brompheniramine, chlorpheniramine, diphenhydramine, doxylamine), antitussive (dextromethorphan), expectorant (guaifenesin), and decongestant (pseudoephedrine, phenylephrine). Although antihistamines typically cause CNS depression, children often react paradoxically with excitement, hallucinations, delirium, ataxia, tremors, and convulsions followed by CNS depression, respiratory failure, or cardiovascular collapse. Anticholinergic effects such as dry mouth, fixed dilated pupils, flushed face, fever, and hallucinations may be prominent. Dextromethorphan can lead to altered mentation, hallucinations, nystagmus, and serotonin toxicity in large ingestions or when taken with other serotonergic agents.

They are absorbed rapidly and metabolized by the liver, lungs, and kidneys. A potentially toxic dose is 10–50 mg/kg of the most commonly used antihistamines, but toxic reactions have occurred at much lower doses.

Treatment

Benzodiazepines, such as lorazepam (0.1 mg/kg IV), can be used to control seizures or agitation. Physostigmine (0.5–2.0 mg IV, slowly administered) dramatically reverses the central and peripheral anticholinergic effects of antihistamines; however the duration of effect is short. It can also be used only for diagnostic purposes in patients without cardiotoxicity or seizures. Cardiac dysrhythmias and hypotension should be treated with normal saline at a dose of 10–20 mg/kg and a vasopressor if necessary. Sodium bicarbonate may be useful if there is QRS widening at a dose of 1–2 mEq/kg, making certain that the arterial pH does not exceed 7.55. Forced diuresis is not helpful. Exchange transfusion was reported to be effective in one case.

BARBITURATES & BENZODIAZEPINES

Barbiturates are rarely used today, and have mostly been replaced with benzodiazepines for their use in seizures or for sedation. The toxic effects of barbiturates include confusion, poor coordination, coma, miotic or fixed dilated pupils, and respiratory depression. Respiratory acidosis is commonly associated with pulmonary atelectasis, and hypotension. Ingestion of more than 6 mg/kg of long-acting or 3 mg/kg of short-acting barbiturates is usually toxic. Benzodiazepines typically cause CNS depression and lethargy without hemodynamic compromise in unintentional oral ingestions. Large oral overdoses, co-ingestants with other sedative/hypnotics, or iatrogenic IV overdose can cause cardiovascular or respiratory depression.

Treatment

Careful, conservative management with emphasis on maintaining a clear airway, adequate ventilation, and control of hypotension is critical. Urinary alkalinization and the use of multiple-dose charcoal may decrease the elimination halflife of phenobarbital but have not been shown to alter the clinical course. Flumazenil can be considered if severe CNS depression or respiratory depression develops after benzodiazepine overdose using a dose of 0.01 mg/kg IV (maximum dose of 0.2 mg).

- Kreshak AA et al: Flumazenil administration in poisoned pediatric patients. Pediatr Emerg Care 2012;28(5):488 [PMID: 22531190].

BELLADONNA ALKALOIDS (ATROPINE, JIMSONWEED, POTATO LEAVES, SCOPOLAMINE, STRAMONIUM)

The effects of anticholinergic (or antimuscarinic) compounds include dry mouth; thirst; decreased sweating with hot, dry, red skin; high fever; and tachycardia that may be preceded by bradycardia. The pupils are dilated, and vision is blurred. Speech and swallowing may be impaired. Hallucinations, delirium, and coma are common. Leukocytosis may occur, confusing the diagnosis.

Atropinism has been caused by normal doses of atropine or homatropine eye drops. Many common plants and overthe-counter medications (antihistamines and sleep aids) contain belladonna alkaloids or medications with anticholinergic effects.

POISONING

Treatment

Gastric emptying is slowed by anticholinergics, so that gastric decontamination may be useful even if delayed. If the patient is awake and showing no signs or symptoms, administration of activated charcoal can be considered. Benzodiazepines should be administered to control agitation. Bolus dosing should be given in escalating doses, and high doses may be required. Physostigmine (0.5–2.0 mg IV, administered slowly) dramatically reverses the central and peripheral signs of atropinism but should be used only as a diagnostic agent, but clinical improvement is not sustained. Physostigmine infusions have been safely administered. It should not be given in patients with cardiotoxicity or seizures. Hyperthermia should be aggressively controlled. Catheterization may be needed if the patient cannot void.

β-BLOCKERS & CALCIUM CHANNEL BLOCKERS

 β -Blockers and calcium channel blockers primarily cause cardiovascular toxicity; bradycardia, hypotension, and various degrees of heart block; cardiac dysrhythmias may develop. Severe toxicity can cause CNS depression (typically due to hemodynamic collapse). The β -blocker propranolol is associated with seizures and also QRS widening. Hyperglycemia can be seen with calcium channel blocker toxicity.

Treatment

Initial stabilization with IV fluid resuscitation with isotonic fluids should be initiated. Atropine can be given for symptomatic bradycardia. Calcium at doses of 20 mg/kg and repeated as needed should be administered. Infusions of calcium chloride 10%, 0.2–0.5 mL/kg/h, can be started after initial bolus dosing. Glucagon can be administered; 50–100 mcg/kg (5–10 mg) IV bolus followed by 2–5 mg/h infusion if patient improves. Vasopressors such as epinephrine or norepinephrine should be started if patient continues to be hypotensive and bradycardic. In patients who are severely poisoned and refractory to these initial measures, hyperinsulinemia euglycemic therapy should be started. Your regional poison control center or medical toxicologist should be contacted for further details on dosing of this therapy.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced from burning various fuels. The degree of toxicity correlates well with the carboxyhemoglobin concentration taken soon after acute exposure but not after oxygen has been given or when there has been some time since exposure. Onset of symptoms may be more rapid and more severe if the patient lives at a high altitude, has a high respiratory rate (ie, infants), is pregnant, or has myocardial insufficiency or lung disease. Normal blood may contain up to 5% carboxyhemoglobin (10% in smokers). Neonates may have elevated carboxyhemoglobin levels due to breakdown of bilirubin.

Presenting symptoms can include nonspecific symptoms such as headache or flu-like illness. Other effects include confusion, unsteadiness, and coma. Proteinuria, glycosuria, elevated serum aminotransferase levels, or ECG changes may be present in the acute phase. Other signs may include improvement of symptoms after leaving the exposed environment. Permanent cardiac, liver, renal, or CNS damage occurs occasionally. The outcome of severe poisoning may be complete recovery, vegetative state, or any degree of mental injury between these extremes. The primary delayed mental deficits are neuropsychiatric.

Treatment

The biologic half-life of carbon monoxide on room air is approximately 200–300 minutes; on 100% oxygen, it is 60–90 minutes. Thus, 100% oxygen should be administered immediately. Hyperbaric oxygen therapy at 2.0–2.5 atm of oxygen shortens the half-life to 30 minutes. The use of hyperbaric oxygen therapy for delayed neurologic sequelae can be considered, but remains controversial and the primary focus of care should be acute resuscitation and stabilization. After the level has been reduced to near zero, therapy is aimed at the nonspecific sequelae of anoxia. Evaluation of the source should be performed before the patient returns to the home.

CAUSTICS

Both acids and alkalis can burn the skin, mucous membranes, and eyes. Painful swallowing, mucous membrane burns, hematemesis, and abdominal pain can occur after ingestion. Respiratory distress may be due to edema of the epiglottis, pulmonary edema resulting from inhalation of fumes, or pneumonia. In severe cases, mediastinitis, intercurrent infections, or shock can occur. Perforation of the esophagus or stomach is rare. Residual lesions include esophageal, gastric, and pyloric strictures as well as scars of the cornea, skin, and oropharynx.

1. Acids (Hydrochloric, Hydrofluoric, Nitric, & Sulfuric Acids; Sodium Bisulfate)

Strong acids are commonly found in metal and toilet bowl cleaners, batteries, and other products, and can lead to coagulative necrosis.

Hydrofluoric acid is a particularly dangerous acid. Dermal exposure creates a penetrating burn that can progress for hours or days. Large dermal exposure or small ingestion may produce life-threatening hypocalcemia.

2. Bases (Clinitest Tablets, Clorox, Drano, Liquid-Plumr, Purex, Sani-Clor—Examine the Label or Call a Poison Center to Determine Contents)

Alkalis can produce more severe injuries than acids, resulting in liquefactive necrosis. Some substances, such as Clinitest tablets or Drano, are quite toxic, whereas the chlorinated bleaches (3%–6% solutions of sodium hypochlorite) are usually not toxic. When sodium hypochlorite comes in contact with acid in the stomach, hypochlorous acid, which is very irritating to the mucous membranes and skin, is formed. Chlorinated bleaches, when mixed with a strong acid (toilet bowl cleaners) or ammonia, may produce irritating chlorine or chloramine gas, which can cause serious lung injury if inhaled in a closed space (eg, bathroom).

Treatment

Emetics and lavage are contraindicated. Can be diluted with water, but take care not to induce emesis by excessive fluid administration. Neutralization should not be attempted. Burned areas of the skin, mucous membranes, or eyes should be washed with copious amounts of warm water. The eye should be irrigated for at least 20–30 minutes. Ophthalmologic consultation should be obtained for all alkaline eye burns. Opioids for pain may be needed. An endotracheal tube may be required to alleviate laryngeal edema. The absence of oral lesions does not rule out the possibility of laryngeal or esophageal burns following granular alkali ingestion. Esophagoscopy should be performed if the patient has significant burns or difficulty in swallowing, drooling, vomiting or stridor. Evidence is not conclusive, but corticosteroids may be helpful in significant esophageal burns. Antibiotics may be needed if mediastinitis develops, but they should not be used prophylactically.

Hydrofluoric acid burns on skin are treated with 10% calcium gluconate gel or calcium gluconate infusion. Severe exposure may require large doses of IV calcium or cardio-vascular monitoring. Therapy should be guided by calcium levels, the ECG, and clinical signs.

CENTRAL α, ADRENERGIC AGONIST

Central α_2 -adrenergic agonists are common over-the-counter and prescribed medication. The imidazolines are found in nasal decongestants and eye drops to relieve redness. Clonidine and guanfacine are used most commonly to treat attention deficit hyperactivity disorder or hypertension. Dexmedetomidine is an IV central α_2 -adrenergic agonist used for sedation. These medications exert their effects by stimulating presynaptic α_2 -adrenergic receptors in the brain, resulting in decreased norepinephrine release and decreased sympathetic outflow.

Clinical Findings

Most common effects are related to CNS sedation. They can present similar to an opioid toxidrome with miosis, CNS depression, and respiratory depression. Other common effects include bradycardia and hypotension.

Treatment

If the patient becomes obtunded, or has inability to protect their airway, intubation may be indicated. Naloxone has been tried to reverse signs of toxicity with varying success. Symptomatic bradycardia can be treated with IV fluid resuscitation or atropine. Hypotension should be treated initially with IV fluid resuscitation, followed by vasopressors if needed. Wang et al: Unintentional pediatric exposures to central alpha-2 agonists reported to the National Poison Data System. J Pediatr 2014;164(1):149–152 [PMID: 24094880].

COCAINE

Cocaine is absorbed intranasally or via inhalation or ingestion. Effects are noted almost immediately when the drug is taken intravenously or smoked. Peak effects are delayed for about an hour when the drug is taken orally or nasally. Cocaine prevents the reuptake of endogenous catecholamines, thereby causing an initial sympathetic discharge, followed by catechol depletion after chronic abuse.

Clinical Findings

A local anesthetic and vasoconstrictor, cocaine is also a potent stimulant to both the CNS and the cardiovascular system. The initial tachycardia, hyperpnea, hypertension, and stimulation of the CNS are often followed by coma, seizures, hypotension, and respiratory depression. In severe cases of overdose, various dysrhythmias may be seen, including sinus tachycardia, atrial arrhythmias, premature ventricular contractions, bigeminy, and ventricular tachycardia and fibrillation. If large doses are taken intravenously, cardiac failure, dysrhythmias, rhabdomyolysis, or hyperthermia may result in death.

In addition to those poisoned through recreational use of cocaine, others are at risk of overdose. A "body stuffer" is one who quickly ingests the drug, usually poorly wrapped, to avoid discovery. A "body packer" wraps the drug carefully for prolonged transport. A stuffer typically manifests toxicity within hours of ingestion; a packer is asymptomatic unless the package ruptures, usually days later. Newborns of cocaine using mothers may continue to have seizures for months after birth. Cocaine can be contaminated with levamisole, which can lead to systemic vasculitis and agranulocytosis.

Treatment

Activated charcoal should be considered in body stuffers, and whole bowel irrigation may be useful in cases of body packers. Testing for cocaine in blood or plasma is generally not clinically useful, but a qualitative analysis of the urine may aid in confirming the diagnosis. Cocaine metabolites can be positive in urine for 3–5 days after exposure. For severe cases, an ECG is indicated. In suspected cases of body packing, radiographs of the GI tract may show multiple packets, but are usually not helpful for identifying stuffers. Seizures are treated with IV benzodiazepines such as lorazepam, titrated to response. Hypotension is treated with standard agents. Because cocaine abuse may deplete norepinephrine, an indirect agent such as dopamine may be less effective than a direct agent such as norepinephrine. Agitation is best treated with a benzodiazepine.

COSMETICS & RELATED PRODUCTS

Cosmetics and personal care products are the most frequently involved substance in pediatric patients younger than 5 years (14% of all calls reported to NPDS) and second most common in all ages. Luckily, most of them do not cause significant toxicity. The relative toxicities of commonly ingested products in this group are listed in Table 13–4.

CYCLIC ANTIDEPRESSANTS

Cyclic antidepressants (eg, amitriptyline, imipramine) have a very low ratio of toxic to therapeutic doses, and even a moderate overdose can have serious effects. Diphenhydramine toxicity can have similarly symptoms as cyclic antidepressants and is more readily available.

Cyclic antidepressant overdosage can cause a progression of illness beginning with sudden onset coma within 1–2 hours of ingestion, followed by convulsions, hypotension, and dysrhythmias. Usually significant clinical effects occur within hours after the ingestion, may be

 Table 13-4.
 Relative toxicities of cosmetics and similar products.

High toxicity	Low toxicity
Permanent wave neutralizers	Perfume
Moderate toxicity	Hair removers
Fingernail polish	Deodorants
Fingernail polish remover	Bath salts
Metallic hair dyes	No toxicity
Home permanent wave lotion	Liquid makeup
Bath oil	Vegetable hair dye
Shaving lotion	Cleansing cream
Hair tonic (alcoholic)	Hair dressing (nonalcoholic)
Cologne, toilet water	Hand lotion or cream
3 1 1 1	Lipstick

life-threatening and require rapid intervention. One agent, amoxapine, differs in that it causes fewer cardiovascular complications, but it is associated with a higher incidence of seizures.

Treatment

After a significant ingestion, decontamination should include administration of activated charcoal unless the patient is already symptomatic. Benzodiazepines should be given for seizures.

An ECG should be obtained in all patients. A QRS interval greater than 100 milliseconds specifically identifies patients at risk to develop seizures and dysrhythmias. If dysrhythmias or tachycardia are demonstrated, the patient should be admitted and monitored until free of irregularity for 24 hours. The onset of dysrhythmias is rare beyond 24 hours after ingestion.

Alkalinization with sodium bicarbonate (0.5–1.0 mEq/kg IV) may dramatically reverse ventricular dysrhythmias and narrow the QRS interval. If intubated, hyperventilation may be helpful. Lidocaine may be added for treatment of arrhythmias. Bolus administration of sodium bicarbonate (1–2 mEq/kg) is recommended for all patients with QRS widening to above 120 milliseconds and for those with significant dysrhythmias, to achieve a pH of 7.5–7.6. Lipid-emulsion therapy has been used in the setting of cardiotoxicity.

Cyclic antidepressants block the reuptake of catecholamines, thereby producing initial hypertension followed by hypotension. Vasopressors (such as norepinephrine, 0.1–1 mcg/kg/min, titrated to response) are generally effective. Diuresis and hemodialysis are not effective and physostigmine is contraindicated.

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Acute toxicity is typically the result of incorrect dosing, and chronic toxicity is due to unrecognized renal insufficiency. Clinical features include nausea, vomiting, diarrhea, headache, delirium, confusion, and, occasionally, coma. Cardiac dysrhythmias typically involve bradydysrhythmias, but every type of dysrhythmia has been reported in digitalis intoxication, including atrial fibrillation, paroxysmal atrial tachycardia, and atrial flutter. Transplacental intoxication by digitalis has been reported. Cardiac glycosides, such as yellow oleander and foxglove, can cause digitalis toxicity in large ingestions as well.

Treatment

If patient is awake and alert, consider administering activated charcoal. Potassium is contraindicated in acute overdosage unless there is laboratory evidence of hypokalemia. In acute overdosage, hyperkalemia is more common. Hypokalemia is common in chronic toxicity.

The patient must be monitored carefully for ECG changes. Bradycardias have been treated with atropine. Phenytoin, lidocaine, magnesium salts (not in renal failure), amiodarone, and bretylium have been used to correct arrhythmias.

Definitive treatment is with digoxin immune Fab (ovine) (Digifab). Indications for its use include hypotension or any dysrhythmia, typically ventricular dysrhythmias and progressive bradydysrhythmias, or hyperkalemia (K > 5) in an acute overdose. Elevated T waves indicate high potassium and may be an indication for digoxin immune Fab (DigiFab) use. Techniques of determining dosage and indications related to levels, when available are described in product literature. High doses of digoxin immune Fab may be needed in cardiac glycoside overdose. Extracorporeal treatment is not indicated for digoxin poisoning.

Mowry JB: Extracorporeal treatment for digoxin poisoning: systematic review and recommendations from the EXTRIP Workgroup. Clin Toxicol (Phila) 2016;54(2):103–114. doi:10.31 09/15563650.2015.1118488.26795743.

- Woolf AD et al: The use of digoxin-specific Fab fragments for severe digitalis intoxication in children. N Engl J Med 1992;326:17-39 [PMID: 1997016].

DIPHENOXYLATE WITH ATROPINE (LOMOTIL) & LOPERAMIDE (IMODIUM)

Loperamide (Imodium) has largely replaced Lomotil and does not produce significant toxicity. Ingestions of up to 0.4 mg/kg can safely be managed at home. Both acute and chronic abuse of loperamide has been associated with cardiac dysrhythmias.

Lomotil is still widely available and contains diphenoxylate hydrochloride, a synthetic narcotic, and atropine sulfate. Small amounts are potentially lethal in children; it is contraindicated in children younger than 2 years. Early signs of intoxication with this preparation result from its anticholinergic effect and consist of fever, facial flushing, tachypnea, and lethargy. However, the miotic effect of the narcotic predominates. Later, hypothermia, increasing CNS depression, and loss of the facial flush occur. Seizures are probably secondary to hypoxia. Any ingestion of Lomotil must be observed for 8–12 hours as delayed respiratory arrest may be encountered.

Treatment

Prolonged monitoring (24 hours) with pulse oximetry and careful attention to airway is sufficient in most cases. Naloxone hydrochloride (0.4–2.0 mg IV in children and adults) should be given for signs of respiratory depression. Repeated doses may be required because the duration of action of diphenoxylate is considerably longer than that of naloxone.

DISINFECTANTS & DEODORIZERS

1. Naphthalene

Naphthalene is now less commonly found in mothballs, disinfectants, and deodorizers. Naphthalene's toxicity is often not fully appreciated. It is absorbed not only when ingested but also through the skin and lungs. It is potentially hazardous to store baby clothes in naphthalene, because baby oil is an excellent solvent that may increase dermal absorption. Metabolic products of naphthalene may cause severe hemolytic anemia, similar to that due to primaquine toxicity, 2–7 days after ingestion. Other physical findings include vomiting, diarrhea, jaundice, oliguria, anuria, coma, and convulsions.

Treatment

If the patient is awake and alert, consideration can be given for administering activated charcoal. Methemoglobinemia and hemolysis may occur 24–48 hours after ingestion. Life-threatening hemolysis and anemia may require blood transfusions.

Siegel E, Wason S: Mothball toxicity. Pediatr Clin North Am 1986;33:369 [PMID: 3515301].

2. *p*-Dichlorobenzene, Phenolic Acids, & Others

Disinfectants and deodorizers containing *p*-dichlorobenzene or sodium sulfate are now more commonly found in mothballs and much less toxic than those containing naphthalene. They typically cause mucous membrane irritation and GI upset. Camphor can cause seizures after ingestion.

Disinfectants containing phenolic acids are highly toxic, especially if they contain a borate ion. Phenol precipitates tissue proteins and can also cause systemic toxicity resulting in respiratory alkalosis followed by metabolic acidosis. Some phenols cause methemoglobinemia. Phenol is readily absorbed topically and from the GI tract, causing local injury, diffuse capillary damage and, in some cases, methemoglobinemia. Pentachlorophenol, which has been used in terminal rinsing of diapers, has caused infant fatalities by causing metabolic acidosis.

The toxicity of alkalis, quaternary ammonium compounds, pine oil, and halogenated disinfectants varies with the concentration of active ingredients. Wick deodorizers are usually of moderate toxicity. Iodophor disinfectants are the safest. Spray deodorizers are not usually toxic, because a child is not likely to swallow a very large dose.

Signs and symptoms of acute quaternary ammonium compound ingestion include diaphoresis, strong irritation, thirst, vomiting, diarrhea, cyanosis, hyperactivity, coma, convulsions, hypotension, abdominal pain, and pulmonary edema. Acute liver or renal failure may develop later.

Treatment

Mainstay to phenol toxicity is symptomatic and supportive care. The metabolic acidosis must be managed carefully. Anticonvulsants or measures to treat shock may be needed.

Because phenols are absorbed through the skin, exposed areas should be irrigated copiously with water. Undiluted polyethylene glycol may be a useful solvent as well.

Van Berkel M, de Wolff FA: Survival after acute benzalkonium chloride poisoning. Hum Toxicol 1988;7:191 [PMID: 3378808].

Vearrier D, Jacobs D, Greenberg MI: Phenol toxicity following cutaneous exposure to creolin^{*}: a case report. J Med Toxicol Jun 2015;11(2):227–231. doi: 10.1007/s13181-014-0440-1. 25326371.

DISK-SHAPED "BUTTON" BATTERIES

Small, flat, smooth disk-shaped batteries measure between 10 and 25 mm in diameter. About 69% of them pass through the GI tract in 48 hours and 85% in 72 hours. Some may become entrapped and lead to caustic injury.

Batteries impacted in the esophagus may cause symptoms of refusal to take food, increased salivation, vomiting with or without blood, and pain or discomfort. Aspiration into the trachea may also occur. Fatalities have been reported in association with esophageal perforation or fistula formation.

When a history of disk battery ingestion is obtained, radiographs of the entire respiratory tract and GI tract should be taken immediately so that the battery can be located and the proper therapy determined.

CHAPTER 13

Treatment

Any disk battery ingestion should be referred for evaluation and radiographs. If the disk battery is located in the esophagus, it must be removed immediately. Any prolonged time in the esophagus can cause injury, leading to esophageal perforation, or erosion/fistula formation into a blood vessel. Consultation with GI or surgical subspecialty is recommended.

Location of the disk battery below the esophagus has been rarely associated with tissue damage, but the course is benign in most cases. Perforated Meckel diverticulum has been the major complication. It may take as long as 7 days for spontaneous passage to occur, and lack of movement in the GI tract may not require removal in an asymptomatic patient.

Some researchers have suggested repeated radiographs and surgical intervention if passage of the battery pauses, but this approach may be excessive. Batteries that have opened in the GI tract have been rarely associated with some toxicity due to mercury, but the patients have recovered.

Asymptomatic patients, with known time of ingestion, and with disk batteries past the lower esophageal junction may simply be observed and stools examined for passage of the battery. If the battery has not passed within 7 days or if the patient becomes symptomatic, radiographs should be repeated. If the battery has come apart or appears not to be moving, a purgative, enema, or nonabsorbable intestinal lavage solution should be considered. If these methods are unsuccessful, surgical intervention may be required. Levels of heavy metals (mainly mercury) should be measured in patients in whom the battery has opened or symptoms have developed.

ETHYLENE GLYCOL & METHANOL

Ethylene glycol and methanol are the toxic alcohols. The primary source of ethylene glycol is antifreeze, whereas methanol is present in windshield wiper fluid and also as an ethanol denaturant. Ethylene glycol causes severe metabolic acidosis and renal failure. Methanol causes metabolic acidosis and blindness. Onset of symptoms with both agents occurs within several hours after ingestion, longer if ethanol was ingested simultaneously. Rarely, glycol ethers can cause acidosis, but only in the setting of large ingestions.

Treatment

The primary treatment is to block the enzyme alcohol dehydrogenase, which converts both agents to their toxic metabolites. This is accomplished with fomepizole (loading dose of 15 mg/kg). Ethanol could be used if fomepizole is unavailable, but can lead to CNS depression and hypoglycemia in children. Hemodialysis is indicated with high concentrations, persistent metabolic acidosis, or end-organ toxicity.

γ-HYDROXYBUTYRATE, γ-BUTYROLACTONE, BUTANEDIOL, FLUNITRAZEPAM, & KETAMINE

 γ -Hydroxybutyrate (GHB), γ -butyrolactone (GBL), and butanediol have become popular drugs of abuse in adolescents and adults. GHB is a CNS depressant that is structurally similar to the inhibitory neurotransmitter γ -aminobutyric acid. GBL and butanediol are converted in the body to GHB. These drugs cause deep but short-lived coma; the coma often lasts only 1–4 hours. Flunitrazepam (Rohypnol) is a benzodiazepine that can lead to somnolence and CNS depression. Ketamine is a disassociative anesthetic that can also cause rapid onset altered mental status and CNS depression. Although all of these drugs are often referred to as "date rape" drugs, ethanol is the most commonly used substance in drug-facilitated assault.

Treatment consists of supportive care with close attention to airway and endotracheal intubation if respiratory depression or decreased gag reflex complicates the poisoning. Atropine has been used successfully for symptomatic bradycardia.

Withdrawal from GHB, GBL, or butanediol can cause several days of extreme agitation, hallucination, or tachycardia. Treatment with high doses of sedatives such as benzodiazepines or with butyrophenones (eg, haloperidol or droperidol) or secobarbital may be needed for several days.

Schep LJ et al: The clinical toxicology of gamma-hydroxybutyrate, gamma-butyrolactone and 1,4-butanediol. Clin Toxicol (Phila) 2012;50(6):458–470 [PMID: 22746383].

HYDROCARBONS (BENZENE, CHARCOAL LIGHTER FLUID, GASOLINE, KEROSENE, PETROLEUM DISTILLATES, TURPENTINE)

Ingestion of hydrocarbons may cause irritation of mucous membranes, CNS depression, or aspiration pneumonitis. Hydrocarbons with high volatility, low viscosity, and low surface tension have more risk or aspiration pneumonitis. Benzene, kerosene, red seal oil furniture polish, and some of the essential oils are very dangerous. A dose exceeding 1 mL/kg is likely to cause CNS depression. A history of coughing or choking, as well as vomiting, suggests aspiration with resulting hydrocarbon pneumonia. Several weeks may be required for full resolution of hydrocarbon pneumonia. Pulmonary edema and hemorrhage, blebs, cardiac dilation and dysrhythmias, hepatosplenomegaly, proteinuria, and hematuria can occur following large overdoses.

Treatment

Both emetics and lavage should be avoided. Initial supportive care, observing for CNS depression or respiratory distress. Patients who are asymptomatic with a normal chest x-ray (CXR) after 8 hours are unlikely to develop significant illness; however, patients who develop respiratory symptoms, hypoxia, or CXR changes should be observed.

Epinephrine should be avoided with halogenated hydrocarbons because it may affect an already sensitized myocardium. The usefulness of corticosteroids is debated, and antibiotics should be reserved for patients with infections (pneumonitis can cause fevers and infiltrates). Oxygen and mist are helpful. Surfactant therapy for severe hydrocarboninduced lung injury has been used successfully. Extracorporeal membrane oxygenation has been successful in at least two cases of failure with standard therapy.

IBUPROFEN

Most exposures in children do not produce symptoms. In one study, for example, children ingesting up to 2.4 g remained asymptomatic. When symptoms occur, the most common are abdominal pain, vomiting, drowsiness, and lethargy. In rare cases, apnea (especially in young children), seizures, metabolic acidosis, and CNS depression leading to coma have occurred.

Treatment

If a child has ingested less than 100 mg/kg, supportive care for GI upset is typically all that is needed. When the ingested amount is more than 400 mg/kg, seizures or CNS depression may occur. There is no specific antidote. Neither alkalinization of the urine nor hemodialysis is helpful in elimination of ibuprofen. However, hemodialysis may be needed to correct acid-base abnormalities.

Cuzzolin L et al: NSAID-induced nephrotoxicity from the fetus to the child. Drug Safety 2001;242:9 [PMID: 11219488].

Marciniak KE et al: Massive ibuprofen overdose requiring extracorporeal membrane oxygenation for cardiovascular support. Pediatr Crit Care Med 2007;8:180–182 [PMID: 17273120].

INSECT STINGS (BEE, WASP, & HORNET)

Insect stings are painful but not usually dangerous; however, death from anaphylaxis may occur. Bee venom has hemolytic, neurotoxic, and histamine-like activities that can on rare occasion cause hemoglobinuria and severe anaphylactoid reactions. Massive envenomation from numerous stings may cause hemolysis, rhabdomyolysis, and shock leading to multiple-organ failure.

Treatment

The physician should remove the stinger, taking care not to squeeze the attached venom sac. For allergic reactions, epinephrine 1:1000 solution, 0.01 mL/kg, should be administered IV or SQ above the site of the sting. Albuterol, corticosteroids, and diphenhydramine are useful ancillary drugs but have no immediate effect. Ephedrine or antihistamines may be used for 2 or 3 days to prevent recurrence of symptoms.

For the more usual stings, cold compresses, aspirin, and diphenhydramine (1 mg/kg PO) are sufficient.

Ross RN et al: Effectiveness of specific immunotherapy in the treatment of hymenoptera venom hypersensitivity: a meta-analysis. Clin Ther 2000;22:351 [PMID: 10963289].

INSECTICIDES

The petroleum distillates or other organic solvents used in these products are often as toxic as the insecticide itself.

1. Chlorinated Hydrocarbons (eg, Aldrin, Carbinol, Chlordane, DDT, Dieldrin, Endrin, Heptachlor, Lindane, Toxaphene)

Signs of intoxication include salivation, GI irritability, abdominal pain, vomiting, diarrhea, CNS depression, and

Vetter RS et al: Mass envenomations by honey bees and wasps. West J Med 1999;170:223 [PMID: 10344177].

350

convulsions. Inhalation exposure causes irritation of the eyes, nose, and throat; blurred vision; cough; and pulmonary edema.

Chlorinated hydrocarbons are absorbed through the skin, respiratory tract, and GI tract. Decontamination of skin with soap and evacuation of the stomach contents should be considered in significant ingestions. All contaminated clothing should be removed. Convulsions should be treated with diazepam (0.1–0.3 mg/kg IV). Epinephrine should cautiously be used as it may precipitate cardiac arrhythmias.

2. Organophosphate (Cholinesterase-Inhibiting) Insecticides (eg, Chlorothion, Co-Ral, DFP, Diazinon, Malathion, Paraoxon, Parathion, Phosdrin, TEPP, Thio-TEPP)

Dizziness, headache, blurred vision, miosis, tearing, salivation, nausea, vomiting, diarrhea, hyperglycemia, cyanosis, sense of constriction of the chest, dyspnea, sweating, weakness, muscular twitching, convulsions, loss of reflexes and sphincter control, and coma can occur.

The clinical findings are the result of cholinesterase inhibition, which causes an accumulation of acetylcholine. The onset of symptoms occurs within 12 hours of the exposure. Red cell cholinesterase levels should be measured as soon as possible. (Some normal individuals have a low serum cholinesterase level.) Normal values vary in different laboratories. In general, a decrease of red cell cholinesterase to below 25% of normal indicates significant exposure.

Repeated low-grade exposure may result in sudden, acute toxic reactions. This syndrome usually occurs after repeated household spraying rather than agricultural exposure.

Although all organophosphates act by inhibiting cholinesterase activity, they vary greatly in their toxicity. Parathion, for example, is 100 times more toxic than malathion. Toxicity is influenced by the specific compound, type of formulation (liquid or solid), vehicle, and route of absorption (lungs, skin, or GI tract).

Treatment

Decontamination of skin, nails, hair, and clothing with soapy water is extremely important. Atropine plus a cholinesterase reactivator, pralidoxime, is an antidote for organophosphate insecticide poisoning. After assessment and management of the ABCs, atropine should be given and repeated every few minutes until airway secretions diminish. An appropriate starting dose of atropine is 2–4 mg IV in an adult and 0.05 mg/kg in a child. The patient should receive enough atropine to stop secretions (mydriasis in not an appropriate stopping point). Severe poisoning may require gram quantities of atropine administered over 24 hours. Glycopyrrolate can also be used if delirium occurs. Because atropine antagonizes the muscarinic parasympathetic effects of the organophosphates but does not affect the nicotinic receptor, it does not improve muscular weakness. Pralidoxime should also be given immediately in more severe cases and repeated every 6–12 hours as needed (25–50 mg/kg diluted to 5% and infused over 5–30 minutes at a rate of no > 500 mg/min). Pralidoxime should be used in addition to—not in place of—atropine if red cell cholinesterase is less than 25% of normal. Pralidoxime is most useful within 48 hours after the exposure but has shown some effects 2–6 days later. Morphine, theophylline, aminophylline, succinylcholine, and tranquilizers of the reserpine and phenothiazine types are contraindicated. Hyperglycemia is common in severe poisonings.

