As described in the CHB treatment section, pegIFN has frequent and sometimes severe adverse effects (Table 24–7). In addition, up to 35% of patients require either a dosage reduction or drug discontinuation due to hematologic complications (thrombocytopenia, neutropenia, anemia).[34] Ribavirin causes a dose-related hemolytic anemia that may require dosage reductions or discontinuation.[34] Dermatological effects (eg, rash, pruritus, dry skin) occur commonly with ribavirin. Because ribavirin can be teratogenic and embryocidal, all women of childbearing age and men who are able to father a child must use two forms of contraception during HCV therapy containing ribavirin and for 6 months after completion of treatment.

▶ *Direct-Acting Antiviral Agents—First Generation*

Since 2011, a new category of drugs for HCV known as direct-acting antivirals (DAAs) have emerged. The first-generation DAAs approved were the protease inhibitors boceprevir and telaprevir, which resulted in higher SVR rates of 63% to 66% when coadministered with pegIFN and ribavirin.[32] Despite higher SVR rates, first-generation DDAs are no longer commercially available in the United States or recommended due to significant adverse effects (ie, blood dyscrasias, dermatological effects), increased pill burden (11–22 pills daily), complicated dosing regimens, significant and multiple drug interactions, and increased rates of viral resistance.[8]

▶ *Direct-Acting Antiviral Agents—Second Generation*

Drug development for HCV continues to evolve, resulting in higher SVR rates (well above 90%), fewer adverse effects, and shorter treatment durations with less complex regimens compared to pegIFN and ribavirin with or without a first-generation DAA. Selection of a DAA regimen is based on HCV genotype, previous HCV treatment history, severity of liver disease, current medical conditions and medications, and presence or absence of resistance-associated substitutions (RAS). Prior to administering any second-generation DAA regimen, presence of HBV should be excluded because cases of HBV reactivation have occurred, leading to fulminant hepatitis or death. Patents positive for HBV should be treated for it either prior to or concomitantly with HCV therapy. HCV patients who do not have immunity against HBV should receive the HBV vaccine.[8] Selected DAAs require RAS testing before starting HCV therapy (Table 24–8). If RAS are present, the options are to choose a drug from a different DAA class, add ribavirin, and/or treat for longer than 12 weeks. Many of the current regimens require addition of ribavirin (see Table 24–7 for adverse effect monitoring). The approved DAAs for HCV are described below; however, refer to www.hcvguidelines.org for the most up-to-date treatment recommendations.[8]

Simeprevir (Olysio) This agent is an NS3/4A serine protease inhibitor indicated for HCV genotype 1 without cirrhosis or with compensated (Child-Pugh A) cirrhosis when administered with sofosbuvir. Simeprevir is also indicated for genotype 1 or 4 when administered with pegIFN and ribavirin. The simeprevir triple therapy SVR rate varies depending on the patient's genotype 1 subtype. In clinical trials the overall SVR rate was about 80%, but the rate was lower in patients with genotype 1a (24% to 43%) than genotype 1b (78% to 84%).[8,34] The lower SVR rate with genotype 1a may be due to the baseline presence of NS3 Q80K polymorphism, a naturally occurring variation of the HCV virus. Therefore, baseline screening for NS3 Q80K polymorphism is recommended if prescribing simeprevir with PegIFN and ribavirin; if positive for the polymorphism, then an alternative HCV therapy should be used. Triple therapy with simeprevir, pegIFN, and ribavirin is not recommended due to its significant adverse effect profile, long treatment duration, and low SVR rates compared to newer IFN-free HCV regimens.[8]

Sofosbuvir (Sovaldi) This is the first agent of the NS5B polymerase inhibitor class approved for treatment of HCV genotypes 1, 2, 3, and 4; it also has efficacy in genotypes 5 and 6.[8] Sofosbuvir is commonly administered with other DAAs to achieve SVR rates above 90%. Treatment durations range from 8 to 24 weeks with the most common being 12 weeks.[8] Sofosbuvir plus PegIFN and ribavirin is no longer recommended for genotype 1 disease.[8] Sofosbuvir has fewer drug interactions than other DAAs; however, some may be significant because sofosbuvir is a substrate of intestinal P-glycoprotein. Agents that should be avoided with sofosbuvir include amiodarone, St. John's wort, certain anticonvulsants (carbamazepine, phenytoin), some HIV protease inhibitors (tipranavir/ritonavir), and some antimycobacterials (rifampin).

Sofosbuvir and Ledipasvir (Harvoni) This product is the first fixed-dose combination tablet and the first FDA-approved all-oral HCV regimen that does not require administration with pegIFN or ribavirin. Ledipasvir has a different mechanism of action than sofosbuvir; it inhibits the HCV NS5A protein,

[i]Uridine glucuronosyltransferase

[j]PRS = Prior treatment experience with interferon, pegylated interferon, ribavirin, and/or sofosbuvir, but no prior treatment with an HCV NS3/4A protease inhibitor or NS5A inhibitor

which is required for viral replication. The product is indicated for chronic HCV genotype 1, 4, 5, and 6 infection in patients older than age 12 or weighing at least 35 kg. See Table 24–8 for additional approved indications. The dose is one tablet (sofosbuvir 400 mg/ledipasvir 90 mg) daily (with or without food) for 8, 12, or 24 weeks depending on prior HCV treatment history, cirrhosis status, and baseline viral load.[8] Adverse effects are minimal, and drug interactions are similar to those receiving sofosbuvir alone. Use of high-dose acid suppressing agents with Harvoni decreases efficacy of ledipasvir; if these medications are required, doses should not exceed the equivalent of famotidine 40 mg twice daily or omeprazole 20 mg once daily.

Ombitasvir, Paritaprevir, Ritonavir, and Dasabuvir (Viekira XR) *and* Ombitasvir, Paritaprevir, and Ritonavir (Technivie) These two fixed-dose combination products are indicated for patients with HCV infections with or without Child-Pugh A compensated cirrhosis. Viekira XR is indicated for genotype 1 and Technivie is for genotype 4. See Table 24–8 for additional approved indications. The duration of treatment and the decision to add ribavirin are based on genotype and whether cirrhosis is present. The drugs have different mechanisms of action to inhibit HCV viral replication. Ombitasvir is an NS5A inhibitor, paritaprevir is an NS3/4A protease inhibitor, and dasabuvir is a nonnucleoside NS5B polymerase inhibitor with ritonavir, a CYP3A inhibitor. The SVR rate (80% to 100%) is affected by certain patient factors, including treatment experience, genotype, and presence of cirrhosis. Patients without cirrhosis and naïve to treatment are more likely to achieve an SVR rate greater than 90%.

Viekira XR and Technivie are contraindicated in patients with decompensated liver disease (Child-Pugh B and C) because fulminant hepatitis, need for liver transplant, or death may occur. Patients with cirrhosis should be monitored for hepatic decompensation. These agents may be used in patients with renal impairment including dialysis. However, renal dosage adjustments are required when used with ribavirin.

Treatment is well tolerated with minimal side effects; however, elevated ALT greater than 5 times the upper limit of normal may be seen in about 1% of patients. If it occurs, this effect is usually seen within the first 4 weeks of therapy. Elevated ALT levels are more pronounced in females using contraceptives contacting ethinyl estradiol, so these products should be discontinued before initiating Viekira XR or Technivie. Additional adverse effects may occur if given with ribavirin (Table 24–7).[8] Ritonavir is also an HIV-1 protease inhibitor, and patients coinfected with HCV and HIV may develop ritonavir resistance; HCV/HIV-1 coinfected patients should be started on a suppressive antiretroviral drug regimen before starting Viekira XR or Technivie to reduce the risk of HIV-1 protease inhibitor drug resistance. Drugs utilizing the CYP3A and/or CYP2C8 metabolic pathway are contraindicated with both products.

Daclatasvir (Daklinza) This NS5A inhibitor is approved for HCV genotype 1 or 3 and is co-administered with sofosbuvir for 12 weeks. Patients with decompensated (Child-Pugh B or C) disease require addition of ribavirin and perhaps a longer treatment duration of 24 weeks.[8] Daclatasvir has several significant drug interactions requiring dosage modifications. Because daclatasvir is co-administered with sofosbuvir with or without ribavirin, refer to those sections for additional adverse effects and drug interactions. The usual dose is 60 mg daily; patients taking CYP3A inducers should take 90 mg daily, and those using CYP3A inhibitors should use 30 mg daily.

Elbasvir and Grazoprevir (Zepatier) This fixed-dose combination tablet is approved for HCV genotype 1 or 4. Elbasvir is an NS5A inhibitor and grazoprevir is a NS3/4A protease inhibitor; these mechanisms inhibit different parts of the virus to halt viral replication. Patients with genotype 1a disease should be tested for the NS5A RAS; if NS5A polymorphism is absent, monotherapy with Zepatier for 12 weeks results in a SVR rate above 90%. If the polymorphism is present, ribavirin is added and treatment is extended to 16 weeks. Zepatier is a safe and well-tolerated option for patients with renal insufficiency including patients on hemodialysis because the drugs are primarily eliminated via the feces. Zepatier is contraindicated in patients with decompensated liver disease (Child-Pugh B and C) because fulminant hepatitis, need for liver transplant, or death may occur. All patients with cirrhosis should be monitored for hepatic decompensation while on treatment. Drug–drug interactions with elbasvir/grazoprevir should be evaluated prior to administration.

Sofosbuvir and Velpatasvir (Epclusa) This is the first fixed-dose combination tablet approved for all 6 HCV genotypes (known as a pangenotypic DAA). Sofosbuvir (400 mg), an NS5B polymerase inhibitor, is combined with velpatasvir (100 mg), an NS5A inhibitor that does not require administration of pegIFN or ribavirin to achieve a SVR well above 90% for all HCV genotypes. This is especially important for patients with genotype 3, which is more difficult to treat. Epclusa (one tablet daily with or without food for 12 weeks) is indicated for adult patients with or without compensated cirrhosis. Patients with decompensated Child-Pugh B or C cirrhosis should take Epclusa for 12 weeks with weight-based ribavirin, if tolerated, to increase the likelihood of achieving SVR. Adverse effects are minimal, and drug interactions are similar to those associated with Harvoni.[8]

Sofosbuvir, Velpatasvir, and Voxilaprevir (Vosevi) This pangenotypic fixed-dose combination tablet contains drugs targeting three different sites to inhibit HCV viral replication. Similar to the components of Epclusa, Vosevi also includes a NS3/4A protease inhibitor, voxilaprevir. The dose is one tablet (sofosbuvir 400 mg/velpatasvir 100 mg/voxilaprevir 100 mg) daily (with food) for 12 weeks for adult patients with or without compensated cirrhosis (Child-Pugh A) who have been previously treated with a HCV regimen that included an NS5A inhibitor or sofosbuvir. Patients with decompensated Child-Pugh B or C should not be treated with Vosevi because hepatic decompensation may be associated with the protease inhibitor. This triple therapy has SVR rates above 95%, particularly in DAA-experienced patients. Vosevi is approved for all genotypes and is well tolerated, with adverse effect and drug interaction profiles similar to Epclusa. However, the protease inhibitor voxilaprevir has potential interactions with drugs metabolized via the OATP1B1 and OATP1B3 pathways. There are no dosage recommendations for patients with renal insufficiency or end-stage renal disease.

Glecaprevir and Pibrentasvir (Mavyret) This is the first pangenotypic fixed-dose combination tablet containing an NS3/4A protease inhibitor (glecaprevir) and an NS5A inhibitor (pibrentasvir). It is approved for adults with or without compensated cirrhosis (Child-Pugh A) or patients who are treatment experienced with either an HCV NS3/4A or NS5A inhibitor. This is the first 8-week DAA treatment that is effective for all HCV genotypes in: (1) noncirrhotic patients, (2) patients co-infected with HIV, and (3) patients with renal insufficiency.

The dose is three tablets (glecaprevir 300 mg/pibrentasvir 120 mg) daily (with a moderate- to high-fat meal) in adults without cirrhosis. Patients with compensated Child-Pugh A cirrhosis require 12 weeks of therapy. Treatment-experienced patients require either 12 or 16 weeks of treatment. Patients with decompensated Child-Pugh B cirrhosis should not be treated with Mavyret, and Child-Pugh C cirrhosis is considered a contraindication because hepatic decompensation associated with the protease inhibitor may occur.

The 8-week dual therapy has SVR rates greater than 98% for genotypes 1, 2, 5, and 6 and approximately 95% for genotype 3 noncirrhotic patients. Mavyret is well tolerated; the most common adverse effects are headache and fatigue. There are numerous drug interactions, especially with drugs metabolized via the P-gp, OATP1B1/3, CYP3A, and UGT1A1 pathways.

▶ *Cost of HCV Treatment*

The new generation of HCV agents is associated with improved SVR rates and side-effect profiles. However, their high cost may prohibit some patients from receiving HCV treatment. Typically, 12 weeks of DAA therapy has a wholesale acquisition price of $72,000 to $95,000 (Table 24–8). For example, the cost of the first PegIFN-free DAA regimen with sofosbuvir was $1000 per day, or $84,000 to $168,000 for a 12- or 24-week treatment regimen, excluding the cost of other coadministered medications. The price has steadily declined as more DAA regimens became available. In August 2017, Mavyret (glecaprevir plus pibrentasvir) was approved for an 8-week course of therapy costing $26,400. Extending treatment to 12 or 16 weeks adds an additional $13,200 or $26,400, respectively, making this treatment the least expensive of all DAAs. In an ideal world, all patients infected with HCV would be treated. The unfortunate reality is that the high cost of HCV regimens strains health care resources, making it infeasible to treat everyone. The AASLD recommends that all patients be treated regardless of severity of the liver disease, except those with short life expectancies.[8] Despite this recommendation, insurers have restricted access to treatment due to cost and have used stage of fibrosis as one of the criteria to prioritize approval of treatment.[36,37] It is hoped that HCV medications will someday be affordable so all infected individuals may receive treatment.

Hepatitis D Prevention and Treatment

Hepatitis D infection is possible only if the patient is also infected with HBV; therefore, hepatitis B vaccination can indirectly prevent hepatitis D infections. The recommended treatment for HDV is pegIFN for 48 weeks.[10] For patients with mild liver disease, treatment should be withheld with HDV RNA and ALT levels monitored every 12 to 24 weeks. Treatment should be considered for individuals with advanced liver disease.[10] First-line oral agents for treating HBV infections (eg, tenofovir) may be co-administered with pegIFN; however, studies have shown no additional benefit in achieving viral clearance.[10] Monotherapy with nucleoside/nucleotide analogs is ineffective in reducing HDV DNA levels but may decrease hepatitis B viral loads.[10]

Hepatitis E Prevention and Treatment

Because hepatitis E is transmitted via the fecal–oral route, good personal hygiene and proper disposal of sanitary waste are the most effective ways to prevent viral acquisition. There are no commercially available vaccines in the United States to prevent hepatitis E. However, a hepatitis E vaccine has been licensed in China since 2011 and may become available for countries with high HEV infection incidence rates.[16]

Patient Encounter Part 3

The patient received treatment for hepatitis C for 4 weeks, and the following laboratory test results have just been obtained:

Sodium 138 mEq/L (mmol/L)
Potassium 5.7 mEq/L (mmol/L)
Chloride 98 mEq/L (mmol/L)
CO_2 19 mEq/L (mmol/L)
BUN 52 mg/dL (18.6 mmol/L)
SCr 4.7 mg/dL (415 µmol/L)
Glucose 103 mg/dL (5.7 mmol/L)
Hgb 10.8 g/dL (108 g/L; 6.70 mmol/L)
Hct 32.1% (0.321)
WBC 4.1 × 10^3/mm^3 (10^9/L)
Plt 114 × 10^3/mm^3 (10^9/L)
AST 18 IU/L (0.30 µkat/L)
ALT 19 IU/L (0.32 µkat/L)
T. bilirubin 1.7 mg/dL (29.1 µmol/L)
Albumin 3.1 g/dL (31 g/L)
Alk phos 168 IU/L (2.80 µkat/L)
HCV RNA level: undetectable

What questions should you ask the patient?