3. Carbamates (eg, Carbaryl, Sevin, Zectran)

Carbamate insecticides are reversible inhibitors of cholinesterase. The signs and symptoms of intoxication are similar to those associated with organophosphate poisoning but are generally less severe. Atropine titrated to effect is sufficient treatment. In combined exposures to organophosphates, give atropine but reserve pralidoxime for cases in which the red cell cholinesterase is depressed below 25% of normal or marked effects of nicotinic receptor stimulation are present.

4. Botanical Insecticides (eg, Black Flag Bug Killer, Black Leaf CPR Insect Killer, Flit Aerosol House & Garden Insect Killer, French's Flea Powder, Raid)

Allergic reactions, asthma-like symptoms, coma, and convulsions have been reported. Pyrethrins, allethrin, and rotenone do not commonly cause significant toxicity. Antihistamines, short-acting benzodiazepines, and atropine are helpful as symptomatic treatment.

IRON

Iron has many different formulations with varying amounts of elemental iron. Three common formulations include ferrous fumarate (33%), ferrous sulfate (20%), and ferrous gluconate (12%). Typically, doses of more than 20 mg/kg of elemental iron will cause symptoms. Five stages of intoxication may occur in iron poisoning: (1) Hemorrhagic gastroenteritis, which occurs 30–60 minutes after ingestion and may be associated with shock, acidosis, coagulation defects, and coma; this phase usually lasts 4–6 hours; (2) phase of improvement, lasting 2–12 hours, during which patient looks better; (3) delayed shock, which may occur 12–48 hours after ingestion; Metabolic acidosis, fever, leukocytosis, and coma may also be present; (4) liver damage with hepatic failure; and (5) residual pyloric stenosis, which may develop about 4 weeks after the ingestion.

Once iron is absorbed from the GI tract, it is not normally eliminated in feces but may be partially excreted in the urine, giving it a red color prior to chelation. A reddish discoloration of the urine suggests a serum iron level greater than 350 mg/dL, but is neither sensitive nor specific.

Treatment

GI decontamination is based on clinical assessment. The patient should be referred to a health care facility if symptomatic or if the history indicates toxic amounts (typically > 20 mg/kg of elemental iron). Gastric lavage and whole bowel irrigation should be considered in potentially life-threatening overdoses.

Shock is treated in the usual manner. Deferoxamine, a specific chelating agent for iron, is a useful adjunct in the treatment of severe iron poisoning. It forms a soluble complex that is excreted in the urine. It is contraindicated in patients with renal failure unless dialysis can be used. IV deferoxamine chelation therapy should be instituted if the patient has a metabolic acidosis, persistent symptoms, and a serum iron determination cannot be obtained readily, or if the peak serum iron exceeds 500 mcg/dL at 4–5 hours after ingestion.

Deferoxamine should not be delayed until serum iron levels are available in serious cases of poisoning. IV administration is indicated if the patient is in shock, in which case it should be given at a dosage of 10–15 mg/kg/h. Infusion rates up to 35 mg/kg/h have been used in life-threatening poisonings. Rapid IV administration can cause hypotension, facial flushing, urticaria, tachycardia, and shock. Deferoxamine, 90 mg/kg IM every 8 hours (maximum, 1 g), may be given if IV access cannot be established, but the procedure is painful. The indications for discontinuation of deferoxamine have not been clearly delineated. Generally, it can be stopped after 12–24 hours if the acidosis has resolved and the patient is improving. Use of deferoxamine for greater than 24 hours has been associated with acute respiratory distress syndrome (ARDS).

Hemodialysis, peritoneal dialysis, or exchange transfusion can be used to increase the excretion of the dialyzable complex. Urine output should be monitored and urine sediment examined for evidence of renal tubular damage. Initial laboratory studies should include blood typing and crossmatching; total protein; serum iron, sodium, potassium, and chloride; Pco₂; pH; and liver function tests. Serum iron levels fall rapidly even if deferoxamine is not given. After the acute episode, liver function studies and an upper GI series are indicated to rule out residual damage.

LEAD

Lead poisoning (plumbism) causes vague symptoms, including weakness, irritability, weight loss, vomiting, personality changes, ataxia, constipation, headache, and colicky abdominal pain. Late manifestations consist of developmental delays, convulsions, and coma associated with increased intracranial pressure, which is a medical emergency.

Plumbism usually occurs insidiously in children younger than age 5 years. The most likely sources of lead include flaking leaded paint, artist's paints, fruit tree sprays, solder, brass alloys, home-glazed pottery, fumes from burning batteries and foreign country remedies. Only paint containing less than 1% lead is safe for interior use (eg, furniture, toys). Repetitive ingestions of small amounts of lead are far more serious than a single massive exposure. Toxic effects are likely to occur if more than 0.5 mg of lead per day is absorbed. In the United States, lead levels continue to decline and are more common abroad, so particular attention should be paid to immigrant and refugee populations or use of foreign remedies.

Blood lead levels are used to assess the severity of exposure. A complete blood count and serum ferritin concentration should be obtained; iron deficiency increases absorption of lead. Glycosuria, proteinuria, hematuria, and aminoaciduria occur frequently. Abnormal capillary blood lead levels should be repeated with venous sample in asymptomatic patients to rule out laboratory error. Specimens must be meticulously obtained in acid-washed metal-free containers. A normocytic, slightly hypochromic anemia with basophilic stippling of the red cells and reticulocytosis may be present in plumbism. Stippling of red blood cells is absent in cases involving only recent ingestion.

The cerebrospinal fluid (CSF) protein is elevated, and the white cell count usually is less than 100 cells/mL. CSF pressure may be elevated in patients with encephalopathy; lumbar punctures must be performed cautiously to prevent herniation.

Treatment

Refer to the CDC guidelines for the most up to date recommendations on lead treatment and evaluation. There

CHAPTER 13

is no "safe" concentration of lead. Removing the source of exposure is the most important initial treatment to toxicity. Succimer is an orally administered chelator approved for use in children and reported to be as efficacious as calcium edetate. Succimer should be initiated in asymptomatic children at blood lead levels over 45 mcg/ dL. The initial dose is 10 mg/kg (350 mg/m²) every 8 hours for 5 days. The same dose is then given every 12 hours for 14 days. At least 2 weeks should elapse between courses. Blood lead levels increase somewhat (ie, rebound) after discontinuation of therapy. Courses of dimercaprol/BAL (300– 450 mg/m²/day) and calcium sodium edetate/CaNa2EDTA (1000–1500 mg/m²/day) should be considered in symptomatic children or levels over 70 mcg/dL.

Encephalopathy associated with cerebral edema needs to be treated with standard measures. Anticonvulsants may be needed. A high-calcium, high-phosphorus diet and large doses of vitamin D may remove lead from the blood by depositing it in the bones. A public health team should evaluate the source of the lead. Necessary corrections should be completed before the child is returned home.

MAGNETS

Although not strictly toxic, small magnets have been found to cause bowel obstructions in children. Recent cases have resulted in warnings and a recall by the Consumer Product Safety Commission following intestinal perforation and death in a 20-month-old child. Obstruction may occur following ingestion of as few as two magnets. Radiographs should be obtained and surgical consultation may be indicated.

MARIJUANA

Marijuana is becoming more readily available as over half of US states have allowed medical marijuana, and several more allowing recreational marijuana. It is also available for use in multiple forms including high concentrated products (dabs, butters, waxes), vaporizers and infused edible products that all can have high concentrations of THC (tetrahydrocannabinol), the most psychoactive component.

Young children who ingest edible products can have a range of symptoms. These symptoms can be mild such as sleepiness and ataxia. However, more severe symptoms can develop including CNS depression, coma, and respiratory depression requiring mechanical ventilation. Symptoms in young children can sometimes last over 24 hours. Inhalational use/abuse of high concentrated products can lead to tachycardia, hypertension, agitation, and acute psychosis. Symptomatic and supportive care is mainstay for treatment: supporting cardiorespiratory adverse effects, and treating psychosis and agitation with benzodiazepines or antipsychotics.

MUSHROOMS

Toxic mushrooms are often difficult to distinguish from edible varieties. Contact a poison control center to obtain identification assistance. Symptoms vary with the species ingested, time of year, stage of maturity, quantity eaten, method of preparation, and interval since ingestion. Most mushrooms lead to early GI symptoms and do not lead to significant toxicity; however, some can be fatal and so it is critical to determine from poison center experts what mushroom may have been involved. A mushroom that is toxic to one individual may not be toxic to another. Drinking alcohol and eating certain mushrooms may cause a reaction similar to that seen with disulfiram and alcohol. Cooking destroys some toxins but not the deadly one produced by Amanita phalloides, which is responsible for 90% of deaths due to mushroom poisoning. Mushroom toxins are absorbed relatively slowly. Onset of symptoms within 2 hours of ingestion suggests muscarinic toxin, whereas a delay of symptoms for 6-48 hours after ingestion strongly suggests Amanita (amanitin) poisoning. Patients who have ingested A phalloides may relapse and die of hepatic or renal failure following initial improvement.

Treatment

Treatment of mushroom poisoning is highly specialized and consultation with a poison center is highly recommended. Supportive care with IV fluid resuscitation may be needed due to emesis and diarrhea. If the patient has muscarinic signs, give atropine, 0.05 mg/kg IM (0.02 mg/kg in toddlers), and repeat as needed (usually every 30 minutes) to keep the patient atropinized. Atropine, however, is used only when cholinergic effects are present and not for all mushrooms. Hypoglycemia is most likely to occur in patients with delayed onset of symptoms. Try to identify the mushroom if the patient is symptomatic. Local botanical gardens, university departments of botany, and societies of mycologists may be able to help. Supportive care is usually all that is needed; however, in the case of A phalloides, silibinin, biliary drainage, and aggressive management of fluids including hemodialysis may be indicated. Currently, there is clinical trial using intravenous silibinin for amatoxin induced hepatic failure, protocol available on http://www.clinicaltrials.gov.

NITRITES, NITRATES, ANILINE, PENTACHLOROPHENOL, & DINITROPHENOL

Nausea, vertigo, vomiting, cyanosis (methemoglobinemia), cramping, abdominal pain, tachycardia, cardiovascular collapse, tachypnea, coma, shock, convulsions, and death are possible manifestations of nitrite or nitrate poisoning.

Nitrite and nitrate compounds found in the home include amyl nitrite, butyl nitrates, isobutyl nitrates, nitroglycerin, pentaerythritol tetranitrate, sodium nitrite, nitrobenzene, and phenazopyridine. Pentachlorophenol and dinitrophenol, which are found in wood preservatives, produce methemoglobinemia and acidosis because of uncoupling of oxidative phosphorylation. Headache, dizziness, and bradycardia have been reported. High concentrations of nitrites in well water or spinach have been the most common cause of nitrite-induced methemoglobinemia. Other common causes of methemoglobinemia include local anesthetics. Symptoms do not usually occur until 15%-50% of the hemoglobin has been converted to methemoglobin. A rapid test is to compare a drop of normal blood with the patient's blood on a dry filter paper. Brown discoloration of the patient's blood indicates a methemoglobin level of more than 15%.

Treatment

In the setting of a recent ingestion, consider administering activated charcoal if the patient is awake and alert. Decontaminate affected skin with soap and water. Oxygen and artificial respiration may be needed. If the blood methemoglobin level exceeds 30%, or if levels cannot be obtained and the patient is symptomatic, give a 1% solution of methylene blue (0.2 mL/kg IV) over 5–10 minutes. Avoid perivascular infiltration, because it causes necrosis of the skin and subcutaneous tissues. A dramatic change in the degree of cyanosis should occur. Transfusion is occasionally necessary. If reflex bradycardia occurs, atropine should be used.

OPIOIDS & OPIATES

Opioid and opiate-related medical problems may include drug addiction, withdrawal in a newborn infant, and accidental overdoses. They can vary in onset of action and duration of action. Opioids, including heroin, methadone, morphine, and codeine are routinely detected on most urine drug assays. However, many of the more commonly used oral opiates, such as oxycodone, hydrocodone, buprenorphine are not detected on standard urine drug assays. Use of fentanyl analogs (carfentanyl) and fentanyl contamination in heroin and other drugs of abuse have been reported which can lead to severe toxicity and death. Care should be directed on clinical suspicion of ingestion.

Narcotic-addicted adolescents often have other medical problems, including cellulitis, abscesses, thrombophlebitis, tetanus, infective endocarditis, human immunodeficiency virus (HIV) infection, tuberculosis, hepatitis, malaria, foreign body emboli, thrombosis of pulmonary arterioles, diabetes mellitus, obstetric complications, nephropathy, and peptic ulcer.

Treatment

A. Overdose

Opioids and opiates can cause respiratory depression, stridor, coma, increased oropharyngeal secretions, sinus bradycardia, and urinary retention. Pulmonary edema rarely occurs in children but has been reported; deaths usually result from aspiration of gastric contents, respiratory arrest, and cerebral edema. Convulsions may occur with propoxyphene overdosage.

The indication for the administration of naloxone is respiratory depression. Although suggested doses for naloxone hydrochloride range from 0.01 to 0.1 mg/kg, it is generally unnecessary to calculate the dosage on this basis. This extremely safe antidote should be given in sufficient quantity to reverse opioid-binding sites. Doses as low as 0.04 mg have been affective for reversal. For children younger than 1 year, one ampoule (0.4 mg) should be given initially; if there is no response, five more ampoules (2 mg) should be given rapidly. Older children should be given 0.4-0.8 mg, followed by 2-4 mg if there is no response. An improvement in respiratory status may be followed by respiratory depression, because the antagonist's duration of action is less than 1 hour. Neonates poisoned in utero may require 10-30 mg/kg to reverse the effect. Naloxone infusion can be used for persistent symptoms. Depending on the formulation, some exposures (such as buprenorphine and methadone) may need to be observed for 24 hours due to the duration of effect.

B. Withdrawal in the Addict

Benzodiazepines such as diazepam (10 mg every 6 hours PO) and antiemetics have been recommended for the treatment of mild narcotic withdrawal in ambulatory adolescents. Management of withdrawal in the confirmed addict may be accomplished with the administration of clonidine, by substitution with methadone or buprenorphine, or with reintroduction of the original addicting agent, if available through a supervised drug withdrawal program. A tapered course over 3 weeks will accomplish this goal. Death rarely, if ever, occurs. The abrupt discontinuation of narcotics (cold turkey method) is not recommended and may cause severe physical withdrawal signs.

C. Withdrawal in the Newborn

A newborn infant in opioid withdrawal is usually small for gestational age and demonstrates yawning, sneezing, decreased Moro reflex, hunger but uncoordinated sucking action, jitteriness, tremor, constant movement, a shrill protracted cry, increased tendon reflexes, convulsions, vomiting, fever, watery diarrhea, cyanosis, dehydration, vasomotor instability, seizure, and collapse.

The onset of symptoms commonly begins in the first 48 hours but may be delayed as long as 8 days, depending on the timing of the mother's last fix and her predelivery medication. The diagnosis can be confirmed easily by identifying the narcotic in the urine of the mother and the newborn.

Several treatment methods have been suggested for narcotic withdrawal in the newborn. Phenobarbital (8 mg/kg/day IM or PO in four doses for 4 days and then reduced by onethird every 2 days as signs decrease) may be continued for as long as 3 weeks. Methadone may be necessary in those infants with congenital methadone addiction who are not controlled in their withdrawal by large doses of phenobarbital. Dosage should be 0.5 mg/kg/day in two divided doses but can be increased gradually as needed. After control of the symptoms is achieved, the dose may be tapered over 4 weeks.

It is unclear whether prophylactic treatment with these drugs decreases the complication rate. The mortality rate of untreated narcotic withdrawal in the newborn may be as high as 45%.

ORAL ANTI-DIABETICS (SULFONYLUREAS, METFORMIN)

Noninsulin hypoglycemic and antidiabetic medications include α -glucosidase inhibitors, biguanides (metformin), dipeptidyl peptidase-4 inhibitors (-gliptins), glucagon-like peptides (-glutide), meglitinides (-glinide), sodium glucose transporter inhibitors (-flovzin), sulfonylureas, and thiazolidinediones (-glitazone). They are all used to treat hyperglycemia in diabetics. Sulfonylureas (acetohexamide, glipizide, glyburide) are the only oral hypoglycemic that actively secretes endogenous insulin and can cause hypoglycemia. The meglitinides (nateglinide, repaglinide) have scarce reports of hypoglycemia. Biguanides can rarely cause lactic acidosis in acute large overdose or in renal failure. Hypoglycemic symptoms are variable but can include altered mental status, diaphoresis, seizures, or coma.

Treatment

Children with possible exposures to sulfonylureas should be admitted for 12–24 hours. Mainstay of treatment is treating hypoglycemia. If patient is awake and alert, with minimal symptoms, PO glucose can be given. With more severe hypoglycemia or symptomatic, immediate treatment with 0.5–1 g/kg IV dextrose bolus should be administered. With repeated episodes of hypoglycemia, once euglycemia is achieved, octreotide should be considered at 1 mcg/kg SC/IV every 6–8 hours as needed for hypoglycemia. Metformin

POISONING

toxicity should be treated supportively, and hemodialysis may be needed for severe acid-base abnormalities or patients with renal failure.

ANTIPSYCHOTICS (TYPICAL & ATYPICAL)

Typical antipsychotics include butyrophenones (droperidol, haloperidol), and the phenothiazines (promethazine, chlorpromazine, thioridazine). Atypical antipsychotics include benzapines (clozapine, olanzapine, quetiapine) and indoles (risperidone, ziprasidone).

Clinical Findings

A. Extrapyramidal Crisis

Episodes characterized by torticollis, stiffening of the body, spasticity, poor speech, catatonia, and inability to communicate although conscious are typical manifestations. Extrapyramidal crises may represent idiosyncratic reactions and are aggravated by dehydration. The signs and symptoms occur most often in children who have received prochlorperazine. They are commonly mistaken for psychotic episodes. These extrapyramidal symptoms are more common with typical antipsychotics (butyrophenones, phenothiazines).

B. Overdose

Lethargy and deep prolonged coma are the most common symptoms seen in toxicity. Of the typical antipsychotics, promazine, chlorpromazine, and prochlorperazine are the drugs most likely to cause respiratory depression and precipitous drops in blood pressure. Risperidone and quetiapine are atypical antipsychotics that can cause CNS depression. Clozapine, olanzapine, and quetiapine most commonly cause hypotension and also antimuscarinic symptoms. QTc prolongation can occur, most commonly with thioridazine and ziprasidone. Occasionally, paradoxic hyperactivity and extrapyramidal signs as well as hyperglycemia and acetonemia are present. Seizures are uncommon.

C. Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome is a rare idiosyncratic complication that may be lethal. It is a syndrome involving mental status change (confusion, coma), motor abnormalities (lead pipe rigidity, clonus), and autonomic dysfunction (tachycardia, hyperpyrexia). Typically it occurs 1–2 weeks after starting therapy, can occur at therapeutic doses, and may last for several days.

Treatment

Extrapyramidal signs are alleviated within minutes by the slow IV administration of diphenhydramine, 1–2 mg/kg (maximum, 50 mg), or benztropine mesylate, 1–2 mg IV (1 mg/min). No other treatment is usually indicated. Further doses may be needed.

Patients with overdoses should receive conservative supportive care. Hypotension may be treated with standard agents, starting with isotonic saline administration. Agitation is best treated with benzodiazepines. Neuroleptic malignant syndrome is treated by discontinuing the drug, and treating hyperthermia and agitation aggressively with benzodiazepines and sedation. In refractory cases, bromocriptine can be considered, although the evidence for its use is not clear.

PLANTS

Many common ornamental, garden, and wild plants are potentially toxic. Only in a few cases will small amounts of a plant cause severe illness or death. Table 13–5 lists the most toxic plants, symptoms and signs of poisoning, and treatment. Contact your poison control center for assistance with identification.

PSYCHOTROPIC DRUGS

Psychotropic drugs consist of four general classes: stimulants (amphetamines, cocaine, nicotine), depressants (eg, narcotics, barbiturates), antidepressants and tranquilizers, and psychoactive drugs (hallucinogens such as lysergic acid diethylamide [LSD], phencyclidine [PCP]).

Clinical Findings

The following clinical findings are commonly seen in patients abusing drugs. See also other entries discussed in alphabetic order in this chapter.

A. Stimulants

Agitation, euphoria, grandiose feelings, tachycardia, fever, abdominal cramps, visual and auditory hallucinations, mydriasis, coma, convulsions, and respiratory depression.

Table 13–5. Poisoning due to plants.^a

	Symptoms and Signs	Treatment
Arum family: <i>Caladium, Dieffenbachia,</i> calla lily, dumb cane (oxalic acid)	Burning of mucous membranes and airway obstruction secondary to edema caused by calcium oxalate crystals.	Accessible areas should be thoroughly washed. Corticosteroids relieve airway obstruction. Apply cold packs to affected mucous membranes.
Castor bean plant (ricin—a toxal- bumin) Jequirity bean (abrin—a toxalbumin)	Mucous membrane irritation, nausea, vomiting, bloody diarrhea, blurred vision, circulatory collapse, acute hemolytic anemia, convulsions, uremia.	Fluid and electrolyte monitoring. Saline cathartic. Forced alkaline diuresis will prevent complications due to hemagglutination and hemolysis.
Foxglove, lily of the valley, and oleander ^b	Nausea, diarrhea, visual disturbances, and cardiac irregularities (eg, heart block).	See treatment for digitalis drugs in text.
Jimsonweed: See Belladonna Alkaloids section in text	Mydriasis, dry mouth, tachycardia, and hallucinations.	Benzodiazepines for agitation, physostigmine.
Larkspur (ajacine, <i>Delphinium</i> , delphinine)	Nausea and vomiting, irritability, muscular paralysis, and central nervous system depression.	Symptomatic. Atropine may be helpful.
Monkshood (aconite)	Numbness of mucous membranes, visual disturbances, tingling, dizziness, tinnitus, hypotension, bradycardia, and convulsions.	Activated charcoal, oxygen. Atropine is probably helpful.
Poison hemlock (coniine)	Mydriasis, trembling, dizziness, bradycardia. Central nervous system depression, muscular paralysis, and convulsions. Death is due to respiratory paralysis.	Symptomatic. Oxygen and cardiac monitoring equipment are desirable. Assisted respiration is often necessary. Give anticonvulsants if needed.
<i>Rhododendron</i> (grayanotoxin)	Abdominal cramps, vomiting, severe diarrhea, muscular paralysis. Central nervous system and circulatory depression. Hypertension with very large doses.	Atropine can prevent bradycardia. Epinephrine is contraindicated. Antihypertensives may be needed.
Yellow Jessamine (active ingredient, gelsemine, is related to strychnine)	Restlessness, convulsions, muscular paralysis, and respiratory depression.	Symptomatic. Because of the relation to strychnine, activated charcoal and diazepam for seizures are worth trying.
Water hemlock (cicutoxin).	Nausea, vomiting, abdominal pain. Followed by seizures. Severe ingestions can result in rhabdomyolysis, metabolic acidosis, and renal failure.	Symptomatic. Benzodiazepines for seizures.

^aMany other plants cause minor irritation but are not likely to cause serious problems unless large amounts are ingested. ^bDone AK: Ornamental and deadly. Emerg Med 1973;5:255.

Data from Lampe KF, McCann MA: AMA Handbook of Poisonous and Injurious Plants. American Medical Association; 1985.

Nicotine is associated with vomiting, hypertension and tachycardia, followed by symptoms of cholinergic excess, seizures and weakness.

B. Depressants

Emotional lability, ataxia, diplopia, nystagmus, vertigo, poor accommodation, respiratory depression, coma, apnea, and convulsions. Narcotics cause miotic pupils and, occasionally, pulmonary edema.

C. Antidepressants and Tranquilizers

Hypotension, lethargy, respiratory depression, coma, and extrapyramidal reactions.

D. Hallucinogens and Psychoactive Drugs

Belladonna alkaloids cause mydriasis, dry mouth, nausea, vomiting, urinary retention, confusion, disorientation, paranoid delusions, hallucinations, fever, hypotension, aggressive behavior, convulsions, and coma. Psychoactive drugs such as LSD cause mydriasis, unexplained bizarre behavior, hallucinations, and generalized undifferentiated psychotic behavior. Marijuana can cause tachycardia, anxiety, and dysphoria.

Treatment

Only a small percentage of the persons using drugs come to the attention of physicians; those who do are usually experiencing adverse reactions such as panic states, drug psychoses, homicidal or suicidal thoughts, or respiratory depression.

Even with cooperative patients, an accurate history is difficult to obtain. A drug history is most easily obtained in a quiet spot by a gentle, nonthreatening, honest examiner, and without the parents present. Street drugs are often adulterated with one or more other compounds and the exact dose is unknown. Multiple drugs are often taken together. Friends may be a useful source of information.

Hallucinogens are not life-threatening unless the patient is frankly homicidal or suicidal. A specific diagnosis is usually not necessary for management; instead, the presenting signs and symptoms are treated. Does the patient appear intoxicated? In withdrawal? "Flashing back?" Is some illness or injury (eg, head trauma) being masked by a drug effect? (Remember that a known drug user may still have hallucinations from meningoencephalitis.)

The signs and symptoms in a given patient are a function not only of the drug and the dose but also of the level of acquired tolerance, the "setting," the patient's physical condition and personality traits, the potentiating effects of other drugs, and many other factors.

A common drug problem is the "bad trip," which is usually a panic reaction. This is best managed by "talking the patient down" and minimizing auditory and visual stimuli. Allowing the patient to sit with a friend while the drug effect dissipates may be the best treatment. This may take several hours. The physician's job is not to terminate the drug effect but to help the patient through the bad experience.

Drug therapy is often unnecessary and may complicate the clinical course of a drug-related panic reaction. Although phenothiazines have been commonly used to treat bad trips, they should be avoided if the specific drug is unknown, because they may enhance toxicity or produce unwanted side effects. Benzodiazepines are the drug of choice if a sedative effect is required. Physical restraints are rarely indicated and usually increase the patient's panic reaction.

After the acute episode, the physician must decide whether psychiatric referral is indicated; in general, patients who have made suicidal gestures or attempts and adolescents who are not communicating with their families should be referred. Chatham-Stephnes K et al: Notes from the field: calls to poison centers for exposures to electronic cigarettes—United States. September 2010–February 2014. MMWR 2014;63(13):292–293 [PMID: 24699766].

SALICYLATES

The use of childproof containers and publicity regarding accidental poisoning have reduced the incidence of acute salicylate poisoning. Oil of wintergreen ingestion can also lead to salicylate toxicity. Nevertheless, serious intoxication still occurs and must be regarded as an emergency.

Salicylates uncouple oxidative phosphorylation, leading to increased heat production, excessive sweating, and dehydration. They also interfere with glucose metabolism and may cause hypo- or hyperglycemia. Respiratory center stimulation occurs early. The severity of acute intoxication can, in some measure, be judged by serum salicylate levels. High levels are always dangerous irrespective of clinical signs, and low levels may be misleading in chronic cases.

In mild and moderate poisoning, stimulation of the respiratory center produces respiratory alkalosis and may complain of tinnitus or hearing loss. Vomiting is also a common presenting symptom. In severe intoxication (occurring in severe acute ingestion with high salicylate levels and in chronic toxicity with lower levels), respiratory response is unable to overcome the metabolic overdose which may lead to fever, diaphoresis, pulmonary edema, seizures, and death.

Once the urine becomes acidic, less salicylate is excreted. Until this process is reversed, the half-life will remain prolonged, because metabolism contributes little to the removal of salicylate. Chronic severe poisoning may occur as early as 3 days after a regimen of salicylate is begun. Findings usually include vomiting, diarrhea, and dehydration.

Treatment

Charcoal binds salicylates well and should be given for acute ingestions in patients now vomiting with normal mentation. Mild poisoning may require only the administration of oral fluids and confirmation that the salicylate level is falling (< 30 mg/dL). Moderate poisoning involves moderate dehydration and depletion of potassium. Fluids must be administered at a rate of 2–3 mL/kg/h to correct dehydration and produce urine with a pH of greater than 7.0. Initial IV solutions should be isotonic (D5W with 150 mEq sodium bicarbonate). Once the patient is rehydrated, the solution can contain more free water and approximately 40 mEq/L of K⁺.

Severe toxicity is marked by major dehydration. Symptoms may be confused with those of Reye syndrome, encephalopathy, and metabolic acidosis. Salicylate levels may even be in the therapeutic range. Major fluid correction of dehydration is required. Once this has been accomplished, hypokalemia must be corrected and sodium bicarbonate given. Usual requirements are sodium bicarbonate, 1-2 mEq/kg/h over the first 6–8 hours, and K⁺, 20–40 mEq/L. A urine flow of 2–3 mL/kg/h should be established. Despite this treatment, some patients will develop the paradoxical aciduria of salicylism. This is due to hypokalemia and the saving of K⁺ and excretion of H⁺ in the renal tubule. Correction of K⁺ will allow the urine to become alkaline and ionize the salicylate, resulting in excretion rather than reabsorption of nonionized salicylate in acid urine.

Patients with renal failure, pulmonary edema, mental status changes, seizures, or concentrations of greater than 100 mg/dL should be considered for hemodialysis.

SCORPION STINGS

Scorpion stings are common in arid areas of the southwestern United States. Scorpion venom is more toxic than most snake venoms, but only minute amounts are injected. Although neurologic manifestations may last a week, most clinical signs subside within 24–48 hours.

The most common scorpions in the United States are *Vejovis, Hadrurus, Androctonus,* and *Centruroides* species. Stings by the first three produce edema and pain. Stings by *Centruroides* (the Bark scorpion) cause tingling or burning paresthesias that begin at the site of the sting; other findings include hypersalivation, restlessness, muscular fasciculation, abdominal cramps, opisthotonos, convulsions, urinary incontinence, and respiratory failure.

Treatment

Sedation with benzodiazepines is the primary therapy. Antivenom is reserved for severe poisoning, recommended dosing of 1–3 vials. In severe cases, the airway may become compromised by secretions and weakness of respiratory muscles. Endotracheal intubation may be required. Patients may require treatment for seizures, hypertension, or tachycardia. The prognosis is good as long as the patient's airway is managed appropriately and sedation is achieved.

- Coorg V, Levitan RD, Gerkin RD, Muenzer J, Ruha AM: Clinical presentation and outcomes associated with different treatment modalities for pediatric bark scorpion envenomation. J Med Toxicol Aug 3, 2016. doi: 10.1007/s13181-016-0575-3.27487782.

SEROTONIN REUPTAKE INHIBITORS

Fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), and many other agents comprise this class of drugs. Adverse effects in therapeutic dosing include suicidal thoughts, aggressive behavior, extrapyramidal effects, and cardiac dysrhythmias, and in overdose may include vomiting, lethargy, seizures, hypertension, tachycardia, hyperthermia, and abdominal pain. The findings in overdose are included in the serotonin syndrome due to the action of these drugs, which results in an increase of serotonin (5-hydroxytryptamine [5-HT]). Despite the degree of toxicity these agents generally are not life-threatening and intervention usually is not necessary.

Laboratory measurements of the drugs are not of benefit other than to establish their presence.

Treatment of agitation, hyperthermia with benzodiazepines is most beneficial. Hypotension may be treated with fluids or norepinephrine. Cyproheptadine is an antagonist of serotonin, but evidence for its use is limited. A dose of 0.25 mg/kg/day divided every 6 hours to a maximum of 12 mg/day may be useful in treating the serotonin syndrome. Adults and older adolescents have been treated with 12 mg initially followed by 2 mg every 2 hours to a maximum of 32 mg/day.

SNAKEBITE

Despite the lethal potential of venomous snakes, human morbidity and mortality rates are surprisingly low. The outcome depends on the size of the child, the site of the bite, the degree of envenomation, the type of snake, and the effectiveness of treatment.

Nearly all poisonous snakebites in the United States are caused by pit vipers (rattlesnakes, water moccasins, and copperheads). A few are caused by elapids (coral snakes), and occasional bites occur from cobras and other nonindigenous exotic snakes kept as pets. Snake venom is a complex mixture of enzymes, peptides, and proteins that may have predominantly cytotoxic, neurotoxic, hemotoxic, or cardiotoxic effects but other effects as well. Up to 25% of bites by pit vipers do not result in venom injection. US pit viper venom causes predominantly local injury with pain, discoloration, edema, and thrombocytopenia.

Swelling and pain occur soon after rattlesnake bite and are a certain indication that envenomation has occurred. During the first few hours, swelling and ecchymosis extend proximally from the bite. The bite is often obvious as a double puncture mark surrounded by ecchymosis. Hematemesis, melena, hemoptysis, and other manifestations of coagulopathy rarely develop in severe cases. Respiratory difficulty and shock are the ultimate causes of death. Even in fatal rattlesnake bites, a period of 6–8 hours usually elapses between the bite and death; as a result, there is usually enough time to start effective treatment.

Coral snake envenomation causes little local pain, swelling, or necrosis, and systemic reactions are often delayed. The signs of coral snake envenomation include bulbar paralysis, dysphagia, and dysphoria; these signs may appear in 5–10 hours and may be followed by total peripheral paralysis and death in 24 hours.

Treatment

Children in snake-infested areas should wear boots and long trousers, should not walk barefoot, and should be cautioned not to explore under ledges or in holes.

A. Emergency (First-Aid) Treatment

The most important first-aid measure is transportation to a medical facility. Splint the affected extremity and minimize the patient's motion. Tourniquets and ice packs are contraindicated. Incision and suction are not useful for either crotalid or elapid snake bite.

B. Definitive Medical Management

Blood should be drawn for hematocrit, clotting time and platelet function, and serum electrolyte determinations. Establish two secure IV sites for the administration of antivenom and other medications.

Specific antivenom is indicated when signs of progressive envenomation are present. For coral snake bites, an eastern coral snake antivenom (Wyeth Laboratories) is sparingly available. Patients with pit viper bites should receive polyvalent CrotalidaeFab (CroFab) antivenom if progressive local injury, coagulopathy, or systemic signs (eg, hypotension, confusion) are present. (Antivenom should not be given IM or SQ.) See package labeling or call your certified poison center for details of use. Antivenom will halt progression of symptoms and improve hemorrhage, pain, and shock. For any history of coral snake bites, give three to five vials of antivenom in 250-500 mL of isotonic saline solution if available and observation for at least 24 hours. An additional three to five vials may be required. While generally considered best if administered within the first 6 hours, recent evidence demonstrates that delayed use may be therapeutic.

Administer an opioid or opiate to control pain. Cryotherapy is contraindicated because it commonly causes additional tissue damage. Early physiotherapy minimizes contractures. In rare cases, fasciotomy to relieve pressure within muscular compartments is required. The evaluation of function and of pulses will better predict the need for fasciotomy. Antihistamines and corticosteroids (hydrocortisone, 1 mg/kg, given PO for a week) are useful in the treatment of serum sickness or anaphylactic shock. Antibiotics are not needed unless clinical signs of infection occur. Tetanus status should be evaluated and the patient immunized, if needed. Recurrent coagulopathy and thrombocytopenia may occur after discharge, and patients should have follow up examinations and repeat laboratory values within 1 week after hospital discharge.

SOAPS & DETERGENTS

1. Soaps

Soap is made from salts of fatty acids. Ingestion of soap bars may cause vomiting and diarrhea, but they have a low toxicity.

2. Detergents

Detergents are nonsoap synthetic products used for cleaning purposes because of their surfactant properties. Commercial products include granules, powders, and liquids. Dishwasher detergents are very alkaline and can cause caustic burns. Low concentrations of bleaching and antibacterial agents as well as enzymes are found in many preparations. The pure compounds are moderately toxic, but the concentration used is too small to alter the product's toxicity significantly, although occasional primary or allergic irritative phenomena have been noted in persons who frequently use such products and in employees manufacturing these products. Unit dose detergents, or packets, have become popular and have packaging attractive to young children. They are usually a mix of glycol ethers, ethyl alcohol and surfactant. They typically cause local irritation but can lead to more severe symptoms including corneal injuries, CNS depression and respiratory distress if ingested. These exposures may need more prolonged observation.

A. Cationic Detergents (Ceepryn, Diaparene Cream, Phemerol, Zephiran)

Cationic detergents in dilute solutions (0.5%) cause mucosal irritation, but higher concentrations (10%–15%) may cause caustic burns to mucosa. Clinical effects include nausea,

vomiting, collapse, coma, and convulsions. As little as 2.25 g of some cationic agents have caused death in an adult. In four cases, 100–400 mg/kg of benzalkonium chloride caused death. Cationic detergents are rapidly inactivated by tissues and ordinary soap.

Because of the caustic potential and rapid onset of seizures, emesis is not recommended. Activated charcoal should be administered. Anticonvulsants may be needed.

B. Anionic Detergents

Most common household detergents are anionic. Laundry compounds have water softener (sodium phosphate) added, which is a strong irritant and may reduce ionized calcium. Anionic detergents irritate the skin by removing natural oils. Although ingestion causes diarrhea, intestinal distention, and vomiting, no fatalities have been reported.

The only treatment usually required is to discontinue use if skin irritation occurs and replace fluids and electrolytes. Induced vomiting is not indicated following ingestion of automatic dishwasher detergent, because of its alkalinity. Dilute with water or milk.

C. Nonionic Detergents (Brij Products; Tritons X-45, X-100, X-102, and X-144)

These compounds include lauryl, stearyl, and oleyl alcohols and octyl phenol. They have a minimal irritating effect on the skin and are almost always nontoxic when swallowed.

SPIDER BITES

Most medically important bites in the United States are caused by the black widow spider (*Latrodectus mactans*) and the North American brown recluse (violin) spider (*Loxosceles reclusa*). Positive identification of the spider is helpful, because many spider bites may mimic those of the brown recluse spider.

1. Black Widow Spider

The black widow spider is endemic to nearly all areas of the United States. The initial bite causes sharp fleeting pain that spreads centripetally. Local and systemic muscular cramping, abdominal pain, nausea and vomiting, tachycardia, and hypertension are common. Systemic signs of black widow spider bite may be confused with other causes of acute abdomen. Although paresthesias, nervousness, and transient muscle spasms may persist for weeks in survivors, recovery from the acute phase is generally complete within 2–3 days. In contrast to popular opinion, death is extremely rare.

Initial pain control should be achieved with use of benzodiazepines and opioids or opiates. Antivenom is effective, but supplies are limited and should be reserved for severe cases in which the previously mentioned therapies have failed.

2. Brown Recluse Spider (Violin Spider)

The North American brown recluse spider is most commonly seen in the central and Midwestern areas of the United States. Its bite characteristically produces a localized reaction with progressively severe pain within 24 hours. The initial bleb on an erythematous ischemic base is replaced by a black eschar within 1 week. This eschar separates in 2–5 weeks, leaving an ulcer that heals slowly. Systemic signs (loxoscelism) include cyanosis, morbilliform rash, fever, chills, malaise, weakness, nausea and vomiting, joint pains, hemolytic reactions with hemoglobinuria, jaundice, and delirium and are more common in children. Fatalities are rare. Fatal disseminated intravascular coagulation has been reported.

Although of unproved efficacy, the following therapies have been used: dexamethasone, 4 mg IV four times a day, during the acute phase; polymorphonuclear leukocyte inhibitors, such as dapsone or colchicine. Supportive wound care is recommended, with possible reconstruction/debridement.

VITAMINS

Accidental ingestion of excessive amounts of vitamins rarely causes significant problems. Very rare cases of hypervitaminosis A do occur, however, particularly in patients with poor hepatic or renal function. Hypervitaminosis A can result in increased intracranial pressure, ocular toxicity, and hepatotoxicity. However, chronic doses more than 50,000– 100,000 IU are required for toxicity. The fluoride contained in many multivitamin preparations is not a realistic hazard, because a 2- or 3-year-old child could eat 100 tablets, containing 1 mg of sodium fluoride per tablet, without experiencing serious symptoms. Iron poisoning has been reported with multivitamin tablets containing iron; most gummy vitamins do not contain iron. Pyridoxine abuse has caused neuropathies; nicotinic acid can result in flushing, and rarely hypotension and hepatotoxicity.

WARFARIN (COUMADIN) & NEWER ORAL ANTICOAGULANTS (NOAC)

Warfarin is used as an anticoagulant and rodenticide. It causes hypoprothrombinemia and capillary injury. A dose of 0.5 mg/kg of warfarin may be toxic in a child. Long-acting anticoagulant rodenticides (brodifacoum, difenacoum, bromadiolone, diphacinone, pinene, valone, and coumatetralyl) can cause a more serious toxicologic problem than warfarin as the anticoagulant activity may persist for periods ranging from 6 weeks to several months. However, most unintentional ingestions can be watched at home without further evaluation. If there are concerns for large ingestions, a prothrombin time at 48 hours can determine extent of toxicity. Treatment with vitamin K_1 at high doses may be needed for weeks for long-acting anticoagulant toxicity.

Refer to published American College of Chest Physicians guidelines on management of bleeding in patient receiving vitamin K antagonists. With evidence for bleeding, give fresh frozen plasma, prothrombin complex concentrated, or activated factor. Without significant bleeding, oral vitamin K is recommended. No clear therapy is available for the newer direct factor inhibitors. Therapy has been focused on using fresh frozen plasma, prothrombin complex concentrate, and activated factor.

Newer oral anticoagulants have been developed that have direct inhibition to specific clotting factors. Examples include direct Xa inhibitors (apixaban, edoxaban, rivaroxaban), and direct thrombin (IIa) inhibitors (dabigatran). Toxic doses have not been established, but accidental ingestions do not typically lead to significant toxicity. If available, chromogenic antifactor Xa assay can quantitate direct Xa inhibition, and ecarin clotting time (ECT) or dilute thrombin time (dTT) is the most the most sensitive coagulation parameter for direct thrombin inhibitors. Activated fourfactor prothrombin complex concentrates or activated Factor VII should be used to treat potentially life-threatening bleeding. Reversal agents are being developed for NOACassociated coagulopathy.

Critical Care

Todd C. Carpenter, MD Amy Clevenger, MD, PhD Angela S. Czaja, MD, MSc Eva N. Grayck, MD Cameron F. Gunville, DO Leslie Ridall, DO Carleen Zebuhr, MD

INTRODUCTION

Critical care medicine is the discipline of caring for patients with acute life-threatening conditions or conditions likely to cause serious harm if not rapidly addressed. This work requires a detailed understanding of human physiology, the pathophysiology of severe illness and injury, the intricate interactions between organ systems and therapies, as well as an understanding of and experience with the rapidly changing technologies available in a modern pediatric intensive care unit (PICU). The science of caring for the critically ill patient continues to advance rapidly as the molecular mediators of illness have become better defined and new therapies are brought into clinical use. Critical care, then, is a highly complex, multidisciplinary field in which optimal patient outcomes require a team-oriented approach, including critical care physicians and nurses; respiratory therapists; pharmacists; consulting specialists; physical, occupational and recreational therapists; and social services specialists.

RESPIRATORY CRITICAL CARE

ACUTE RESPIRATORY FAILURE

- Inability to deliver oxygen or remove carbon dioxide.
- PaO₂ is low while PaCO₂ is normal in hypoxemic respiratory failure (ventilation/perfusion [V/Q] mismatch, diffusion defects, and intrapulmonary shunt).
- PaO₂ is low and PaCO₂ is high in hypercapnic respiratory failure (alveolar hypoventilation seen in central nervous

system [CNS] dysfunction, oversedation, neuromuscular disorders).

- Noninvasive mechanical ventilation can be an effective treatment for hypercapnic respiratory failure and selected patients with hypoxemic failure.
- Conventional mechanical ventilation should be accomplished within a strategy of "lung-protective" ventilation.
- High-frequency oscillatory ventilation (HFOV) and extracorporeal membrane oxygenation (ECMO) are viable options for patients failing conventional mechanical ventilation.

Pathogenesis

Acute respiratory failure, defined as the inability of the respiratory system to adequately deliver oxygen or remove carbon dioxide, is a major cause of morbidity and mortality in infants and children. Anatomic and developmental differences place infants and young children at higher risk than adults for respiratory failure. An infant's thoracic cage is more compliant than that of the adult or older child, allowing a greater tendency toward alveolar collapse. The intercostal muscles are poorly developed and unable to achieve the "bucket-handle" motion characteristic of adult breathing, and the diaphragm is shorter and relatively flat with fewer type I muscle fibers, making it less effective and more easily fatigued. The infant's airways are smaller in caliber than those in older children and adults, resulting in greater resistance to airflow and greater susceptibility to occlusion by mucus plugging and mucosal edema, particularly in the setting of respiratory infections. Compared with adults, the alveoli of children are smaller and have less collateral ventilation, again resulting in a greater tendency to collapse and develop atelectasis. Finally, young infants may have an especially reactive pulmonary vascular bed, impaired immune system, or residual effects from prematurity, all of which increase the risk of respiratory failure.

Respiratory failure can be due to inadequate oxygenation (hypoxemic respiratory failure) or inadequate ventilation (hypercapnic respiratory failure) or both. Hypoxemic respiratory failure occurs in three situations: (1) V/Q mismatch, which occurs when blood flows to parts of the lung that are inadequately ventilated, or when ventilated areas of the lung are inadequately perfused; (2) diffusion defects, caused by thickened alveolar membranes or excessive interstitial fluid at the alveolar-capillary junction; and (3) intrapulmonary shunt, which occurs when structural anomalies in the lung allow blood to flow through the lung without participating in gas exchange. Hypercapnic respiratory failure results from impaired alveolar ventilation, due to conditions such as increased dead space ventilation, reduced respiratory drive due to CNS dysfunction or oversedation, or neuromuscular disorders (Table 14-1).

Clinical Findings

The clinical findings in respiratory failure are the result of hypoxemia, hypercapnia, and arterial pH changes. Common features of respiratory failure are summarized in Table 14–2. These features are not consistently clinically obvious, and most of them have nonrespiratory causes as well. As a result, a strictly clinical assessment of respiratory failure is not always reliable, and clinical findings of respiratory failure should be supplemented by laboratory data such as blood gas analysis.

Table 14–1.	Types of	respiratory	/ failure.
-------------	----------	-------------	------------

Findings	Causes	Examples
Hypoxemic (type I) PaO ₂ low PaCO ₂ normal	Ventilation- perfusion (V/Q) defect	Positional (supine in bed), acute respiratory distress syndrome (ARDS), atelectasis, pneumonia, pulmonary embolus, bronchopulmonary dysplasia
	Diffusion impairment	Pulmonary edema, ARDS, interstitial pneumonia
	Shunt	Pulmonary arteriovenous malformation, congenital adenomatoid malformation
Hypercapnic (type II) PaO ₂ low PaCO ₂ high	Hypoventilation	Neuromuscular disease (polio, Guillain-Barré syndrome), head trauma, sedation, chest wall dysfunction (burns), kyphoscoliosis, severe reactive airways

Noninvasive Monitoring & Blood Gas Analysis

The adequacy of oxygenation and ventilation can be measured both noninvasively and through blood gas analysis. Arterial oxygen saturation (SaO₂) can be measured continuously and noninvasively by pulse oximetry, a technique that should be used in the assessment and treatment of all patients with potential or actual respiratory failure. Pulse oximetry readings, however, become markedly less accurate in patients with saturations below approximately 80%, poor skin perfusion, or significant movement. In addition, pulse oximetry can be dangerously inaccurate in certain clinical settings such as carbon monoxide poisoning or methemoglobinemia. End-tidal CO₂ (ETCO₂) monitoring provides a continuous noninvasive means of assessing the adequacy of ventilation. The ETCO, level closely approximates the alveolar CO₂ level (PaCO₂), which should equal the arterial CO₂ level (PaCO₂) because carbon dioxide diffuses freely across the alveolar-capillary barrier. While most accurate in the intubated patient, this technique can also be used in extubated patients with the proper equipment. Though useful for following trends in ventilation, ETCO₂ monitoring is also susceptible to significant error, particularly in patients with rapid, shallow breathing or increased dead space ventilation.
Given the limitations of these noninvasive techniques, arterial blood gas (ABG) analysis remains the gold standard for assessment of acute respiratory failure. ABGs provide measurements of the patient's acid-base status (with a measured pH and calculated bicarbonate level) as well as PaO_2 and $PaCO_2$ levels. Although measurement of capillary or venous blood gases may provide some reassurance regarding the adequacy of ventilation and can be useful for following trends, they yield virtually no useful information regarding oxygenation and may generate highly misleading information about the ventilatory status of patients who have poor perfusion or who had difficult blood draws. As a result, ABG analysis is important for all patients with suspected respiratory failure, particularly those with abnormal venous or capillary gases.

Knowing the ABG values and the inspired oxygen concentration also enables one to calculate the alveolar-arterial oxygen difference (A-aDO2, or A-a gradient). The A-a gradient is less than 15 mm Hg under normal conditions, though it widens with increasing inspired oxygen concentrations to about 100 mm Hg in normal patients breathing 100% oxygen. This number has prognostic value in severe hypoxemic respiratory failure, with A-a gradients over 400 mm Hg being strongly associated with mortality. Diffusion impairment, shunts, and V/Q mismatch all increase the A-a gradient. In addition to the calculation of the A-a gradient, assessment of intrapulmonary shunting (the percentage of pulmonary blood flow that passes through nonventilated areas of the lung) may be helpful. Normal individuals have less than a 5% physiologic shunt from bronchial, coronary, and thebesian (cardiac intramural) circulations. Shunt fractions greater than 15% usually indicate the need for aggressive respiratory support. Calculation of the shunt fraction requires a pulmonary arterial catheter for measurement of mixed venous blood gases; for patients without pulmonary artery catheters, the A-a gradient is a good surrogate measure of intrapulmonary shunting.

Modes of Respiratory Support

Patients with severe hypoxemia, hypoventilation, or apnea require immediate assistance with bag and mask ventilation until the airway is successfully intubated and controlled mechanical ventilation can be provided. Assisted ventilation with a bag and mask can generally be maintained for some time with a mask of the proper size, but gastric distention, emesis leading to aspiration of gastric contents, and inadequate tidal volumes leading to atelectasis are possible complications. In those patients not requiring immediate intubation, a variety of modalities can be used to provide respiratory support, including supplemental oxygen, heated high-flow nasal cannula (HHFNC), and noninvasive ventilation (NIV) with continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or average volume-assured pressure support (AVAPS).

Supplemental oxygen with a nasal cannula or oxygen mask may be adequate to treat patients with mild respiratory insufficiency (Table 14–3). Patients with hypoventilation and diffusion defects respond better to supplemental oxygen than patients with significant shunts or V/Q mismatch. *HHFNC* devices utilize a nasal cannula for delivery of heated and humidified oxygen mixtures at high flow rates not normally tolerated with cooler drier air, effectively generating positive pressure similar to CPAP. This approach is being used in infants and young children more frequently and is also well tolerated in older patients. Generally, flow rates of greater than 2 L/min in infants and greater than 4 L/min in children with bronchiolitis and appears to be well tolerated, potentially decreasing the need for intubation by

Source	Maximum % 0 ₂ Delivered	Range of Rates (L/min)	Advantages	Disadvantages				
Nasal cannula	35%-40%	0.125–4	Easily applied, relatively comfortable	Uncomfortable at higher flow rates, requires open nasal airways, easily dislodged, lower % O ₂ delivered, nosebleeds				
Simple mask	50%-60%	5–10	Higher % $O_{2'}$ good for mouth breathers	Unsure of delivered % O ₂				
Face tent	40%-60%	8–10	Higher % O _{2'} good for mouth breathers, less restrictive	Unsure of delivered % O ₂				
Nonrebreathing mask	80%-90%	5–10	Highest O ₂ concentration, good for mouth breathers	Unsure of delivered % $\rm O_2$				
Oxyhood	90%-100%	5–10	Stable and accurate O ₂ concentration	Difficult to maintain temperature, hard to give airway care				

Table 14–3.	Supplemental	oxygen the	ару

CRITICAL CARE

providing some amount of airway positive pressure. HHFNC should be considered in patients who need more respiratory support than a simple low-flow nasal cannula, but if the patient is not improving on HHFNC after 60–90 minutes, additional escalation of care may be warranted. Although HHFNC provides some amount of positive pressure, the exact amount of positive pressure cannot be accurately determined from the flow rate. If a patient needs further escalation of care, the device used should be capable of more reliably delivering a fixed amount of positive pressure, such as CPAP or BiPAP.

Noninvasive ventilation (NIV) refers to the administration of mechanical ventilatory support without using an invasive artificial airway (endotracheal tube [ETT] or tracheostomy tube). The use of NIV has become an integral tool in the management of both acute and chronic respiratory failure. NIV can be used to avoid endotracheal intubation for milder cases of respiratory failure and as a bridge after extubation in mechanically ventilated patients with marginal lung function and respiratory mechanics. NIV devices provide positive pressure breathing through a variety of interfaces (mouthpiece or nasal, face, or helmet mask) and using a variety of ventilatory modes, including CPAP, BiPAP, volume ventilation, and pressure support. Ventilators dedicated to NIV exist, and many standard ventilators are capable of providing support through a mask with the appropriate adapters.

Continuous positive airway pressure (CPAP) refers to the constant application of airway pressure, usually in the range of 5-8 cm H₂O, and seeks to improve work of breathing, ventilation, and oxygenation by maintaining the functional residual capacity (FRC) of the lungs. Bilevel positive airway pressure (BiPAP) functions similarly but cycles between a higher inspiratory positive airway pressure (IPAP) and a lower expiratory positive airway pressure (EPAP). The additional inspiratory support in this mode improves tidal volume and ventilation in patients who are breathing shallowly and can improve oxygenation by providing a higher MAP. Typical initial settings would place the IPAP at 10–14 cm H₂O and the EPAP at 6–8 cm H₂O. The IPAP can then be titrated upward to achieve adequate tidal volumes, usually in the range of 5-7 mL/kg, and to reduce the patient's work of breathing and respiratory rate toward the normal range. EPAP and delivered oxygen concentration can be adjusted upward on the basis of pulse oximetry to achieve adequate oxygenation. Average volume-assured pressure support (AVAPS) is similar to BiPAP but a tidal volume, inspiratory pressure maximum, and inspiratory pressure minimum are set. Usually, a tidal volume of approximately 8 mL/kg is set with an IPAP max of 20-30 cm H₂O and IPAP min of EPAP + 4 cm H₂O. Serial blood gas measurements and pulse oximetry are essential to monitoring the response to therapy and to guide further ventilator adjustments.

Successful application of NIV requires careful patient selection. The best candidates are patients in the recovery phases of their illness or those with primarily hypercapnic respiratory failure, such as patients with muscular dystrophies or other forms of neuromuscular weakness. Patients suffering from coma, impaired respiratory drive, an inability to protect their airway, or cardiac or respiratory arrest are not candidates for NIV. Controversy still exists regarding the safety of NIV as an initial strategy in patients with acute hypoxemic respiratory failure, but in general NIV appears to be well tolerated in many children with this condition and it may decrease the risk for intubation. These patients should be closely monitored, however, as NIV may mask symptoms of underlying disease progression, making eventual intubation more precarious. In patients with severe respiratory failure or those who are not improving with NIV, endotracheal intubation should not be delayed.

For patients with respiratory failure not responding adequately to noninvasive support, endotracheal intubation and the initiation of mechanical ventilation can be life-saving. Safe placement of an ETT in infants and children requires experienced personnel and appropriate equipment at the bedside, including a correctly sized mask, Ambu bag, oral airways, ETTs, and Yankauer-type suction catheters. The patient should first be positioned properly to facilitate air exchange while supplemental oxygen is given. The sniffing position is used in infants. Head extension with jaw thrust is used in older children without neck injuries. If obstructed by secretions or vomitus, the airway must be cleared by suction. When not obstructed and properly positioned, the airway should be patent and easily visualized, allowing the placement of an oral or nasopharyngeal ETT of the correct size. Patients with normal airway anatomy may be intubated under intravenous (IV) anesthesia by experienced personnel (Table 14-4). Endotracheal intubation of patients with significant upper airway obstruction (eg, patients with croup, epiglottitis, foreign bodies, or subglottic stenosis) or mediastinal masses should be approached with extreme caution; minimal sedation should be used and paralytic agents should be strictly avoided unless trained airway specialists decide otherwise.

The size of the ETT is of critical importance in pediatrics. An inappropriately large ETT is a risk factor for pressure necrosis in the subglottic region, potentially leading to scarring and stenosis requiring surgical repair. An inappropriately small ETT can result in inadequate pulmonary toilet and excessive air leak around the ETT, making adequate ventilation and oxygenation difficult. Two useful methods for calculating the correct size of ETT for a child are (1) measuring the child's height with a Broselow tape and then reading the corresponding ETT size on the tape, or (2) in children older than 2 years, choosing a tube size using the formula ETT size = $(16 + \text{age in years}) \div 4$. Approximate proper insertion depth (in cm) as measured at the teeth can

CHAPTER 14

Drug	Class of Agent	Dose	Advantages	Disadvantages
Atropine	Anticholinergic	0.02 mg/kg IV, minimum of 0.1 mg	Prevents bradycardia, dries secretions	Tachycardia, fever; seizures and coma with high doses
Fentanyl	Opioid (sedative)	1–3 mcg/kg IV	Rapid onset, hemodynamic stability	Respiratory depression, chest wall rigidity with rapid administration in neonates
Midazolam	Benzodiazepine (sedative)	0.1–0.2 mg/kg IV	Rapid onset, amnestic	Respiratory depression, hypotension
Etomidate	Anesthetic	0.2–0.4 mg/kg IV	Rapid onset, hemodynamic stability, lowers ICP	Suppresses adrenal function, should not be used in sepsis
Ketamine	Dissociative anesthetic	1–2 mg/kg IV 2–4 mg/kg IM	Rapid onset, bronchodilator, hemodynamic stability	Increases oral and airway secretions, may increase ICP and pulmonary artery pressure
Rocuronium	Nondepolarizing muscle relaxant	1 mg/kg	Rapid onset, suitable for rapid sequence intubation, lasts 30 min	Requires refrigeration
Pancuronium	Nondepolarizing muscle relaxant	0.1 mg/kg	Long duration of action (40–60 min)	Tachycardia, slow onset (2–3 min)

Table 14-4.	Drugs common	/ used for controlled	d endotracheal	l intubation
-------------	--------------	-----------------------	----------------	--------------

ICP, intracranial pressure; IM, intramuscularly; IV, intravenously.

be estimated by tripling the size of the ETT. Either cuffed or uncuffed tubes are appropriate though a cuffed tube may provide more effective ventilation in patients with poor lung compliance. Correct placement of the ETT should be confirmed by auscultation for the presence of equal bilateral breath sounds and by the use of either a colorimetric filter or quantitative capnography to detect carbon dioxide. An assessment of air leakage around the ETT is an important measure of the appropriateness of ETT size. An audible leak noted at pressures of 15-20 cm H₂O indicates acceptable ETT size, though higher leak pressures are acceptable in patients who have poor lung compliance and as a result require higher airway pressures to effectively ventilate and oxygenate. A chest radiograph is necessary for final assessment of ETT placement. A correctly positioned ETT will terminate in the mid-trachea between the thoracic inlet and the carina, at approximately the level of the second thoracic vertebrae.

CONVENTIONAL MECHANICAL VENTILATION Indications

The principal indication for institution of mechanical ventilation is respiratory failure caused either by illness, injury, or treatment with sedating medications. The goals of mechanical ventilation are to facilitate the movement of gas into and out of the lungs (ventilation) and to improve oxygen uptake into the bloodstream (oxygenation). While lifesaving in many situations, positive pressure ventilation can also be harmful. As a result, mechanical ventilation strategies must be adapted to achieve these goals in a way that minimizes further injury to the lung. The overriding principles of this "lung-protective ventilation strategy" are to safely recruit underinflated lung, sustain lung volume, minimize phasic overdistention, and decrease lung inflammation. This strategy requires adjustment of ventilator settings with an understanding of the difference between the gas exchange that is permissible and that which is normal.

Modes of Mechanical Ventilation

The parameters used to control the delivery of mechanical ventilation breaths are known as the trigger, cycle, control, and limit variables. The trigger variable describes how breaths are initiated, either by the patient or by the ventilator. The most common triggers are patient effort, sensed as a drop in return pressure or gas flow to the ventilator, and time. A newer trigger method, neurally adjusted ventilatory assist (NAVA), measures the electrical activity of the diaphragm via an esophageal catheter in order to adjust the ventilator breaths to meet the patient's neural activity. While NAVA holds promise as a means to improving patient-ventilator synchrony and facilitating ventilator weaning, its ideal role in clinical practice remains to be determined. The cycle variable describes how the inspiratory phase is terminated, either by the patient or by the ventilator. Most ventilator modes cycle according to a set inspiratory time (I-time) although flow-cycled modes can be used in spontaneously breathing patients. The control variable determines whether the ventilator delivers a specific tidal volume (volume-controlled modes) or a specific pressure (pressure-controlled modes). *Limit variables* are parameters whose magnitude is constrained during inspiration in order to prevent excessive pressure or volume from being delivered by the ventilator.

Breathing during mechanical ventilation can be classified as spontaneous or mandatory. The patient controls the timing and size of spontaneous breaths. The ventilator controls the timing and/or size of mandatory breaths, independent of patient activity. In addition, the breathing pattern provided by the ventilator can be set to one of three configurations. In *continuous mandatory ventilation* (CMV), the ventilator determines the size and duration of all breaths. In *intermittent mandatory ventilation* (IMV), the ventilator delivers mandatory breaths, but additional spontaneous breaths between and during mandatory breaths are allowed. In *continuous spontaneous ventilation* (CSV), the patient initiates and controls all breaths, but the ventilator assists those efforts.

A ventilator mode consists of a specific control variable (pressure or volume), a specific pattern of breathing (CMV, IMV, or CSV), and a specific set of phase variables (trigger, limit, and cycle). Initiation of breaths and the length of exhalation are controlled by setting the respiratory rate. In time-cycled modes of ventilation, the inspiratory time (I-time) determines the length of inspiration and when to allow exhalation. Most modern ventilators can deliver either a pressure-targeted or a volume-targeted breath in several manners. In synchronized IMV (SIMV), the ventilator delivers breaths in an IMV pattern but the machine breaths are synchronized with the patient's efforts. If the patient does not make adequate respiratory efforts to trigger the ventilator, the machine delivers a mandatory breath at a preset time interval. In pressure-support ventilation, the patient's own efforts are assisted by the delivery of gas flow to achieve a targeted peak airway pressure. Pressure support ventilation allows the patient to determine the rate and pattern of breaths (CSV breathing pattern), thus improving patient comfort and decreasing the work of breathing. The most commonly used mode of ventilation in most PICUs is synchronized IMV with pressure support (SIMV + PS), a mixed mode allowing pressure-supported breaths between the synchronized machine breaths.

One of the long-standing controversies in critical care medicine surrounds the relative roles of volume vs pressure-controlled modes of ventilation. In *pressure-controlled ventilation*, air flow begins at the start of the inspiratory cycle and continues until a preset airway pressure is reached. That airway pressure is then maintained until the end of the set I-time, when the exhalation valve on the ventilator opens and gas exits into the machine. With this mode of ventilation, changes in the compliance of the respiratory system will lead to fluctuations in the actual tidal volume delivered to the patient. The advantage of pressure-targeted ventilation lies primarily in the avoidance of high airway pressures that might cause barotrauma or worsen lung injury. The main disadvantage of pressure-controlled ventilation is the possibility of delivering either inadequate or excessive tidal volumes during periods of changing lung compliance. In volume-controlled ventilation, the machine delivers a set tidal volume to the patient. Changes in lung compliance will lead to fluctuations in the peak airway pressure generated by the breath. The main advantage of volume ventilation is more reliable delivery of the desired tidal volume and thus better control of ventilation. More reliable tidal volume delivery may also help prevent atelectasis due to hypoventilation. Disadvantages of volume ventilation include the risk of barotrauma from excessive airway pressures and difficulties overcoming leaks in the ventilator circuit. In either pressureor volume-controlled modes, alarm limits can be set in order to restrict changes in either tidal volume or airway pressure with changing lung compliance; interpreting those alarms and adjusting the ventilator require the ICU clinician to understand the ventilator mode in use.

Finally, in any mode of ventilation, the minimum distending pressure applied to the lung during the respiratory cycle is determined by setting the *positive end-expiratory pressure* (PEEP). PEEP helps prevent the end-expiratory collapse of open lung units, thus preventing atelectasis and shunting. In disease states such as pulmonary edema, pneumonia, or ARDS, a higher PEEP (10–15 cm H_2O) may increase the patient's FRC, helping to keep open previously collapsed alveoli and improve oxygenation. High levels of PEEP may also cause complications such as gas trapping and CO_2 retention, barotrauma with resultant air leaks, and decreased central venous return leading to declines in cardiac output or increases in intracranial pressure (ICP).

Setting & Adjusting the Ventilator

When initiating volume-controlled modes of ventilation, the ICU clinician sets a tidal volume, I-time, rate, and level of PEEP. A typical initial tidal volume is 8 mL/kg, as long as that volume does not cause excessive airway pressures $(> 30 \text{ cm H}_2\text{O})$. The I-time is typically set at 1 second or 33% of the respiratory cycle, whichever is shorter. Rate can be adjusted to patient comfort and blood gas measurements, but generally patients starting on mechanical ventilation require full support at least initially with a rate of 20-30 breaths/min. Pressure-controlled ventilation is set in a similar fashion, although the adequacy of the inspiratory pressure is assessed by observing the patient's chest rise and by measuring the delivered tidal volume. Typically, patients without lung disease require peak inspiratory pressures of 15-20 cm H₂O, while patients with respiratory illnesses may require 20-30 cm H₂O pressure to provide adequate ventilation. In general, PEEP should be set at 5 cm H₂O initially and titrated up to maintain adequate oxygenation at acceptable inspired oxygen concentrations (< 60%–65%) while watching carefully for adverse effects on systemic hemodynamics.

Ventilated patients require careful monitoring for the efficacy of gas exchange, including respiratory rate and activity, chest wall movement, and quality of breath sounds. Oxygenation should be measured by ABGs and by continuous pulse oximetry. Ventilation should be assessed by blood gas analysis or by noninvasive means, such as ETCO, monitoring. $ETCO_2$ monitoring is more valuable for patients with large tidal volumes, lower respiratory rates, and without significant leaks around the ETT. In practice, ETCO₂ values may differ significantly (usually lower) from measured PaCO₂ values and thus are most useful for following trends in ventilation, for early recognition of occluded or malpositioned ETTs, and for assessing the adequacy of chest compressions during CPR. Frequent, preferably continuous, systemic blood pressure monitoring is also necessary for patients ventilated with high PEEP levels, given the risk of adverse hemodynamic effects.