What action should you take to treat any complaints the patient may have?

What action should you take based on the patient's week 4 HCV RNA level?

OUTCOME EVALUATION

LO 7

Monitoring for efficacy in patients treated for chronic hepatitis B or C includes evaluating aminotransferase levels and hepatitis B or C viral levels and serologies.

Hepatitis B

- Obtain an ALT at baseline and then every 3 to 6 months during hepatitis B treatment.
- Monitor HBV DNA levels every 3 to 6 months to determine treatment response.
- Monitor HBeAg and anti-HBe every 6 months to determine if seroconversion to anti-HBe occurred or HBeAg was lost in HBeAg-positive CHB patients.[20]
- Monitor HBsAg every 6 to 12 months to determine if HBsAg was lost or anti-HBs developed in CHB HBeAg-negative patients with persistently undetectable serum HBV DNA levels.[20]
- Continue treatment in CHB HBeAg-positive patients until HBeAg seroconversion has been attained along with undetectable HBV DNA levels. Once anti-HBe appears, complete an additional 12 months of hepatitis B therapy.[20]
- Continue treatment in CHB HBeAg-negative patients until HBsAg is lost.[20]
- Monitor ALT, HBV DNA levels, seroconversion, and signs and symptoms of hepatic decompensation monthly for 6 months then every 3 months for patients with confirmed cirrhosis. Monitor for hepatitis flare and viral relapse when discontinuing hepatitis B therapy.[20]
- Monitor ALT, HBV DNA levels, seroconversion, and signs and symptoms of hepatic decompensation every 3 months for at least 1 year for all patients who discontinued HBV therapy.[20]
- Obtain a CBC with differential every 4 weeks and thyroid-stimulating hormone (TSH) and fasting lipid panel every 12 weeks when receiving pegIFN therapy for hepatitis B.[20]

Patient Encounter Part 4

The patient has now been treated for a total of 12 weeks and the HCV RNA level is undetectable.

What action should you take based on the week 12 HCV RNA level?

What other information should you counsel the patient about in addition to the side effects associated with the hepatitis C therapy?

- For patients receiving tenofovir or adefovir, monitor serum creatinine, phosphorus, urine glucose, and urinary protein for nephrotoxicity at baseline then periodically (more frequently in patients with baseline renal insufficiency).[20]
- For patients taking telbivudine, monitor creatine kinase at baseline and periodically (eg, every 12 weeks) because muscle weakness and myopathy have occurred.[20]

Hepatitis C

- Evaluate the patient's HBV status. If not yet immune to HBV, then vaccinate. If positive for CHB, then have hepatologist evaluate the patient for HBV treatment.
- Evaluate for signs and symptoms of decompensated liver disease prior to initiating DAA therapies containing an HCV NS3 protease inhibitor. Patients with Child-Pugh B or C should not receive NS3 protease inhibitors (Table 24–8).
- Evaluate for the presence of RAS prior to initiating HCV therapy (Table 24–8).
- The ultimate goal of HCV therapy is to achieve SVR, defined as having undetectable HCV RNA levels for at least 3 months posttreatment; this indicates virological cure.[8]

Patient Encounter Part 5

The patient's daughter was recently found to be positive for hepatitis B. She is pregnant and ready to give birth. She has a history of irritability. She has no surgical history. She is taking a neonatal vitamin with iron.

All laboratory test results are normal except for the following:

AST 84 IU/L (1.4 µkat/L)	HBeAg (–)
ALT 87 IU/L (1.45 µkat/L)	Anti-HBc IgG (+)
Anti-HAV IgM (–)	Anti-HBc IgM (–)
Anti-HAV IgG (+)	Anti-HBe (–)
Anti-HBs (–)	Anti-HCV (–)
HBsAg (+)	HBV DNA 109,134 IU/mL (kIU/L)

Based on the information presented:

(a) what additional information do you need before creating a treatment plan for this patient?

(b) create a detailed care plan for the patient;

(c) discuss adverse effects to monitor;

(d) discuss a follow-up plan to determine whether the treatment goals have been achieved.

- Obtain HCV RNA level at week 4 of therapy to assess for efficacy. If detectable, repeat at week 6. If HCV RNA level has increased greater than 1 $\log_{10}$ IU/mL (1 $\log_{10}$ kIU/L), then discontinue all HCV medications.
- End of treatment response (ETR or EOT) is defined as having undetectable HCV RNA levels at the end of treatment.
- Monitor ALT levels every 4 weeks. Biochemical response is defined as normalization of ALT.
- Histologic response is defined as improving inflammation and fibrosis as documented by liver biopsy scores.

Patient Care Process

Collect Information:

- Speak with the patient to identify risk factors for acquiring viral hepatitis (Table 24–1).
- Review social history to determine if any practices may contribute to or worsen the severity of liver disease (ie, alcohol, high-fat food intake).
- Review past medical history focusing on hepatic and renal disorders.
- Review physical assessment findings focusing on mental status changes, edema, and color of skin and eyes (ie, jaundice).
- Perform a medication history (prescription, over-the-counter drugs, dietary supplements) to identify drug interactions (may refer to hep-druginteraction.org) or drug-induced liver toxicity.
- Review use of any drugs in the past for the treatment of hepatitis B or C.
- Obtain a vaccination history to determine which vaccines have been given.
- Review laboratory tests to determine severity of liver disease. Review hepatitis serologies to determine if vaccination is needed (Tables 24–3 and 24–4).
- Speak with the patient and review insurance coverage records for medical and medication history.

Assess the Information:

- Determine if treatment is indicated by reviewing laboratory values, liver serologies, and liver biopsy report (if available) or imaging (CT, Fibroscan, ultrasound).
- If the patient does not qualify for hepatitis therapy, then schedule return visits every 3 to 6 months to monitor health condition and laboratory tests.
- If the patient qualifies for treatment, assess for uncontrolled medical conditions, and if present, treat or refer to an appropriate medical specialty for evaluation (eg, HIV, diabetes, renal disease, HBV).
- Determine which vaccines need to be administered.
- For patients with HCV, assess severity of liver disease to recommend appropriate anti-HCV regimen (Table 24–9).

(*Continued*)

Patient Care Process (*Continued*)

- Document, trend, and review laboratory values to determine severity of liver disease (platelet counts, AST, ALT, INR, albumin).
- Assess the efficacy, safety, and patient adherence of current pharmacotherapy.
- Assess current medications before initiating hepatitis therapy to identify potential drug–drug interactions and ensure that doses are appropriate based on organ function.
- Assess laboratory values, and medications with potential for drug interactions or adherence problems for patients currently on treatment.

LO 6

Develop a Care Plan:

- Refer to AASLD HBV guidelines for CHB treatment recommendations.
- Refer to www.hcvguidelines.org for HCV treatment guidelines.
- Refer to https://www.hepatitisc.uw.edu/ for HCV treatment regimens.
- Obtain a pregnancy test in women of childbearing potential who are prescribed ribavirin-based therapies.

Implement the Care Plan:

- Educate the patient about the hepatitis drug regimen, potential side effects, and duration of therapy.
- Inform the patient about the importance of drug adherence to minimize the risk of developing resistance.
- Educate the patient to avoid alcohol and illicit drug use during treatment and after completion of therapy.
- Work with the local specialty pharmacy to ensure that medications are covered by insurance and continued without disruption in treatment.
- Educate all men and women who are of childbearing age and are receiving ribavirin to use two forms of birth control during treatment and for 6 months after treatment.
- Address any patient concerns about the liver disease and its management.
- Discuss the importance of lifestyle modification to reduce the progression of liver disease.

LO 7

Follow-up: Monitor and Evaluate:

- At each clinic visit, review the medication list, assess for medication adverse effects and drug interactions, and review laboratory tests to assess efficacy and toxicity.
- Confirm adherence and number of missed doses to minimize drug resistance.
- Obtain laboratory test results every week to every 2 to 4 weeks until complete treatment if ribavirin is prescribed.
- Assess for decompensated liver disease while on HCV therapy (Table 24–9).
- Follow up with a hepatologist every 6 months for cirrhosis surveillance.

- Monitor WBC, absolute neutrophil count (ANC), and platelets either weekly or biweekly during the first month of therapy and monthly thereafter if stable while on pegIFN (Table 24–7).
- Monitor WBC with platelet count, creatinine, and LFTs after 4 weeks of initiating DAA therapy, then monthly until treatment is completed.
- Monitor TSH and fasting lipid panel every 12 weeks while receiving pegIFN.
- Monitor hemoglobin weekly or biweekly during the first month and monthly thereafter if stable while on ribavirin (Table 24–7).
- Monitor for fatigue, shortness of breath, chest pain, and dermatological complications while on ribavirin; discontinue treatment if complaints are significant.
- Monitor serum creatinine in patients receiving ribavirin to detect renal insufficiency that may result in ribavirin accumulation and toxicity (eg, hemolytic anemia).
- Conduct a thorough medication reconciliation of prescription, over-the-counter, and dietary and herbal supplements prior to and during HCV therapy.

Table 24–9

Child-Turcotte-Pugh (CTP) Classification of the Severity of Cirrhosis

	Points		
Parameter	**1**	**2**	**3**
Albumin (g/dL [g/L])	> 3.5 [35]	2.8–3.5 [28–35]	< 2.8 [28]
Bilirubin (mg/dL [μmol/L])	< 2 [34]	2–3 [34–51]	> 3 [51]
Prothrombin time (sec prolonged)	< 4	4–6	> 6
OR			
International normalized ratio	< 1.7	1.7–2.3	2.3
Ascites	None	Mild to moderate (diuretic responsive)	Severe (diuretic refractory)
Encephalopathy	None	Grade 1–2 (suppressed with medication)	Grade 3–4 (refractory)

Calculation of CTP score: Add the points for each parameter. CTP Class A: 5–6 points; Class B: 7–9 points; Class C: 10–15 points.

Abbreviations Introduced in This Chapter

ALT	Alanine aminotransferase
ANC	Absolute neutrophil count
Anti-HAV	Hepatitis A virus antibody
Anti-HBc	Hepatitis B core antibody
Anti-HBe	Hepatitis B envelope antibody
Anti-HBs	Hepatitis B surface antibody
Anti-HCV	Hepatitis C antibody
Anti-HDV	Hepatitis D antibody
Anti-HEV	Hepatitis E antibody
AST	Aspartate aminotransferase
CHB	Chronic hepatitis B infection
CrCl	Creatinine clearance
DAA	Direct-acting antiviral
ETR	End of treatment response
ESLD	End-stage liver disease
HAV	Hepatitis A virus
HBcAg	Hepatitis B core antigen
HBeAg	Hepatitis B envelope antigen
HBIG	Hepatitis B immunoglobulin
HBsAg	Hepatitis B surface antigen
HBV	Hepatitis B virus
HBV DNA	Hepatitis B deoxyribonucleic acid
HCV	Hepatitis C virus
HCV RNA	Hepatitis C virus ribonucleic acid
HDV	Hepatitis D virus
HDVAg	Hepatitis D antigen
HDV RNA	Hepatitis D virus ribonucleic acid
HEV	Hepatitis E virus
IgG	Immunoglobulin G
IgG anti-HD	IgG antibodies to hepatitis D virus antigen
IgM	Immunoglobulin M
IgM anti-HD	IgM antibodies to hepatitis D virus antigen
IG	Immune globulin
IGIM	Immune globulin for intramuscular administration
IGIV	Immune globulin for IV administration
pegIFN	Pegylated interferon
RAS	Resistance-associated substitutions
RVR	Rapid virologic response
SVR	Sustained virologic response
WBC	White blood cell counts

25 Acute Kidney Injury

Mary K. Stamatakis

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Assess a patient's kidney function based on clinical presentation, laboratory results, and urinary indices.
2. Identify pharmacotherapeutic outcomes and endpoints of therapy in a patient with acute kidney injury (AKI).
3. Apply knowledge of the pathophysiology of AKI to development of a treatment plan.
4. Develop strategies to minimize the occurrence of drug- and radiocontrast-induced AKI.
5. Monitor and evaluate the safety and efficacy of the therapeutic plan.

INTRODUCTION

Acute kidney injury (AKI) is a potentially life-threatening syndrome that occurs primarily in hospitalized patients and frequently complicates the course of those who are critically ill. It is characterized by a rapid decrease in glomerular filtration rate (GFR) and the resultant accumulation of nitrogenous waste products (eg, creatinine), with or without a decrease in urine output.

The term acute kidney injury has replaced the name acute renal failure because it more completely encompasses the entire spectrum of acute injury to the kidney, from mild changes in kidney function to end-stage kidney disease requiring renal replacement therapy (RRT).

KEY CONCEPT AKI is defined as an increase in serum creatinine (SCr) of at least 0.3 mg/dL (27 μmol/L) within 48 hours, a 50% increase in baseline serum creatinine within 7 days, or a urine output of less than 0.5 mL/kg/h for at least 6 hours. Only one criterion needs to be met for diagnosis of AKI.[1]

EPIDEMIOLOGY AND ETIOLOGY

Approximately 7% to 18% of all hospitalized patients develop AKI.[2] More than half of those who are critically ill develop AKI,[3] and 30% to 40% of survivors of AKI develop chronic kidney disease (CKD).[3] Despite improvements in the medical care of individuals with AKI, mortality remains high. About 4% of hospital admissions are community-acquired AKI[4] with an incidence of 20 to 200 cases per million population.[2]

PATHOPHYSIOLOGY

There are three categories for the causes of AKI: prerenal, intrinsic, and postrenal AKI. The pathophysiologic mechanisms differ for each of the categories.

Prerenal AKI

Prerenal AKI occurs in approximately 10% to 25% of patients diagnosed with AKI and is characterized by reduced blood delivery to the kidney. A common cause is intravascular volume depletion due to conditions such as hemorrhage, dehydration, or gastrointestinal (GI) fluid losses. Early volume restoration can prevent progression and improve recovery because it can restore renal blood flow before structural damage to the kidney has occurred.[5] Conditions of reduced cardiac output (eg, congestive heart failure [CHF], myocardial infarction), septic shock, and hypotension can also reduce renal blood flow, resulting in decreased glomerular perfusion and prerenal AKI. With a mild to moderate decrease in renal blood flow, intraglomerular pressure is maintained by dilation of afferent arterioles (arteries supplying blood to the glomerulus), constriction of efferent arterioles (arteries removing blood from the glomerulus), and redistribution of renal blood flow to the oxygen-sensitive renal medulla.