Ventilator settings can be adjusted to optimize both ventilation (PaCO₂) and oxygenation (PaO₂). Ventilation is most closely associated with the delivered minute volume, or the tidal volume multiplied by the respiratory rate. As a result, abnormal PaCO₂ values can be most effectively addressed by changes in the respiratory rate or the tidal volume. Increased respiratory rate or tidal volume should increase minute volume and thus decrease PaCO₂ levels; decreases in respiratory rate or tidal volume should act in the opposite fashion. In some circumstances, additional adjustments may also be necessary. For example, for patients with disease characterized by extensive alveolar collapse, increasing PEEP may improve ventilation by helping to keep open previously collapsed lung units. Also, for patients with disease characterized by significant airway obstruction, decreases in respiratory rate may allow more time for exhalation and improve ventilation despite an apparent decrease in the minute volume provided.

The variables most closely associated with oxygenation are the inspired oxygen concentration and the mean airway pressure (MAP) during the respiratory cycle. Increases in inspired oxygen concentration will generally increase arterial oxygenation, unless right-to-left intracardiac or intrapulmonary shunting is a significant component of the patient's illness. Concentrations of inspired oxygen above 60%-65%, however, may lead to hyperoxic lung injury. For patients requiring those levels of oxygen or higher to maintain adequate arterial saturations, increases in MAP should be considered as a means to recruit underinflated lung units. MAP is affected by PEEP, peak inspiratory pressure, and I-time. Increases in any one of those factors will increase MAP and should improve arterial oxygenation. Importantly, increases in MAP may also lead to decreases in cardiac output, primarily by decreasing venous return to the heart. In this circumstance, raising MAP may increase arterial oxygenation, but actually compromise oxygen delivery to the tissues. For patients with severe hypoxemic respiratory failure, these tradeoffs highlight the need for careful monitoring by experienced personnel.

Supportive Care of the Mechanically Ventilated Patient

Patients undergoing mechanical ventilation require meticulous supportive care. Mechanical ventilation is often frightening and uncomfortable for critically ill children. In order to reduce dyssynchrony with the ventilator and impaired gas exchange, careful attention must be directed toward optimizing patient comfort and decreasing anxiety. Sedative anxiolytics are typically provided as intermittent doses or continuous infusions. Since oversedation of the ventilated patient may lead to longer durations of ventilation and difficulty weaning from the ventilator, standardized assessments of sedation level and targeting treatment to the minimum sedation level necessary to maintain patient comfort and adequate gas exchange are important.

For patients with severe respiratory illness, even small physical movements can compromise gas exchange. In such cases, muscle paralysis may facilitate oxygenation and ventilation. Nondepolarizing neuromuscular blocking agents are most commonly used for this purpose, given as intermittent doses or as continuous infusions. When muscle relaxants are given, extra care must be taken to ensure that levels of sedation are adequate, as paralytics will mask many of the usual signs of patient discomfort. In addition, ventilator support may need to be increased to compensate for the elimination of patient respiratory effort.

Mechanically ventilated patients can usually be fed enterally with the use of nasogastric or nasojejunal feeding tubes. In patients where reflux or emesis is a major concern, transpyloric feeding or parenteral nutrition should be considered. Ventilator-associated pneumonia (VAP) is a significant complication of mechanical ventilation, leading to longer ICU stays and increased hospital costs. As a result, many local and national quality improvement initiatives have focused on minimizing the risks of VAP. These preventative measures include proper hand washing, elevation of the head of the bed to 30 degrees to prevent reflux, frequent turning of the patient, proper oral care, the use of closed suction circuits on all ventilated patients and avoidance of breaking the closed suction system, sedation protocols to minimize sedation administration, and daily assessment of extubation readiness.

Mechanical ventilation should be weaned and discontinued as soon as safely possible. Extubation failure rates in mechanically ventilated children have been estimated between 4% and 20%. Considerable effort has been devoted to identifying predictors of extubation readiness and success. Unfortunately, the available literature does not clearly support any specific weaning protocol or extubation readiness test. Successful extubation requires adequate gas exchange, adequate respiratory muscle strength, and the ability to protect the airway. Most intensivists as a test of extubation readiness will perform a trial of spontaneous breathing in which the patient, while remaining intubated, breathes either without assistance (through a T-piece) or with a low level of pressure support (through the ventilator) for a defined period of time, usually 1–2 hours. The patient is observed carefully for signs of rapid shallow breathing or worsened gas exchange during this trial, and if neither is observed, the patient can generally be safely extubated.

Troubleshooting

Troubleshooting a sudden deterioration in the mechanically ventilated patient should begin with determining whether the ETT is still in place using direct laryngoscopy and/ or ETCO₂ measurements. Determine whether the ETT is patent and in the correct position by attempting to pass a suction catheter and by obtaining a chest x-ray if necessary. If the ETT is patent and correctly positioned, the next step is to determine whether any changes in the physical examination-such as poor or unequal chest rise, or absent or unequal breath sounds-suggest atelectasis, bronchospasm, pneumothorax, or pneumonia. Next, determine whether hemodynamic deterioration could be underlying acute respiratory compromise (shock or sepsis). If the problem cannot be readily identified, take the patient off the ventilator and begin manual ventilation by hand-bagging while the ventilator is checked for malfunction. Hand-bagging the patient can also determine the root of the problem if it lies within the patient and can help determine the next ventilator adjustments.

OTHER MODES OF RESPIRATORY SUPPORT

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation (HFOV) is an alternative mode of mechanical ventilation in which the ventilator provides very small, very rapid tidal volumes at high rates. Respiratory rates used during oscillatory ventilation typically range from 5 to 10 Hz (rates of 300-600 breaths/min) in most PICU patients. This mode of ventilation has been used successfully in neonates, older pediatric patients, and adults, although recent work has suggested that HFOV use may be associated with worse outcomes in adults with ARDS. HFOV is most widely used in severe, diffuse lung diseases, such as ARDS, which require high MAP to maintain lung expansion and oxygenation. Diseases characterized by significant heterogeneity or extensive gas trapping often respond too poorly to HFOV, although reports do exist of successful HFOV use in asthma. The advantage of HFOV is that high levels of MAP can be achieved without high peak inspiratory pressures or large tidal volumes, thus theoretically protecting the lung from ventilator-induced lung injury. Disadvantages of HFOV include general poor tolerance by patients who are not heavily sedated or paralyzed, the risk of cardiovascular compromise due to high MAP, and the risk of gas-trapping and barotrauma in patients with highly heterogeneous lung disease. Although HFOV clearly can be useful as a rescue mode for selected patients, it remains unclear whether HFOV provides any benefit compared with carefully managed conventional modes of ventilation.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) has been used as a rescue therapy to support pediatric patients with severe respiratory failure who have not improved with less invasive therapies. ECMO circuits generally consist of a membrane oxygenator, a heater, and a pump. Central venous blood from the patient is directed out of the body, oxygenated, warmed and returned back to the patient. ECMO can be provided in two major modes: venoarterial (VA) and venovenous (VV). VA ECMO bypasses the lungs and the heart, thus supporting both the cardiovascular and respiratory systems, and requires cannulation of a large central artery and vein. VV ECMO utilizes central venous cannulation to provide extracorporeal oxygenation and carbon dioxide removal, thus augmenting the function of the patient's lungs, but the patient's own cardiac output is required to provide systemic oxygen delivery. VV ECMO use has increased over the past 15 years and provides the advantage of a reduced risk of systemic and, particularly, cerebral emboli. Patients with moderate hemodynamic compromise prior to ECMO initiation can also experience improvements in circulatory status on VV ECMO, likely due to the improvements in acid base status, oxygenation, and decreased intrathoracic pressures that can be achieved with ECMO. ECMO is indicated for patients with reversible cardiovascular and/or respiratory failure and is not recommended in patients with severe neurologic compromise or who is in the terminal stages of a lethal condition. Despite an increase in the complexity of patients placed on ECMO, survival has remained acceptable over the past two decades. According to recent registry data, 57% of pediatric respiratory failure patients who are supported with ECMO survive, and survival rates are even better for ECMO patients with a diagnosis of viral pneumonia (especially due to respiratory syncytial virus) and without significant co-morbidities. Of note, in both neonatal and adult randomized controlled trials, patients with severe respiratory failure who were referred to an ECMO center for consideration of ECMO had improved survival, even though not all patients were actually placed on ECMO. These results emphasize the importance of early referral to experienced centers if ECMO is to be considered.

Determining the optimal time to consider ECMO initiation is one of the most challenging aspects of using this technology. Survival appears equally good for most indications with mechanical ventilation for up to 14 days prior to ECMO initiation. Patients placed on ECMO later in the course of their illness or with prolonged ECMO runs (> 14 days) may have worse outcomes. Protocols to improve secretion clearance and lung recruitment have been described and should be considered to hasten lung recovery and shorten ECMO runs.

While ECMO remains a viable therapy for selected patients with severe respiratory failure, serious complications such as CNS injury, hemorrhage, renal insufficiency, infection, and complications of immobility do occur, and each patient should be carefully evaluated by experienced personnel in order to choose the optimal timing and mode of ECMO support.

MAJOR RESPIRATORY DISEASES IN THE PEDIATRIC ICU

ACUTE RESPIRATORY DISTRESS SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute respiratory distress syndrome (ARDS) is a severe form of lung injury characterized by hypoxemia, bilateral pulmonary infiltrates, and no clinical evidence of left atrial hypertension.
- ARDS can arise as a consequence of either direct pulmonary injury or systemic conditions that are nonpulmonary in origin, such as sepsis.
- Lung protective mechanical ventilation and careful fluid management are crucial to good outcomes in ARDS patients.

Acute respiratory distress syndrome (ARDS) is a syndrome of acute respiratory failure characterized by increased pulmonary capillary permeability resulting in bilateral diffuse alveolar infiltrates on chest radiography, decreased lung compliance, and hypoxemia that is refractory to supplemental oxygen alone. Mortality rates for pediatric ARDS have fluctuated over time, depending on the criteria used to diagnose the disease, the presence of important coexisting conditions, and the quality and consistency of supportive care provided in the ICU. Mortality rates as high as 60%–75% were reported in the 1980s and early 1990s. Since that time there has been a trend toward decreased mortality in pediatric ARDS, ranging from 8% to 40%, though mortality among immunocompromised patients still approaches 60%. Across all subpopulations of pediatric ARDS patients, nonpulmonary organ failure remains an important cause of mortality.

Current consensus diagnostic criteria for ARDS in adult patients include (1) acute onset; (2) bilateral pulmonary infiltrates on chest radiograph; (3) no clinical evidence of left atrial hypertension; and (4) severe hypoxemia in which the ratio of the arterial oxygen level (PaO₂) to inspired oxygen concentration (FIO₂) is \leq 300 while receiving a PEEP of at least 5 cm H₂O via mechanical ventilation. When the PaO₂:FIO₂ ratio is between 200 and 300, the case is defined as mild ARDS, between 100 and 200 is moderate ARDS, and under 100 is severe ARDS. Recently proposed pediatric criteria for diagnosing ARDS are similar, although the requirement for bilateral infiltrates has been dropped and oxygenation criteria broadened to include measures based on pulse oximetry saturations.

Presentation & Pathophysiology

ARDS may be precipitated by a variety of insults (Table 14–5). Pneumonia and sepsis account for the majority of ARDS cases in children. Despite the diversity of potential causes, the clinical presentation is remarkably similar in most cases. ARDS can be divided roughly into four clinical phases (Table 14–6). In the earliest phase, the patient may have dyspnea and tachypnea with a relatively normal PaO₂ and hyperventilation-induced respiratory alkalosis. No significant abnormalities are noted on physical or radiologic examination of the chest. Experimental studies suggest that neutrophils accumulate in the lungs at this stage and that their products damage lung endothelium.

Over the next few hours, hypoxemia worsens and respiratory distress becomes clinically apparent, with cyanosis, tachycardia, irritability, and dyspnea. Early radiographic changes include the appearance of increasingly confluent alveolar infiltrates initially appearing in dependent lung fields, in a pattern suggestive of pulmonary edema. Proteinaceous exudates into the alveolar space and direct injury to type II alveolar pneumocytes cause surfactant inactivation and deficiency. As a result, the injured lung requires high inflation pressures to achieve lung opening, and increased PEEP to maintain end-expiratory volume.

Direct Lung Injury	Indirect Lung Injury
Pneumonia	Sepsis
Aspiration of gastric	Shock
contents	Burns
Inhalation injury (heat	Trauma
or toxin)	Fat embolism
Pulmonary contusion	Drug overdoses (including aspirin, opioids,
Hydrocarbon ingestion	barbiturates, tricyclic antidepressants)
or aspiration	Transfusion of blood products
Near-drowning	Pancreatitis

Injury to the alveolar type II cell also reduces the capacity for alveolar fluid clearance. Under normal conditions, sodium is taken up from the alveolar space by channels on the apical surface of type II cells and then actively transported across the basolateral cell membrane into the interstitial space. This process creates a gradient for the passive movement of water across the alveolar epithelium and back into the interstitium. In ARDS, this mechanism becomes overwhelmed as direct lung injury depopulates the alveolar epithelium, creating conditions that favor alveolar fluid accumulation. Pulmonary hypertension, reduced lung compliance, and increased airways resistance are also commonly observed in ARDS.

Computed tomography (CT) studies of adult patients in the acute phases of ARDS demonstrate a heterogeneous pattern of lung involvement. The most dependent lung regions remain consolidated throughout the respiratory cycle and can only be recruited using exceedingly high inflation pressures. The most nondependent regions are overinflated throughout the respiratory cycle. Between these two zones lies a region that is either normally inflated or repetitively cycles between inflation and collapse. Attempts to improve oxygenation by recruiting the collapsed dependent lung regions occur at the expense of damaging nondependent regions by hyperinflation. This process, termed volutrauma, incites a potent inflammatory response that is capable of worsening non-pulmonary organ dysfunction. Even in normal lungs, ventilation with large tidal volumes and low PEEP levels can produce a lung injury that is indistinguishable from ARDS. This phenomenon is called ventilatorinduced lung injury. Taken together, these findings suggest that mechanical injury from positive pressure ventilation is superimposed on the initial insult and is an integral part of the pathogenesis of ARDS. Appreciation of this phenomenon has prompted a shift toward ventilating ARDS patients with smaller tidal volumes and a tolerance for the relative

Table 14–6. Pathophysiologic changes of acute respiratory distress syndrome.						
Radiography	Symptoms	Laboratory Findings	Pathophysiology			
Phase 1 (early changes)						
Normal radiograph	Dyspnea, tachypnea, normal chest examination	Mild pulmonary hypertension, normoxemic or mild hypoxemia, hypercapnia	Neutrophil sequestration, no clear tissue damage			
Phase 2 (onset of parenchymal changes)					
Patchy alveolar infiltrates; normal heart size	Dyspnea, tachypnea, cyanosis, tachycardia, coarse rales	Moderate to severe hypoxemia, increasing shunt, decreased lung compliance, pulmonary hypertension, normal wedge pressure	Neutrophil infiltration, vascular congestion, increased lung permeability, pulmonary edema, fibrin strands, platelet clumps, type I epithelial cell damage			
Phase 3 (acute respiratory failure with p	progression, 2–10 days)					
Diffuse alveolar infiltrates; air bronchograms; decreased lung volume; normal heart size	Tachypnea, tachycardia, sepsis syndrome, signs of consolidation, diffuse rhonchi	Worsening shunt fraction, further decrease in compliance, increased minute ventilation, impaired oxygen extraction	Increased interstitial and alveolar inflammatory exudate with neutrophils and mononuclear cells, type II cell proliferation, beginning fibroblast proliferation, thromboembolic occlusion			
Phase 4 (pulmonary fibrosis, pneumonia	a with progression, > 10 da	ys)				
Persistent diffuse infiltrates; superimposed new pneumonic infiltrates; air leak; normal heart size or enlargement due to cor pulmonale	Symptoms as above, recurrent sepsis, evidence of multiorgan system failure	Phase 3 changes persist; recurrent pneumonia, progressive lung restriction, impaired tissue oxygenation, impaired oxygen extraction; multiorgan system failure	Type II cell hyperplasia, interstitial thickening; infiltration of lymphocytes, macrophages, fibroblasts; loculated pneumonia or interstitial fibrosis; medial thickening and remodeling of arterioles			

Table 14–5. ARDS risk factors.

hypercarbia that typically ensues. Published evidence currently supports using PEEP levels sufficient to stabilize those alveoli with tendency to collapse at end-expiration but below a threshold level that would overdistend nondependent lung regions at end-inspiration. Volutrauma is then mitigated by tidal volume reduction or peak pressure limitation. This approach is termed the "open-lung strategy" of mechanical ventilation.

The subacute phase of ARDS (2-10 days after lung injury) is characterized by type II pneumocyte and fibroblast proliferation in the interstitium of the lung. This results in decreased lung volumes and signs of consolidation that are noted clinically and radiographically. Worsening of the hypoxemia with an increasing shunt fraction occurs, as well as a further decrease in lung compliance. Some patients develop an accelerated fibrosing alveolitis. The mechanisms responsible for these changes are unclear. Current investigation centers on the role of growth and differentiation factors, such as transforming growth factor- β and platelet-derived growth factor released by resident and nonresident lung cells, such as alveolar macrophages, mast cells, neutrophils, alveolar type II cells, and fibroblasts. During the chronic phase of ARDS (10-14 days after lung injury), fibrosis, emphysema, and pulmonary vascular obliteration occur. During this phase of the illness, oxygenation defects generally improve, and the lung becomes more fragile and susceptible to barotrauma. Air leak is common among patients ventilated with high airway pressures at this late stage. Also, patients have increased dead space and difficulties with ventilation are common. Airway compliance remains low because of ongoing pulmonary fibrosis and insufficient surfactant production.

Secondary infections are common in the subacute and chronic phases of ARDS and can impact clinical outcomes. The mechanisms responsible for increased host susceptibility to infection during this phase are not well understood. Mortality in the late phase of ARDS can exceed 80%. Death is usually caused by multiorgan failure and systemic hemodynamic instability rather than by hypoxemia.

Treatment

Contemporary *ventilator management* of ARDS is directed at protecting vulnerable lung regions from cyclic alveolar collapse at end expiration and protecting overinflated lung regions from hyperinflation at end inspiration. The actual mode of ventilation (eg, volume limited vs pressure limited) employed for ARDS is ultimately not as important as limiting phasic alveolar stretch and stabilizing lung units that are prone to repetitive end expiratory collapse. A landmark multicenter trial established that adult ARDS patients who were ventilated using a 6-mL/kg (ideal body weight) tidal volume had a 22% mortality reduction and fewer extrapulmonary organ failures relative to those randomized to receive tidal volumes of 12 mL/kg. Although this trial has never been replicated in pediatric patients, application of these same management principles has gained widespread acceptance among pediatric ICU clinicians.

Given the large body of evidence supporting the benefits of low tidal volume ventilation, we suggest that mechanical ventilation of pediatric ARDS patients be initiated using a tidal volume of 6-8 mL/kg (ideal body weight), combined with PEEP sufficient to produce target arterial saturations (\geq 88%–90%) using an FIO₂ of 0.6 or less. In general, this can be accomplished by incremental increases in PEEP until adequate oxygenation is achieved or until a limiting side effect of the PEEP is reached. Whenever escalating mechanical ventilator settings, clinicians should minimize the ETT cuff leak (if possible), ensure an appropriate plane of patient sedation, and optimize the ventilation to perfusion relationship by verifying that the patient's intravascular volume status is appropriate. Permissive hypercapnia should be used unless a clear contraindication exists (eg, increased ICP). Throughout the course, efforts should be made to limit the alveolar plateau pressure (pressure at end-inspiration) to 25-30 cm H₂O or less.

Fluid management is an important element of the care of patients with ARDS. Given the increased pulmonary capillary permeability in ARDS, further pulmonary edema accumulation is likely with any elevation in pulmonary hydrostatic pressures. Evidence in adults has shown that a "conservative" fluid strategy targeting lower cardiac filling pressures (CVP < 4 mm Hg) is associated with better oxygenation and a shorter duration of mechanical ventilation compared to a "liberal" fluid strategy targeting CVP 10–14 mm Hg. Fluid restriction should only be implemented after hemodynamic variables stabilize and volume resuscitation should not be denied to hemodynamically unstable patients with ARDS.

Hemodynamic support is directed toward increasing perfusion and oxygen delivery. Patients should be given adequate intravascular volume resuscitation using either crystalloid or colloid solutions to restore adequate circulating volume, and inotropes or vasopressors should be titrated to achieve adequate end-organ perfusion and oxygen delivery. While blood transfusions are excellent volume expanders and should theoretically increase oxygen-carrying capacity, transfusion incurs the risks of volume overload and transfusion-related lung injury. There is no evidence to support transfusion above a normal hemoglobin level in ARDS patients.

Patients with ARDS require careful *monitoring*. Given the risks of ventilator-induced lung injury and the inherent limitations of pulse oximetry and capnography, ABG analysis is preferred for accurate assessment of oxygenation and ventilation and careful titration of mechanical ventilation. Indwelling arterial catheters are useful for continuous blood pressure monitoring and frequent laboratory sampling.

CRITICAL CARE

Many clinicians advocate the use of CVP measurements to help determine the level of cardiac preload, although it is important to emphasize that the CVP value must be interpreted in the context of intrathoracic pressure and myocardial compliance. Since secondary infections are common and contribute to increased mortality rates, surveillance for infection is important by obtaining appropriate cultures and following the temperature curve and white blood cell count. Renal, hepatic, and GI function should be watched closely because of the prognostic implications of multiorgan dysfunction in ARDS.

For patients failing these standard approaches of mechanical ventilation and fluid restriction, several alternative or rescue therapies are available. HFOV has been used successfully for many years in pediatric patients with ARDS. No studies to date have compared HFOV to a modern lung protective conventional ventilation strategy, and whether HFOV provides any advantage over conventional ventilation for pediatric ARDS remains unknown. Whether HFOV is best used as a first-line ventilator strategy or as a rescue therapy for patients failing conventional ventilation remains a matter of institutional and clinician preference. Prone *positioning* is a technique of changing the patient's position in bed from supine to prone, with the goal of improving ventilation of collapsed dependent lung units via postural drainage and improved V/Q matching. This technique can dramatically improve gas exchange in the short term, particularly for patients early in the course of ARDS, but the gains are often not sustained. Clinical trials examining the role of prone positioning in adults have shown a survival benefit in those with severe disease, but no study in children with ARDS has shown a clear improvement in mortality or in duration of mechanical ventilation. Based on the ability of inhaled nitric oxide (iNO) to reduce pulmonary artery pressure and to improve the matching of ventilation with perfusion without producing systemic vasodilation, iNO can be used as a therapy for refractory ARDS. Several multicenter trials of iNO in the treatment of ARDS, both in adults and in children, showed acute improvements in oxygenation in subsets of patients, but no significant improvement in overall survival. As a result, iNO cannot be recommended as a standard therapy for ARDS. Finally, ECMO has been used to support pediatric patients with severe ARDS. Recent registry data suggest the overall survival rate for children who require ECMO for ARDS is around 50%-60%. To date, the efficacy of ECMO has not been evaluated against lung protective ventilation strategies for pediatric ARDS in a prospective randomized trial. In addition, recent improvements in outcome for pediatric ARDS patients receiving "conventional" therapies have made the role of ECMO less clear and have made further prospective randomized studies of ECMO difficult to complete. For now, ECMO remains a viable rescue therapy for patients with severe ARDS that is unresponsive to other modalities.

Outcomes

Information regarding the long-term outcome of pediatric patients with ARDS remains limited. One report of 10 children followed 1–4 years after severe ARDS showed that three children were still symptomatic and seven had hypoxemia at rest. Until further information is available, all patients with a history of ARDS need close follow-up of pulmonary function.

STATUS ASTHMATICUS

- Status asthmaticus is reversible small airway obstruction refractory to sympathomimetic and anti-inflammatory agents that may progress to respiratory failure without prompt and aggressive intervention.
- Dyspnea at rest that interferes with the ability to speak can be an ominous sign.
- Absence of wheezing may be misleading because, to produce a wheezing sound, the patient must take in sufficient air.
- Patients with severe respiratory distress, signs of exhaustion, alterations in consciousness, elevated PaCO₂, or acidosis should be admitted to the PICU.

Pathogenesis

Life-threatening asthma exacerbations are caused by severe bronchospasm, excessive mucus secretion, inflammation, and edema of the airways (see Chapter 36). Infants and children are at particular risk for respiratory failure from asthma due to several structural and mechanical features of their lungs. They have less elastic recoil than the adult lung, thicker airway walls leading to greater peripheral airway resistance for any degree of bronchoconstriction, increased airway reactivity to bronchoconstrictors, fewer collateral channels of ventilation, and a more compliant chest wall which can lead to increased work of breathing with airway obstruction. Additional risk factors for severe asthma exacerbation include obesity, lower socioeconomic status, non-Caucasian race, and a prior history of previous ICU admissions or intubations.

Clinical Findings

Patients admitted to the PICU with severe asthma exacerbations can have a variety of constitutional and cardiorespiratory findings. They often have tachypnea, increased use of accessory muscles, and variable aeration. Diffuse wheezing is usually present, but absence of wheeze may indicate severe obstruction impeding airflow. Dyspnea at rest that interferes with the ability to speak and cyanosis are also ominous signs of severe airflow obstruction. These children may also display signs of panic or exhaustion and an altered level of consciousness. Agitation, drowsiness, or confusion can be signs of elevated $PaCO_2$ levels and impending respiratory failure. Likewise, gasping respirations or frank apnea are indications of respiratory failure and need for intubation.

These patients generally have elevated heart rates (HRs) secondary to stress, dehydration, and β -agonist therapy, and may have systolic and/or diastolic hypotension. Diastolic pressures less than 40 mm Hg in conjunction with extreme tachycardia may impair coronary artery filling and predispose to cardiac ischemia, which can present with chest pain and ST changes on electrocardiogram. Pulsus paradoxus (ie, an exaggerated decrease in systolic blood pressure with inspiration) may be observed and can be used as a marker of disease severity and response to treatment.

Laboratory Findings

In addition to pulse oximetry, blood gas measurements should be performed in critically ill patients with status asthmaticus to evaluate gas exchange and acid-base balance. Although venous blood gas measurements may be acceptable for screening, ABG measurements provide the most accurate and complete information. Patients with severe asthma exacerbations typically have increased minute ventilation and should be expected to have a PaCO₂ less than 40 mm Hg. Normal to elevated PaCO₂ levels suggest respiratory failure. Desaturation or reduced PaO₂ on room air may indicate severely impaired gas exchange and impending respiratory failure but also may occur with initiation of β -agonist therapy and associated ventilation/perfusion mismatching. The presence of metabolic acidosis may signify relative dehydration, inadequate cardiac output, or underlying infection.

Other laboratory evaluations may include serum electrolytes, complete blood counts, and other inflammatory markers if clinically indicated. Patients may demonstrate decreased serum potassium, magnesium, and/or phosphate, especially with prolonged β -agonist use. Leukocytosis is commonly observed during asthma exacerbations and may be due to infection or to demargination of polymorphonuclear leukocytes as a result of stress or corticosteroid treatment. Differentiating between these two etiologies of leukocytosis can be difficult, and measurement of other inflammatory markers can be useful if there is concern for infection.

Chest x-rays should be obtained in patients presenting with severe asthma exacerbations to evaluate for treatable conditions such as pneumonia, foreign-body aspiration, air leak, or a chest mass. Pneumothorax and pneumomediastinum are common complications of severe exacerbations and may only be revealed with chest radiography. Severe wheezing without a prior history of asthma should raise suspicion for alternative diagnoses. Electrocardiograms are not routinely recommended but may be indicated to rule out cardiac ischemia, especially in patients with known cardiac disease, extreme tachycardia and low diastolic blood pressure, or complaints of chest pain.

Although measurements of pulmonary function such as forced expiratory volume in 1 second (FEV₁) or peak expiratory flow (PEF) are recommended in other clinical settings, their use in patients admitted to the PICU with severe asthma exacerbations is limited as those patients are often unable to cooperate with testing. When obtained, values of less than 40% of predicted indicate a severe exacerbation and values less than 25% of predicted indicate imminent respiratory arrest.

Treatment

The key treatment strategy for status asthmaticus is to reverse the underlying process swiftly and aggressively before respiratory failure that requires endotracheal intubation and mechanical ventilation ensues. This approach is particularly important as much of the morbidity associated with the treatment of severe asthma is related to the complications of providing mechanical ventilation in patients with severe airflow obstruction. Children with status asthmaticus require IV access, continuous pulse oximetry, and cardiorespiratory monitoring, as close monitoring of gas exchange, cardiovascular status, and mental status are crucial to assessing response to therapy and determining appropriate interventions.

Because of inadequate minute ventilation and V/Q mismatching, patients with severe asthma are almost always hypoxemic and should receive supplemental humidified oxygen immediately to maintain saturations more than 90%. The delivery method will depend upon the child's age, level of oxygen required, and institutional resources, as described earlier in this chapter. Children with clinical signs of dehydration should receive appropriate fluid resuscitation, while avoiding volume overload. Additionally, the hemodynamic effects of certain asthma therapy (peripheral dilation, diastolic hypotension) may also require further fluid resuscitation to maintain cardiac output and avoid metabolic acidosis. Antibiotics are generally not recommended for treatment of status asthmaticus unless a coexisting infection is identified or suspected.

The first-line treatment for rapidly reversing airflow obstruction is the repetitive or continuous administration of inhaled selective short-acting β_2 -*agonist* therapy such as albuterol. The frequency of administration will vary based on the severity of symptoms and the occurrence of adverse side effects. Nebulized albuterol may be given intermittently at a dose of 2.5–5 mg every 10–15 minutes, or it can be administered continuously at a dose of 10 mg/h to a maximum of 20–30 mg/h, usually without serious side effects.

Patients with severe distress and poor inspiratory flow rates may have inadequate delivery of inhaled medications and may require subcutaneous or IV medication. Subcutaneous epinephrine or terbutaline, a relatively specific β_2 -agonist, may be used for initial treatment with an acute exacerbation. Continuous IV therapy with *terbutaline* may also be used with an infusion of 0.5–5 mcg/kg/min after a loading dose of 10 mcg/kg. Because significant tachycardia and other arrhythmias as well as diastolic hypotension are recognized side effects of inhaled and IV β_2 -agonist therapy, these children should have close cardiovascular monitoring. An indwelling arterial catheter may be useful for continuous hemodynamic and blood gas monitoring in the most severely ill patients on IV therapy.

In addition to β_2 -agonist therapy, immediate administration of systemic *corticosteroids* is critical to the early management of life-threatening status asthmaticus. Because enteral medications may not be tolerated in patients with severe exacerbations, administration of IV or IM steroids should be considered early in these children. Both methylprednisolone and dexamethasone have been used in the treatment of status asthmaticus.

For severe exacerbations unresponsive to the initial treatments listed previously, additional treatments may be considered despite limited clinical pediatric evidence. Ipratropium bromide, an inhaled anticholinergic bronchodilator, is commonly used in emergency medicine and is a reasonable intervention in the PICU, despite limited evidence of efficacy. Administration of magnesium sulfate may also be considered for patients who are unresponsive to early treatment or who have impending respiratory failure. The bronchodilatory properties of magnesium sulfate are thought to be caused by interference with calcium flux in the bronchial smooth muscle cell. Hypotension and flushing may occur with administration and should be anticipated with adequate fluid resuscitation. Helioxdriven albuterol nebulization can also be considered for patients refractory to conventional therapy. Heliox is a mixture of helium and oxygen that has a lower viscosity than ambient air and can improve airway delivery of albuterol and gas exchange. However, a mixture of at least 60%-70% helium is required to be effective, thus limiting its use in patients with severe hypoxia.

Methylxanthines, such as theophylline and aminophylline, may also be considered for the management of severe asthma, although their use remains controversial. The theoretical benefit of methylxanthines is relaxation of airway smooth muscle by preventing degradation of cyclic guanosine monophosphate, a mechanism of action distinct from that of β_2 -agonists. In addition, mucociliary inflammatory mediators and microvascular permeability are reduced. Unfortunately, the pharmacokinetics of these agents are erratic, and the narrow therapeutic window can be difficult to manage, with serious side effects such as seizures and cardiac arrhythmias occurring with higher drug levels. These concerns, in addition to mixed evidence of benefit, have led to a general recommendation against the routine use of methylxanthines for asthma exacerbations. However, they may still have a role in individual cases of severe refractory asthma as a means to prevent intubation. When a methylxanthine is added to a patient's care, close therapeutic drug monitoring is essential and consultation with a pharmacist recommended.

NIV may be used to support patients with severe asthma exacerbations and help avoid the need for intubation and mechanical ventilation. Positive-pressure ventilation may help avoid airway collapse during exhalation as well as to unload fatigued respiratory muscles by reducing the force required to initiate each breath. Because of its noninvasive interface, spontaneous breathing and upper airway function are preserved, allowing the patient to provide his/her own airway clearance. Data on the effectiveness of NIV for acute severe asthma in children are limited, but some small studies and case series have shown improvements in gas exchange and respiratory pressures is essential, however, to avoid complications of positive pressure.

If aggressive management fails to result in significant improvement, endotracheal intubation and *mechanical ventilation* may be necessary. Patients who present with apnea or coma should be intubated immediately. If there is steady deterioration despite intensive therapy for asthma, intubation should occur before acute respiratory arrest. The intubation procedure can be dangerous for these patients, given the high risk of barotrauma and cardiovascular collapse, and should be performed by the most experienced provider available.