Drugs may cause a functional AKI when they interfere with these autoregulatory mechanisms. Nonsteroidal anti-inflammatory drugs (NSAIDs) impair prostaglandin-mediated dilation of afferent arterioles. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) inhibit angiotensin II–mediated efferent arteriole vasoconstriction and cause prerenal AKI in 6% to 38% of treated patients.[6] The calcineurin inhibitors cyclosporine and tacrolimus, particularly in high doses, are potent renal vasoconstrictors. All of these agents can reduce intraglomerular pressure, with a resultant decrease in GFR. Prompt discontinuation of the offending drug can often return kidney function to normal.

Other causes of prerenal AKI are renovascular obstruction (eg, renal artery stenosis), hyperviscosity syndromes (eg, multiple myeloma), and systemic vasoconstriction (eg, hepatorenal syndrome).

Intrinsic AKI

Intrinsic renal failure is caused by diseases that can affect the structure of the nephron, such as the tubules, glomerulus, interstitium, or blood vessels. Acute tubular necrosis (ATN) is a term that is often used synonymously with intrinsic AKI, but ATN relates more specifically to necrosis of tubular epithelial cells resulting from nephrotoxins (eg, aminoglycosides, contrast agents, amphotericin B), sepsis, or ischemia. ATN accounts for

50% of all cases of AKI.[7] In addition, prerenal AKI can progress to ATN if the underlying cause of it is not promptly corrected.

Glomerular, interstitial, and blood vessel diseases may also lead to intrinsic AKI but occur with a much lower incidence. Examples include **glomerulonephritis**, systemic lupus erythematosus, **interstitial nephritis**, and vasculitis.

Postrenal AKI

Postrenal AKI is due to obstruction of urinary outflow. Causes include benign prostatic hypertrophy, pelvic tumors, and precipitation of renal **calculi**.[7] Rapid resolution of postrenal AKI without structural damage to the kidney can occur if the underlying obstruction is corrected. Postrenal AKI accounts for less than 10% of cases of AKI.

CLINICAL PRESENTATION AND DIAGNOSIS

The definition and categorization of AKI has evolved over the past decade. The first AKI classification system was *RIFLE* (Risk, Injury, Failure, Loss, and End stage), which defined and stratified the severity of kidney disease.[1]

The Acute Kidney Injury Network (AKIN) modified the *RIFLE* definition and staging for AKI. The AKIN staging system is based on changes in SCr and uses three stages (stages 1 to 3); stage 1 also includes an absolute increase in SCr of 0.3 mg/dL (27 μmol/L) or greater.[1] This highlights the association of even small increases in SCr concentration with morbidity and mortality, making early detection critical. It also categorizes all patients receiving RRT as stage 3.[8] Studies have validated both RIFLE and AKIN criteria in identifying hospitalized patients at risk of mortality associated with AKI.[9] A common classification and definition of AKI is advocated by the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for Acute Kidney Injury (**Table 25–1**).[1]

LO 1 Decreased urine output may be a more sensitive marker than increases in SCr in early AKI; however, decreased urine output is not universally present in AKI. **Oliguria** and **anuria** are defined as daily urine outputs of less than 400 mL and 50 mL, respectively. Reduced urine output is associated with increased mortality and may represent a more severe form of AKI. Nonoliguric AKI is defined as urine output greater than 400 mL/day. It may still represent severe AKI but is associated with better patient outcomes.[10]

LO 1 As kidney function declines, SCr and blood urea nitrogen (BUN) rise. Monitoring SCr and BUN and comparing them to baseline can assist in determining if a patient's kidney function is worsening or improving. BUN is a less sensitive marker for evaluation of AKI compared to SCr. Urea is a product of amino acid metabolism, and although it is eliminated via glomerular filtration, it also undergoes reabsorption in the proximal tubules. Increased blood urea reabsorption occurs at lower urine flow rates within the kidney, such as that which occurs in prerenal AKI. Thus, an elevated BUN to SCr ratio can indicate prerenal AKI. Other conditions that can result in an elevated BUN are excessive protein intake and GI bleeding (because of blood breakdown to amino acids in the gut).

LO 1 Although some clinical and laboratory findings assist in the general diagnosis of AKI, others are used to differentiate among prerenal, intrinsic, and postrenal AKI. For example, patients with prerenal AKI typically demonstrate enhanced sodium reabsorption, which is reflected by a low urine sodium concentration and a low fractional excretion of sodium (FENa). The FENa is calculated by the following equation:

$$\text{Fractional excretion of sodium (FENa)} = 100 \times \frac{(\text{Urinary sodium concentration} \times \text{Plasma creatinine concentration})}{(\text{Plasma sodium concentration} \times \text{Urinary creatinine concentration})}$$

FENa is a measure of the percentage of sodium excreted by the kidney. Ordinarily, 1% to 2% of sodium intake is excreted by the kidneys. A FENa less than 1% may indicate prerenal AKI because it represents the response of the kidney to decreased renal perfusion by decreasing sodium excretion. Loop diuretics such as furosemide enhance sodium excretion and increase FENa, confounding the interpretation of the test.

LO 1 Urine is typically more concentrated with prerenal AKI, and there is a higher urine osmolality and urine-to-plasma creatinine ratio (> 20:1 for units of mg/dL) compared to intrinsic and postrenal AKI. Other factors, such as patient symptoms, laboratory test results, urinary indices, and results of diagnostic procedures, aid in the diagnosis and assessment of disease severity.

Early Detection of AKI

Serum creatinine lacks sensitivity in detecting AKI; thus, identifying novel biomarkers that are released within hours of injury with sensitivity and specificity would aid in early detection of AKI.[11] Nephrocheck® is the first commercially available point-of-care test for critically ill patients with cardiovascular or respiratory compromise that measures urine

Table 25–1

Staging System for AKI

Stage	Change in Serum Creatinine from Baseline		Urine Output	Need for Renal Replacement Therapy
1	0.3 mg/dL (27 μmol/L) or greater increase from baseline	150%–199% (1.5%–1.9-fold)	< 0.5 mL/kg per hour for 6–12 hours	No
2	—	200%–299% (2–2.9-fold)	< 0.5 mL/kg per hour for 12 hours or longer	No
3	Increase to 4 mg/dL (354 μmol/L) or greater	300% or greater (> 3-fold)	< 0.3 mL/kg per hour for 24 hours or anuria for ≥ 12 hours	Initiation of renal replacement therapy indicates stage 3 regardless of serum creatinine or urine output

Based on the KDIGO staging system for AKI. Only one of the three criteria needs to be met in order to qualify for the higher stage.

Clinical Presentation and Diagnosis of AKI

Symptoms of AKI

- Weight gain
- Nausea, vomiting, diarrhea, anorexia
- Fatigue
- Shortness of breath
- Pruritus
- Weight loss (prerenal AKI)
- Anuria alternating with polyuria (postrenal AKI)
- Colicky abdominal pain radiating from flank to groin (postrenal AKI)

Physical Examination Findings

- Increased blood pressure
- Peripheral edema
- Change in mental status
- Jugular venous distention (JVD)
- Pulmonary edema
- Crackles
- Asterixis
- Pericardial or pleural friction rub
- Hypotension or orthostatic hypotension (prerenal AKI)
- Rash (intrinsic AKI due to acute interstitial nephritis)
- Bladder distention (postrenal bladder outlet obstruction)
- Prostatic enlargement (postrenal AKI)

Laboratory Tests

- Elevated SCr (reference range ~0.6 to 1.2 mg/dL [53 to 106 µmol/L])
- Elevated BUN (reference range ~8 to 25 mg/dL [2.9 to 8.9 mmol/L])
- BUN-to-creatinine ratio greater than 20:1 for units of mg/dL (prerenal AKI); (urea to creatinine ratio cutoff of 100:1 when both urea and creatinine are expressed in molar units [eg, µmol/L])
- Hyperkalemia
- Metabolic acidosis

Urinalysis

- Sediment
  - Scant or bland (prerenal or postrenal AKI)
  - Brown, muddy granular casts (intrinsic ATN)
  - Proteinuria (glomerulonephritis or allergic interstitial nephritis)
  - Eosinophiluria (acute interstitial nephritis)
  - Hematuria or red blood cell casts (glomerular disease or bleeding in urinary tract)
  - WBCs or casts (acute interstitial nephritis or severe pyelonephritis)

Urinary Indices	Prerenal AKI	Intrinsic and Postrenal AKI
Urine osmolality (solute concentration in the urine in mOsm/kg or mmol/kg)	> 500	< 350
Urine sodium concentration (mEq/L or mmol/L)	< 20	> 40
Specific gravity	> 1.020	< 1.015
Urine-to-plasma creatinine ratio	> 40:1	< 20:1
Fractional excretion of sodium (FENa)	< 1%	> 1%–2%

Common Diagnostic Procedures

- Urinary catheterization is performed to rule out urethral obstruction; increased urine output may occur if postrenal obstruction is present.
- Renal ultrasound can assist in differentiating AKI [normal-sized kidneys] from CKD [small kidneys]. It can also show urinary tract obstruction and hydronephrosis, which indicates postrenal AKI.
- Computed tomography (CT) provides similar information as renal ultrasound but with greater spatial resolution. It assists in the diagnosis of masses, stones, and pyelonephritis.
- Magnetic resonance imaging (MRI) can be used as an alternative to CT scanning to avoid administering radiocontrast media.
- Renal angiography can be useful in identifying conditions such as renal artery stenosis and renal vein thrombosis.
- Retrograde pyelography is used to localize the site of urinary tract obstruction.
- Kidney biopsy may aid in the diagnosis of glomerular and interstitial diseases.

concentrations of IGF-binding protein 7 and tissue inhibitor of metalloproteinase-2. The test provides a positive risk score to indicate risk for moderate to severe kidney injury within 12 hours.[12] Although this test is not yet widely used, a positive score could trigger an early nephrology consult, avoidance of nephrotoxic medications, fluid resuscitation, and other therapies to prevent progression. Studies are underway to explore the utility of different biomarkers for early diagnosis/prognosis of AKI, to guide clinical decision-making, and to detect early drug-induced nephrotoxicity.[12]

The furosemide stress test is being investigated to predict the development of stage 3 AKI in early AKI. Initial studies have found that a urine volume of less than 200 mL at 2 hours following a one-time furosemide dose of 1.0 mg/kg in furosemide-naïve patients or 1.5 mg/kg in patients with prior furosemide exposure is predictive of severe AKI. Additional studies to validate the test, used alone and in combination with other biomarker tests, are needed to aid in the early detection of AKI.

TREATMENT

Desired Outcomes

LO 2

A primary goal in the care of patients with AKI is ameliorating identifiable underlying causes of AKI such as hypovolemia, nephrotoxic drugs, or ureter obstruction. Prerenal and postrenal AKI can be reversed if the underlying problem is promptly

identified and corrected, whereas treatment of intrinsic renal failure is primarily supportive until kidney function recovers. KEY CONCEPT There is no evidence that drug therapy hastens patient recovery, decreases length of hospitalization, or improves survival in intrinsic AKI.

Pharmacologic Therapy

▶ *Hydration*

To ensure adequate tissue perfusion in patients with prerenal AKI, isotonic crystalloid solutions such as 0.9% normal saline are used to expand intravascular volume and return volume status to neutral fluid balance (euvolemia).[14] Crystalloids (eg, normal saline, balanced solutions such as Lactated Ringer's or Plasma-Lyte A) are preferred over colloidal solutions (eg, albumin, hydroxyethyl starch) for fluid resuscitation.[14] Additionally, 0.9% normal saline is generally preferred over lower tonicity saline fluids such as 0.45% normal saline because a smaller fraction of hypotonic fluid remains in the intravascular space. Dextrose 5% in water is isotonic, but after the dextrose is absorbed by the body, only water is left in the intravascular space. Because plain water is hypotonic, it can have the same effect as 0.45% normal saline; therefore, it is not ideal for fluid resuscitation. Caution must be taken with hydration because overzealous fluid resuscitation can result in pulmonary edema, increased postoperative complications, and ultimately, increased mortality.[15] In addition, excess chloride from 0.9% normal saline can cause hyperchloremic metabolic acidosis.[16] Some evidence suggests that too much fluid can worsen AKI; thus, the goal of treatment is to return to a state of euvolemia or slightly negative fluid balance.[15] In instances of acute blood loss, blood transfusions may be indicated.

In addition to fluids, vasopressors (ie, norepinephrine, dopamine, vasopressin) may be needed in patients with shock to restore adequate organ perfusion. There are no definitive data to support one agent as superior over another; however, greater number of arrhythmic events have been reported with dopamine compared to norepinephrine.[17]

▶ *Loop Diuretics*

Most studies evaluating loop diuretics (ie, furosemide, bumetanide, torsemide, and ethacrynic acid) for prevention or treatment of AKI demonstrated improved urine output but no improvement in survival or need for dialysis. There are some reports that loop diuretics may worsen kidney function and may be harmful if given for prevention of AKI.[18] Thus, loop diuretics should be reserved for treating volume overload and should not be given to prevent AKI or hasten recovery of kidney function in euvolemic or hypovolemic individuals.[19]

Although bumetanide and torsemide are more potent than furosemide on a weight basis, all of the loop diuretics are equally effective in fluid removal when given in equipotent IV doses (40 mg furosemide = 1 mg of bumetanide = 10–20 mg torsemide). Therefore, selection is based on the side-effect profile, cost, and pharmacokinetic differences. **Ototoxicity** is a well-established side effect of ethacrynic acid and limits its use; this side effect occurs rarely with bumetanide and torsemide. The risk of ototoxicity with furosemide is significant when administered by the IV route at a rate exceeding 4 mg/min. Bioavailability is lower and more variable for furosemide compared to bumetanide and torsemide; therefore, the IV-to-oral ratio for furosemide is about 1:2. Furosemide, bumetanide, and torsemide all contain a sulfa moiety; however, a previous sulfonamide antimicrobial allergy does not prohibit loop diuretic administration. In the rare instance of a sulfonamide-like allergic reaction to one of the commonly used loop diuretics, ethacrynic acid could be given because it does not contain a sulfa moiety.

Loop diuretics exert their effect from the luminal (urinary) side of the tubule. Decreased tubular secretion of loop diuretics occurs in kidney disease and reduces drug concentration at the active site in the tubule lumen. Therefore, large doses of loop diuretics are often necessary in kidney disease to ensure that adequate drug reaches the nephron lumen. Loop diuretics also have a ceiling effect where maximal **natriuresis** occurs.[20] Thus, very large doses of furosemide (eg, 1 g) are not necessary and may unnecessarily increase the risk of ototoxicity.

Several adaptive mechanisms by the kidney limit effectiveness of loop diuretic therapy. As the concentration of diuretic in the loop of Henle decreases, postdiuretic sodium retention can occur. This effect can be minimized by decreasing the dosage interval (ie, dosing more frequently) or by administering a continuous infusion.[21]

Prolonged administration of loop diuretics can lead to a second type of diuretic resistance. Hypertrophy of distal convoluted tubule cells can occur secondary to enhanced delivery of sodium to the distal tubule.[20] Subsequently, increased sodium chloride absorption occurs in the distal tubule, which diminishes the effect of the loop diuretic on overall sodium excretion. Combining a distal convoluted tubule diuretic, such

Patient Encounter Part 1

A 65-year-old woman presents to the clinic with complaints of nausea and vomiting. She has a past medical history of stage 2 chronic kidney disease with proteinuria (baseline SCr 1.0 mg/dL [88 µmol/L]), gout, hypertension, and osteoarthritis. Her estimated GFR is 60 mL/min/1.73 m^2. She reports having nausea, vomiting, and a low-grade fever last week. Her fever resolved with ibuprofen, but she still feels weak and nauseated. She states that "her feet are swollen" even though she takes her "water pill." Her weight is usually about 150 pounds (68.2 kg), and today she weighs 155 lbs (70.5 kg). Upon preliminary examination, she was found to have bilateral 2 + pitting edema up to the knees, BP 170/94 mm Hg, and crackles on auscultation.

Meds:

Losartan/Hydrochlorothiazide 100/25 mg orally once daily

Simvastatin 40 mg orally daily in the evening

Metformin 500 mg orally twice daily

Glyburide 5 mg orally daily

Metoprolol 25 mg orally twice daily

Allopurinol 300 mg orally daily

Ibuprofen 400 mg orally four times as day as needed for arthritis and fever

What signs and symptoms suggest acute kidney injury (AKI)?

What risk factors does she have for developing AKI?

What additional laboratory information do you need to fully assess the patient?

What questions would you ask her regarding her pharmacotherapy?

as metolazone or hydrochlorothiazide, with a loop diuretic can result in a synergistic increase in urine output. There are no data demonstrating greater efficacy of one distal convoluted tubule diuretic over another. It is common practice to administer these diuretics 30 to 60 minutes prior to the loop diuretic to inhibit sodium reabsorption at the distal convoluted tubule before it is inundated with sodium from the loop of Henle. However, the effectiveness of this strategy has not been studied.

The usual starting dose of IV furosemide for treatment of AKI ranges from 40 to 80 mg (Figure 25–1). Reasonable starting doses for bumetanide and torsemide are 1 mg and 20 mg, respectively.[20] Efficacy of diuretic administration can be determined by assessing a patient's hourly fluid balance. Other methods to minimize volume overload, such as fluid restriction and concentration of IV medications, should be initiated as needed. If urine output does not increase to about 1 mL/kg/h, the diuretic dosage can be increased to a ceiling dose of 160 to 200 mg of furosemide or its equivalent (Figure 25–1).[22] Dosing frequency is based on the patient's response, the ability to restrict sodium intake, and the duration of action of the diuretic. Methods to improve diuresis can be initiated sequentially, such as (a) shortening the dosing interval, (b) adding hydrochlorothiazide or metolazone, and (c) switching to a continuous infusion loop diuretic. Continuous infusion loop diuretics may be easier to titrate than bolus dosing, require less nursing administration time, and may lead to fewer adverse reactions. The hemodynamic and fluid status of the patient should be monitored closely when loop diuretics are administered in high doses or with a continuous infusion, particularly in combination with distal convoluted tubule diuretics. Additionally, the electrolyte status of the patient should be monitored at least daily to prevent profound diuresis and electrolyte abnormalities, such as hypokalemia.

▶ *Other Agents*

Thiazide diuretics, when used as single agents, are generally not effective for fluid removal in patients with AKI. Mannitol is also not recommended for treating volume overload associated with AKI. In patients with renal dysfunction, mannitol excretion is decreased, resulting in expanded blood volume and hyperosmolality. Potassium-sparing diuretics, which inhibit sodium reabsorption in the distal nephron and collecting duct, are not sufficiently effective in removing fluid. In addition, they increase the risk of hyperkalemia in patients already at risk. KEY CONCEPT Thus, loop diuretics are the diuretics of choice for the managing volume overload in AKI.

Low-dose dopamine (LDD), in doses ranging from 0.5 to 3 mcg/kg/min, predominantly stimulates dopamine-1 receptors, leading to renal vasodilation and increased renal blood flow. Although this effect has been substantiated in healthy euvolemic individuals with normal kidney function, there is no conclusive efficacy data in patients with AKI. For this reason, LDD is not indicated for treatment of AKI.

Fenoldopam, a selective dopamine-1 receptor agonist approved for short-term management of severe hypertension, has also been studied for prevention and treatment of AKI. No results from adequately powered, multicenter trials conclusively support its use, and the risk of hypotension further limits routine administration. The current KDIGO Clinical Practice Guidelines do not recommend fenoldopam for prevention or treatment of AKI.[1]

Studies are underway to investigate the utility of atrial natriuretic peptide, a hormone secreted by the heart that generates sodium loss, in prevention or early treatment of AKI.

Nonpharmacologic Treatment

▶ *Renal Replacement Therapy*

RRT may be necessary in patients with established AKI to treat pulmonary edema and volume overload that is unresponsive to diuretics, to minimize accumulation of nitrogenous waste products, and to correct electrolyte and acid–base abnormalities, such as hyperkalemia and metabolic acidosis, while renal function recovers. There is wide variation in practice on indications for RRT, timing of initiation and discontinuation of RRT, intensity of treatment, and optimal type of RRT. Absolute indications for dialysis usually include:

- BUN greater than 100 mg/dL (35.7 mmol/L)
- Potassium greater than 6 mEq/L (mmol/L) with EKG abnormalities
- Magnesium greater than 8 mg/dL (3.29 mmol/L) with anuria and no deep tendon reflexes
- Metabolic acidosis with a pH less than 7.15
- Diuretic-resistant fluid overload.[23]

Approximately 10% to 30% of patients with AKI treated with RRT will not have recovery of kidney function and will need to remain on long-term dialysis.[24]

Two processes for solute removal occur during RRT: diffusion and convection. Diffusion is the movement of molecules from an area of high concentration in the blood to an area of low concentration in the dialysate across a semi-permeable dialysis membrane. Convection is removal of solutes secondarily to fluid removal from ultrafiltration, commonly known as "solute drag."

Two types of RRT modalities are used in AKI: intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT). IHD is a higher efficiency form of dialysis that results in fluid removal by ultrafiltration and solute removal by diffusion that is provided for several hours a day at a variable frequency (usually daily or three to five times per week). CRRT is a form of dialysis that provides slow fluid and/or solute removal on a continuous (up to 24-hour) basis. The characteristics of the different types of CRRTs and their associated fluid and solute removal are described in Table 25–2.

The primary advantage of CRRT is hemodynamic stability and better volume control, particularly in patients who are unable to tolerate rapid fluid removal. The primary disadvantages associated with CRRT are continuous nursing requirements, continuous anticoagulation, frequent clotting of the dialyzer, patient immobility, and increased cost. There is no conclusive evidence that one type of dialysis is preferred over another in terms of mortality and recovery of renal function. Thus, selection of CRRT over IHD is often governed by the critical illness of the patient and by the comfort level of the institution with one particular type of dialysis. KDIGO Clinical Practice Guidelines suggest CRRT in hemodynamically unstable patients.[1] Mortality in critically ill patients receiving CRRT is 40% to 53%.[25]

▶ *Supportive Therapy*

Supportive therapy in AKI includes adequate nutrition, correction of electrolyte and acid–base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities. Because AKI can be associated with multiorgan failure, treatment may include the medical management of infections, cardiovascular and GI conditions, and respiratory failure.

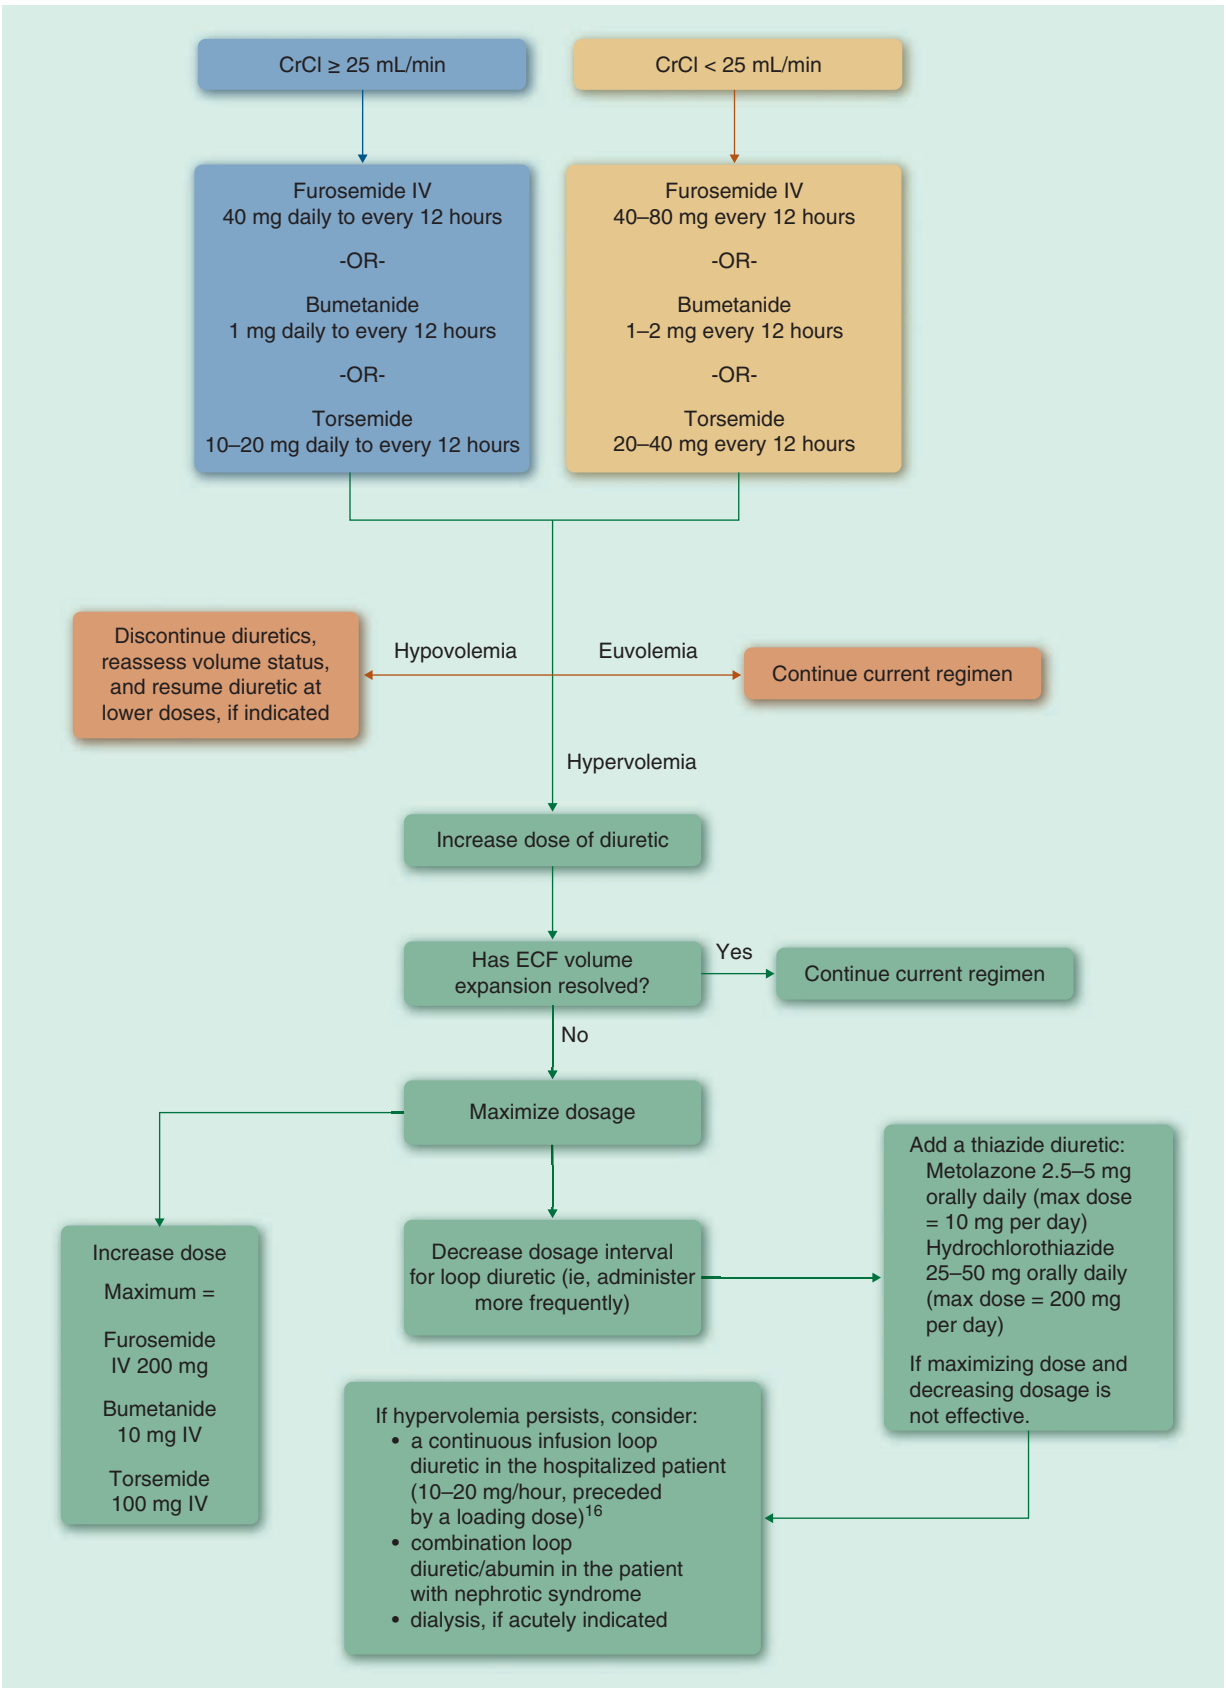

FIGURE 25–1. Algorithm for treatment of extracellular fluid expansion. (CrCl, creatinine clearance; ECF, extracellular fluid.)