Mechanical ventilation for patients with asthma is difficult because the severe airflow obstruction often leads to very high airway pressures, air trapping, and resultant barotrauma. Therefore, the goal of mechanical ventilation in this setting is to maintain adequate oxygenation and ventilation with the least amount of barotrauma until other therapies become effective. This approach typically means accepting some degree of hypercarbia in order to avoid complications of aggressive ventilation. Because of the severe inspiratory and expiratory airflow obstruction, these patients will

CHAPTER 14

require long inspiratory times to deliver a breath and long expiratory times to avoid air trapping. Either volume- or pressure-targeted modes of ventilation can be used, although volume and pressure limits should be closely monitored and low (≤ 6 cc/kg) tidal volumes used initially. In general, the ventilator rate should be decreased until the expiratory time is long enough to allow emptying prior to the next machine breath. The level of PEEP should be titrated to minimize air trapping from either auto-PEEP or dynamic obstruction. If possible, and when a patient moves toward extubation, a support mode of ventilation is useful, as the patient can set his or her own I-time and flow rate.

These ventilator strategies and the resulting hypercarbia typically are uncomfortable, requiring that patients be heavily sedated. Ketamine is a dissociative anesthetic with bronchodilatory properties that can be used to facilitate intubation and also as a sedative infusion for intubated patients. Ketamine can also increase bronchial secretions, which may limit its use in certain patients or require administration of an anticholinergic agent. Barbiturates and morphine should be avoided, as both can increase histamine release and worsen bronchospasm. Many patients will also require neuromuscular blockade initially to optimize ventilation and minimize airway pressures. In intubated patients not responding to the preceding strategies, inhaled anesthetics, such as isoflurane, should be considered. These agents act not only as anesthetics but also cause airway smooth muscle relaxation. Inhalational anesthetics must be used with caution, however, as they can also cause significant hypotension due to vasodilation and myocardial depression.

Prognosis

Status asthmaticus remains among the most common reasons for admission to the PICU, and it is associated with a surprisingly high mortality rate (1%–3%), especially in patients with a previous PICU admission. Careful but expedient management, however, can reduce the associated morbidities and mortality. As many as 75% of patients admitted to the PICU with life-threatening asthma flares will be readmitted with a future exacerbation, emphasizing the need for careful outpatient follow-up of this high-risk population.

CARDIOVASCULAR CRITICAL CARE

SHOCK

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Shock is defined as the inadequate delivery of oxygen and nutrients to tissues to meet metabolic needs.
- Shock can result from decreased delivery of oxygen, inadequate delivery of oxygen in the face of increased demands, or from impaired utilization of oxygen.
- Shock can be categorized as compensated, hypotensive, or irreversible.
- Early recognition and intervention are essential to improving patient outcomes from shock.

Pathogenesis

Shock is a syndrome characterized by inadequate oxygen delivery to meet the body's metabolic demands. Shock can complicate multiple different disease processes and can be categorized based on the primary physiologic disturbance (Table 14–7).

Shock, regardless of underlying etiology, can be best understood by examining the factors affecting the balance between delivery of oxygen to the tissues and consumption of oxygen by the tissues. Metabolic failure may occur as a result of reduced oxygen delivery (as in respiratory or cardiac failure or acute hemorrhage), increased tissue demand (as in infection, burns, or other major physiologic stresses), or impaired oxygen utilization (as in severe sepsis), or combinations of all three conditions. Defects in oxygen delivery and utilization that result in failure to meet the metabolic

Table 14–7. Categories of shock.

Type of Shock	Examples
Hypovolemic	Dehydration due to vomiting and/or diarrhea Trauma with severe hemorrhage
Cardiogenic	Viral myocarditis Postoperative cardiac patient with poor heart function
Distributive	Septic shock Vasodilation secondary to anaphylaxis
Dissociative	Carbon monoxide poisoning

demands of a tissue leads to anaerobic cellular metabolism, hypoxia, lactic acidosis, and, ultimately, irreversible cellular damage.

Oxygen delivery (DO₂) is defined as the product of the cardiac output (CO) and the oxygen content of arterial blood (CaO₂) delivered by the heart. Cardiac output in turn is determined by ventricular stroke volume (SV) and HR. SV is influenced by preload, afterload, contractility, and cardiac rhythm. Numerous conditions can disrupt one or more of these factors. Preload can be decreased as a result of hypovolemia due to hemorrhage or dehydration or as a result of vasodilation due to anaphylaxis, medications, or septic shock. Impaired contractility can lead to shock in conditions such as cardiomyopathy, myocardial ischemia/reperfusion following a cardiac arrest, postcardiac surgery, and sepsis. Age-dependent differences in myocardial physiology can also affect systolic performance and contractility. For example, in the infant heart, the sarcolemma, sarcoplasmic reticulum, and T-tubules are less well developed than in older children, resulting in a greater dependency on extracellular serum calcium concentrations for contraction. Afterload can be increased, as seen in late septic shock and cardiac dysfunction, or decreased, as in "warm" septic shock. Cardiac dysrhythmias can also alter cardiac output and contribute to inadequate oxygen delivery. One common example is supraventricular tachycardia, in which reduced time for ventricular filling can lead to reduced SV and cardiac output.

The oxygen content of arterial blood consists of the oxygen bound to hemoglobin and the oxygen dissolved in the blood. The bound oxygen is determined by the hemoglobin concentration and the percent of the hemoglobin saturated by oxygen. The dissolved oxygen is calculated from the partial pressure of oxygen in the arterial blood (PaO₂). In general, the main determinant of arterial oxygen content is the bound oxygen. Both illnesses that affect the oxygen saturation of hemoglobin and illnesses that alter hemoglobin concentration can impair oxygen delivery. Low hemoglobin oxygen saturations most commonly occur as a result of impaired uptake of oxygen in the lungs. Low hemoglobin concentrations, as in hemorrhage or other causes of anemia, reduce oxygen delivery, as do abnormal hemoglobins. For example, carboxyhemoglobin (formed in carbon monoxide poisoning) and methemoglobin have different oxygencarrying capacities than normal hemoglobin, resulting in impaired oxygen delivery.

Clinical Findings

The clinical presentation of shock can be categorized into a series of recognizable stages: compensated, hypotensive, and irreversible. Patients in *compensated shock* have relatively normal blood pressures, and compensatory mechanisms preserve oxygen delivery. In infants, a compensatory increase in cardiac output is achieved primarily by increases in HR, given the limited ability of infants to increase SV. In older patients, SV and HR both increase to improve cardiac output. Blood pressure remains normal initially because of peripheral vasoconstriction and increased systemic vascular resistance. Drop in blood pressure occurs late, defining *hypotensive shock*. Patients in hypotensive shock are at risk of developing multiorgan system failure (MOSF), which carries a high risk of mortality. In extreme cases, organ damage can progress to the point that restoration of oxygen delivery will not improve organ function, a condition known as *irreversible shock*.

The symptoms and signs of shock result from end-organ dysfunction caused by inadequate oxygen delivery. Because this condition can progress rapidly to serious illness or death, rapid assessment of a child in shock is essential to determining the need for resuscitation. In patients with impaired cardiac output and peripheral vasoconstriction, the skin will be cool and pale with delayed capillary refill (> 3 seconds) and thready pulses. Additionally, the skin may appear gray or ashen, particularly in newborns, and mottled or cyanotic in patients with decreased cardiac output. In contrast, patients with "warm" or septic shock can present with warm skin with brisk capillary refill and bounding pulses. The detection of peripheral edema is a worrisome sign and can indicate severe vascular leak due to sepsis or poor cardiac output with fluid and sodium retention. The skin examination can also provide insight into the diagnosis (eg, the presence of rash such as purpura fulminans may indicate an infectious etiology) or reveal the site and extent of traumatic injury. Cracked, parched lips, and dry mucous membranes may indicate severe volume depletion.

Tachycardia is an important and early sign of shock and is typically apparent well before hypotension, which is a late feature in pediatric shock. Not all patients can mount an appropriate increase in HR, however, and the presence of bradycardia in a patient with shock is particularly ominous. Peripheral pulses will weaken first in shock as cardiac output is diverted to the body core. Shock in an infant associated with a discrepancy in pulses between lower extremities and upper extremities may indicate a critical coarctation of the aorta with closure of the ductus arteriosus. A gallop cardiac rhythm can indicate heart failure, while a pathologic murmur suggests the possibility of congenital heart disease or valvular dysfunction. A rub or faint, distant heart sounds may indicate a pericardial effusion. Rales, hypoxia, and increased work of breathing occur in patients with shock from heart failure or acute lung injury, and a patient with severe metabolic acidosis due to shock will have compensatory tachypnea and respiratory alkalosis. Urine output is directly proportionate to renal blood flow and the glomerular filtration rate and, therefore, is a good reflection of cardiac output. Normal urine output is greater than 1 mL/kg/h; output less than 0.5 mL/kg/h is considered significantly decreased. Hepatomegaly may suggest heart failure or fluid overload, while splenomegaly may suggest an oncologic process and abdominal distension may suggest obstruction or perforated viscus as the etiology of shock.

The level of consciousness reflects the adequacy of brain cortical perfusion. When brain perfusion is severely impaired, the infant or child first fails to respond to verbal stimuli, then to light touch, and finally to pain. Lack of motor response and failure to cry in response to venipuncture or lumbar puncture is ominous. In uncompensated shock with hypotension, brainstem perfusion may be decreased. Poor thalamic perfusion can result in loss of sympathetic tone. Finally, poor medullary flow produces irregular respirations followed by gasping, apnea, and respiratory arrest.

Monitoring

Laboratory studies in the patient with suspected shock should be directed at evaluating the etiology of shock, assessing the extent of impaired oxygen delivery, and identifying signs of end-organ dysfunction due to inadequate oxygen delivery (Table 14–8). Assessments of oxygen delivery require measurement of oxygen saturation and hemoglobin concentration. Pulse oximetry is adequate to measure oxygen saturation in patients with low oxygen requirements.

Table 14–8. Laboratory studies in the case of shock.
Evaluation for infectious etiology Sources include blood, urine, tracheal secretions, CSF, wound, pleural fluid, or stool Stains, cultures, and other microbiologic tests (PCR, immunofluorescent antibody stains) for bacteria, fungus, viruses
Evaluation of organ function Pulmonary: ABG (evaluate acid-base status, evaluation of oxygen delivery/consumption) Cardiac: ABG, mixed venous saturation, lactate Liver: LFTs, coagulation studies Renal (and hydration status): BUN, creatinine, bicarbonate, serum sodium
Hematology: WBC count with differential, hemoglobin, hematocrit, platelet count Evaluation for DIC: PT, PTT, fibrinogen, D-dimer Extent of inflammatory state: CRP, WBC, ESR, procalcitonin
Additional studies

Ionized calcium Magnesium Phosphate

ABG, arterial blood gas; ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen; CRP, C-reactive protein; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; ESR, erythrocyte sedimentation rate; LFTs, liver function tests; PCR, polymerase chain reaction; PT, prothrombin time; PTT, partial thromboplastin time; WBC, white blood cell. ABG analyses provide more accurate oxygen measurements, which are important for optimizing mechanical ventilation in patients with significant hypoxemia, and provide measurements of arterial pH, which can reflect the adequacy of tissue perfusion. Measurements of central venous oxygen saturation can serve as a measure of the adequacy of overall oxygen delivery. If oxygen delivery is inadequate for the needs of the tissues, a greater portion of that oxygen will be consumed and the central venous saturation will be lower than normal (< 70% in a patient without cyanotic heart disease). In contrast, patients with septic shock may have an elevated central venous saturation due to impaired oxygen utilization by the tissues (> 80%).

Additional laboratory signs of organ dysfunction include evidence of anaerobic metabolism such as acidemia and elevated lactate, increased serum creatinine, or abnormal liver function tests such as elevated transaminases or reduced production of clotting factors. Blood chemistry measurements are also essential in patients with shock. Hypo- or hypernatremia are common, as are potentially life-threatening abnormalities in potassium levels, particularly hyperkalemia in patients with impaired renal function due to shock. Patients in shock may have decreased serum ionized calcium levels, which will adversely impact cardiac function, especially in infants. Calcium homeostasis also requires normal magnesium levels, and renal failure may disrupt phosphorus levels. Evaluation of a coagulation panel is required to detect disseminated intravascular coagulation (DIC), particularly in patients with purpura fulminans or petechiae, or in those at risk for thrombosis.

The selection of *imaging studies*, similar to laboratory studies, should be guided by the presumed etiology of shock. For patients presenting with shock secondary to trauma, standard trauma protocols to evaluate organ damage and potential sites of hemorrhage are indicated. Chest x-rays are routinely performed for critically ill patients to check ETT or central line placement, evaluate the extent of airspace disease and presence of pleural effusions or pneumothorax, and evaluate for pulmonary edema and cardiomegaly. CT of the chest or abdomen may be indicated to better evaluate sites of infection in septic shock, and echocardiography can provide important information about cardiac anatomy and function.

Patients with shock often need *invasive hemodynamic monitoring* for diagnostic and therapeutic reasons. *Arterial catheters* provide constant blood pressure readings, and to an experienced interpreter, the shape of the waveform is helpful in evaluating cardiac output. *Central venous catheters* allow monitoring of central venous pressure (CVP) and central venous oxygen saturation. CVP monitoring does not provide information about absolute volume status, but can provide useful information about relative changes in volume status as therapy is given. *Pulmonary artery catheters* can also provide valuable information on cardiac status and vascular resistance and enables calculations of oxygen

, ,		
Parameter	Calculation	Normal Values
Alveolar partial pressure of oxygen	$PaO_2 = (Barometric pressure - 47) \times \%$ inspired oxygen concentration	
Alveolar-arterial oxygen difference (mm Hg)	$A-aDO_2 = PaO_2 - (PaCO_2/R) - PaO_2$	5–15
Cardiac output (L/min)	$CO = HR \times SV$	
Cardiac index (L/min/m ²)	CI = CO/BSA	3.0-4.5
Oxygen content of arterial blood (mL/dL)	$CaO_2 = (1.34 \times hemoglobin \times SaO_2) + (0.003 \times PaO_2)$	17–24
Oxygen delivery index (mL/min/m ²)	$DO_2 = CaO_2 \times CI \times 10$	550-650
Oxygen content of venous blood (mL/dL)	$CvO_2 = (1.34 \times hemoglobin \times SvO_2) + (0.003 \times PvO_2)$	12–17
Oxygen consumption index (mL/min/m ²)	$VO_2 = (CaO_2 - CvO_2) \times CI \times 10$	120–200

 Table 14–9.
 Hemodynamic parameters.

delivery and consumption (Table 14–9), but these catheters are associated with a higher complication rate than CVP lines and are no longer commonly used in either adult or pediatric critical care.

SEPSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sepsis and septic shock remain major causes of death in children worldwide.
- Early recognition and intervention are keys to improving patient outcome.
- Organized systematic approaches to the treatment of sepsis within an institution can improve survival.

Sepsis and septic shock require particular consideration because sepsis is one of the major illnesses leading to admission to the PICU. Worldwide, an estimated 18 million patients develop sepsis each year, with 750,000 of those cases in North America. Sepsis is the tenth leading cause of death in the United States and accounts for approximately 40% of intensive care unit (ICU) expenditures in the United States and Europe. Among children, an estimated 42,000 cases of severe sepsis occur annually in the United States, accompanied by a mortality rate of nearly 10%. The incidence of severe sepsis is highest in infancy, remains relatively low from age 1 to mid-life, then rises again in later life.

Published literature regarding sepsis uses a number of overlapping and sometimes confusing terminologies. In earlier definitions, *systemic inflammatory response syndrome* (SIRS) referred to a nonspecific syndrome of systemic inflammation typically associated with fever, tachycardia, tachypnea, and an abnormal white blood cell count. Sepsis was defined as documented or suspected infection accompanied by clinical and laboratory signs of systemic inflammation (SIRS), and severe sepsis was defined as sepsis along with evidence of at least one sepsis-induced major organ dysfunction such as hypotension, hypoxemia, lactic acidosis, oliguria, renal failure, thrombocytopenia, coagulopathy, or hyperbilirubinemia. Septic shock is severe sepsis associated with impaired oxygen delivery, typically defined clinically as hypotension requiring either intravenous fluid boluses or pressor agents and a persistently elevated blood lactate level. A 2016 revision to the definitions effectively eliminated the terms SIRS and severe sepsis, and redefined sepsis as documented or suspected infection with at least one organ failure. Though the criteria used to define sepsis in adults and children differ in published guidelines (Table 14-10), the more specific adult criteria provide a useful framework for thinking about sepsis-related organ dysfunction. Of note, the number of organ systems affected by severe sepsis is an important prognostic factor. The risk of death from sepsis rises with the number of organ failures, with a mortality rate of 7%-10% with single-organ failure and up to 50% mortality with four-organ failures.

In addition to impaired oxygen delivery, sepsis and septic shock are also associated with impaired utilization of delivered oxygen. The etiology of this impaired oxygen utilization is not well understood but is likely multifactorial and includes maldistribution of blood flow in the microcirculation as well as mitochondrial dysfunction. Recent work has also brought to light the critical role of the *innate immune system* in sepsis. Infectious agents release *pathogenassociated molecular patterns* (PAMPs) such as lipopolysaccharide or peptidoglycans, and damaged tissues release endogenous proteins and nucleic acids that act as molecular triggers, collectively referred to as *damage-associated molecular patterns* (DAMPs). These molecules are recognized by

Table 14–10. Diagnostic criteria for sepsis.

Adults

Infection, documented or suspected, and some of the following: General signs and symptoms

- Fever (> 38.3°C)
- Hypothermia (core temperature < 36°C)
- Heart rate 90/min or > 2 SD above the normal value for age
- Tachypnea
- Altered mental status
- Significant edema or positive fluid balance (> 20 mL/kg over 24 h)
- Hyperglycemia (plasma glucose > 140 mg/dL or 7.7 mmol/L) in the absence of diabetes

Evidence of inflammation

- Leukocytosis (WBC count > 12,000/µL)
- Leukopenia (WBC count < 4000/µL)
- Normal WBC count with > 10% immature forms
- Plasma CRP > 2 SD above the normal value
- Plasma procalcitonin > 2 SD above the normal value

Hemodynamics

 Arterial hypotension (SBP < 90 mm Hg; MAP < 70 mm Hg; or an SBP decrease 40 mm Hg in adults or > 2 SD below normal for age)

Organ dysfunction

- Arterial hypoxemia (PaO₂/FIO₂ < 300)
- Acute oliguria (urine output < 0.5 mL/kg/h for at least 2 h, despite adequate fluid resuscitation)
- Creatinine increase > 0.5 mg/dL or 44.2 μmol/L
- Coagulation abnormalities (INR > 1.5 or a PTT > 60 s)
- Ileus (absent bowel sounds)
- Thrombocytopenia (platelet count < 100,000/µL)
- + Hyperbilirubinemia (plasma total bilirubin > 4 mg/dL or 70 $\mu mol/L)$

Tissue perfusion

- Hyperlactatemia (upper limit of lab normal)
- Decreased capillary refill or mottling

Children

Signs and symptoms of inflammation plus infection with hyperor hypothermia (rectal temperature > 38.5°C or < 35°C), tachycardia (may be absent in hypothermic patients), and at least one of the following indications of altered organ function: altered mental status, hypoxemia, increased serum lactate level, or bounding pulses.

aPTT, activated partial thromboplastin time; CRP, C-reactive protein; INR, international normalized ratio; MAP, mean arterial blood pressure; SBP, systolic blood pressure; SD, standard deviation; WBC, white blood cell.

Data from Dellinger RP et al: Surviving Sepsis Campaign: international guidelines for management of severe sepsis and septic shock: 2008. Crit Care Med 2008;Jan;36(1):296–327.

pattern recognition receptors of the innate immune system, most prominently the *Toll-like receptors*, which then trigger inflammatory cascades throughout the body. Derangements of adaptive immunity also contribute to the pathogenesis of sepsis. Toll-like receptor signaling may activate subsets of regulatory T cells in septic patients, leading to either immune paralysis or uncontrolled inflammation depending on the pathophysiologic setting. Cytokine production and leukocyte activation lead to endothelial damage and activation of the clotting system. Microvascular thrombi lead to impaired tissue perfusion, which leads to further tissue damage, which in turn leads to further activation of the immune system. The end result of these processes is impaired oxygen delivery to the tissues, impaired oxygen utilization, and metabolic downregulation, leading to end-organ dysfunction and ultimately to death if the process is not reversed.

Treatment of Shock & Sepsis

Much attention has been directed in recent years to the role of standardized treatment guidelines in improving outcomes from shock and sepsis, and detailed guidelines are now available from several professional organizations, most prominently the American Heart Association Pediatric Advanced Life Support (PALS) guidelines for initial management of shock in children, and the Surviving Sepsis Campaign guidelines for management of sepsis in adults and children. A key principle of both guidelines is that early recognition and treatment of shock and sepsis, preferably stemming from a consistent organized clinical approach, improve outcomes in all age ranges.

Regardless of the etiology, the end result of shock is organ dysfunction, which if untreated can lead to irreversible MOSF. Therefore, early recognition of shock, coupled with early intervention, is necessary to minimize end-organ injury and improve survival. Airway, breathing, and circulation should be rapidly assessed, with appropriate stabilization of the airway, support of breathing, and stabilization of circulation. Indications for intubation and mechanical ventilation include altered mental status, significant hemodynamic instability, inability to protect the airway, poor respiratory effort, high work of breathing, or poor gas exchange. In addition, patients in shock who will require surgery or other interventions requiring general anesthesia will also require mechanical ventilation. Because of low FRC, infants and neonates are more likely to require early initiation of NIV or endotracheal intubation. In patients with septic shock, use of etomidate for sedation during intubation should be avoided due to its association with adrenal suppression and increased mortality. A temporary intraosseous line should be placed if IV access cannot be rapidly obtained for resuscitation fluids and medications. A central venous line should be considered in patients with hemodynamic instability, particularly if they require ongoing resuscitation and infusions of vasoactive medications. While femoral venous lines are simpler and safer to place, subclavian and internal jugular lines are preferred for more accurate and consistent central venous saturation and pressure monitoring, although they do carry the additional risk of pneumothorax. The rapidity and accuracy of placing central venous lines may be improved with the use of ultrasound guidance.

CRITICAL CARE

Empiric antimicrobials should be delivered promptly, ideally within 1 hour of presentation in patients with suspected sepsis. Antibiotics should be chosen according to the most likely cause of infection. While it is highly desirable to obtain cultures prior to initiation of antibiotics in order to guide the choice and duration of antibiotic coverage, the acquisition of cultures should never delay antibiotic administration in patients with suspected sepsis. Early and aggressive control of sources of infection is also essential for patients with sepsis and septic shock, including surgical drainage of abscesses or other infected spaces or removal of infected foreign bodies such as vascular catheters.

An important element of the treatment of shock is early aggressive fluid resuscitation targeted to measurable physiologic endpoints of organ perfusion, so-called "early goal directed therapy." Fluid resuscitation should begin with 20 mL/kg increments administered over 5-10 minutes and repeated as necessary. Fluid administration should be titrated to reverse hypotension and achieve normal capillary refill, pulses, level of consciousness, and urine output. Trends in serum lactate measurements can also provide a useful marker of reversal of shock to guide fluid administration. If pulmonary edema or hepatomegaly develop, inotropes should be used in place of more fluid, and cardiac function evaluated for evidence of cardiogenic shock. Large volumes of fluid for acute stabilization in children with hypovolemic or septic shock may be necessary to restore adequate oxygen delivery and do not increase the incidence of ARDS or cerebral edema. Patients who do not respond rapidly to 40-60 mL/kg should be monitored in an intensive care setting and considered for inotropic therapy and invasive hemodynamic monitoring. Initial fluid resuscitation should consist of crystalloid (salt solution), which is readily available and inexpensive. Albumin has been shown to be safe in adults and children with septic shock and should be considered when patients have received large volumes of crystalloid and require ongoing resuscitation. Hydroxyethyl starches (HES) are not recommended as resuscitation fluids in septic shock based on adult studies, which showed no improvement in mortality with HES versus normal saline, but an increased risk of renal failure.

Inotropic and vasopressor agents should be considered for patients with refractory shock despite receiving 60 mL/kg of fluid resuscitation (Table 14-11). Inotropes

	Dece a Advancenia - Vacadilator					
Drug	Dose (mcg/kg/min)	α-Adrenergic Effectª	β-Adrenergic Effect ^a	Effect	Actions and Advantages	Disadvantages
Dopamine	1–20	+ to +++ (dose-related)	+ to ++ (dose-related)	None	Moderate inotrope, wide and safe dosage range, short half-life	Neuroendocrine effects; may increase pulmonary artery pressure
Dobutamine	1–10	None	++	+ (via β ₂)	Moderate inotrope; less chronotropy, fewer dysrhythmias than epinephrine	Marked variation among patients, tachycardia
Epinephrine	0.05–1	++ to +++ (dose-related)	+++	+ (at lower doses, via β_2)	Strong inotrope and chronotrope; increases SVR	Tachycardia, dysrhythmias; can cause myocardial necrosis at high doses
Norepinephrine	0.05–1	+++	+++	None	Potent vasoconstrictor (systemic and pulmonary), increases SVR	Reduced cardiac output if afterload is too high; renal and splanchnic ischemia
Milrinone	0.25–0.75	None	None	++	Decreases SVR and PVR; increases cardiac contractility but only mild increase in myocardial O ₂ consumption	
Nitroprusside	0.05–8	None	None	+++ (arterial and venous vasodilation)	Potent vasodilator, decreases SVR and PVR, very short-acting.	Toxic metabolites (thiocyanates and cyanide); increased intracranial pressure; ventilation- perfusion mismatch; methemoglobinemia

a+, small effect; ++, moderate effect; +++, potent effect. PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

improve cardiac contractility but can increase myocardial oxygen demand and arrhythmia risk; vasopressors increase vascular tone and resistance but can increase cardiac afterload. Inotropes or vasopressor therapy should be selected based on the hemodynamic state, which may include high or low cardiac output and high or low systemic vascular resistance and which may also change during the clinical course. An inotropic agent may be required to maintain cardiac output when patients require vasopressors for refractory hypotension. Inotropic support can be delivered through an intraosseous or peripheral line until stable central access is secured to prevent a delay in initiation. Although dopamine (α - and β -adrenergic agonist) is no longer recommended for adults with septic shock due to arrhythmogenic effects in this population, dopamine remains an acceptable first-line vasopressor in the pediatric population. Either *norepinephrine* (α - and β_1 -adrenergic agonist) or epinephrine (potent α - and β -adrenergic agonist) may be useful for dopamine-refractory shock; generally epinephrine has a greater net effect on cardiac output and is preferred for cold shock states, while norepinephrine has a greater net effect on vascular tone and is preferred for warm shock states. Vasopressin may be considered as a rescue therapy for patients failing catecholamine infusions but has not been clearly shown to improve outcomes from severe sepsis in children. In patients with low cardiac output and high systemic vascular resistance, milrinone, a type III phosphodiesterase inhibitor with inotropic and vasodilator activity, can be added to other more potent inotropic agents. Alternatively, dobutamine (selective β-agonist) may be used to improve myocardial contractility and reduce afterload. Hypocalcemia also often contributes to cardiac dysfunction in shock; calcium replacement should be given to normalize ionized calcium levels.

If perfusion is still inadequate despite aggressive fluid and pressor support, the patient can be considered to have catecholamine-resistant septic shock. This condition may be related to critical illness-related corticosteroid insufficiency (CIRCI), which is a condition of impaired adrenal responsiveness that may occur in as many as 30%-50% of critically ill patients. Absolute adrenal insufficiency, characterized by impaired adrenal responsiveness, lowcirculating cortisol concentrations, and often associated with adrenal hemorrhage, is less common and occurs in fewer than 25% of children with septic shock. Children with fulminant meningococcemia, congenital adrenal hyperplasia, or recent steroid exposure are at the highest risk of absolute adrenal insufficiency, while CIRCI can occur in any critically ill patient. Pediatric patients with fluid-refractory, catecholamine-resistant septic shock and suspected or proven adrenal insufficiency should receive hydrocortisone. The recommended dose of hydrocortisone is 50 mg/m²/day (up to 200 mg/day) either as a continuous infusion or divided doses; however, some children may require higher doses.

Hydrocortisone is generally continued until catecholamine support can be successfully discontinued, and a taper should be considered in those children requiring longer than 7 days of therapy.

Cardiogenic shock can also be associated with elevated ventricular filling pressures (> 20 mm Hg). Although increasing preload to patients in this condition may result in augmented cardiac output (to a degree), volume should be administered cautiously as improvement may occur at the expense of elevated pulmonary venous pressure with resultant pulmonary edema. In this setting, judicious administration of *diuretics* combined with inotropic support can reduce pulmonary edema and improve pulmonary compliance, the work of breathing, and oxygenation.

Blood products can be important supportive therapies in patients with shock. Red blood cells can be administered to patients with shock to improve oxygen-carrying capacity. In hemodynamically stable patients, hemoglobin levels should be maintained over 7 g/dL, while the transfusion threshold can be increased to 10 g/dL in unstable patients. DIC is common in shock, particularly septic shock, due to endothelial damage, formation of microvascular emboli, and consumptive coagulopathy. Thus, a process beginning as increased coagulation leads to a bleeding diathesis. Platelets are generally transfused when platelet counts are less than 20,000/µL, or less than 40,000-60,000/µL in a patient with bleeding or requiring surgical intervention. For severe coagulopathies associated with bleeding in the setting of shock, the standard treatment is fresh frozen plasma (FFP) or, for fibrinogen replacement, cryoprecipitate, with close monitoring of prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT).

Other supportive therapies for shock and sepsis include mechanical ventilation, sedation and analgesia, renal replacement therapy for renal insufficiency, deep vein thrombosis prophylaxis, stress ulcer prophylaxis, nutrition and glucose control. Finally, *ECMO* can be considered as a life-saving measure in the treatment of severe shock in patients with recoverable cardiac and pulmonary function who have failed conventional management.

NEUROCRITICAL CARE

Pediatric neurocritical care is an emerging multidisciplinary field focused on critically ill pediatric patients with neurologic injury due to conditions such as traumatic brain injury (TBI), stroke, status epilepticus, and hypoxic-ischemic brain injury, as well as brain injury that is secondary to other types of critical illness. Neurointensivists work to better understand the distinct pathophysiological and clinical features of pediatric brain injury, develop and apply new diagnostic and monitoring strategies to better understand brain function and dysfunction in real time, and formulate pediatricspecific management guidelines for common neurocritical care problems. While the field is still relatively young, some basic tenets of support for the injured brain are beginning to emerge.

TRAUMATIC BRAIN INJURY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Traumatic brain injury (TBI) presents in a variety of ways, from alterations in memory or alertness (mild confusion to unresponsiveness), irritability, seizures, and even poor feeding/emesis. TBI should be high on the differential for all patients matching these descriptions.
- Hypotension, hypoxia, hypoglycemia, hyperthermia, and hypermetabolic states can exacerbate brain injury. Timely identification and correction of these factors are essential.
- Early signs and symptoms of intracranial hypertension tend to be nonspecific. The classic Cushing triad of bradycardia, hypertension, and apnea occurs late and is often incomplete.

Trauma is the leading killer of children in the United States. Fifty percent of trauma-related deaths are due to TBI, and many survivors endure lifelong disabilities. Traumatic brain injuries can be conceptualized as occurring in two phases. *Primary injury* occurs at the moment that injury disrupts bone, blood vessels, and brain tissue. Prevention through helmets, safety belts, and other injury prevention efforts is the only true means to reduce primary injury. *Secondary injury* is the indirect result of the primary injury and develops within minutes to days after the initiating event. Management of the head-injured child is directed at preventing or modifying events such as hypoxia, hypotension, hyperthermia, and hypoglycemia that contribute to secondary injury.

Pathogenesis

The skull contains a fixed total volume composed of the brain, cerebrospinal fluid (CSF), and cerebral blood. Because of this physical constraint, an increase in volume of one component must be offset by a decrease in one of the other components to maintain a constant ICP (Monro-Kellie doctrine). As a result of a brain injury, the volume of any or all of these components may increase, resulting in increased ICP. *Intracranial hypertension* is defined as an ICP over 20 mm Hg (vs < 15 mm Hg in healthy children) and is associated with increased morbidity and mortality in brain-injured patients. Intracranial hypertension may occur due to other illnesses in addition to TBI (Table 14–12), but, in all cases, the pathogenesis of intracranial hypertension can be understood by considering each of the intracranial components.

The uninjured brain occupies about 80% of the volume within the skull, but this volume can increase dramatically after brain injury as a result of cerebral edema. *Vasogenic edema* is frequently associated with trauma, tumors, abscesses, and infarct, and is due to breakdown of the tight endothelial junctions that make up the blood-brain barrier (BBB). As plasma constituents cross the BBB, extracellular

water moves into the brain parenchyma. *Cytotoxic edema* is the most common form of cerebral edema seen in the PICU and is the least easily treated. Cytotoxic edema occurs as a result of direct injury to brain cells, often leading to irreversible cell swelling and death. This form of cerebral edema is typical of traumatic brain injuries as well as hypoxicischemic injuries and metabolic disease. *Hydrostatic edema*, due to transudation of fluid from the capillaries into the parenchyma as a result of elevated cerebral vascular pressures, and *interstitial edema*, which results from obstructed CSF flow and appears in a typical periventricular distribution, are less common. Cerebral edema can be diagnosed by characteristic findings on either CT or magnetic resonance imaging (MRI) brain imaging.