Table 25–2

Modalities for Continuous Renal Replacement Therapy

		Technique		Process of Solute Removal		
Type of CRRT	Abbreviation	Filtration	Dialysis	Convection	Diffusion	Description
Slow **C**ontinuous **U**ltra**f**iltration	SCUF	√		√ (limited)		Low rate of fluid removal without significant solute removal
Continuous **V**eno**v**enous **H**emofiltration	CVVH	√		√		Higher rate of fluid removal and solute removal (small and large molecule)
Continuous **V**eno**v**enous **H**emo**d**ialysis	CVVHD		√		√	Diffusive removal of solutes (small molecule) with limited fluid removal
Continuous **V**eno**v**enous **H**emo**d**ia**f**iltration	CVVHDF	√	√	√	√	Fluid removal and removal of solutes (small and large molecule) via diffusion (dialysis)

Historically, patients were often placed on a protein-restricted diet to avoid the production of uremic toxins and minimize the rise in BUN. However, adequate protein intake should be administered to maintain metabolic balance. Protein intake of 0.8 to 1 g/kg/day is recommended in patients with AKI who are not undergoing dialysis, and higher protein intake in patients undergoing RRT or who are hypercatabolic.[1] Some studies have shown a beneficial effect of tight glycemic control on decreasing the incidence and severity of AKI, whereas others have shown a higher incidence of hypoglycemia. Thus, glycemic control in the range of 110 to 149 mg/dL (6.1–8.3 mmol/L) is recommended.[1]

PREVENTION OF ACUTE KIDNEY INJURY

KEY CONCEPT It is critically important to identify patients at high risk for developing AKI and to implement preventive methods to decrease its occurrence or severity.

Avoidance of Nephrotoxic Medications

The best preventive measure for AKI, especially in individuals at high risk, is to avoid medications known to precipitate AKI. Nephrotoxicity is a significant side effect of aminoglycosides, ACE inhibitors, ARBs, amphotericin B, NSAIDs, cyclosporine, tacrolimus, and radiographic contrast agents.[6] Unfortunately,

Patient Encounter Part 2: Medical History and Physical Examination

PMH: Type 2 diabetes mellitus for 10 years (labs from 3 months ago: A1C 7.4% [0.074; 57 mmol/mol hemoglobin], SCr 1.0 mg/dL [88 µmol/L])

Dyslipidemia for 10 years

Hypertension for 20 years

Gout

Osteoarthritis

FH: Father with history of type 2 diabetes and chronic kidney disease; mother with history of hypertension

SH: No smoking, no alcohol use

PE:

VS: BP 170/94 mm Hg, pulse 85 bpm, RR 22/min, temperature 37.6°C, Wt 70.5 kg (155 lb), Ht 5′4″ (163 cm)

Chest: Basilar crackles, inspiratory wheezes

CV: RRR, S_1 and S_2 normal

MS/Ext: bilateral 2 + pitting edema up to the knees

Urinalysis: Color, yellow; character, hazy; glucose (–); ketones (–); specific gravity 1.010; pH 5; (+) protein; no bacteria; nitrite (–); blood (–); osmolality 325 mOsm/kg (mmol/kg); urinary sodium 77 mEq/L (mmol/L); creatinine 25 mg/dL (2210 µmol/L)

Laboratory values: Sodium 136 mEq/L (mmol/L), potassium 5.0 mEq/L (mmol/L), chloride 105 mEq/L (mmol/L), bicarbonate 22 mEq/L (mmol/L), BUN 35 mg/dL (12.5 mmol/L), SCr 1.5 mg/dL (133 µmol/L), magnesium 1.6 mg/dL (0.66 mmol/L), glucose 120 mg/dL (6.7 mmol/L), WBC 8.0 × 10^3/mm^3 (8.0 × 10^9/L), hemoglobin 14.4 g/dL (144 g/L; 8.94 mmol/L), hematocrit 42% (0.42).

Interview information: Patient takes all of her medications as prescribed. She has been taking all of her medications for years, with the exception of ibuprofen. She started taking it for osteoarthritis last month, and then 3 to 4 doses over the past few days to treat her fever. She checks her fasting glucose each morning. It ranges from 110 to 125 mg/dL (6.1–6.9 mmol/L). She also checks it in the afternoons and it runs low 4 to 5 times per week (in the range of 60 to 70 mg/dL [3.3–3.9 mmol/L]).

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

an effective, nonnephrotoxic alternative may not always be appropriate for a given patient, and the risks and benefits of selecting a drug with nephrotoxic potential must be considered. For example, serious gram-negative infections may require double antibiotic coverage, and an aminoglycoside may be necessary based on culture and sensitivity reports. Monitoring of serum aminoglycoside concentrations is warranted in these situations.

▶ *Drug-Induced AKI*

Aminoglycosides Aminoglycosides (gentamicin, tobramycin, and amikacin) cause nonoliguric intrinsic AKI in about 10% to 25% of treated patients.[26] Injury is due to binding of aminoglycosides to proximal tubular cells in the renal cortex, with subsequent cellular uptake and cell death. In addition, aminoglycosides cause renal vasoconstriction and mesangial contraction.[27] In clinical practice, all aminoglycosides have comparable nephrotoxicity; thus, similar precautions should be used for all of the agents. Risk factors for aminoglycoside-induced AKI include high cumulative drug exposure, prolonged course of therapy (typically after 7 to 10 days of therapy), preexisting CKD, increased age, and concurrent administration of other nephrotoxic drugs. If feasible, alternative antibiotics should be selected in individuals at high risk for developing AKI.

Methods to minimize drug exposure with conventional dosing (multiple doses per day) include maintaining trough concentrations less than 2 mcg/mL (mg/L; 4.2 µmol/L) for gentamicin and tobramycin and less than 10 mcg/mL (mg/L; 17.1 µmol/L) for amikacin, minimizing length of therapy, and avoiding repeated courses of aminoglycosides. Concurrent exposure to other nephrotoxic medications and dehydration may also worsen AKI. There is conflicting evidence as to whether the combination of vancomycin and an aminoglycoside has a higher incidence of AKI than aminoglycoside therapy alone. Aminoglycoside-induced AKI is usually reversible upon drug discontinuation; however, dialysis may be needed in some individuals while kidney function improves.

Aminoglycosides demonstrate concentration-dependent killing and a prolonged postantibiotic effect.[28] Extended-interval (eg, once daily) aminoglycoside dosing reduces the incidence of nephrotoxicity by providing high transient concentrations of drug that saturate proximal tubule uptake sites. Once saturated, the remaining aminoglycoside molecules pass through the proximal tubule and are excreted in the urine.[28] Thus, less drug is available for cellular uptake during a 24-hour period. Extended-interval aminoglycoside dosing is as effective as conventional dosing and is not more nephrotoxic; some studies have shown it to be less nephrotoxic than conventional dosing. Extended-interval dosing is not recommended for patients with preexisting kidney disease, conditions where high concentrations are not needed (eg, urinary tract infections), hyperdynamic patients who may demonstrate increased drug clearance (eg, burn patients), and others where you would suspect altered pharmacokinetics or increased risk of ototoxicity.

Amphotericin B The reported incidence of amphotericin B-induced AKI varies widely in the literature, from about 30% to as high as 80% of patients treated with the conventional desoxycholate formulation.[28] Nephrotoxicity is due to renal arterial vasoconstriction and distal renal tubule cell damage. Risk factors for development of AKI include high daily dosage, large cumulative dose (> 2 to 3 g), preexisting kidney dysfunction, dehydration, and concomitant use of other nephrotoxic drugs. Tubular abnormalities manifesting as hypomagnesemia and hypokalemia often occur within the first 2 weeks of treatment, followed by the overt development of AKI.

Three lipid-based formulations of amphotericin B have been developed in an attempt to improve efficacy and limit toxicity, particularly nephrotoxicity: (1) amphotericin B lipid complex, (2) liposomal amphotericin B, and (3) amphotericin B cholesteryl sulfate (no longer available in the United States). The reported incidence of nephrotoxicity ranges from 15% to 25% with these formulations. The mechanism for decreased nephrotoxicity is thought to be due to preferential delivery of amphotericin B to the site of infection, with less affinity for the kidney.[30] Costs for lipid-based formulations are significantly higher than for the conventional formulation; thus, lipid-based formulations are typically recommended for individuals with risk factors for AKI. Administration of IV normal saline (1 L during the course of therapy) may also attenuate nephrotoxicity associated with amphotericin B.

It is unclear whether there are significant differences in nephrotoxicity among the lipid-based formulations. In a meta-analysis of eight studies evaluating the nephrotoxicity of liposomal amphotericin B compared with amphotericin B lipid complex, nephrotoxicity was similar.[31] However, large prospective studies are needed to definitively ascertain differences in nephrotoxicity among liposomal formulations.

Radiocontrast Agents Radiocontrast agents are administered during radiologic studies and are associated with a well-documented risk of contrast-induced AKI (CI-AKI). Although definitions vary, CI-AKI is frequently defined as a rise in SCr of at least 0.5 mg/dL (44 µmol/L) or a 25% increase in SCr within 48 hours of contrast administration. Patient-related risk factors for CI-AKI are CKD, diabetes, dehydration, older age, concomitant nephrotoxic drug administration, and high doses of contrast dye.[32]

Contrast agents are water-soluble, triiodinated, benzoic acid salts. Nephrotoxicity results from both ischemia and direct proximal tubule toxicity, with a resultant decrease in GFR and increase in SCr within 24 to 48 hours of the damage.[33] The incidence of nephrotoxicity with ionic and nonionic agents is similar in patients at low risk for developing AKI; however, in high-risk patients, nephrotoxicity is significantly greater when high ionic, high osmolar contrast agents are used. The cost of nonionic agents is approximately 10-fold higher, and their use is usually limited to high risk patients.

LO 4 Therapeutic measures to decrease the incidence of CI-AKI include extracellular volume expansion with isotonic solution, judicious use of contrast media, and use of nonionic contrast agents in high-risk patients.[34] Treatment with oral acetylcysteine has produced mixed results. Theophylline, fenoldopam, furosemide, mannitol, dopamine, statins, vitamins C and E, and calcium antagonists have been studied, but with no strong evidence that these agents prevent CI-AKI.[32, 35]

LO 4 KEY CONCEPT The most effective therapeutic maneuver to decrease the incidence of CI-AKI is extracellular volume expansion with an isotonic solution.[35] Hydration with normal saline or sodium bicarbonate is recommended.[36,37] Sodium bicarbonate may have the theoretical benefit of alkalinizing renal tubule fluid, which is thought to reduce the formation of oxygen free radicals. However, studies comparing sodium chloride to sodium bicarbonate have produced conflicting results.[1] The KDIGO Clinical Practice Guidelines workgroup recommends either agent until more definitive data is available.[1] The infusion should begin from 3 to 12 hours before the procedure and continue for 6 to 12 hours afterward to achieve a urine flow rate of at least 150 mL per hour.[1]

Fluid should be administered cautiously to patients with CHF, left ventricular dysfunction, and significant renal dysfunction.

Because production of reactive oxygen species has been implicated in the pathophysiology of contrast-induced AKI, prophylactic administration of the antioxidant acetylcysteine has been investigated, usually in combination with hydration. LO 4 Doses of acetylcysteine in clinical studies ranged from 600 to 1200 mg orally every 12 hours for 2 days, with the first one or two doses administered prior to the contrast procedure. A plethora of studies evaluating the efficacy of oral acetylcysteine have been conducted with mixed results.[38,39] The KDIGO Clinical Practice Guidelines suggest that oral acetylcysteine can be used in combination with IV fluids in patients at risk for CI-AKI due to its low risk of adverse effects and low cost.[1] It is not considered a replacement for adequate hydration, which remains the standard of care for prevention of CI-AKI.

Cyclosporine and Tacrolimus The calcineurin inhibitors cyclosporine and tacrolimus are administered as part of immunosuppressive regimens in kidney, liver, heart, lung, and bone marrow transplant recipients. They are also used in autoimmune disorders such as psoriasis and multiple sclerosis. The pathophysiologic mechanism for AKI is renal afferent arteriole vasoconstriction and ATN.[40,41] AKI often occurs within the first 6 to 12 months of treatment and can be reversible with dose reduction or drug discontinuation.[40] Risk factors include high dose, elevated trough blood concentrations, increased age, and concomitant therapy with other nephrotoxic drugs.[41] Cyclosporine and tacrolimus are extensively metabolized by the liver through the cytochrome P450 3A pathway; drugs that inhibit their metabolism (eg, erythromycin, clarithromycin, fluconazole, ketoconazole, verapamil, diltiazem, nicardipine) can increase blood concentrations of cyclosporine and tacrolimus and precipitate AKI. Pharmacogenetic variability in drug absorption and metabolism can also alter blood concentrations.

Careful monitoring of cyclosporine or tacrolimus trough concentrations and maintaining them in the target range can reduce the occurrence of AKI; however, AKI can still occur with therapeutic or even low blood concentrations. Calcium channel blockers may have a renoprotective effect through dilation of the afferent arterioles and are often used preferentially as antihypertensive agents in kidney transplant recipients.[42] However, the calcineurin inhibitor dose would need to be reduced to avoid high blood concentrations because of reduced metabolism.

It is often difficult to differentiate AKI from acute organ rejection in kidney transplant recipients because the conditions may present with similar symptoms and physical examination findings. However, fever and graft tenderness are more likely to occur with rejection, whereas neurotoxicity is more likely to occur with cyclosporine or tacrolimus toxicity. Kidney biopsy is often needed to confirm the diagnosis of rejection.

ACE Inhibitors and ARBs In instances of decreased renal blood flow (eg, kidney disease, renal artery stenosis, CHF, volume depletion), production of angiotensin II increases, causing efferent arteriole vasoconstriction and maintenance of glomerular capillary pressure and GFR. However, ACE inhibitors decrease angiotensin II synthesis, and ARBs block the action of angiotensin II at the receptor, which results in dilation of efferent arterioles, a reduction in glomerular capillary pressure, and a decrease in GFR.[29]

When initiating therapy with an ACE inhibitor or ARB for management of hypertension or prevention of CKD progression, a modest increase in SCr should be anticipated within the first week of starting therapy in predisposed individuals.[29] However, an increase of greater than 30% that does not plateau after several weeks of therapy suggests AKI, and the drug should be discontinued.[29] Risk factors for developing AKI are preexisting renal dysfunction, severe atherosclerotic renal artery stenosis, volume depletion, and severe CHF. Discontinuation of the drug usually results in return to baseline kidney function. Initiating therapy with low doses of a short-acting agent such as captopril is recommended for patients at risk of developing AKI. If tolerated, patients can later be converted to a longer-acting agent.

Nonsteroidal Anti-inflammatory Drugs Traditional non-selective NSAIDs (eg, ibuprofen, naproxen, sulindac) and the cyclooxygenase-2 (COX-2) selective inhibitor celecoxib can cause prerenal AKI through inhibition of prostaglandin-mediated renal vasodilation.[29] Risk factors are similar to those for ACE inhibitors and ARBs. Concurrent use of NSAIDs in patients on diuretics and ACE inhibitors or ARBs results in increased risk of AKI, particularly within the first 30 days of co-administration.[43]

The onset of AKI is often within days of initiating therapy, and patients typically present with oliguria, which is usually reversible with drug discontinuation. COX-2 selective inhibitors and traditional nonselective NSAIDs pose similar risk for AKI.

Patient Encounter Part 3: Follow-Up

The patient is admitted to the hospital for treatment of AKI.