CSF occupies an estimated 10% of the intracranial space. Intracranial hypertension due primarily to obstructed CSF flow or increased CSF volume (eg, primary or secondary hydrocephalus) is generally easily diagnosed by CT scan and treated with appropriate drainage and shunting. CSF drainage can be of benefit in managing intracranial hypertension even in the absence of overt hydrocephalus.

Cerebral blood volume comprises the final 10% of the intracranial space. Changes in cerebral blood volume generally result from alterations in vascular diameter in response to local metabolic demands or local vascular pressures, responses termed autoregulation. Metabolic autoregulation matches cerebral blood flow to tissue demands. High metabolic rates, such as those induced by fever or seizure activity, increase cerebral blood flow by causing vasodilation, which in turn increases cerebral blood volume; lower metabolic rates allow the vessels to constrict, reducing cerebral blood volume. Partial pressure of carbon dioxide is another important determinant, as elevations in blood PaCO₂ lead to cerebral vasodilation and decreases in PaCO₂ lead to vasoconstriction. Pressure autoregulation, which works to maintain a constant cerebral blood flow in spite of variable systemic blood pressures, links cerebral blood pressure to cerebral blood flow. Within the autoregulatory range of blood pressure, cerebral vessels dilate or constrict as appropriate to maintain constant cerebral blood flow. Once cerebral vessels are maximally constricted, continued increases in systemic pressure may further increase cerebral blood flow and volume; conversely, once vessels are maximally dilated, flow will fall as perfusing pressure falls. It is not unusual to see partial or complete loss of cerebral blood flow autoregulation following TBI. Cerebral blood flow then becomes dependent on systemic blood pressure (traditionally termed "pressure passive" blood flow).

In addition to direct damage from elevated ICP and cerebral edema, secondary injury following trauma may also occur due to ischemia and/or excitotoxicity. Ischemia results from hypoperfusion (an outcome of alterations in cerebral blood flow) or hypoxemia. Excitotoxicity occurs via excessive glutamate exposure, sodium-dependent neuronal swelling, and calcium-dependent mitochondrial failure. Depletion of adenosine triphosphate (ATP), oxidative stress, calcium fluxes, hypomagnesemia, and hyponatremia may all contribute to these processes.

Clinical Findings

The clinical presentation of TBI is dependent on the nature, location, and size of affected areas in the brain, as well as the amount of edema and infringement of CSF pathways. Physical deformities such as skull fractures and exposure of the brain parenchyma may or may not be apparent. Clinical presentation can be subtle, such as a headache from a concussion, or more severe, such as manifestations of intracranial hypertension (Table 14–13) or complete unresponsiveness. Often, early signs and symptoms are nonspecific, particularly in young children. For these reasons, TBI should be included in the differential diagnosis for a wide range of clinical presentations.

Initial examination of the patient with TBI should include assessment of airway patency, breathing, and cardiovascular function. Mental status should be evaluated, and the Glasgow Coma Scale (GCS) score calculated. Once stabilized from a cardiac and respiratory standpoint, a more detailed neurologic examination including cranial nerves, spontaneous movement of extremities, strength, sensory perception, and presence or absence of deep tendon reflexes should be performed. Similar considerations apply in patients with suspected intracranial hypertension but no clinical history of trauma. In either setting, repeated neurologic examinations are needed to monitor for progression of intracranial hypertension. Head imaging (CT or MRI) is generally needed to identify intracranial injuries, to determine the need for surgical intervention, to monitor the progression of injuries and cerebral edema, and to monitor for the development of complications.

Treatment

Initial stabilization should begin with support of the airway, breathing, and circulation, but prevention of further neurologic injury should be considered as these steps are completed. Cervical spine immobilization should be strongly considered prior to securing the airway to avoid worsening spinal cord injury. If the GCS is less than 8, or if the patient demonstrates apnea, irregular respirations, significant hypoxia, or other signs concerning for intracranial hypertension, the airway should be secured via endotracheal intubation. Care should be taken during this process to avoid hypercapnia, which will further increase ICP. Similarly, sedative agents used in the process of intubation should be chosen carefully, as adequate sedation is important to blunt further elevations in ICP with airway manipulation. Maintenance of systemic blood pressure is also critically important during this time.

Following intubation and support of systemic blood pressure, treatment strategies for TBI in children are largely focused on reducing ICP. Current treatment guidelines for children with TBI recommend ICP monitoring for all patients with GCS of 8 or less. This can be accomplished by numerous modalities, including placement of an external ventricular drain (EVD) in the lateral ventricle and/or an intraparenchymal pressure monitor. Little evidence exists to support the utility of ICP measurement and ICP-directed therapies in conditions associated with global CNS injuries (eg, anoxic brain injuries).

Mechanical therapies to reduce ICP range from simple positioning to surgical decompression. Midline positioning and head elevation to 30 degrees can aid in cerebral venous drainage. Timely surgical evacuation of hematomas and other pathologic masses remains a mainstay of TBI treatment, and decompressive craniectomy (removal of a portion of the skull and opening of the dura) can be of benefit in the treatment of refractory intracranial hypertension secondary to focal or diffuse injury. CSF drainage reduces ICP by reducing CSF volume and can be accomplished by placement of an EVD in the lateral ventricles of the brain.

Medical treatment strategies for TBI in children are largely based on reducing ICP to normal levels. *Cerebral perfusion pressure* (CPP) is another important concept for the treatment of intracranial hypertension. CPP is the driving pressure across the cerebral circulation and is defined as mean arterial pressure minus CVP or ICP, whichever is higher. Maintenance of CPP remains a second-tier goal in most published guidelines for management of TBI. Although the ideal target value is not clear in children, most practitioners use 50–60 mm Hg, while others use a graded response based on age (eg, 45–55 in infants/ toddlers, 50–60 in children, and > 60 in adolescents). A suggested treatment algorithm for patients with documented intracranial hypertension based on best available evidence is presented in Figure 14–1. The information is largely drawn from experience with traumatic brain injuries, and the direct applicability of these concepts to other illnesses associated with intracranial hypertension remains unclear. *Osmotic therapies* such as hypertonic (\geq 3%) saline and mannitol can be effective treatments for elevated ICP

▲ **Figure 14–1.** Proposed treatment algorithm for intracranial hypertension in head injury. CSF, cerebrospinal fluid; ICP, intracranial pressure; PCO₂, partial pressure of arterial CO₂.

regardless of etiology. Hypertonic saline, given in bolus doses of 5 mL/kg of 3% saline or as a continuous infusion, encourages intravascular volume expansion and increases serum osmolality, enhancing movement of excess water out of brain cells and interstitium and into blood vessels for removal by the kidneys. Serum sodium and osmolality should be followed closely to avoid severe hypernatremia or severe hypertonicity when this agent is used. Mannitol, given in doses of 0.25-1 g/kg, exerts a rapid rheologic effect, reducing blood viscosity which improves blood flow and subsequent autoregulatory vasoconstriction. Mannitol also exerts a potent osmotic and diuretic effect. While this may further reduce ICP, it can also result in hypovolemia and hypotension, which reduces CPP and exacerbates secondary injury. Volume status and systemic blood pressures should therefore be monitored closely following administration, and treatment should be prompt to reduce these side effects. Renal failure due to intravascular volume depletion and acute tubular necrosis is a rare side effect and is associated with serum osmolality greater than 320 mOsm/L.

Controlled ventilation is an important element of treating intracranial hypertension. Although acutely effective in causing cerebral vasoconstriction, hyperventilation leads to much larger decreases in blood flow than in blood volume, such that hyperventilation necessary to control ICP may actually compromise CNS perfusion and exacerbate secondary injury. This concept was confirmed by studies showing worse outcomes in head-injured patients consistently hyperventilated to a PaCO₂ of 25 mm Hg or less. Hyperventilation to PaCO₂ levels less than 30 mm Hgin the past a mainstay in the treatment of intracranial hypertension-should only be used in emergent situations involving patients with acute ICP elevations unresponsive to other measures, such as sedation, paralysis, ventricular drainage, and osmotic diuretics. Controlled normocapnia, to maintain PaCO_2 between 35 and 40 mm Hg, is the current standard of care.

Hemodynamic support is also crucial in managing patients with traumatic brain injuries. In addition to reduction in ICP, maintenance of CPP is also important to deliver oxygen and remove metabolites. Hypotension, which may occur due to hemorrhage from comorbid injuries or as a part of a systemic inflammatory response following TBI, results in a linear decrease in CPP. Studies in both adult and pediatric patients with head injury show that even a single episode of hypotension is associated with a marked increase in mortality rates. Maintenance of systemic blood pressure can be accomplished using volume and/or vasopressors.

Current guidelines suggest the use of *barbiturates* for treating intracranial hypertension refractory to other measures. Barbiturates suppress cerebral metabolism and, through metabolic auto-regulatory effects, reduce cerebral blood volume and ICP. These agents are potent cardiac depressants and their use often leads to hypotension, necessitating the use of a pressor to maintain adequate cerebral and systemic perfusion pressures. Plasma barbiturate levels correlate poorly with effect on ICP, and monitoring of CNS electrical activity by EEG is necessary to accurately titrate their use.

Finally, optimizing oxygen and nutrient delivery to the injured brain should be facilitated by reducing metabolic demands. Aggressive control of fevers (controlled normothermia), using antipyretics and surface cooling devices, is warranted, and continuous temperature monitoring helps prevent over- or undercorrection. Induced hypothermia lowers cerebral metabolism, cerebral blood flow, and cerebral blood volume, but has not been shown to improve overall outcome. Adequate sedation to reduce episodes of agitation and/or pain can further reduce metabolic demands and ICP. If these methods are ineffective, neuromuscular blockade can be an effective adjunctive therapy. Seizures occur in approximately 30% of patients with severe head injury and result in increased metabolic demand and secondary injury. Continuous electroencephalography (EEG) should be used in patients with persistent altered mental status or in those requiring heavy sedation. A short course of empiric antiepileptic medication is frequently used, and seizures noted on EEG should be treated rapidly. Corticosteroids may be of use in reducing vasogenic cerebral edema surrounding tumors and other inflammatory CNS lesions, but in general they have no role in the treatment of TBI.

Complications

Complications are frequent in patients with traumatic brain injuries and should be anticipated. Nosocomial infections are more common in these patients than other critically ill populations and may lead to worse outcomes. Abnormalities of sodium handling such diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), or cerebral salt wasting are also relatively common following serious brain injuries, and require careful monitoring and intervention. In more severe cases, cerebral infarctions may occur as a result of ischemia, thrombosis, and progressive edema compromising blood supply. Finally, cerebral herniation presenting with Cushing triad of bradycardia, hypertension, and altered respirations is an ominous and life-threatening medical emergency, often leading to death or serious disability in brain-injured patients.

Prognosis

Many factors will affect prognosis of patients with TBI, especially the inciting event and severity of injury. Experience has shown that it is difficult to predict overall outcome in the initial stabilization period, but lack of improvement in neurologic examination after 24–72 hours (the peak period for swelling) is associated with poor outcome. Follow-up studies have also demonstrated that "recovery" occurs over time, even months to years.

Inflicted Traumatic Brain Injury

Inflicted traumatic brain injury (iTBI), also referred to as nonaccidental trauma (NAT), accounts for a significant portion of traumatic brain injuries in infants and young children. The pathophysiology underlying severe iTBI is often more complex than in accidental head trauma, as a result of several factors, including repetitive brain injuries prior to presentation and additional acute global hypoxicischemic brain damage as a result of trauma-induced respiratory failure or cardiac arrest. Management of children with iTBI is similar to those with accidental TBI, but additional evaluations should include an ophthalmologic assessment for retinal hemorrhages and a radiologic skeletal survey to identify occult bone fractures. Child advocacy and law enforcement groups should be notified when abuse is suspected. Unfortunately, children with iTBI often have a worse neurologic outcome compared to accidentally injured children.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Hypoxic-ischemic encephalopathy (HIE) results from global brain hypoxia and ischemia produced by systemic hypoxemia and/or reduced blood flow to the brain. Pediatric HIE is commonly caused by cardiopulmonary arrest due to drowning, severe respiratory distress, shock, drug overdose/poisoning, lethal arrhythmia, and other insults. Pediatric HIE is associated with poor neurologic outcome. Like TBI, the extent of brain injury in HIE depends on the duration and severity of the initial inciting event and the development of secondary injury over the minutes to days following reestablishment of cerebral blood flow and oxygen delivery.

Clinical Findings

Signs and symptoms of brain injury secondary to hypoxicischemic injury are variable and depend on injury severity and affected brain regions. Manifestations of HIE can include cognitive dysfunction, seizures (clinical and subclinical), status epilepticus, stroke, coma, a persistent vegetative state, and brain death.

Treatment

The initial stabilization of a patient with HIE includes airway management, respiratory support, and maintenance of cardiovascular stability. As with traumatic brain injuries, treatment strategies for victims of HIE are focused on optimizing cerebral blood flow and mitigating neuronal loss. Blood flow to the brain is dependent on cardiac output, which may be impaired following cardiac arrest and/or injury. Optimization of cardiac function and systemic hemodynamics with fluid resuscitation and inotropic and/or vasopressor agents is necessary to ensure adequate delivery of oxygen and nutrients to the injured brain. Cerebral pressure auto-regulation may also be impaired in children who develop HIE as a result of cardiac arrest. Several studies in adult victims of cardiac arrest suggest that maintaining a higher mean blood pressure may better support the postischemic brain, but the degree of pressure dysregulation and blood pressure targets to optimize cerebral blood flow in the ischemic pediatric brain remain unclear. Intracranial hypertension may develop as a result of cerebral edema. The utility of ICP monitoring and titration of therapies to a normal ICP in HIE patients has not been clearly defined, and use of those approaches varies across pediatric referral centers. Seizures should be aggressively treated, and continuous EEG monitoring is useful for identifying subclinical seizure activity. Similar to the case with traumatic brain injuries, temperature regulation and maintenance of normothermia are also essential, since the risk of severe disability in patients with HIE increases with fevers. Therapeutic hypothermia (target body temperature 33-35°C) is a mainstay of treating postcardiac arrest HIE in adults and postanoxic HIE in newborns, but published data in the pediatric population do not demonstrate significant benefit.

Prognosis

Accurately predicting outcome in children with HIE is difficult. While practice parameters for prognosticating neurologic outcome after cardiac arrest in adult patients have been published, no clear roadmap for predicting outcome in pediatric HIE exists. A prolonged cardiopulmonary resuscitation (> 10-15 minutes) is a significant risk factor for poor outcome. Other indicators of likely poor outcome include any of the following, 24 hours or more after the inciting event: (1) GCS score less than 3-5, (2) absent pupillary and motor responses, (3) absent spontaneous respiratory effort, (4) bilateral absence of median nerve somatosensory evoked potential (N20), (5) discontinuous, nonreactive, or silent EEG (in the absence of confounding drug administration), (6) MRI demonstrating watershed, basal ganglia, and brainstem injury. Outcome prediction is enhanced when several assessment modalities are combined.

ACUTE KIDNEY INJURY & RENAL REPLACEMENT THERAPY

Definitions

The kidney is important in maintaining homeostasis for a number of important physiologic processes, including fluid and electrolyte balance, acid-base status, erythropoiesis, and vascular tone. Acute renal failure is a frequent problem in critically ill children, with a range of manifestations from modest reductions in creatinine clearance with preserved urine output to anuria. The term *acute kidney injury* (AKI) has been adopted to reflect the broad range of clinically important manifestations of renal failure, and a number of diagnostic scoring systems have been developed. The most widely accepted of these is the pRIFLE system (Table 14–14), which specifies thresholds for increasing degrees of renal injury.

Pathophysiology

The etiology of AKI in critically ill children is most often multifactorial. Altered renal perfusion is a common contributing factor, due to combinations of systemic hypotension, impaired venous return to the heart (as with heart failure or high intrathoracic pressure), or high intra-abdominal pressures (abdominal compartment syndrome). Sepsis is another common contributing factor to AKI. The renal effects of sepsis are thought to be due to disturbances of the renal microvasculature caused by inflammatory mediators and activation of the coagulation system, as well as to sepsisrelated alterations in systemic hemodynamics. Nephrotoxic medications contribute to as much as 25% in cases of AKI, most commonly antibiotics (aminoglycosides, vancomycin), and immunosuppressives such as cytotoxic cancer chemotherapeutics and calcineurin inhibitors. Other contributing factors include hypoxia, pulmonary-renal and hepatorenal syndromes, and toxic metabolic byproducts as in rhabdomyolysis or tumor lysis syndrome.

 Table 14–14.
 pRIFLE criteria for diagnosis of acute kidney injury in children.

Stage	Creatinine Criteria	Urine Output Criteria		
R (risk)	eCCL down > 25%	< 0.5 cc/kg/h × 8 h		
l (injury)	eCCL down > 50%	< 0.5 cc/kg/h $ imes$ 16 h		
F (failure)	eCCL down > 75% or < 20 mL/min/m ²	$<$ 0.3 cc/kg/h \times 24 h or anuria \times 12 h		
L (loss)	Meets F criteria for > 4 wk			
E (end stage)	Meets F criteria for > 3 mo			

eCCL, estimated creatinine clearance = $0.413 \times \text{height (cm)/serum}$ creatinine.

Clinical Findings

In general PICU populations, 10%–40% of patients are found to have or develop AKI, defined as "I" or worse on the pRIFLE scale. Of those who develop AKI, most do so within the first 24–48 hours of hospitalization and almost all within the first week. Importantly, the development of AKI is a strong independent risk factor for increased ICU length of stay and increased mortality. Even after adjusting for severity of illness, AKI is associated with a two- to sixfold increase in mortality risk.

One of the most important clinical consequences of AKI is fluid overload. Excess fluid over 10% of body weight is an independent risk factor for increased ICU length of stay and mortality, and patients overloaded by 20% of their body weight in fluid may have as much as an eightfold increased risk of death. The mechanism behind this association remains unclear, but based on these findings some authorities recommend consideration of renal replacement therapies for patients reaching 10%–20% fluid overload. Other potential clinical consequences of AKI include electrolyte abnormalities, hypertension, and reduced clearance of medications.

Treatment

The management of AKI is directed at alleviating potential contributing factors. Methods to improve *renal perfusion* include maintenance of adequate cardiac output and systemic blood pressure with fluids and/or pressors, and relief of excess intrathoracic and intraabdominal pressures when feasible. Unfortunately, prospectively validated thresholds of adequate renal perfusion pressures to prevent or reverse AKI do not exist. The use of direct renal vasodilators such as dopamine or fenoldopam to increase renal blood flow does not improve outcomes in AKI.

Diuretics are commonly used to address fluid overload associated with AKI, but these agents have not been shown to improve renal recovery in children and have been associated with an increased risk of death in adults with AKI. *Fluid restriction* can be helpful in managing fluid overload and may be of particular benefit in patients with concomitant lung injury.

Renal replacement therapies should be considered for serious electrolyte disturbances, drug or toxin overdoses, or when fluid overload associated with AKI is not responsive to fluid restriction and/or diuretic use. Renal replacement modalities include peritoneal dialysis, intermittent hemodialysis, and continuous renal replacement therapy (CRRT), also known as continuous venovenous hemofiltration (CVVH). This latter technique involves sending patient venous blood through an extracorporeal filtration circuit and pump to provide slow, continuous fluid removal and/or dialysis. While the ideal modality depends on the individual clinical situation, CRRT is often the preferred modality of renal replacement for managing AKI in PICU patients. CRRT can be performed as ultrafiltration alone if control of intravascular volume is the primary goal, or CRRT can be performed with a dialysate to allow solute control as well. Advantages of CRRT include (1) in hemodynamically labile patients, a slower continuous rate of fluid removal may be better tolerated and can be more precisely controlled than intermittent dialysis; (2) solute and fluid removal can be regulated separately; and (3) CRRT may allow easing of fluid restrictions so that nutrition can be improved. Disadvantages include the technical complexity of the procedure, including anticoagulation of the circuit, and the need for central venous access. Importantly, no prospective studies have compared CRRT with other modes of renal replacement or demonstrated that early initiation of CRRT improves outcomes in AKI, although retrospective studies have suggested that early initiation of CRRT may be associated with lower mortality. The decision to proceed with CRRT should involve a careful assessment of risks and possible benefits in each individual patient.

FLUID MANAGEMENT & NUTRITIONAL SUPPORT OF THE CRITICALLY ILL CHILD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fluid overload is an important predictor of poor outcome in critically ill children.
- Hyponatremia is also common in the PICU and may be associated with worse outcomes.
- Critically ill children are more susceptible to metabolic stress than adults due to lower muscle and fat mass and higher resting energy requirements.
- Obese children are more likely to develop complications including sepsis, wound infection, and increased length of stay in the PICU.
- Changes in nutritional status can persist for up to 6 months after discharge from a prolonged ICU stay.
- Early enteral and parenteral feeding can improve nutrition deficits, and may influence morbidity and mortality in critically ill infants and children.

Fluid Management

The majority of critically ill children will be unable to take oral fluids and food, and, as a result, the ICU provider must carefully consider the needs of the individual patient in prescribing a fluid and nutrition regimen. Especially in the complex environment of the ICU, the prescription of a fluid and nutrition regimen is a decision that should be approached with the same care as prescription of antibiotics or vasopressors.

Perhaps the most important issue in prescribing fluids is the patient's overall fluid balance. Standard maintenance IV fluid calculations are based on the assumption of a normotensive, spontaneously breathing patient. Patients presenting with hypovolemia or poor perfusion will usually benefit from an infusion rate greater than maintenance. Additional fluid losses may occur from increased urinary losses (eg, with glucosuria), hemorrhage, or externalized surgical drains. Insensible fluid losses may be elevated due to increased work of breathing or fever. Furthermore, any patient with evidence of hypovolemic shock should have appropriate fluid resuscitation regardless of the continuous fluid rate.

While some patients require administration of large volumes of IV fluid early in their course, PICU patients are more likely to develop fluid overload than hypovolemia. Patients may be oliguric due to AKI or have reduced urine output due to excess ADH secretion, as is seen with certain lung diseases and/or positive pressure ventilation. In addition, mechanically ventilated patients generally require less fluid than non-intubated patients because the ventilator delivers humidified gas and the insensible fluid loss that occurs with normal breathing is greatly reduced. Therefore, maintenance fluid requirements for these patients may be as little as 2/3 that of someone who is not mechanically ventilated. Fluid overload more than 10%-20% of body weight is an independent risk factor for increased length of stay and death in general ICU populations, and fluid overload has been associated with worse outcomes in many critically ill subpopulations, including patients with acute lung injury, TBI, and acute renal failure. If systemic hemodynamics allows, early consideration of fluid restriction and/or diuretic use may be warranted in these situations.

Another important parameter in prescribing fluids in the ICU is the tonicity of the fluid chosen. Hyponatremia has been associated with significant morbidity and mortality in neurocritical care patients, and even mild to moderate abnormalities in serum sodium are associated with worse outcomes in adult ICU patients. For these reasons, in children with acute brain injury (traumatic or hypoxicischemic), isotonic maintenance fluids are generally recommended to avoid worsening the risk of cerebral edema. For other children who are also at high risk for cerebral edema or hyponatremia, such as patients with diabetic ketoacidosis or meningitis, it may also be prudent to use isotonic fluid. When using isotonic fluid, close electrolyte monitoring is warranted to avoid the complications of undesired hypernatremia and hyperchloremic acidosis. No matter the choice of fluid, the critical care practitioner should closely monitor the patient's fluid balance based on physical examination, weight, and laboratory values and modify the fluid management strategy accordingly.

Nutritional Support

When severely ill pediatric patients are admitted to the PICU, provision of adequate nutritional support is often overlooked early in the course of therapy. Malnutrition is, however, a major problem in hospitalized patients, leading to higher rates of infectious and noninfectious complications as well as longer hospital stays and increased hospital costs. In the pediatric ICU, it is estimated that as many as 20% of patients experience either acute or chronic malnutrition, a rate that is largely unchanged over the past 30 years. The etiology of malnutrition in PICU patients is typically multifactorial, related to increased demands due to the physiologic and metabolic stresses associated with critical illness (Table 14–15), to inaccurate assessments of caloric needs, and to inadequate delivery of nutrition at the bedside.

Nutritional Assessment

Early assessment by a pediatric dietitian or nutritionist can be helpful to establish nutritional requirements and goals in critically ill children and identify factors impeding adequate nutrition intake and tolerance. The caloric needs of the critically ill child can be estimated beginning with calculations of the basal metabolic rate (BMR) or the resting energy expenditure (REE). BMR represents the energy requirements of a healthy, fasting person who recently awoke from sleep, with normal temperature, and no stress, while REE represents the energy requirements of a healthy person at rest, with normal temperature and not fasting (Table 14-16). These closely related parameters are for practical purposes used interchangeably, although the REE tends to be approximately 10% above the BMR. The estimated basal metabolic need (BMR or REE) can then be multiplied by a stress factor related to the severity of the patient's illness to more accurately estimate overall energy requirements. Unfortunately, because these calculations are based on studies of healthy adults and children, they can be very inaccurate for use in critically ill children and lead to underfeeding or overfeeding. For example, studies have demonstrated significant metabolic instability and alterations in REEs with a predominance of hypometabolism in the PICU population, resulting in a higher risk of overfeeding when using calculations alone.

Indirect calorimetry (IC) is a more accurate means of directly measuring energy expenditure and determining caloric needs, but it is more difficult and expensive
 Table 14–15.

to perform and as a result is not always readily available. Identification of patients at highest risk for malnutrition (see Table 14–16) for targeted use of IC assessment has been suggested as one strategy for optimizing the cost-benefit ratio of IC. This technique requires collection of exhaled gases from the patient and can be inaccurate if a significant ETT leak is present, if the FIO₂ is more than 60%, and during hemodialysis or continuous renal replacement.

Delivery of Nutrition

In adult ICU patients, *enteral nutrition* is associated with fewer infectious complications than parenteral nutrition. No such comparisons in pediatric patients exist, but it is generally

Table 14–16. Markers of high risk of malnutrition

suggested as indications for targeted indirect calorimetry assessment of REE.

- Underweight (< 5th percentile for age) or overweight (> 85th percentile for age)
- > 10% weight gain or loss during ICU stay
- · Failure to consistently meet prescribed caloric goals
- Failure to wean from respiratory support
- Need for muscle relaxants for > 7 days
- · Neurologic injury with evidence of dysautonomia
- Oncologic diagnoses
- Burns
- Requiring mechanical ventilation for > 7 days
- Suspected hypermetabolic state (eg, status epilepticus, SIRS) or hypometabolic state (eg, hypothermia, induced coma)
 ICU length of stay > 4 wk
- ICO length of stay > 4 wk

accepted that enteral nutrition is preferred in critically ill children as well. Enteral nutrition is generally well tolerated in hemodynamically stable children, with a goal protein intake of 2–3 g/kg/day. Patients with unstable hemodynamics or requiring vasopressor support may not tolerate full-volume enteral feeding, although low-volume continuous "trophic" feeding is generally safe and feasible in all but the most unstable patients and may reduce the incidence of nosocomial infections by protecting GI tract integrity. Use of an enteral feeding protocol and early transpyloric feeding may improve tolerance. Complications of enteral feeding include GI intolerance (vomiting, bleeding, diarrhea, and necrotizing enterocolitis), aspiration events/pneumonia, and mechanical issues (occlusion of tube, errors in tube placement).

Parenteral nutrition should be considered in critically ill children when enteral nutrition cannot be delivered or tolerated within 3–5 days. Although it is common practice to gradually increase the amino acid dose, evidence from preterm neonates shows that it is safe and efficacious to start parenteral amino acids at the target dose. Lipids should be included to decrease carbon dioxide production, minute ventilation, and fat storage, enhance lipid oxidation, augment protein retention, and prevent essential fatty acid deficiency. Hyperglycemia, hypertriglyceridemia, infection, and hepatobiliary abnormalities are all potential complications of parenteral nutrition. Metabolic evaluation (electrolytes, glucose, lipase, and liver function tests) should be performed regularly and the components of parenteral nutrition adjusted as needed.

Regardless of route of nutrition, *monitoring* should include routine physical examination, serial measures of growth (weight, skinfold thickness), serial monitoring of serum electrolyte and mineral concentrations, and repeated measurements of REE when available. Measurements of serum albumin provide limited information about nutritional status given the multiple other influences on albumin concentrations. Prealbumin and CRP measurements may be helpful, however. Prealbumin levels are a good marker of nutritional protein status; they drop during acute illness and return to normal during recovery. CRP levels are a marker of the acute phase response to illness and injury; they rise during acute illness and drop with recovery, typically in association with a return to anabolic metabolism and before increases in prealbumin.

SEDATION & ANALGESIA IN THE PEDIATRIC ICU

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pain control and relief of anxiety are standard of care for all patients in the PICU.
- Sedation and analgesia must be individualized for each patient and reassessed frequently to avoid inadequate or excessive medication.
- Sedative and analgesic medications have unique sets of physiologic effects and side effects, and these agents should only be used with adequate monitoring and support to address potential adverse events.

Children admitted to the PICU often require anxiolytic and analgesic medications to minimize discomfort and keep them safe. Sedation and anxiolysis may also be needed to facilitate mechanical ventilation or the performance of procedures, and analgesia may be needed for postoperative pain or pain related to traumatic injuries. Thus, careful consideration of a patient's sedative and analgesic needs is a vital part of ICU management.

When determining which anxiolytic and analgesic medications to initiate, it is important to distinguish between anxiety and pain, because pharmacologic therapy may be directed at either or both of these symptoms (Table 14–17). Additional considerations in sedative selection are the

Drug	Suggested Starting Dose	Advantages	Disadvantages	Usual Duration of Effect
Morphine	0.1 mg/kg; continuous infusion, 0.05–0.1 mg/kg/h	Excellent pain relief, reversible	Respiratory depression, hypotension, nausea, suppression of GI motility, histamine release	2–4 h
Hydromorphone	0.015 mg/kg; continuous infusion, 1.5–3 mcg/kg/h	Good pain relief, reversible	Respiratory depression, histamine release, nausea, suppression of GI motility	2–4 h
Fentanyl	1–2 mcg/kg; continuous infusion, 0.5–2 mcg/kg/h	Excellent pain relief, reversible, short half-life	Respiratory depression, chest wall rigidity, severe nausea and vomiting	30 min
Midazolam	0.1 mg/kg; continuous infusion 0.05–0.2 mg/kg/h	Short half-life, only benzodiazepine given as continuous infusion	Respiratory depression	20–40 min
Lorazepam	0.1 mg/kg	Longer half-life, sedation and seizure control	Nausea and vomiting, respiratory depression, phlebitis	2–4 h
Diazepam	0.1 mg/kg	Sedation and seizure control	Respiratory depression, jaundice, phlebitis	1–3 h
Dexmedetomidine	0.2–0.7 mcg/kg/h	Sedation, anxiolysis, analgesia without respiratory depression	Bradycardia, hypotension	10 min–2 h

route of administration and the anticipated duration of treatment. Routes of administration may be limited by the patient's IV access or ability to tolerate oral medications. Children who require more frequent dosing or tighter control of sedation level may benefit from a continuous infusion whereas patients undergoing a bedside procedure may only require a small number of discrete doses. Potential adverse effects in particular clinical circumstances are another important consideration in sedative and analgesic selection.

Sedation

Sedative (anxiolytic) medications may be indicated when the goals of treatment are to reduce anxiety, facilitate treatment or procedures, manage acute confusional states, and diminish physiologic responses to stress, such as tachycardia, hypertension, or increased ICP. The most commonly used agents in the PICU are the benzodiazepines and the opioids. These should be carefully titrated to effect to avoid oversedation and resultant respiratory depression and/or hemodynamic instability.

Benzodiazepines

Benzodiazepines work through the neuroinhibitory transmitter γ -aminobutyric acid (GABA) system, resulting in anxiolysis, sedation, hypnosis, skeletal muscle relaxation,

and anticonvulsant effects. Benzodiazepines provide little to no analgesia and thus need to be combined with other medications when pain control is required. Most benzodiazepines are metabolized in the liver, with

Most benzodiazepines are metabolized in the liver, with their metabolites subsequently excreted in the urine; thus, patients in liver failure are likely to have long elimination times. Benzodiazepines can cause respiratory depression if given rapidly in high doses, an important consideration for the non-intubated patient. They can also cause cardiovascular compromise in critically ill patients, making careful titration of doses essential.

In some children, benzodiazepines can cause a paradoxical effect, producing greater agitation than sedation. In those cases, selection of an alternative agent may be more appropriate than escalation in dose. When overdose is a concern, flumazenil may be used to reverse benzodiazepine effects. Flumazenil must be used with care, however, as its effects generally wear off faster than those of most benzodiazepines. Additionally, in tolerant patients rapid reversal may result in withdrawal symptoms, including seizures.

Commonly used benzodiazepines in the PICU include midazolam, lorazepam, and diazepam. Each has differing half-lives, resulting in varying durations of effect, and multiple possible routes of administration. *Midazolam* has the shortest half-life and produces excellent retrograde amnesia lasting for 20–40 minutes after a single IV dose. Therefore, it can be used for short-term procedural sedation and anxiolysis with single or intermittent doses or for prolonged sedation as a continuous infusion. Lorazepam has a longer half-life than midazolam (or diazepam) and can achieve sedation for as long as 6-8 hours. It has less effect on the cardiovascular and respiratory systems than other benzodiazepines and is commonly used for short-term sedation or initial treatment of seizures. Continuous infusions of lorazepam should be avoided because its preservative, polyethylene glycol, can accumulate in patients with renal insufficiency and produce a metabolic acidosis. Diazepam has a longer half-life than midazolam and is used most commonly to treat muscle spasticity and seizures. A disadvantage of diazepam in the PICU is the long half-life of its intermediary metabolite, nordazepam, which may accumulate and prolong sedation, making diazepam less ideal for short-term sedation.

Other Sedative Medications

Opioids are strong analgesics that also have sedative effects. They are commonly used as adjuncts in combination with other sedatives such as benzodiazepines. Specific medications are described further in the analgesic medication section later.

Ketamine (IV or IM) is a phencyclidine derivative that produces a trance-like state of immobility and amnesia known as dissociative anesthesia. Ketamine does not cause significant respiratory depression at nonanesthetic doses, an advantage for the nonintubated patient. Ketamine has negative inotropic effects, although these are countered by stimulation of the sympathetic nervous system resulting in an increase in HR, blood pressure, and cardiac output for most patients. These effects may make ketamine a good choice for hemodynamically unstable patients. Additionally, ketamine has bronchodilatory properties and, thus, may be useful for children with status asthmaticus. Finally, it has strong analgesic effects and therefore may be used as a single agent for sedation for painful procedures. The main side effects seen with ketamine are increased salivary and tracheobronchial secretions and unpleasant dreams or hallucinations. Atropine or glycopyrrolate may be administered ahead of time to reduce secretions, and concurrent administration of benzodiazepines may reduce the hallucinatory effects. Although most frequently used for short-term sedation, lowdose continuous infusions may be used in selected patients.

Dexmedetomidine is a selective α_2 -adrenoreceptor agonist that produces sedation, anxiolysis, and some analgesia with minimal respiratory depression. It allows for the ability to rouse the patient easily if necessary. These advantages have resulted in increasing use in critically ill children for procedural sedation as well as sedation to facilitate mechanical ventilation. The most frequent side effects observed are dose-related bradycardia and hypotension. Dexmedetomidine is primarily used as a short- or long-term continuous

infusion. The use of dexmedetomidine may also mitigate the need for increasing doses of opioids and benzodiazepines in patients requiring multiple sedative medications.

Propofol is an anesthetic IV induction agent with strong sedative effects. Its main advantages are a rapid onset and rapid recovery time resulting from its rapid hepatic metabolism. Because propofol has no analgesic properties, an analgesic agent should be concurrently administered for painful procedures. Propofol can cause significant vasodilation, resulting in dose-related hypotension, in addition to dose-dependent respiratory depression. Owing to concerns for propofol infusion syndrome, a sudden-onset, profound, and often fatal acidosis associated with prolonged infusions, propofol is now used in children mostly for procedural or short-term sedation.

Barbiturates (phenobarbital and thiopental) can cause direct myocardial and respiratory depression and are, in general, poor choices for sedation of seriously ill patients. Phenobarbital has a very long half-life (up to 4 days), and recovery from thiopental, although it is a short-acting barbiturate, can be prolonged because remobilization from tissue stores occurs.

Analgesia

Opioid and nonopioid analgesics are the mainstay of treatment for acute and chronic pain in the PICU. Although several other medications used for sedation also have analgesic properties, they are uncommonly used for primary treatment of pain.

Opioid Analgesics

All opioids provide analgesia and have dose-dependent sedative effects. A range of plasma concentrations produce analgesia without sedation; the dose required to produce adequate analgesia varies significantly between patients. Therefore, the best approach to dosing with opioids is to start with a low-end dose but then titrate to effect, monitoring for side effects. The most common side effects of these agents are nausea, pruritus, slowed intestinal motility, miosis, cough suppression, and urinary retention. Opioids can also cause respiratory depression, particularly in infants. Morphine can cause histamine release leading to pruritus and even hypotension; fentanyl generally has few hemodynamic effects in a volume-replete patient. Opioids are metabolized in the liver, with metabolites excreted in the urine. Thus, patients with hepatic or renal impairment may have prolonged responses to their administration.

The choice and mode of delivery of agents within this class depends upon the physiologic state of the child and the etiology of pain. In an awake and developmentally capable patient, a patient-controlled analgesia (PCA) approach with an infusion pump may be appropriate. Each of these medications may also be administered intermittently, in which case half-life and tolerability of side effects may be the primary considerations. For many patients in the PICU, a continuous infusion may be the best option. Several IV medications are commonly used as a continuous infusion or by PCA, including fentanyl, morphine, and hydromorphone. For children who have more chronic, less severe pain and who can tolerate oral medications, there are many different options, including codeine, hydrocodone, hydromorphone, morphine, methadone, and oxycodone.

Naloxone may be used as an opioid reversal agent for narcotic overdoses. Because of its relatively short half-life compared to many opioids, symptoms may recur and repeat dosing or even a continuous infusion may be necessary. Caution should be used in patients with chronic opioid exposure to avoid precipitating severe withdrawal symptoms.

Non-opioid Analgesics

Nonopioid analgesics used to treat mild to moderate pain include acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs). Because the effects of these agents can be additive with opiates, a combination of opiate and nonopiate medications can be a very effective approach to pain management in the ICU.

Acetaminophen is the most commonly used analgesic in pediatrics in the United States and is the drug of choice for mild to moderate pain because of its low toxicity and minimal side-effect profile. With chronic use and higher doses, acetaminophen may cause liver and renal toxicity.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are reasonable alternatives for the treatment of pain, particularly those conditions associated with inflammation. All NSAIDs carry the risk of gastritis, renal compromise, and bleeding due to inhibition of platelet function, limiting their use in patients with thrombocytopenia, bleeding, and kidney disease. *Ketorolac* is the only IV NSAID currently available. It can be very effective for children who cannot take oral medication or require a faster onset of action. Because of the concerns for more serious renal toxicity with longer-term use, ketorolac is primarily used for shorter-term pain control. *Ibuprofen* and *naproxen* are options for patients who can tolerate oral medications. Ibuprofen has a shorter halflife and therefore requires more frequent dosing.

Titration of Sedative & Analgesic Dosing, Delirium, & Withdrawal Syndromes

Sedative analgesic and anxiolytic agents have a number of serious disadvantages, including short- and long-term cognitive deficits, an increased risk of delirium, and withdrawal syndromes. Daily interruption of all continuous sedation with titrated reintroduction as necessary has been shown in adult ICU patients to dramatically reduce the duration of mechanical ventilation and length of stay in the ICU. Similar data are not yet available for pediatric patients. Another proposed intervention to decrease sedation use in children is protocolized, nurse-driven sedation goals. A recent large multicenter, randomized study of this approach in pediatrics demonstrated decreased overall opioid exposure but failed to show a decreased length of mechanical ventilation. The untoward effects of sedation in critically ill children remain a concern and, in general, doses of these agents should be titrated downward daily to the minimum required doses.

Standardized scales have been developed to assist in the titration of sedatives and analgesics in children. In the awake and verbal patient, a pain scale can be used to determine the level of pain and need for treatment. In a nonverbal patient, this assessment can be more difficult, and the medical team may need to depend upon changes in physiologic parameters such as HR and blood pressure to indicate pain and the effect of treatment. When using these measures, however, the provider should also exclude or address physiologic causes of agitation, such as hypoxemia, hypercapnia, or cerebral hypoperfusion caused by low cardiac output.

Several scoring systems are available to assess the level of sedation and help guide sedation management decisions. These include the Ramsay scale, the COMFORT score, and the State Behavioral Scale (SBS). The SBS is the most recently developed and has been validated for infants and children who are mechanically ventilated. Utilizing such a measurement tool allows for better communication among team members with regard to the goals of treatment and the effectiveness of any changes in sedation plan.

As with adult patients, critically ill children are at risk for developing *delirium* while in the ICU. Delirium may present with a wide variety of symptoms, commonly grouped as hypoactive or hyperactive. Hyperactive delirium is associated with restlessness, agitation, emotional lability and combativeness. Hypoactive delirium, on the other hand, may be more difficult to recognize; patients may be quiet, withdrawn, and apathetic with decreased responsiveness. Parents may notice their child's personality is quite different from baseline. A newly developed PICU delirium scale (Pediatric Confusion Assessment Method for the ICU [pCAM-ICU]) may help better assess for delirium in the PICU population.

In critically ill children, as in adults, the risk of developing delirium appears to increase with severity of illness, administration of sedative medications such as benzodiazepines, and greater sleep disturbances. Suggested strategies for preventing and treating delirium include reducing sedative exposure, promoting normal circadian rhythms with greater activity during the day and quiet, dark rooms at night, and ensuring the presence of parents and objects familiar to the child. Finally, in more extreme situations, treatment with medications can be considered. Quetiapine is a newer antipsychotic agent that has shown promise in early studies for treating pediatric delirium. Older antipsychotics such as haloperidol are still used at times but their side effect profile demands caution. Benzodiazepines may calm the patient but also may induce a paradoxical reaction. Dexmedetomidine may also be an effective medication for treatment of delirium but this use has not been well studied in the pediatric population.

Withdrawal syndromes are another important aspect of the use of sedative and analgesic agents in the ICU. Longterm administration and high doses of continuous infusions of opioids or benzodiazepines can lead to tolerance and physical dependence. Acute reductions or cessation of these medications can result in withdrawal symptoms such as agitation, tachypnea, tachycardia, sweating, and diarrhea. The risk of withdrawal varies among individuals, but the longer patients receive opiates or benzodiazepines, the more likely they are to have withdrawal symptoms. Gradual tapering of the medication dosage over 7-10 days often effectively prevents withdrawal symptoms. This gradual reduction may be facilitated by transitioning to intermittent dosing of longer half-life agents, such as methadone or lorazepam. While weaning opiates or benzodiazepines, providers should assess daily for symptoms of withdrawal. This assessment can be facilitated by symptom scores such as the Withdrawal Assessment Tool-1 (WAT-1). A higher WAT-1 score suggests greater withdrawal symptoms and may indicate a need to slow the weaning plan. Conversely, if the WAT-1 score is consistently low, the patient is likely to tolerate the current pace or, possibly, an accelerated dose reduction.

END-OF-LIFE CARE & DEATH IN THE PICU

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- End-of-life discussions in the PICU should include the patient, if possible, and family members as well as the medical team.
- PICU providers may assist in defining the limits of care provided, facilitating withdrawal of life support, and providing compassionate palliative care.

- The palliative care and ethics teams, if available, may facilitate end-of-life discussions in the PICU.
- Withdrawal of life-sustaining therapies should include a plan to treat any pain and discomfort in the patient.
- Brain death determination requires a systematic and age-appropriate evaluation consistent with institutional policies.
- Tissue and organ donation must be considered with every death.
- Grief/bereavement support for the family as well as medical team members should be provided following every death in the PICU.

Death in the PICU

In-hospital pediatric deaths occur infrequently. A large proportion of pediatric deaths occur in the PICU, however, and pediatric intensivists may be called upon to help define the limits to care provided, assist in the withdrawal of life-sustaining medical therapies (LSMTs), and provide compassionate palliative care. End-of-life discussions may have occurred prior to PICU admission for some children with congenital or chronic diseases. For other children, their PICU stay may be the first time a child or family discusses end-of-life decisions. Regardless of the individual patient's situation, the medical team has a responsibility to facilitate discussions regarding the goals of care in an honest and sensitive manner.

Deaths without any limitations on patient care comprise a small minority (10%–12%) of pediatric ICU deaths. In these circumstances, most recent studies have found greater family satisfaction with the care provided if family members are allowed to witness ongoing resuscitative efforts. The remainder of pediatric deaths is divided between brain death declarations (23%) and decisions to limit or withdraw medical care (65%).

🕨 Brain Death

Patients with severe neurologic injuries may meet the criteria for a diagnosis of brain death. The concept of brain death arose when advances in ICU technologies allowed heart and lung function to be supported even in the absence of any discernible brain activity. Brain death is diagnosed by a clinical examination (Table 14–18) based on published guidelines and is recognized as legally equivalent to somatic (cardiopulmonary) death in all 50 US states. The general approach to the diagnosis of brain death is similar in most medical centers, but subtle institutional variations make it imperative for PICU providers to be familiar with their own institutional policies on brain death declaration. Once a patient is declared legally brain dead, further medical support is no

CHAPTER 14

Table 14–18. Brain death examination.

- Patient must have normal blood pressure, core temperature > 35°C, normal electrolytes and glucose, and not be receiving sedating medications or muscle relaxants.
- 24-h waiting period suggested following CPR or severe brain injury before first brain death exam.
- · Flaccid coma with no evidence of cortical function.
- Absence of brain stem reflexes:
- Apnea ("apnea test": no respirations seen with PaCO₂ > 60 mm Hg and a change in PaCO₂ > 20 mm Hg).
- Fixed dilated pupils with no response to light.
- · Absence of corneal reflexes.
- Absence of eye movements including spontaneous, oculocephalic (doll's eye), or oculovestibular (cold caloric). Do not perform oculocephalic maneuver if there is potential for cervical spine injury.
- Absence of gag and cough reflex.
- Examination consistent throughout observation period as documented by two separate clinical examinations by two different attending physicians.
- Recommended observation periods between brain death examinations:
- Term newborn to 30 d old—24 h
- 31 d-18 y-12 h
- Ancillary testing (cerebral angiography, radionuclide scanning, electroencephalography, or transcranial Doppler ultrasonography) recommended if unable to perform cranial nerve examination or apnea testing due to patient instability or injuries.

longer indicated, although the timing of discontinuation of mechanical life support should be discussed and agreed upon with the patient's family.

Brain death is determined through a complete clinical assessment of the patient. First and foremost, the provider must be confident that the patient's condition is irreversible and must exclude any potentially reversible conditions that may produce signs similar to brain death. These may include hypotension, hypothermia, or the presence of excessive doses of sedating medications. The brain death examination is a formal clinical examination directed at demonstrating the absence of cortical function (flaccid coma without evidence of response to stimuli) and brainstem function (cranial nerve testing). In order to meet the definition of brain death, guidelines require that qualified physicians document two separate clinical examinations consistent with brain death (ie, no evidence of brain function) separated by a period of observation. If a patient cannot tolerate some portion of the clinical examination (typically apnea testing) or is very young (especially < 1 year of age), an ancillary test such as EEG or cerebral perfusion scan may provide supporting evidence of brain death. Once a child has been declared brain dead, the time of death is noted as occurring at the

completion of the second examination even if the child is still receiving cardiopulmonary support.

Limitation or Withdrawal of Medical Care

Most patients who die in the pediatric ICU will do so following a decision to limit or withdraw medical support rather than via a brain death declaration. The discussions leading to these decisions should include the patient (to the extent possible given their medical condition and developmental age), family members, and members of the medical team. The primary goals of these discussions should be to (1) communicate information regarding the patient's medical status and anticipated prognosis and (2) clarify the goals of ongoing medical care both in regard to the patient's current status and in the event of an acute decompensation. If the opinion of the medical team is that the patient's condition is likely irreversible, the options for care include (1) continuing current support with escalation as deemed medically reasonable by the health care team; (2) continuing current support but not adding any new therapies; (3) withdrawal of life-sustaining therapies such as mechanical ventilation and hemodynamic support. The first two options may include a decision to withhold cardiopulmonary resuscitation in the event of a respiratory or cardiac arrest (Do Not Attempt Resuscitation [DNAR]). The third option presumes a DNAR but this must be explicitly written in the medical record and communicated to team members.

Discussions with patients and families regarding the decision to limit resuscitation or to withdraw LSMT should be conducted by experienced personnel with the ability to communicate in a clear and compassionate manner and should occur at an appropriate time and place. Cultural needs should be considered prior to major discussions and may include the need for a translator or spiritual guidance. Discussions should begin with a clear statement that the goal is to make decisions in the best interest of the patient and that the health care team will support the patient and family in making reasonable decisions based on that goal. Potential options regarding limitations of care or withdrawal of care should be clearly explained for the decision makers. Withdrawal of LSMT can be considered when the pain and suffering inflicted by prolonging and supporting life outweighs the potential benefit for the individual. If there is no reasonable chance of recovery, the patient has the right to a natural death in a dignified and pain-free manner. The health care team should emphasize that decisions are not irrevocable and that if at any time the family or health care providers wish to reconsider the decision, full medical therapy can be reinstituted until the situation is clarified.

Prior to the withdrawal of LSMT, the patient's family and care team should be prepared for the physiologic process of dying that the child will undergo. Key facets of the process to discuss include the possibility of agonal respirations, which can be disturbing to witness for family members and care providers, as well as the unpredictable length of time that the process may require. Additionally, the fact that patient will ultimately have a cardiopulmonary arrest and a member of the medical team will declare the time of death should be discussed. The family should also be reassured that the patient will be given appropriate doses of medications to treat signs and symptoms of pain or discomfort and that neither they nor the patient will be abandoned by the medical team during this process.

Palliative Care & Bioethics Consultation

Palliative care teams and ethics consultation services are important resources to help the health care team and families address difficult end-of-life decision making. For families of children with congenital or chronic diseases, the palliative care team may have established relationships with the patient and family during prior medical episodes. For patients with new conditions or whose prognosis has changed, the palliative care team may be newly introduced in the PICU. In either case, the palliative care team can bring invaluable support and resources for families during end-of-life discussions. If conflict arises, surrounding decisions about limiting medical care, an ethics consultation in the ICU setting can aid the process by helping to identify, analyze, and resolve ethical problems. Ethics consultation can independently clarify views and allow the health care team, patient, and family to make decisions that respect patient autonomy and promote maximum benefit and minimal harm to the patient.

A more comprehensive discussion of palliative care can be found elsewhere in this book. Briefly, palliative care medicine has developed as a specialized field of practice to address the needs of dying children or children with a shortened lifespan. Many centers have developed palliative care teams that include medical personnel, social workers, and spiritual leaders to help families navigate the difficult process of dying and end-of-life decision making, including withdrawal of support. Once the decision is made to limit or withdraw LSMT, a palliative care plan should be agreed on by all decision makers, clarified to other health care providers and instituted with the primary goal of optimizing the patient's and family's experience prior to and following death. The plan, at minimum, should address (1) adequate pain control and sedation, (2) provision of warmth and cleanliness, and (3) ongoing patient and family support and dignity.

Tissue & Organ Donation

Organ transplantation is standard therapy for many pediatric conditions and many children die while awaiting a transplant due to short supply of organs. The gift of organ donation can be a positive outcome for a family from the otherwise tragic loss of their child's life. The 1986 U.S. Federal Required Request Law mandates that all donor-eligible families be approached about potential organ donation. The decision to donate must be made free of coercion, with informed consent, and without financial incentive. The state organ-procurement agencies provide support and education to care providers and families to make informed decisions.

To be a solid-organ donor, the patient must be declared dead and have no conditions contraindicating donation. The most frequent type of solid-organ donor in the PICU is a brain dead donor. The unmet demand for donor organs has, however, led to the emergence of protocols for procuring solid organs from non-heart-beating donors. Although this practice has been described by many terms including Donation after Cardiac Death, the most recent nomenclature is Donation after Circulatory Determination of Death (DCDD). In these cases, the patient does not meet brain death criteria but has an irreversible disease process and the family or patient has decided to withdraw life-sustaining therapy and consented to attempted organ donation. In the DCDD process, LSMT is withdrawn and comfort measures are provided as per usual care. The withdrawal of care may take place in the PICU or the operating room without any surgical staff present, depending upon institutional policy. Once the declaring physician has determined cessation of cardiac function, the patient is observed for an additional short time period for auto-resuscitation (the return of cardiac activity without medical intervention). After this waiting period, the patient is declared dead and the organs are immediately harvested for donation. If the patient does not die within a predetermined time limit after discontinuation of LSMT, comfort measures continue but solid-organ donation is abandoned due to unacceptably long ischemic times.

Tissue (heart valves, corneas, skin, and bone) can be donated following a "traditional" cardiac death (no pulse or respirations), brain death, or DCDD.

Bereavement & Grief Support

After any pediatric death, bereavement and grief support for families and health care providers are essential components of comprehensive end-of-life care. Families may need information about care of the body after the death, funeral arrangements, and autopsy decisions as well as about educational, spiritual, and other supportive resources available. Members of the medical team may feel their own grief and sense of loss with the death of a patient. These emotions, if not appropriately addressed, can negatively affect their personal and professional lives. Therefore, similar supportive services should be available to health care workers caring for dying children.

QUALITY IMPROVEMENT INITIATIVES IN THE PICU

Given the complexity of both the illnesses faced and the care provided in PICUs, these environments are among the most susceptible to medical error. As a result, critical care units also tend to be the areas that are likely to benefit from quality improvement and patient safety initiatives. National and local reporting requirements for a number of hospital-acquired conditions, such as central line-associated bloodstream infections, catheter-associated urinary tract infections, pressure injuries, and venous thromboembolisms, have led to the development of national collaboratives focused on data gathering and sharing of best practices for prevention of those conditions. Improving quality and safety practices relies on creating both a culture of awareness and safe reporting of adverse events and tools or workflows designed to help reduce the likelihood of error. As an example, multipronged efforts to reduce catheter-related bloodstream infections include checklists or tools to ensure strict adherence to sterile procedure during catheter insertion, sterile practice when accessing the catheter during care, reductions in the number of times the catheter is accessed, and removal of catheters at the earliest safe opportunity. More recent efforts have begun to focus on early identification and treatment of sepsis using defined diagnostic triggers and order sets. Most of the data supporting these interventions have been derived from adult ICU populations, and, to date, few large-scale studies have been published documenting efficacy of these measures in the pediatric ICU population. Data that are available suggest that these initiatives are beneficial, although additional studies will likely be needed to refine and optimize these approaches in the pediatric ICU setting.

GENERAL PRINCIPLES

DIAGNOSIS OF SKIN DISORDERS

Examination of the skin requires that the entire surface of the body be palpated and inspected in good light. The onset and duration of each symptom should be recorded, together with a description of the primary lesion and any secondary changes, using the terminology in Table 15–1. In practice, characteristics of skin lesions are described in an order opposite to that shown in the table. Begin with distribution, then configuration, color, secondary changes, and primary changes. For example, guttate psoriasis could be described as "generalized, discrete, red, or scaly papules."

TREATMENT OF SKIN DISORDERS

Topical Therapy

Treatment should be simple and aimed at preserving normal skin physiology. Topical therapy is often preferred because medication can be delivered in optimal concentrations to the desired site.

Water is an important therapeutic agent, and optimally hydrated skin is soft and smooth. This occurs at approximately 60% environmental humidity. Because water evaporates readily from the cutaneous surface (epidermal stratum corneum), skin hydration is dependent on the water concentration in the air, and sweating contributes little. However, if sweat is prevented from evaporating (eg, in the axilla, groin), local humidity and hydration of the skin are increased. As humidity falls below 15%–20%, the stratum corneum shrinks and cracks; the epidermal barrier is lost and allows irritants to enter the skin and induce an inflammatory response. Decrease in transepidermal water loss will correct this condition. Therefore, dry and scaly skin is treated by using barriers to prevent evaporation. Oils and ointments prevent evaporation for 8–12 hours, so they must be applied once or twice a day. In areas already occluded (axilla, diaper area), creams or lotions are preferred, but more frequent application may be necessary.

Overhydration (maceration) can also occur. As environmental humidity increases to 90%–100%, the number of water molecules absorbed by the stratum corneum increases and the tight lipid junctions between the cells of the stratum corneum are gradually replaced by weak hydrogen bonds. The cells eventually become widely separated, and the epidermal barrier falls apart. This occurs in immersion foot, diaper areas, axillae, and the like. It is desirable to enhance evaporation of water in these areas by air drying.

Wet Dressings

By placing the skin in an environment where the humidity is 100% and allowing the moisture to evaporate to 60%, pruritus is relieved. Evaporation of water stimulates colddependent nerve fibers in the skin, and this may prevent the transmission of the itching sensation via pain fibers to the central nervous system (CNS). It also is vasoconstrictive, thereby helping to reduce the erythema and also decreasing the inflammatory cellular response.

The simplest form of wet dressing consists of one set of wet underwear (eg, long johns) worn under dry pajamas. Cotton socks are also useful for hand or foot treatment. The underwear should be soaked in warm (not hot) water and wrung out until no more water can be expressed. Dressings can be worn overnight for a few days up to 1 week. When the condition improves, wet dressings are discontinued.

Topical Glucocorticoids

Twice-daily application of topical corticosteroids is the mainstay of treatment for all forms of dermatitis (Table 15–2). Topical steroids can also be used under wet dressings. After
Table 15–1. Examination of the skin.

Clinical Appearance	Description and Examples
Primary lesions (first to appea	r)
Macule	Any flat circumscribed color change in the skin < 1 cm. Examples: white (vitiligo), brown (junctional nevus), purple (petechia).
Patch	Any flat circumscribed color change in the skin > 1 cm. Examples: white (nevus depigmentosa), brown (café au lait macule), purple (purpura).
Papule	A solid, elevated area < 1 cm in diameter whose top may be pointed, rounded, or flat. Examples: acne, warts, small lesions of psoriasis.
Plaque	A solid, circumscribed area > 1 cm in diameter, usually flat-topped. Example: psoriasis.
Vesicle	A circumscribed, elevated lesion < 1 cm in diameter and containing clear serous fluid. Example: blisters of herpes simplex.
Bulla	A circumscribed, elevated lesion > 1 cm in diameter and containing clear serous fluid. Example: bullous impetigo.
Pustule	A vesicle containing a purulent exudate. Examples: acne, folliculitis.
Nodule	A deep-seated mass with indistinct borders that elevates the overlying epidermis. Examples: tumors, granuloma annulare. If it moves with the skin on palpation, it is intradermal; if the skin moves over the nodule, it is subcutaneous.
Wheal	A circumscribed, flat-topped, firm elevation of skin resulting from tense edema of the papillary dermis. Example: urticaria.
Secondary changes	
Scales	Dry, thin plates of keratinized epidermal cells (stratum corneum). Examples: psoriasis, ichthyosis.
Lichenification	Induration of skin with exaggerated skin lines and a shiny surface resulting from chronic rubbing of the skin. Example: chronic atopic dermatitis.
Erosion and oozing	A moist, circumscribed, slightly depressed area representing a blister base with the roof of the blister removed. Examples: burns, impetigo. Most oral blisters present as erosions.
Crusts	Dried exudate of plasma on the surface of the skin following disruption of the stratum corneum. Examples: impetigo, contact dermatitis.
Fissures	A linear split in the skin extending through the epidermis into the dermis. Example: angular cheilitis.
Scars	A flat, raised, or depressed area of fibrotic replacement of dermis or subcutaneous tissue. Examples: acne scar, burn scar.
Atrophy	Depression of the skin surface caused by thinning of one or more layers of skin. Example: lichen sclerosus.
Color	
	The lesion should be described as white, red, yellow, brown, tan, or blue. Particular attention should be given to the blanching of red lesions. Failure to blanch suggests bleeding into the dermis (petechiae).
Configuration of lesions	
Annular (circular)	Annular nodules represent granuloma annulare; annular scaly papules are more apt to be caused by dermatophyte infections.
Linear (straight lines)	Linear papules represent lichen striatus; linear vesicles, incontinentia pigmenti; linear papules with burrows, scabies.
Grouped	Grouped vesicles occur in herpes simplex or zoster.
Discrete	Discrete lesions are independent of each other.
Distribution	
	Note whether the eruption is generalized, acral (hands, feet, buttocks, face), or localized to a specific skin region.

Glucocorticoid	Concentrations		
Low potency ^a = 1–9			
Hydrocortisone	0.5%, 1%, 2.5%		
Desonide	0.05%		
Moderate potency = 10–99			
Mometasone furoate	0.1%		
Hydrocortisone valerate	0.2%		
Fluocinolone acetonide	0.025%		
Triamcinolone acetonide	0.01%		
Amcinonide	0.1%		
High potency = 100–499			
Desoximetasone	0.25%		
Fluocinonide	0.05%		
Halcinonide	0.1%		
Super potency = 500–7500			
Betamethasone dipropionate	0.05%		
Clobetasol propionate	0.05%		

Table 15–2. Topical glucocorticoids.

^a1% hydrocortisone is defined as having a potency of 1.

wet dressings are discontinued, topical steroids should be applied only to areas of active disease. They should not be applied to normal skin to prevent recurrence. Only lowpotency steroids (see Table 15–2) are applied to the face or intertriginous areas.

DISORDERS OF THE SKIN IN NEWBORNS

TRANSIENT DISEASES IN NEWBORNS

1. Milia

Milia are tiny epidermal cysts filled with keratinous material. These 1- to 2-mm white papules occur predominantly on the face in 40% of newborns. Their intraoral counterparts are called Epstein pearls and occur in up to 60%–85% of neonates. These cystic structures spontaneously rupture and exfoliate their contents.

2. Sebaceous Gland Hyperplasia

Prominent white to yellow papules at the opening of pilosebaceous follicles without surrounding erythema—especially over the nose—represent overgrowth of sebaceous glands in response to maternal androgens. They occur in more than half of newborns and spontaneously regress in the first few months of life.

3. Neonatal Acne

Inflammatory papules and pustules with occasional comedones predominantly on the face occur in as many as 20% of newborns. Although neonatal acne can be present at birth, it most often occurs between 2 and 4 weeks of age. Spontaneous resolution occurs over a period of 6 months to 1 year. A rare entity that is often confused with neonatal acne is **neonatal cephalic pustulosis**. This is a more monomorphic eruption with red papules and pustules on the head and neck that appears in the first month of life. There is associated neutrophilic inflammation and yeasts of the genus *Malassezia (Pityrosporum)*. This eruption will resolve spontaneously but responds to topical antiyeast preparations.

4. Harlequin Color Change

A cutaneous vascular phenomenon unique to neonates in the first week of life occurs when the infant (particularly one of low birth weight) is placed on one side. The dependent half develops an erythematous flush with a sharp demarcation at the midline, and the upper half of the body becomes pale. The color change usually subsides within a few seconds after the infant is placed supine but may persist for as long as 20 minutes.

5. Mottling

A lacelike pattern of bluish, reticular discoloration representing dilated cutaneous vessels appears over the extremities and often the trunk of neonates exposed to lowered room temperature. This feature is transient and usually disappears completely on rewarming.

6. Erythema Toxicum

Up to 50% of full-term infants develop erythema toxicum. At 24–48 hours of age, blotchy erythematous macules 2–3 cm in diameter appear, most prominently on the chest but also on the back, face, and extremities. These are occasionally present at birth. Onset after 4–5 days of life is rare. The lesions vary in number from a few up to as many as 100. Incidence is much higher in full-term versus premature

infants. The macular erythema may fade within 24–48 hours or may progress to formation of urticarial wheals in the center of the macules or, in 10% of cases, pustules. Examination of a Wright-stained smear of the lesion reveals numerous eosinophils. No organisms are seen on Gram stain. These findings may be accompanied by peripheral blood eosinophilia of up to 20%. The lesions fade and disappear within 5–7 days. Transient neonatal pustular melanosis is a pustular eruption in newborns of African-American descent. The pustules rupture leaving a collarette of scale surrounding a macular hyperpigmentation. Unlike erythema toxicum, the pustules contain mostly neutrophils and often involve the palms and soles.

7. Sucking Blisters

Bullae, either intact or as erosions (representing the blister base) without inflammatory borders, may occur over the forearms, wrists, thumbs, or upper lip. These presumably result from vigorous sucking in utero. They resolve without complications.

8. Miliaria

Obstruction of the eccrine sweat ducts occurs often in neonates and produces one of two clinical scenarios. Superficial obstruction in the stratum corneum causes miliaria crystallina, characterized by tiny (1- to 2-mm), superficial grouped vesicles without erythema over intertriginous areas and adjacent skin (eg, neck, upper chest). More commonly, obstruction of the eccrine duct deeper in the epidermis results in erythematous grouped papules in the same areas and is called miliaria rubra. Rarely, these may progress to pustules. Heat and high humidity predispose the patient to eccrine duct pore closure. Removal to a cooler environment is the treatment of choice.

9. Subcutaneous Fat Necrosis

This entity presents in the first 7 days of life as reddish or purple, sharply circumscribed, firm nodules occurring over the cheeks, buttocks, arms, and thighs. Cold injury is thought to play an important role, and the clinical manifestations have been observed after iatrogenically induced and therapeutic hypothermia. These lesions resolve spontaneously over a period of weeks, although in some instances they may calcify. Affected infants should be screened for hypercalcemia.

- Blume-Peytavi U et al: Skin care practices for newborns and infants: review of the clinical evidence for best practices. Pediatr Dermatol 2012 Jan–Feb;29(1):1–14 [PMID: 22011065].

PIGMENT CELL BIRTHMARKS, NEVI, & MELANOMA

Birthmarks may involve an overgrowth of one or more of any of the normal components of skin (eg, pigment cells, blood vessels, lymph vessels). A nevus is a hamartoma of highly differentiated cells that retain their normal function.

1. Mongolian Spot

A blue-black macule found over the lumbosacral area in 90% of infants of Native-American, African-American, and Asian descent is called a "mongolian spot." A more descriptive term is "dermal melanocytosis." These spots are occasionally noted over the shoulders and back and may extend over the buttocks. Histologically, they consist of spindle-shaped pigment cells suspended deep in the dermis. The lesions fade somewhat with time as a result of darkening of the overlying skin, but some traces may persist into adult life.