Based on the information available, create a care plan for this patient's AKI and provide overall recommendations for her drug therapy. The plan should include (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

OUTCOME EVALUATION

LO 5 Goals of therapy are to maintain a state of euvolemia with good urine output (at least 0.5 to 1 mL/kg/h), to return SCr to baseline, and to correct electrolyte and acid–base abnormalities. Additional goals include appropriate drug dosages based on kidney function and avoidance of nephrotoxic drugs. Assess vital signs, weight, fluid intake, urine output, BUN, creatinine, and electrolytes daily in unstable patients.

LO 5 In patients with volume overload, monitoring includes body weight changes, fluid input compared to urine output, signs of pulmonary and peripheral edema, and blood pressure.

DRUG DOSING CONSIDERATIONS IN AKI

Assessment of Kidney Function

Appropriate drug dosing in kidney disease requires an accurate assessment of kidney function. The best index of overall kidney function is GFR. Defined as the volume of plasma filtered across the glomerulus per unit time, GFR correlates with the excretory, endocrine, and metabolic functions of the kidney. Creatinine clearance (CrCl) is routinely used as a measure of kidney function for the purposes of drug dosing; however, equations to estimate CrCl (eg, Cockcroft–Gault equation) are not accurate or reliable in AKI, particularly in critically ill patients because they tend to overestimate CrCl.[44,45] Use of such equations should be limited to instances when SCr is at steady state, with no more than a 10% to 15% change in serum creatinine within 24 hours.

Measurement of 24-hour urinary creatinine clearance may be more accurate, and is calculated by the following formula:

$$\text{Measured CrCl (mL/min)} = \frac{[\text{Urine creatinine concentration (mg/dL)} \times \text{urine volume (mL)}]}{[\text{Plasma creatinine concentration (mg/dL)} \times \text{time (minutes)}]}$$

One study evaluated an abbreviated CrCl urinary measurement (eg, 4 hours) in critically ill patients which allowed early detection of AKI.[46] Equations and creatinine clearance measurements that rely on a single SCr will usually overestimate kidney function.

As part of kidney function test results, many laboratories report an estimated GFR (eGFR), typically calculated from the Modification of Diet in Renal Disease Study (MDRD) equation. This estimation is not accurate in AKI because nonsteady state conditions for serum creatinine are present, leading to inaccurate estimates.

Several equations (Jelliffe, Brater, Chiou) have been used to assess fluctuating or unstable kidney function. These equations estimate CrCl by considering the change in serum creatinine over a specified time period. These methods have not been validated, and drug dosage adjustments based on CrCl estimates from these formulas in patients with AKI have not been evaluated.

Factors Influencing Drug Dosing in AKI

Determining the optimal dose of drugs in AKI is challenging. A variety of factors influence drug dosing, such as (1) alterations in drug pharmacokinetics that occur during AKI, (2) difficulties in accurately quantifying kidney function in AKI, (3) the influence of intermittent or continuous RRT on drug clearance, and (4) challenges in interpreting information from the literature and applying it to a specific patient. See Table 25–3 for a more complete list of considerations when dosing medications in patients with AKI.

For drugs with a narrow therapeutic window, serum drug concentration monitoring may be available to guide drug dosing. If this is not available, dosing based on an estimated CrCl is recommended, with frequent reassessment of kidney function and evaluation of the patient's status to assess efficacy and adverse effects of therapy. Selection of a drug with hepatic elimination rather than renal excretion is a reasonable alternative, if possible.

In critically ill septic patients, interpatient variability in pharmacokinetics renders dosing of antibiotics difficult. Underdosing a critically ill patient may be a greater risk than potential adverse effects attributed to higher plasma concentrations, particularly with antibiotics such as beta lactams, quinolones, and carbepenems, for which therapeutic drug monitoring is not available.[47] Thus, the risk of undertreatment of the infection needs to be balanced with the risk of adverse effects from the antimicrobial agent.

DRUG DOSING CONSIDERATIONS IN DIALYSIS

Several characteristics of a drug influence its removal during dialysis: percentage of drug eliminated by the kidney, volume of distribution, and protein binding. Drug elimination is greater when renal clearance accounts for 30% or more of total body clearance of the drug, volume of distribution is less than 1 L/kg, and protein binding is less than 50%.[48] Other factors that affect drug clearance include type of RRT (ie, IHD, CVVH, CVVHD); permeability of the dialysis membrane; and blood, ultrafiltrate, and dialysate flow rates. Higher permeable filters result in greater drug elimination than lower permeable membranes, particularly for middle molecular weight drugs, such as vancomycin, that can pass through the pores of higher permeable filters.[49]

CRRT procedures that rely on convection for solute removal (eg, CVVH, CVVHDF) result in greater solute removal than procedures utilizing diffusion (eg, CVVHD, IHD). At low dialysate and/or ultrafiltration rates, drug clearance may be similar. However, at higher rates, drug removal with CVVH and CVVHDF is greater than with CVVHD.[49] Furthermore, creatinine clearance can be roughly approximated in CRRT by summing the dialysate and ultrafiltration rates, which may assist with initial drug dosing.[49] In the case of antibiotics, residual renal function, the seriousness of the infection, the minimum inhibitory concentration (MIC) of the organism, and the clinical status of the patient must also be considered to avoid underdosing the patient.

Table 25–3

Drug Dosing Considerations in AKI

Alteration in drug pharmacokinetics	• Increase in volume of distribution due to fluid retention may occur. • Reduction in excretion of both drugs and metabolites eliminated by the kidney. • Nonrenal clearance of some drugs may be reduced.
Difficulty in quantifying an accurate assessment of kidney function in AKI	• Cockcroft-Gault and MDRD equations are not meant for AKI population; equations are based on a single SCr. • SCr as a marker for kidney function is influenced by nonrenal factors (such as nutritional status and liver function). • Equations to estimate kidney function in cases of changing kidney function have not been well studied.
AKI patients undergoing dialysis	• Different types of dialysis modalities result in differences in drug removal (eg, IHD vs. CRRT). • Differences in intensity of dialysis dose may affect drug removal (eg, length of dialysis treatment, blood and dialysate flow rate). • Populations studied in the literature are likely to be different than the specific patient being treated (eg, different types of dialysis, length of treatment).
Textbook dosing and literature recommendations	• Studies in patients with AKI are sparse. • Many drug information resource recommendations on dosing are based on the manufacturer's original pharmacokinetics information, often in patients with chronic kidney disease. • Most drug dosing guidelines were developed prior to standardization of SCr measurements between labs; thus today's SCr measurements are 5% to 10% higher than those reported prior to 2010.[49] • There is growing support for incorporation of the MDRD equation in future pharmacokinetic studies and to guide drug dosing, although use of this equation is limited to chronic kidney disease.

MDRD, Modification of Diet in Renal Disease Study equation; SCr, serum creatinine.

Patient Care Process

Collect Information:

- Obtain a thorough and accurate drug history including the use of nonprescription drugs such as NSAIDs.
- Review the medical history, physical examination findings, and laboratory tests.

Assess the Information:

- Assess kidney function by evaluating a patient's signs and symptoms, laboratory test results (eg, SCr, BUN, electrolytes), and urinary indices; calculate creatinine clearance, if appropriate.
- Assess whether any current medications may be contributing to AKI. Consider not only drugs that can directly cause AKI (eg, aminoglycosides, amphotericin B, NSAIDs, cyclosporine, tacrolimus, ACE inhibitors, and ARBs) but also drugs that can predispose a patient to nephrotoxicity or prerenal AKI (ie, diuretics and antihypertensive agents).
- Based on physical examination and review of systems, determine whether the patient is experiencing hypervolemia or hypovolemia as a consequence of AKI.

Develop a Care Plan:

- Determine if any drugs need to be discontinued, or alternative drugs selected, to prevent worsening of kidney function based on the assessment of kidney function.
- Determine if any drugs undergo significant kidney elimination and require dosage reduction or specific monitoring during AKI.
- Determine if additional therapy is warranted. For example, determine if a patient should receive hydration (for volume depletion) or a loop diuretic (for volume overload).

Implement the Care Plan:

- Adjust drug dosages based on estimated kidney function or evidence of adverse drug reactions or interactions.
- Provide supportive therapy, including adequate nutrition, correction of electrolyte and acid–base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities.
- Implement preventative strategies to decrease the risk of AKI, such as administration of saline with contrast media.
- Educate the patient and/or caregiver about changes in drug therapy, potential adverse effects related to new medications, and how to manage adverse effects that may occur.

Follow-up: Monitor and Evaluate:

- Monitor the patient's weight, urine output, electrolytes (such as potassium), and blood pressure to assess efficacy of the medication regimen.
- Monitor SCr to evaluate whether kidney function is worsening or improving.
- Review and encourage medication adherence.

Drug information references provide drug dosing recommendations in IHD and CRRT; however, they must be interpreted cautiously due to the variability in dialysis techniques used. Referring to more than one drug information resource is recommended due to variability in published recommendations.[49]

Abbreviations Introduced in This Chapter

ACE	Angiotensin-converting enzyme
AKI	Acute kidney injury
ARB	Angiotensin II receptor blocker
ARF	Acute renal failure
ATN	Acute tubular necrosis
BUN	Blood urea nitrogen
CHF	Congestive heart failure
CI-AKI	Contrast-induced acute kidney injury
CKD	Chronic kidney disease
CrCl	Creatinine clearance
CRRT	Continuous renal replacement therapy
CVVH	Continuous venovenous hemofiltration
CVVHD	Continuous venovenous hemodialysis
CVVHDF	Continuous venovenous hemodiafiltration
FENa	Fractional excretion of sodium
GFR	Glomerular filtration rate
IHD	Intermittent hemodialysis
KDIGO	Kidney Disease: Improving Global Outcomes
JVD	Jugular venous distention
LDD	Low-dose dopamine
NSAIDs	Nonsteroidal anti-inflammatory drugs
RIFLE	Risk, Injury, Failure, Loss, and End-stage
RRT	Renal replacement therapy
SCr	Serum creatinine concentration

26 Chronic and End-Stage Renal Disease

Kristine S. Schonder

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. List the risk factors that increase susceptibility for chronic kidney disease (CKD).
2. Explain the mechanisms associated with progression of CKD.
3. Outline the desired outcomes for treatment of CKD.
4. Develop a therapeutic approach to slow progression of CKD including lifestyle modifications and pharmacologic therapies.
5. Identify specific consequences associated with CKD.
6. Design an appropriate therapeutic approach for specific consequences associated with CKD.
7. Recommend an appropriate monitoring plan to assess the effectiveness of pharmacotherapy for CKD and specific consequences.
8. Educate patients with CKD about the disease state, the specific consequences, lifestyle modifications, and pharmacologic therapies used for treatment of CKD.

INTRODUCTION

The kidney is made up of approximately 2 million **nephrons** that are responsible for filtering, reabsorbing, and excreting solutes and water. The kidney has three primary functions: excretory (excrete fluid, electrolytes, and solutes); metabolic (metabolize vitamin D and some drugs, such as insulin and some beta-lactams); and endocrine (produce **erythropoietin** [EPO]). As the number of functioning nephrons declines, the primary functions of the kidney that are affected include:

- Production and secretion of EPO
- Activation of vitamin D
- Regulation of fluid and electrolyte balance
- Regulation of acid–base balance

Chronic kidney disease (CKD) is defined as abnormalities in the structure or function of the kidney, present for 3 months or more, with implications for health.[1] Markers of structural abnormalities include albuminuria (30 mg/24 hours or more or an albumin:**creatinine** ratio [ACR] of more than 30 mg/g [or 3.5 mg/mmol for female and 2.5 mg/mmol for male, but varies between different guidelines and location]); hematuria or casts in urine sediment; electrolyte and other abnormalities caused by renal tubular disorders; abnormalities detected by histology or imaging; or history of kidney transplantation. Functional abnormalities are indicated by a decline in **glomerular filtration rate** (GFR) less than 60 mL/min/1.73m^2 (0.58 mL/s/m^2). Generally, CKD is a progressive decline in kidney function (number of functioning nephrons) that occurs over several months to years. A rapid decline in kidney function over days to weeks is known as acute kidney injury (AKI), which is discussed in Chapter 25. Because the decline in kidney function in CKD is often irreversible, treatment of CKD is aimed at slowing the progression to end-stage kidney disease (ESKD).

EPIDEMIOLOGY AND ETIOLOGY

The United States Renal Data System (USRDS), using data from the National Health and Nutrition Examination Survey (NHANES), estimates the prevalence of CKD in the United States is 14.8%, corresponding to nearly 47 million people.[2] CKD is more common in people over age 60 years and African Americans. Diabetes increases the risk of developing CKD by more than threefold and hypertension increases the risk more than twice than those who do not have either disease.[2]

KEY CONCEPT The Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group developed a classification system for CKD.[1] The staging system defines the stages of CKD based on cause and GFR category (Table 26–1). The GFR is calculated using the abbreviated Modification of Diet in Renal Disease (MDRD) study equation[3]:

$$GFR = 175 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if African American})$$

Alternatively, GFR can be calculated using the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI)[1]:

$$GFR = 141 \times \min(S_{Cr}/\kappa, 1)^{\alpha} \times \max(S_{Cr}/\kappa, 1)^{-1.209} \times 0.993^{Age} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if African American]}$$

where, κ is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of S_{Cr}/κ or 1.

KEY CONCEPT CKD is a progressive disease that eventually leads to ESKD. The prevalence of ESKD has increased every year since 1980 to over 700,000 people in 2015 with over 124,000 new cases of ESKD diagnosed in 2015.[2] The prevalence of ESKD is related to ethnicity, affecting 9.5 times more American Indians/Alaska Natives, 3.7 times more African Americans, 1.5 times more Asians, and 1.4 more Hispanics as whites.[2]

Table 26–1

GFR Categories in CKD

GFR Category	GFR (mL/min/1.73 m²)	GFR (mL/s/m²)	Terms
G1[a]	≥ 90	≥ 0.87	Normal or high
G2[a]	60–89	0.58–0.86	Mildly decreased
G3a	45–59	0.43–0.57	Mildly to moderately decreased
G3b	30–44	0.29–0.42	Moderately to severely decreased
G4	15–29	0.14–0.28	Severely decreased
G5	< 15	< 0.14	Kidney failure

[a]Kidney damage must be present to meet criteria of CKD.

CKD, chronic kidney disease; GFR, glomerular filtration rate.

Data from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. Kidney Int Suppl. 2013;3:1–150.

Risk Factors for CKD

LO 1

Identifying risk factors for CKD is difficult because CKD progresses slowly and is often not diagnosed until late in the disease. Disease states and factors that can increase susceptibility to CKD are listed in Table 26–2. These factors can be used to identify targets for CKD screening programs. For example, older patients, those with low kidney mass or birth weight, or those with a family history of kidney disease should be routinely screened for CKD. Minority and low socioeconomic communities may be targets for more widespread CKD screening programs.

The three most common causes of CKD in the United States are diabetes mellitus (DM), hypertension, and glomerulonephritis, accounting for more than 82% of CKD cases.[2] These are discussed in further detail below. Other causes of CKD include polycystic kidney disease, Wegener granulomatosis, vascular diseases, human immunodeficiency virus (HIV) nephropathy, and AKI.