2. Café au Lait Macule

A café au lait macule is a light-brown, oval macule (dark brown on brown or black skin) that may be found anywhere on the body. Café au lait spots over 1.5 cm in greatest diameter are found in 10% of white and 22% of black children. These lesions persist throughout life and may increase in number with age. The presence of six or more such lesions over 1.5 cm in greatest diameter is a major diagnostic criterion for neurofibromatosis type 1 (NF-1). Patients with McCune-Albright syndrome (see Chapter 34) have a large, unilateral café au lait macule.

3. Spitz Nevus

A Spitz nevus presents as a reddish-brown smooth solitary papule appearing on the face or extremities. Histologically, it consists of epithelioid and spindle-shaped nevomelanocytes that may demonstrate nuclear pleomorphism. Although these lesions can look concerning histologically, they follow a benign clinical course in most cases.

MELANOCYTIC NEVI

1. Common Moles

Well-demarcated, brown to brown-black macules represent junctional nevi. They can appear in the first years of life and increase with age. Histologically, single and nested melanocytes are present at the junction of the epidermis and dermis. Approximately 20% may progress to compound nevi—papular lesions with melanocytes both in junctional and intradermal locations. Intradermal nevi are often lighter in color and can be fleshy and pedunculated. Melanocytes in

SKIN

these lesions are located purely within the dermis. Nevi look dark blue (blue nevi) when they contain more deeply situated spindle-shaped melanocytes in the dermis.

2. Melanoma

Melanoma in prepubertal children is very rare. Pigmented lesions with variegated colors (red, white, blue), notched borders, asymmetrical shape, and very irregular or ulcerated surfaces should prompt suspicion of melanoma. Ulceration and bleeding are advanced signs of melanoma. If melanoma is suspected, wide local excision and pathologic examination should be performed.

3. Congenital Melanocytic Nevi

One in 100 infants is born with a congenital nevus. Congenital nevi tend to be larger and darker brown than acquired nevi and may have many terminal hairs. If the pigmented plaque covers more than 5% of the body surface area, it is considered a giant or large congenital nevus; these large nevi occur in 1 in 20,000 infants. Other classification systems characterize lesions over 20 cm as large. Often the lesions are so large they cover the entire trunk (bathing trunk nevi). Histologically, they are compound nevi with melanocytes often tracking around hair follicles and other adnexal structures deep in the dermis. The risk of malignant melanoma in small congenital nevi is controversial in the literature, but most likely very low, and similar to that of acquired nevi. Transformation to malignant melanoma in giant congenital nevi has been estimated between 1% and 7%. Of note, these melanomas often develop early in life (before puberty) and in a dermal location. Two-thirds of melanomas in children with giant congenital nevi develop in areas other than the skin.

- Simons EA: Congenital melanocytic nevi in young children: Histopathologic features and clinical outcomes. J Am Acad Dermatol Feb 2017; Epub ahead of print.

VASCULAR BIRTHMARKS

1. Capillary Malformations

Clinical Findings

Capillary malformations are an excess of capillaries in localized areas of skin. The degree of excess is variable. The color of these lesions ranges from light red-pink to dark red.

Nevus simplexes are the light red macules found over the nape of the neck, upper eyelids, and glabella of newborns. Fifty percent of infants have such lesions over their necks. Eyelid and glabellar lesions usually fade completely within the first year of life. Lesions that occupy the total central forehead area usually do not fade. Those on the neck persist into adult life.

Port-wine stains are dark red macules appearing anywhere on the body. A bilateral facial port-wine stain or one covering the entire half of the face may be a clue to Sturge-Weber syndrome, which is characterized by seizures, mental retardation, glaucoma, and hemiplegia (see Chapter 25). Most infants with smaller, unilateral facial port-wine stains do not have Sturge-Weber syndrome. Similarly, a port-wine stain over an extremity may be associated with hypertrophy of the soft tissue and bone of that extremity (Klippel-Trénaunay syndrome).

Treatment

The pulsed dye laser is the treatment of choice for infants and children with port-wine stains.

Richter GT, Friedman AB: Hemangiomas and vascular malformations: current theory and management. Int J Pediatr 2012;2012:645–678 [PMID: 22611412].

2. Hemangioma

Clinical Findings

A red, rubbery vascular plaque or nodule with a characteristic growth pattern is a hemangioma. The lesion is often not present at birth but is represented by a permanent blanched area on the skin that is supplanted at age 2-4 weeks by red papules. Hemangiomas then undergo a rapid growth or "proliferative" phase, where growth of the lesion is out of proportion to growth of the child. At 9-12 months, growth stabilizes, and the lesion slowly involutes over the next several years. Histologically, hemangiomas are benign tumors of capillary endothelial cells. They may be superficial, deep, or mixed. The terms strawberry and cavernous are misleading and should not be used. The biologic behavior of a hemangioma is the same despite its location. Fifty percent reach maximal regression by age 5 years, 70% by age 7 years, and 90% by age 9 years, leaving redundant skin, hypopigmentation, and telangiectasia. Local complications include superficial ulceration and secondary pyoderma. Rare complications include obstruction of vital structures such as the orbit or airway.

Treatment

Complications that require immediate treatment are (1) visual obstruction (with resulting amblyopia), (2) airway

CHAPTER 15

obstruction (hemangiomas of the head and neck ["beard hemangiomas"] may be associated with subglottic hemangiomas), and (3) cardiac decompensation (high-output failure). Historically, the preferred treatment for complicated hemangiomas was systemic prednisolone. Currently, oral propranolol (2 mg/kg/day divided bid) has replaced systemic steroids as the treatment of choice at most institutions. Reported side effects are sleep disturbance, hypoglycemia, and bradycardia. Recommendations on pretreatment cardiac evaluation vary between institutions. The topical β-adrenergic receptor antagonist timolol, administered as a gel-forming solution (GFS), has also been used for problematic lesions on the lip or eyelid, with variable results. If the lesion is ulcerated or bleeding, pulsed dye laser treatment is indicated to initiate ulcer healing and immediately control pain. The Kasabach-Merritt syndrome, characterized by platelet trapping with consumption coagulopathy, does not occur with solitary cutaneous hemangiomas. It is seen only with internal hemangiomas or the rare vascular tumors such as kaposiform hemangioendotheliomas and tufted angiomas.

- Raphael MF et al: Is cardiovascular evaluation necessary prior to and during beta-blocker therapy for infantile hemangiomas? A cohort study. J Am Acad Dermatol 2015 Mar;72(3):465–472 [PMID: 25592625].
- Semkova K, Kazandjieva J: Rapid complete regression of an early infantile hemangioma with topical timolol gel. Int J Dermatol 2014 Feb;53(2):241–242 [PMID: 24261914].
- Smithson SL: Consensus statement for the treatment of infantile haemangiomas with propranolol. Australas J Dermatol Mar 1, 2017; Epub ahead of print.

3. Lymphatic Malformations

Lymphatic malformations may be superficial or deep. Superficial lymphatic malformations present as fluid-filled vesicles often described as resembling "frog spawn." Deep lymphatic malformations are rubbery, skin-colored nodules occurring most commonly in the head and neck. They often result in grotesque enlargement of soft tissues. Histologically, they can be either macrocystic or microcystic.

Treatment

Therapy includes sclerotherapy with injection of picibanil, or doxycycline, radiotherapy, or surgical excision.

EPIDERMAL BIRTHMARKS

1. Epidermal Nevus

Clinical Findings

The majority of these birthmarks present in the first year of life. They are hamartomas of the epidermis that are warty to papillomatous plaques, often in a linear array. They range in color from skin-colored to dirty yellow to brown. Histologically they show a thickened epidermis with hyperkeratosis. The condition of widespread epidermal nevi associated with other developmental anomalies (CNS, eye, and skeletal) is called the epidermal nevus syndrome.

Treatment

Treatment once or twice daily with topical calcipotriene or keratolytic may flatten some lesions. The only definitive cure is surgical excision.

2. Nevus Sebaceous Clinical Findings

This is a hamartoma of sebaceous glands and underlying apocrine glands that is diagnosed by the appearance at birth of a yellowish, hairless plaque in the scalp or on the face. The lesions can be contiguous with an epidermal nevus on the face, and widespread lesions can constitute part of the epidermal nevus syndrome.

Histologically, nevus sebaceus represents an overabundance of sebaceous glands without hair follicles. At puberty, with androgenic stimulation, the sebaceous cells in the nevus divide, expand their cellular volume, and synthesize sebum, resulting in a warty mass.

Treatment

Because it has been estimated that approximately 15% of these lesions will develop secondary epithelial tumors, including basal cell carcinomas (BCCs), trichoblastomas, and other benign tumors, surgical excision at puberty is recommended by most experts. The majority of the tumors develop in adulthood, although BCCs have been reported in childhood and adolescence.

CONNECTIVE TISSUE BIRTHMARKS (JUVENILE ELASTOMA, COLLAGENOMA)

Clinical Findings

Connective tissue nevi are smooth, skin-colored papules 1–10 mm in diameter that are grouped on the trunk. A solitary, larger (5–10 cm) nodule is called a shagreen patch and is histologically indistinguishable from other connective tissue nevi that show thickened, abundant collagen bundles with or without associated increases of elastic tissue. Although the shagreen patch is a cutaneous clue to tuberous sclerosis (see Chapter 25), the other connective tissue nevi occur as isolated events.

Treatment

These nevi remain throughout life and need no treatment.

HEREDITARY SKIN DISORDERS

1. Ichthyosis

Ichthyosis is a term applied to several diseases characterized by the presence of excessive scales on the skin. These disorders represent a large and heterogeneous group of genetic and acquired defects of cornification of the skin. Classification of these diseases is clinically based, although the underlying genetic causes and pathophysiologic mechanisms responsible continue to be elucidated.

Disorders of keratinization are characterized as syndromic when the phenotype is expressed in the skin and other organs, or nonsyndromic when only the skin is affected. Ichthyoses may be inherited or acquired. Inherited disorders are identified by their underlying gene defect if known. Acquired ichthyosis may be associated with malignancy and medications, or a variety of autoimmune, inflammatory, nutritional, metabolic, infectious, and neurologic diseases. These disorders are diagnosed by clinical examination, with supportive findings on skin biopsy (including electron microscopy) and mutation analysis if available.

Treatment

Treatment consists of controlling scaling with ammonium lactate (Lac-Hydrin or AmLactin) 12% or urea cream 10%–40% applied once or twice daily. Daily lubrication and a good dry skin care regimen are essential.

Oji V et al: Revised nomenclature and classification of inherited ichthyoses: results of the First Ichthyosis Consensus Conference in Sorèze 2009. J Am Acad Dermatol 2010 Oct;63(4):607–641 [PMID: 20643494].

2. Epidermolysis Bullosa

This is a group of heritable disorders characterized by skin fragility with blistering. Four major subtypes are recognized, based on the ultrastructural level of skin cleavage (Table 15–3).

For the severely affected, much of the surface area of the skin may have blisters and erosions, requiring daily wound care and dressings. These children are prone to frequent skin infections, anemia, growth problems, mouth erosions and esophageal strictures, and chronic pain issues. They are also at increased risk of squamous cell carcinoma, a common cause of death in affected patients.

Treatment

Treatment consists of protection of the skin with topical emollients as well as nonstick dressings. The other medical needs and potential complications of the severe forms of epidermolysis bullosa require a multidisciplinary approach. For the less severe types, protecting areas of greatest trauma with padding and dressings as well as intermittent topical or oral antibiotics for superinfection are appropriate treatments. If hands and feet are involved, reducing skin friction with 5% glutaraldehyde every 3 days is helpful.

Table 13-3. Major epidemolysis bullosa subtypes.				
Cleavage Level	Common Name	Targeted Protein(s)	Inheritance Pattern	Characteristic Clinical Features
Suprabasilar	Epidermolysis Bullosa Superficialis	Unknown	Autosomal dominant	Superficial erosions at birth; rare to no blistering
Suprabasilar	Plakophilin-deficient EB, Lethal acantholytic EB	Plakophilin, Desmoplakin	Autosomal recessive	Similar to above
Basilar	Epidermolysis bullosa simplex	Keratin 5 and 14	Autosomal dominant	Palm and sole blistering presents in early childhood with trauma
Basilar	EB simplex with muscular dystrophy	Plectin	Autosomal recessive	Blisters, muscular dystrophy
Basilar	EB with pyloric atresia	α-6 β-4 integrin	Autosomal recessive	Blisters, pyloric atresia
Junctional (within the basement mem- brane zone)	Junctional EB—Herlitz or non-Herlitz	Laminin 5, α-6 β-4 integrin, type XVII collagen	Autosomal recessive	Severe generalized blistering, oral involvement
Sub-basilar	Dystrophic EB or "dermolytic" EB	Type VII collagen	Autosomal dominant or recessive	Severe blisters and scarring

Fine JD et al: The classification of inherited epidermolysis bullosa (EB): report of the Third International Consensus Meeting on Diagnosis and Classification of EB. J Am Acad Dermatol 2008 Jun;58(6):931–950 [PMID: 18374450] [Epub 2008 Apr 18].

COMMON SKIN DISEASES IN INFANTS, CHILDREN, & ADOLESCENTS

ACNE

Acne affects 85% of adolescents. The onset of adolescent acne is between ages 7 and 10 years in 40% of children. The early lesions are usually limited to the face and are primarily closed comedones.

Pathogenesis

The primary event in acne formation is obstruction of the sebaceous follicle and subsequent formation of the microcomedo (not evident clinically). This is the precursor to all future acne lesions. This phenomenon is androgendependent in adolescent acne. The four primary factors in the pathogenesis of acne are (1) plugging of the sebaceus follicle, (2) increased sebum production, (3) proliferation of *Propionibacterium acnes* in the obstructed follicle, and (4) inflammation. Many of these factors are influenced by androgens.

Drug-induced acne should be suspected in teenagers if all lesions are in the same stage at the same time and if involvement extends to the lower abdomen, lower back, arms, and legs. Drugs responsible for acne include corticotropin (ACTH), glucocorticoids, androgens, hydantoins, and isoniazid, each of which increases plasma testosterone.

Clinical Findings

Open comedones are the predominant clinical lesion in early adolescent acne. The black color is caused by oxidized melanin within the stratum corneum cellular plug. Open comedones do not progress to inflammatory lesions. Closed comedones, or whiteheads, are caused by obstruction just beneath the follicular opening in the neck of the sebaceous follicle, which produces a cystic swelling of the follicular duct directly beneath the epidermis. Most authorities believe that closed comedones are precursors of inflammatory acne lesions (red papules, pustules, nodules, and cysts). In typical adolescent acne, several different types of lesions are present simultaneously. Severe, chronic, inflammatory lesions may rarely occur as interconnecting, draining sinus tracts. Adolescents with cystic acne require prompt medical attention, because ruptured cysts and sinus tracts result in severe scar formation.

Differential Diagnosis

Consider rosacea, nevus comedonicus, flat warts, miliaria, molluscum contagiosum, and the angiofibromas of tuberous sclerosis.

Treatment

Different treatment options are listed in Table 15–4. Recent data have indicated that combination therapy that targets multiple pathogenic factors increases the efficacy of treatment and rate of improvement.

A. Topical Keratolytic Agents

Topical keratolytic agents address the plugging of the follicular opening with keratinocytes and include retinoids, benzoyl peroxide, and azelaic acid. The first-line treatment for both comedonal and inflammatory acne is a topical retinoid (tretinoin [retinoic acid], adapalene, and tazarotene). These are the most effective keratolytic agents and have been shown to prevent the microcomedone. These topical agents may be used once daily, or the combination of a retinoid applied to acne-bearing areas of the skin in the evening and a benzoyl peroxide gel or azelaic acid applied in the morning

Table 15-4. Acne treatment.

Type of Lesion	Treatment
Comedonal acne	One of the following: Tretinoin, 0.025%, 0.05%, or 0.1% cream; 0.01% or 0.025% gel; 0.4% or 0.1% microgel Adapalene, 0.3% gel, 0.1% gel or solution; 0.05% cream
Papular inflammatory acne	One from first grouping, plus one of the following: Benzoyl peroxide, 2.5%, 4%, 5%, 8%, or 10% gel or lotion; 4% or 8% wash Azelaic acid, 15% or 20% cream Clindamycin, 1% lotion, solution, or gel Combination products include benzoyl peroxide-erythromycin (Benzamycin); benzoyl peroxide-clindamycin (Duac, BenzaClin, Acanya); tretinoin- clindamycin (Ziana, Veltin)
Pustular inflammatory acne	One from first grouping, plus one of the following oral antibiotics: Minocycline or doxycycline, 50–100 mg, bid
Nodulocystic acne	lsotretinoin, 1 mg/kg/day, goal dose 120–150 mg/kg total

may be used. This regimen will control $80\%{-}85\%$ of cases of a dolescent acne.

B. Topical Antibiotics

Topical antibiotics are less effective than systemic antibiotics and at best are equivalent in potency to 250 mg of tetracycline orally once a day. One percent clindamycin phosphate solution is the most efficacious topical antibiotic. Most P acnes strains are now resistant to topical erythromycin solutions. Topical antibiotic therapy alone should never be used. Multiple studies have shown a combination of benzovl peroxide or a retinoid and a topical antibiotic are more effective than the antibiotic alone. Benzoyl peroxide has been shown to help minimize the development of bacterial resistance at sites of application. The duration of application of topical antimicrobials should be limited unless benzoyl peroxide is used. Several combination products (benzoyl peroxide and clindamycin, tretinoin and clindamycin, adapalene and benzoyl peroxide) are available which may simplify the treatment regimen and increase patient compliance.

C. Systemic Antibiotics

Antibiotics that are concentrated in sebum, such as tetracycline, minocycline, and doxycycline, should be reserved for moderate to severe inflammatory acne. The usual dose of tetracycline is 0.5-1.0 g divided twice a day on an empty stomach; minocycline and doxycycline 50-100 mg taken once or twice daily can be taken with food. Monotherapy with oral antibiotics should never be used. Recent recommendations are that oral antibiotics should be used for a finite time period, and then discontinued as soon as there is improvement in the inflammatory lesions. The tetracycline antibiotics should not be given to children younger than 8 years of age due to the effect on dentition (staining of teeth). Doxycycline may induce significant photosensitivity, and minocycline can cause bluish-gray dyspigmentation of the skin, vertigo, headaches, and drug-induced lupus. These antibiotics have anti-inflammatory effects in addition to decreasing P acnes in the follicle.

D. Oral Retinoids

An oral retinoid, 13-*cis*-retinoic acid (isotretinoin), is the most effective treatment for severe cystic acne. The precise mechanism of its action is unknown, but apoptosis of sebocytes, decreased sebaceous gland size, decreased sebum production, decreased follicular obstruction, decreased skin bacteria, and general anti-inflammatory activities have been described. The initial dosage is 0.5–1 mg/kg/day. This therapy is reserved for severe nodulocystic acne, or acne recalcitrant to aggressive standard therapy. Side effects include dryness and scaling of the skin, dry lips, and, occasionally,

dry eyes and dry nose. Fifteen percent of patients may experience some mild achiness with athletic activities. Up to 10% of patients experience mild, reversible hair loss. Elevated liver enzymes and blood lipids have rarely been described. Acute depression and mood changes have been reported, but no definitive relationship to the drug has been proven. Most importantly, isotretinoin is teratogenic. Because of this and other potential side effects, it is not recommended unless strict adherence to the Food and Drug Administration (FDA) guidelines is ensured. The FDA has implemented a strict registration program (iPLEDGE) that must be used to obtain and/or prescribe isotretinoin.

E. Other Acne Treatments

Hormonal therapy (oral contraceptives) is often an effective option for girls who have perimenstrual flares of acne or have not responded adequately to conventional therapy. Adolescents with endocrine disorders such as polycystic ovary syndrome also see improvement of their acne with hormonal therapy. Oral contraceptives can be added to a conventional therapeutic regimen and should always be used in female patients who are prescribed oral isotretinoin unless absolute contraindications exist. There is growing data regarding the use of light, laser, and photodynamic therapy in acne. However, existing studies are of variable quality, and although there is evidence to suggest that these therapies offer benefit in acne, the evidence is not sufficient to recommend any device as monotherapy in acne.

F. Patient Education and Follow-up Visits

The multifactorial pathogenesis of acne and its role in the treatment plan must be explained to adolescent patients. Good general skin care includes washing the face consistently and using only oil-free, noncomedogenic cosmetics, face creams, and hair sprays. Acne therapy takes 8–12 weeks to produce improvement, and this delay must be stressed to the patient. Realistic expectations should be encouraged in the adolescent patient because no therapy will eradicate all future acne lesions. A written education sheet is useful. Follow-up visits should be made every 12–16 weeks. An objective method to chart improvement should be documented by the provider, because patients' assessment of improvement tends to be inaccurate.

BACTERIAL INFECTIONS OF THE SKIN

1. Impetigo

Erosions covered by honey-colored crusts are diagnostic of impetigo. Staphylococci and group A streptococci are important pathogens in this disease, which histologically consists of superficial invasion of bacteria into the upper epidermis, forming a subcorneal pustule.

Treatment

Impetigo should be treated with an antimicrobial agent effective against *Staphylococcus aureus* (β -lactamase–resistant penicillins or cephalosporins, clindamycin, amoxicillin–clavulanate) for 7–10 days. Topical mupirocin, polymyxin, gentamycin, and erythromycin are also effective. In severe and recalcitrant cases, skin swab for bacterial culture should be performed prior to initiation of empiric antibiotic therapy.

2. Bullous Impetigo

In bullous impetigo there is, in addition to the usual erosion covered by a honey-colored crust, a border filled with clear fluid. Staphylococci may be isolated from these lesions, and systemic signs of circulating exfoliatin are absent. Bullous impetigo lesions can be found anywhere on the skin, but a common location is the diaper area.

Treatment

Treatment with oral antistaphylococcal drugs for 7–10 days is effective. Application of cool compresses to debride crusts is a helpful symptomatic measure.

3. Ecthyma

Ecthyma is a firm, dry crust, surrounded by erythema that exudes purulent material. It represents invasion by group A β -hemolytic streptococci through the epidermis to the superficial dermis, therefore it is often referred as a deeper form of impetigo. This should not be confused with ecthyma gangrenosum. Lesions of ecthyma gangrenosum may be similar in appearance, but they are seen in a severely ill or immunocompromised patient and are due to systemic dissemination of bacteria, usually *Pseudomonas aeruginosa*, through the bloodstream.

Treatment

Treatment is with systemic penicillin.

4. Cellulitis

Cellulitis is characterized by erythematous, hot, tender, ill-defined, edematous plaques accompanied by regional

lymphadenopathy. Histologically, this disorder represents invasion of microorganisms into the lower dermis and sometimes beyond, with obstruction of local lymphatics. Group A β -hemolytic streptococci and coagulase-positive staphylococci are the most common causes; pneumococci and *Haemophilus influenzae* (in younger unvaccinated children) are rare causes. Staphylococcal infections are usually more localized and more likely to have a purulent center; streptococcal infections spread more rapidly, but these characteristics cannot be used to specify the infecting agent. An entry site of prior trauma or infection (eg, varicella, dermatophyte) is often present. Septicemia is a potential complication.

Treatment

Treatment is with an appropriate systemic antibiotic.

5. Folliculitis

A pustule at a follicular opening represents folliculitis. Deeper follicular infections are called furuncles (single follicle) and carbuncles (multiple follicles). Staphylococci and streptococci are the most frequent pathogens. Lesions are painless and tend to occur in crops, usually on the buttocks and extremities in children. Methicillin-resistant *Staphylococcus aureus* (MRSA) is now an increasing cause of folliculitis and skin abscesses. Cultures of persistent or recurrent folliculitis for MRSA are advisable.

Treatment

Treatment consists of measures to remove follicular obstruction—either warm, wet compresses for 24 hours or keratolytics such as those used for acne. Topical or oral antistaphylococcal antibiotics may be required.

6. Abscess

An abscess occurs deep in the skin, at the bottom of a follicle or an apocrine gland, and is diagnosed as an erythematous, firm, acutely tender nodule with ill-defined borders. Staphylococci are the most common organisms.

Treatment

Recent studies have suggested that incision and drainage alone may be adequate for uncomplicated MRSA skin abscesses in otherwise healthy patients. In more extensive cases adjuvant systemic antibiotics may be required.

7. Scalded Skin Syndrome

This entity consists of the sudden onset of bright red, acutely painful skin, most obvious periorally, periorbitally, and in the flexural areas of the neck, the axillae, the popliteal and

SKIN

antecubital areas, and the groin. The slightest pressure on the skin results in severe pain and separation of the epidermis (positive Nikolsky sign). The disease is caused by a circulating toxin (exfoliatin) elaborated by phage group II staphylococci. Exfoliatin binds to desmoglein-1 resulting in a separation of cells in the granular layer. The causative staphylococci may be isolated from the nasopharynx, an abscess, sinus, blood culture, joint fluid, or other focus of infection, but not from the skin.

Treatment

Treatment is with systemic antistaphylococcal drugs.

of methicillin-resistant and methicillin-sensitive *Staphylococcus aureus* in an outpatient dermatology facility. JAMA Dermatol 2013Apr;4(149):427–432 [PMID: 23325388].

FUNGAL INFECTIONS OF THE SKIN

1. Dermatophyte Infections

Dermatophytes become attached to the superficial layer of the epidermis, nails, and hair, where they proliferate. Fungal infection should be suspected with any red and scaly lesion.

Classification & Clinical Findings

A. Tinea Capitis

Thickened, broken-off hairs with erythema and scaling of underlying scalp are the distinguishing features (Table 15–5). Hairs are broken off at the surface of the scalp, leaving a "black dot" appearance. Diffuse scaling of the scalp and pustules are also seen. A boggy, fluctuant mass on the scalp called a kerion,

Table 15–5. Clinical features of tinea capitis.

Most Common Organisms	Clinical Appearance	Microscopic Appearance in KOH
Trichophyton tonsurans (90%)	Hairs broken off 2–3 mm from follicle; "black dot"; diffuse pustule; seborrheic dermatitis-like; no fluorescence	Hyphae and spores within hair
Microsporum canis (10%)	Thickened broken-off hairs that fluoresce yellow-green with Wood lamp	Small spores outside of hair; hyphae within hair

represents an exaggerated host response to the organism. *Microsporum canis* and *Trichophyton tonsurans* are the cause. Fungal culture should be performed in all cases of suspected tinea capitis.

B. Tinea Corporis

Tinea corporis presents either as annular marginated plaques with a thin scale at the periphery and clear center or as an annular confluent dermatitis. The most common organisms are *Trichophyton mentagrophytes*, *Trichophyton rubrum*, and *M canis*. The diagnosis is made by scraping thin scales from the border of the lesion, dissolving them in 20% potassium hydroxide (KOH), and examining for hyphae.

C. Tinea Cruris

Symmetrical, sharply marginated lesions in inguinal areas occur with tinea cruris. The most common organisms are *T rubrum*, *T mentagrophytes*, and *Epidermophyton floccosum*.

D. Tinea Pedis

Tinea pedis presents with red scaly soles, blisters on the instep of the foot, or fissuring between the toes. *T rubrum* and *T mentagrophytes* are the cause.

E. Tinea Unguium (Onychomycosis)

Loosening of the nail plate from the nail bed (onycholysis), giving a yellow discoloration, is the first sign of fungal invasion of the nails. Thickening of the distal nail plate then occurs, followed by scaling and a crumbly appearance of the entire nail plate surface. *T rubrum* is the most common cause. The diagnosis is confirmed by KOH examination and fungal culture. Usually only one or two nails are involved. If every nail is involved, psoriasis, lichen planus, or idiopathic trachyonychia is a more likely diagnosis than fungal infection.

Treatment

The treatment of dermatophytosis is quite simple: If hair is involved (ie, scalp infections), systemic therapy is necessary. Griseofulvin and terbinafine are both effective. Terbinafine does not work for *Microsporum canis*. Topical antifungal agents do not enter hair or nails in sufficient concentration to clear the infection. The absorption of griseofulvin from the gastrointestinal tract is enhanced by a fatty meal; thus, whole milk or ice cream taken with the medication increases absorption. The dosage of griseofulvin is 20 mg/kg/day divided BID (maximum 500 mg/dose). With hair infections, cultures should be done every 4 weeks, and treatment should be continued for 4 weeks following a negative culture result. The side effects are few, and the drug has been used successfully in the newborn period. Terbinafine dosing is (62.5 mg/day, < 20 kg-125 mg/day, 20-40 kg-250 mg/day, > 40 kg). For nails, daily administration of topical ciclopirox 8% (Penlac nail lacquer) can be considered, as can terbinafine for 6-12 weeks or pulsed-dose itraconazole (50 mg/twice a day < 20 kg-100 mg/twice a day, 20-40 kg-200 mg/twice a day, > 40 kg) given in three 1-week pulses separated by 3 weeks.

Tinea corporis, tinea pedis, and tinea cruris can be treated effectively with topical medication after careful inspection to make certain that the hair and nails are not involved. Treatment with any of the imidazoles, allyl-amines, benzylamines, or ciclopirox applied twice daily for 3–4 weeks is recommended.

Kelly BP: Superficial fungal infections. Pediatr Rev 2012;33: e22-e37 [PMID: 22474120].

2. Tinea Versicolor

Tinea versicolor is a superficial infection caused by *Malassezia* globosa, a yeast-like fungus. It characteristically causes polycyclic connected hypopigmented macules and very fine scales in areas of sun-induced pigmentation. In winter, the polycyclic macules appear reddish brown. Recurrent infection is common.

Treatment

Treatment consists of application of selenium sulfide (Selsun), 2.5% suspension, zinc pyrithione shampoo, or topical antifungals. Selenium sulfide and zinc pyrithione shampoo should be applied to the whole body and left on overnight. Treatment can be repeated again in 1 week and then monthly thereafter. It tends to be somewhat irritating, and the patient should be warned about this difficulty. Topical antifungals are applied twice a day for 1–2 weeks. Fluconazole 400 mg single dose may also be used.

3. Candida albicans Infections Clinical Findings

Candida albicans causes diaper dermatitis; thick, white patches on the oral mucosa (thrush); fissures at the angles of the mouth (perleche); and periungual erythema and nail plate abnormalities (chronic paronychia) (See also Chapter 43). Candida dermatitis is characterized by sharply defined erythematous patches, sometimes with eroded areas. Pustules, vesicles, or papules may be present as satellite lesions. Similar infections may be found in other moist areas, such as the axillae and neck folds. This infection is more common in children who have recently received antibiotics.

Treatment

A topical imidazole cream is the drug of first choice for C albicans infections. In diaper dermatitis, the cream

form can be applied twice a day. In oral thrush, nystatin suspension should be applied directly to the mucosa with the parent's finger or a cotton-tipped applicator. In candidal paronychia, the antifungal agent is applied over the area, covered with occlusive plastic wrapping, and left on overnight after the application is made airtight. Refractory candidiasis will respond to a brief course of oral fluconazole.

VIRAL INFECTIONS OF THE SKIN

1. Herpes Simplex Infection

Clinical Findings

Painful, grouped vesicles or erosions on a red base suggest herpes simplex (See also Chapter 40). Rapid immunofluorescent tests for herpes simplex virus (HSV) and varicellazoster virus (VZV) are available. A Tzanck smear is done by scraping a vesicle base with a No. 15 blade, smearing on a glass slide, and staining the epithelial cells with Wright stain. The smear is positive if epidermal multinucleated giant cells are visualized. A positive Tzanck smear indicates herpesvirus infection (HSV or VZV). In infants and children, lesions resulting from herpes simplex type 1 are seen most commonly on the gingiva, lips, and face. Involvement of a digit (herpes whitlow) will occur if the child sucks the thumb or fingers. Herpes simplex type 2 lesions are seen on the genitalia and in the mouth in adolescents. Cutaneous dissemination of herpes simplex occurs in patients with atopic dermatitis (eczema herpeticum) and appears clinically as very tender, punched-out erosions among the eczematous skin changes. Herpes gladiatorum occurs on the face, lateral neck, and medial arms and is commonly seen in wrestlers and rugby players.

Treatment

The treatment of HSV infections is discussed in Chapter 40.

2. Varicella-Zoster InfectionClinical Findings

Grouped vesicles in a dermatome, usually on the trunk or face, suggest varicella-zoster reactivation. Zoster in children may not be painful and usually has a mild course. In patients with compromised host resistance, the appearance of an erythematous border around the vesicles is a good prognostic sign. Conversely, large bullae without a tendency to crusting and systemic illness imply a poor host response to the virus. Varicella-zoster and herpes simplex lesions undergo the same series of changes: papule, vesicle, pustule, crust, slightly depressed scar. Lesions of primary varicella appear in crops, and many different stages of lesions are present at the same time (eg, papules), eccentrically placed vesicles on an erythematous base ("dew drop" on a rose petal), erosions, and crusts.

Treatment

The treatment of VZV infections is discussed in Chapter 41.

3. Human Immunodeficiency Virus Infection Clinical Findings

The average time of onset of skin lesions after perinatally acquired HIV infection is 4 months; after transfusionacquired infection, it is 11 months (See also Chapter 41). Persistent oral candidiasis and recalcitrant candidal diaper rash are the most frequent cutaneous features of infantile HIV infection. Severe or recurrent herpetic gingivostomatitis, varicella zoster infection, and molluscum contagiosum infection occur. Recurrent staphylococcal pyodermas, tinea of the face, and onychomycosis are also observed. A generalized dermatitis with features of seborrhea (severe cradle cap) is extremely common. In general, persistent, recurrent, or extensive skin infections should make one suspicious of HIV infection.

Treatment

The treatment of HIV infections is discussed in Chapter 46.

VIRUS-INDUCED TUMORS

1. Molluscum Contagiosum