▶ *Diabetes*

DM is the most common cause of CKD, causing 37% of all CKD.[2] The risk of developing diabetic kidney disease (DKD) associated with DM is closely linked to hyperglycemia and is similar for both type 1 (DM1) and type 2 (DM2). Structural changes appear in the glomerulus as early as 2 years after diagnosis of DM1. Changes in GFR can occur as early as 5 to 7 years after diagnosis.[4] Similar changes occur in DM2, but the timing of onset of DM2 and presentation of kidney disease is more difficult to determine. Albuminuria develops in 40% of patients with DM2 and GFR is less than 30 mL/min/1.73 m² (0.29 mL/s/m²) within 15 years of diagnosis of DM2.[4]

Table 26–2

Risk Factors That Increase Susceptibility for CKD

- Diabetes mellitus
- Hypertension
- Autoimmune disease
- Polycystic kidney disease
- Human immunodeficiency virus (HIV)
- Drug toxicity
- Urinary tract abnormalities (infections, obstruction, stones)
- Advanced age
- Reduced kidney mass
- Low birth weight
- Racial/ethnic minority
- Family history of kidney disease
- Low income or education
- Systemic inflammation
- Dyslipidemia

▶ *Hypertension*

The second most common cause of CKD is hypertension, accounting for 29% of cases of ESKD.[2] It is more difficult to determine the true risk of developing CKD in patients with hypertension because the two are so closely linked, with CKD also being a cause of hypertension. The prevalence of hypertension is correlated with the degree of kidney dysfunction (decreased GFR) with 36% of patients with CKD G1, 48% of patients with CKD G2, and 85% of patients with CKD G3 presenting with hypertension.[5] The risk of developing ESKD increases with the degree of hypertension and is linked to both systolic and diastolic blood pressure.[5]

▶ *Glomerulonephritis*

The term *glomerulonephritis* includes many specific diseases that can affect glomerular function. These include such diseases as IgA nephropathy and glomerulonephritis associated with systemic lupus erythematosus and streptococcal disease, among many others. The etiologic and pathophysiologic features of glomerular diseases vary with the specific disease, making it difficult to extrapolate the risk for progression of CKD in patients affected by glomerular diseases. Certain glomerular diseases are known to rapidly progress to ESKD; others progress more slowly or may be reversible.

Risk Factors for Progression of CKD

Several factors increase the progression of CKD, or rate of decline in GFR. The most important risk factors for progression of CKD include proteinuria, elevated blood pressure, hyperglycemia, hyperlipidemia, and AKI. Smoking tobacco also plays a role in progression of CKD.

▶ *Proteinuria*

The presence of protein in the urine is a marker of glomerular dysfunction and some tubulointerstitial diseases. The degree of proteinuria correlates with the risk for progression of CKD.[6] The effects of proteinuria appear to be worse with milder stages of CKD. Compared with patients with no proteinuria, proteinuric patients with CKD G3 are 15 times more likely to double serum creatinine; patients with CKD G4 are 8 times more likely to double serum creatinine.[6] The mechanisms by which proteinuria potentiates CKD are discussed later.

▶ *Elevated Blood Pressure*

Systemic blood pressure correlates with glomerular pressure, and elevations in both independently contribute to glomerular damage. The rate of GFR decline is related to elevated systolic blood pressure and mean arterial pressure. The decline in GFR is estimated to be 14 mL/min per year (0.23 mL/s per year) in patients with diabetes with a sustained systolic blood pressure of 180 mm Hg. Conversely, the decline in GFR decreases to 2 mL/min per year (0.03 mL/s per year) with a systolic blood pressure of 135 mm Hg.[7]

▶ *Elevated Blood Glucose*

The reaction between glucose and protein in the blood produces advanced glycation end products (AGEs), which are metabolized in the proximal tubules. Hyperglycemia increases the synthesis of AGEs, which affects glomerular, tubular, and vascular function in the kidney. AGEs are known to affect podocyte activity, the epithelial cells responsible for filtering blood in the glomerulus, which contributes to proteinuria, and, in turn, damages tubules.[8]

▶ *Hyperlipidemia*

Dyslipidemia can promote kidney injury and subsequent progression of CKD.[9] The dyslipidemia in CKD is manifested primarily as elevated triglycerides and lipoprotein(a) levels, and decreased high-density lipoprotein cholesterol (HDL-C) levels. Total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels generally remain within normal limits, but LDL-C particles are smaller, denser, and more atherogenic. Furthermore, kidney disease alters lipid metabolism, allowing lipoproteins to remain in circulation longer.[9] In contrast, patients with nephrotic syndrome, characterized by urine protein rates that exceed 3 g/24 hours, often have elevated total cholesterol and LDL-C.[9]

▶ *Acute Kidney Injury*

Nephron damage that results from AKI increases the risk of developing CKD, even if renal function recovers.[10] The most predictive risk factor of whether patients will develop CKD is the severity of AKI. Severe AKI is associated with a 28-fold increased risk of developing CKD, but even mild AKI is associated with a twofold increased risk. Older age also increases the risk of developing CKD after AKI. The cause of AKI may also affect the risk of CKD.[10]

PATHOPHYSIOLOGY

A number of factors can cause initial damage to the kidney. The resulting sequelae, however, follow a common pathway that promotes progression of CKD and results in irreversible damage leading to ESKD (Figure 26–1).

LO 2

Regardless of the initial cause of kidney damage, the result is a decrease in the number of functioning nephrons. The remaining nephrons hypertrophy to increase glomerular filtration and tubular function, both reabsorption and secretion, in an attempt to compensate for the loss of kidney function. Initially, these adaptive changes preserve many of the clinical parameters of kidney function, including creatinine and electrolyte excretion. However, as time progresses, angiotensin II is required to maintain the hyperfiltration state of the functioning nephrons. Angiotensin II is a potent vasoconstrictor of both the afferent and efferent arterioles but has a preferential effect to constrict the efferent arteriole, thereby increasing the pressure in the glomerular capillaries. Increased glomerular capillary pressure expands the pores in the glomerular basement membrane, altering the size-selective barrier and allowing proteins to be filtered through the glomerulus.[11]

Proteinuria increases nephron loss through various complex mechanisms. Filtered proteins are reabsorbed in the renal tubules, which activate the tubular cells to produce inflammatory and

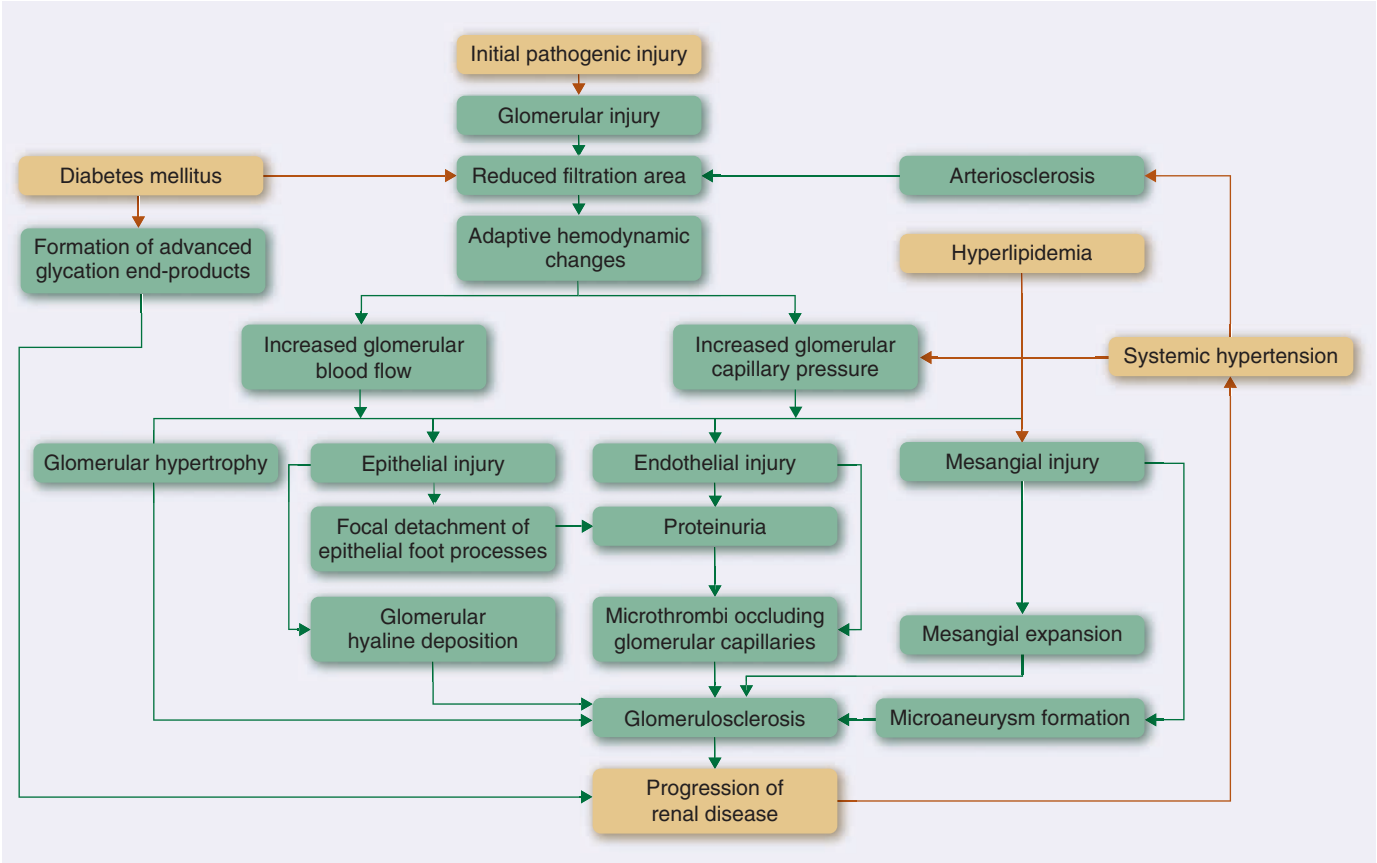

FIGURE 26–1. Proposed mechanisms for progression of kidney disease. (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill Education; 2017:612, with permission.)

vasoactive cytokines and trigger complement activation. These cytokines cause interstitial damage and scarring in the renal tubules, leading to damage and loss of more nephrons. Ultimately, the process leads to progressive loss of nephrons to the point where the number of remaining functioning nephrons is too small to maintain clinical stability, and kidney function declines.

ASSESSMENT

Because CKD often presents without symptoms, assessment for CKD relies on appropriate screening strategies in all patients with risk factors for developing CKD. Evaluation for CKD and the subsequent treatment strategies depend on the diagnosis, comorbid conditions, severity and complications of disease, and risk factors for the progression of CKD. KEY CONCEPT Early treatment of CKD and the associated complications of CKD are the most important factors to decrease morbidity and mortality associated with CKD. Screening for CKD should be performed in all people with an increased risk for developing CKD including patients with DM, hypertension, genitourinary abnormalities, autoimmune disease, increased age, a family history of kidney disease, or following AKI. Assessment for CKD includes measurement of SCr, measurement of creatinine clearance (ie, 24-hour urine collection) or estimation of GFR (ie, MDRD or CKD-EPI), urinalysis, blood pressure, serum electrolytes, and/or imaging studies. It is important to note that SCr should be stable when estimating GFR or measuring creatinine clearance in patients with CKD. In patients with known CKD, the presence and assessment of CKD-related complications, including anemia and secondary hyperparathyroidism (sHPT), involves measurement of blood counts, red blood cell (RBC) indices, iron stores, serum phosphorus, calcium, and parathyroid hormone (PTH) levels.

A key part of CKD assessment is analysis for proteinuria, which is the primary marker of structural kidney damage, even in patients with normal GFR. Protein excretion can be assessed by measuring urine albumin-to-creatinine ratio (ACR), urine protein-to-creatinine ratio, or urinalysis with a reagent strip test. A urinary protein excretion of 30 mg/day or more or an ACR or 30 mg/g (or 3.5 mg/mmol for female and 2.5 mg/mmol for male, but varies between different guidelines and locations) or more on a random untimed urine sample is considered to be significant in the context of CKD. Albuminuria should be assessed with GFR at least annually in people with CKD, and more frequently as GFR declines.[1]

Complications

KEY CONCEPT The decline in kidney function is associated with a number of complications, which are discussed later in the chapter, including:

- *Hypertension*
- *Fluid and electrolyte disorders*
- *Anemia*
- *Metabolic bone disease*

TREATMENT

Desired Outcomes

LO 3

The primary goal is to slow and prevent the progression of CKD to prevent a cardiovascular event, CKD complications, and the need for kidney replacement therapy. This requires early identification of patients at risk for CKD to initiate interventions early in the course of the disease.

Nonpharmacologic Therapy

▶ *Nutritional Management*

Protein intake should be lowered to 0.8 g/kg/day in adults with diabetes or people with a GFR less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) who are not on **dialysis**. Protein intake should not exceed 1.3 mg/kg/day in any adult with CKD.[1] However, protein restriction must be balanced with the risk of malnutrition in patients with CKD. In particular, patients on dialysis are at risk for nutritional abnormalities, which can lead to increased rates of hospitalization and death.[12] Malnutrition is common in patients with ESKD for various reasons, including decreased appetite, protein catabolism due to protein losses in the urine, and nutrient losses through dialysis. For this reason, patients receiving dialysis should maintain protein intake of 1.2 g/kg/day and maintain a caloric intake of 30 to 35 kcal/kg (125–147 kJ/kg) of ideal body weight.[12]

Limiting salt intake to less than 2 g (90 mmol) of sodium per day (equivalent to 5 g sodium chloride) will help to control blood pressure and reduce water retention in CKD. Patients with CKD should be encouraged to increase physical activity, with a goal of at least 30 minutes 5 times per week, to achieve a healthy weight, with a goal BMI of 20 to 25 kg/m^2.[1]

Pharmacologic Therapy

▶ *CKD with Diabetes*

The target hemoglobin A1c (HbA1c) should be less than 7.0% (0.07; 53 mmol/mol Hgb) for patients with DM to decrease the incidence of albuminuria in patients with and without documented DKD.[1,13] This generally involves intensive insulin therapy for type 1 DM or insulin-dependent type 2 DM or optimizing doses of oral hypoglycemic agents in patients with noninsulin-dependent type 2 DM. However, glycemic control should be balanced with the risk of hypoglycemia, especially in patients with CKD and DM with comorbidities,[1,13] and higher A1c targets should be considered for patients with limited life expectancy with late stages of DM and CKD.

▶ *Optimal Blood Pressure Control*

Reductions in blood pressure are associated with a decrease in proteinuria, leading to a decrease in the rate of progression of kidney disease. The 2017 High Blood Pressure Clinical Practice Guideline recommends targeting a goal blood pressure of < 130/80 mm Hg for all patients with CKD.[14]

KEY CONCEPT Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) are the antihypertensive agents of choice in patients with CKD with an AER of 30 mg/day or more because of their greater effect on lowering proteinuria, compared with other antihypertensive agents. ACEIs and ARBs should be started at a low dose and the dose should be titrated upward slowly to minimize the risk of AKI (see Chapter 25). Ideally, the dose of ACEIs and ARBs should be increased to achieve a 30% to 50% reduction in urinary albumin excretion, but this may be limited by side effects, such as hyperkalemia, in patients with CKD.

In patients with CKD G5 who are receiving hemodialysis (HD), cardiovascular mortality is affected by blood pressure both before and after HD.[15] A systolic blood pressure greater than 160 mm Hg and diastolic blood pressure greater than 90 mm Hg after HD are independently associated with an increased risk of cardiovascular mortality (hazard ratio [HR]: 1.2 for each).[16] Similarly, a systolic blood pressure less than 120 mm Hg or diastolic blood pressure

Clinical Presentation and Diagnosis of CKD

General

The development of CKD is usually subtle in onset, often with no noticeable symptoms.

Symptoms

CKD G1 and G2 are generally asymptomatic.

CKD G3a–3b and G4 may be associated with minimal symptoms.

CKD G5 can be associated with pruritus, dysgeusia, nausea, vomiting, constipation, muscle pain, fatigue, and bleeding abnormalities.

Signs

Cardiovascular: Worsening hypertension, edema, dyslipidemia, left ventricular hypertrophy, electrocardiographic changes and chronic heart failure

Musculoskeletal: Cramping

Neuropsychiatric: Depression, anxiety, impaired mental cognition

GI: Gastroesophageal reflux disease, GI bleeding, and abdominal distention

Genitourinary: Changes in urine volume and consistency, "foaming" of urine (indicative of proteinuria), and sexual dysfunction

Laboratory Tests

CKD G1 and G2: Blood urea nitrogen (BUN) and serum creatinine (SCr) are generally within normal limits, despite mildly decreased GFR.

CKD G3a–G3b, G4, and G5: Increased BUN and SCr; decreased GFR.

Advanced stages: Increased potassium, phosphorus, and magnesium; decreased bicarbonate (metabolic acidosis); calcium levels are generally low in earlier stages of CKD and may be elevated in CKD G5, secondary to the use of calcium-containing phosphate binders (CCPBs).

Decreased albumin, if inadequate nutrition intake in advanced stages.

Decreased RBC count, hemoglobin (Hgb) and hematocrit (Hct); decreased iron stores (iron level, total iron binding capacity [TIBC], serum ferritin level, and transferrin saturation [TSat]). EPO levels are not routinely monitored and are generally normal to low. Urine positive for albumin or protein.

Increased PTH level; decreased vitamin D levels (CKD G4 or G5).

Stool may be Hemoccult-positive if GI bleeding occurs from uremia.

Other Diagnostic Tests

Structural abnormalities of kidney may be present on diagnostic examinations.

less than 60 mm Hg before HD is associated with a higher risk of cardiovascular mortality (HR: 1.1 and 1.3, respectively [$p < 0.05$ for each]); the same systolic or diastolic blood pressure at the end of HD is associated with a comparable risk (HR 1.1 and 1.2, respectively [$p < 0.05$ for each]).[16] However, there are no consensus guidelines on the optimal blood pressure goals before or after HD. Some evidence suggests that blood pressure on non-HD days may be a more appropriate measure, and correlates better with cardiovascular outcomes.[16] Cardiovascular outcomes may be impacted by the selection of antihypertensive agent in HD patients. One study found that ACEIs and ARBs increased cardiovascular events in patients on HD, compared to beta-blockers.[17]

Because hypertension and kidney dysfunction are linked, blood pressure control can be more difficult to attain in patients with CKD compared with patients with normal kidney function. All antihypertensive agents have similar effects on reducing blood pressure. However, two or more agents are generally required to achieve the blood pressure goal of less than 130/80 mm Hg in CKD patients.[14] Timing of blood pressure medications may also be important. One study suggests that administration of at least one antihypertensive medication at bedtime decreased cardiovascular risk by 14% in patients with CKD compared with taking all antihypertensive medications in the morning.[18]

▶ *Reduction in Proteinuria*

Albuminuria in CKD predicts long-term renal and cardiovascular prognosis.[19] The ability of antihypertensive agents to reduce protein excretion differs. ACEIs and ARBs decrease glomerular capillary pressure and volume because of their effects on angiotensin II. This, in turn, reduces the amount of protein filtered through the glomerulus, independent of the reduction in blood pressure,[19] which ultimately decreases the progression of CKD. The ability of ACEIs and ARBs to reduce proteinuria is greater than that of other antihypertensives, up to 35% to 40%,[19] making ACEIs and ARBs the antihypertensive agents of choice for all patients with CKD with an AER of 30 mg/day or more, unless contraindicated. While the combination of ACEIs and ARBs reduces proteinuria more than monotherapy, some trials have shown combining full doses of ACEIs and ARBs in patients with high vascular risk increases the risk of progression of CKD and nonfatal strokes.[20] The safety and efficacy of combining lower doses of ACEIs and ARBs continues to be investigated.[20]

The nondihydropyridine calcium channel blockers (CCBs) have been shown to also decrease protein excretion in patients with and without diabetes, but should not be used as first-line agents for proteinuria.[19] Dihydropyridine CCBs, however, do not have the same effects on protein excretion. In fact, dihydropyridine CCBs may worsen protein excretion, despite similar reductions in blood pressure as nondihydropyridine CCBs.[19] When blood pressure goals are not achieved, additional antihypertensive agents should be used to reach goals. Thiazide diuretics have complementary effects when added to ACEIs and ARBs.[19] Other drug classes should be considered when compelling indications warrant or if blood pressure goals are not achieved.

▶ *Hyperlipidemia Treatment*

Hyperlipidemia plays a role in the development of cardiovascular disease (CVD) in patients with CKD. Because

data do not support the use of LDL-C levels to guide treatment of hyperlipidemia, the KDIGO guidelines recommend starting statins for all patients with nondialysis-dependent CKD aged 50 years and older, regardless of GFR category.[21] Ezetimibe should be considered when GFR is less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2). Statins should also be used for patients aged 18 to 49 years who have known coronary artery disease, DM, prior ischemic stroke, or more than a 10% estimated 10-year incidence of coronary death or nonfatal myocardial infarction.[21] However, because of the lack of efficacy in reducing cardiovascular events and the risk of adverse effects associated with statins in patients with ESKD, statins should not be initiated in patients on dialysis, unless they were receiving statins prior to starting dialysis.[21]

Outcome Evaluation

The KDIGO guidelines recommend intervals for monitoring GFR and albuminuria in patients with CKD, based on the CKD stage and the degree of proteinuria.[1] In general, patients should be monitored more frequently as CKD stage increases and the severity of albuminuria increases.

Patients with CKD G3a should be monitored every 12 months until albuminuria is detected, then the frequency of monitoring should be increased to every 4 to 6 months, based on the severity of albuminuria. As CKD progresses, the frequency of monitoring should be increased to every 3 to 6 months.

Monitor SCr and potassium levels and blood pressure within 1 week after initiating ACEI or ARB therapy. Discontinue the medication and switch to another agent if a sudden increase in SCr greater than 30% occurs, hyperkalemia develops, or the patient becomes hypotensive. Titrate the dose of the ACEI or ARB every 1 to 3 months to effect using the maximum tolerable dose. If blood pressure is not reduced to goal, add another agent to the regimen. Refer the patient to a nephrologist to manage complications associated with CKD. As kidney function declines to CKD G4, begin discussion to prepare the patient for renal replacement therapy (RRT).

CONSEQUENCES OF CKD AND ESKD

Anemia of CKD

The progenitor cells of the kidney produce 90% of the hormone EPO, which stimulates red blood cell (RBC) production. KEY CONCEPT Reduction in the number of functioning nephrons decreases renal production of EPO, which is the primary cause of anemia in patients with CKD. The development of anemia of CKD results in decreased oxygen delivery and utilization, leading to increased cardiac output and left ventricular hypertrophy (LVH), which increase the cardiovascular risk and mortality in patients with CKD. Each 1 g/dL (10 g/L; 0.62 mmol/L) decrease in hemoglobin (Hgb) below 12 g/dL (120 g/L; 7.45 mmol/L) is associated with a 5% increase in the relative risk (RR) of mortality.[22]

▶ *Epidemiology and Etiology*

Current KDIGO guidelines define anemia as an Hgb level less than 13 g/dL (130 g/L or 8.07 mmol/L) in males and less than 12 g/dL (120 g/L or 7.45 mmol/L) in females.[23] A number of factors contribute to the development of anemia including deficiencies in vitamin B_{12} or folate, hemolysis, bleeding, or bone marrow resistance to EPO. Many of these can be detected by alterations in RBC indices, which should be included in the evaluation for anemia (see Chapter 66). A complete blood cell count is also helpful in evaluating anemia to determine overall bone marrow function. The prevalence of anemia correlates with the degree of kidney dysfunction. Only 8.4% of patients with CKD G1 have anemia, whereas the number increases to 53.4% with CKD G5.[24]

▶ *Pathophysiology*

The primary cause of anemia in patients with CKD is a decrease in EPO production. With normal kidney function, as Hgb, hematocrit (Hct), and tissue oxygenation decrease, the plasma concentration of EPO increases exponentially. As the number of functioning nephrons decreases, EPO production also decreases. Thus, as Hgb, Hct, and tissue oxygenation decrease in patients with CKD, plasma EPO levels remain constant within the normal

Patient Encounter 1

A 42-year-old African American man presents to the clinic for a routine checkup. He has no complaints today.

PMH: Hypertension, diagnosed 8 years ago

SH: He smokes 2 ppd; drinks alcohol occasionally (socially)

Meds: Amlodipine 10 mg orally daily; atenolol 50 mg orally daily; atorvastatin 20 mg orally daily

ROS: Unremarkable

PE:

VS: BP 166/98 mm Hg; P 82 beats/min; T 98.8°F (37.1°C); ht 5′11″ (180 cm); wt 252 lb (114.5 kg)

CV: RRR, normal S_1, S_2; no murmurs, rubs or gallops; lungs clear

Abd: No organomegaly, bruits or tenderness, (+) bowel sounds; heme (–) stool

Exts: 1+ pedal edema bilaterally; no lesions

Labs (Fasting): Sodium 143 mEq/L (mmol/L); potassium 4.1 mEq/L (mmol/L); chloride 101 mEq/L (mmol/L); carbon dioxide 24 mEq/L (mmol/L); blood urea nitrogen (BUN) 28 mg/dL (10 mmol/L); serum creatinine (SCr) 1.8 mg/dL (159 µmol/L); glucose 102 mg/dL (5.7 mmol/L); total cholesterol 260 mg/dL (6.72 mmol/L); low-density lipoprotein cholesterol (LDL-C) 176 mg/dL (4.55 mmol/L); high-density lipoprotein cholesterol (HDL-C) 24 mg/dL (0.62 mmol/L); triglycerides 300 mg/dL (3.39 mmol/L); urine albumin: creatinine 52 mg/g creatinine (5.9 mg/mmol creatinine)

What risk factors does the patient have for the development of CKD?

What signs and symptoms are consistent with CKD?

How would you classify his CKD?

What lifestyle modifications would you recommend for this patient with CKD?

What pharmacologic alternatives are available for this patient for treatment of CKD?

Clinical Presentation and Diagnosis of Anemia of CKD

General

Anemia of CKD generally presents with fatigue and decreased quality of life.

Symptoms

Anemia of CKD is associated with symptoms of cold intolerance, shortness of breath, and decreased exercise capacity.

Signs

Cardiovascular: Left ventricular hypertrophy, electrocardiogram (ECG) changes, congestive heart failure

Neurologic: Impaired mental cognition

Genitourinary: Sexual dysfunction

Laboratory Tests

Decreased RBC count, Hgb, and Hct

Decreased serum iron level, TSat and serum ferritin, and increased TIBC

range but low relative to the degree of hypoxia present. The result is a normochromic, normocytic anemia.

Several other factors contribute to the development of anemia in patients with CKD. **Uremia**, the accumulation of toxins that results from declining kidney function, decreases the lifespan of RBCs from a normal of 120 days to as low as 60 days in patients with CKD G5. Iron deficiency and blood loss from regular laboratory testing and HD also contribute to the development of anemia in patients with CKD.

▶ *Treatment*

Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/min (1.0 mL/s) or if the SCr rises above 2 mg/dL (177 µmol/L). An anemia workup should be performed if the Hgb is less than 13 g/dL (130 g/L or 8.07 mmol/L) in males or less than 12 g/dL (120 g/L or 7.45 mmol/L) in females. The workup for anemia should rule out other potential causes for anemia (see Chapter 66). Abnormalities found during the anemia workup should be corrected before initiating **erythropoiesis-stimulating agents** (ESAs), particularly iron deficiency, because iron is an essential component of RBC production. If Hgb is below 10 g/dL (100 g/L or 6.21 mmol/L) when all other causes of anemia have been corrected, EPO deficiency should be assumed. EPO levels are not routinely measured and have little clinical significance in monitoring progression and treatment of anemia in patients with CKD.

Nonpharmacologic Therapy Approximately 1 to 2 mg of iron is absorbed daily from the diet. This small amount is generally not adequate to preserve adequate iron stores to promote RBC production in patients with CKD-related anemia. RBC transfusions have been used in the past as the primary means to maintain Hgb and Hct levels in patients with anemia of CKD. This treatment is still utilized today in patients with severe anemia, when rapid Hgb correction is needed, especially for patients with CVD, or if patients have contraindications to ESAs.

Patient Encounter 2, Part 1

A 62-year-old Hispanic woman with a history of diabetes presents to your clinic for a routine checkup. She complains of getting fatigued easily at work. She works as a housekeeper for a hotel and notes that she is not able to keep up with her work. She notes that she feels winded when she walks even short distances.

Current meds: Lisinopril 40 mg orally daily; furosemide 20 mg orally daily; levothyroxine 125 mcg orally daily; insulin detemir 18 units SC daily

ROS: Skin pale in color; fatigue daily throughout the day with minimal exertion; otherwise unremarkable

PE:

VS: BP 127/82 mm Hg; P 88 bpm; T 97.5°F (36.4°C); ht 5′ (152 cm); wt 180 lb (81.8 kg)

CV: RRR, normal S_1, S_2

Abd: No organomegaly, bruits or tenderness; (+) bowel sounds; heme (–) stool

Ext: 1+ pedal edema bilaterally

Labs: Sodium 138 mEq/L (mmol/L); potassium 4.1 mEq/L (mmol/L); chloride 101 mEq/L (mmol/L); carbon dioxide 21 mEq/L (mmol/L); BUN 18 mg/dL (6.4 mmol/L); Scr 2.2 mg/dL (194 µmol/L); glucose 140 mg/dL (7.8 mmol/L); white blood cell (WBC) count 4.8×10^3 cells/mm^3 (4.8×10^9/L); red blood cell (RBC) count 2.8×10^6 cells/mm^3 (2.8×10^{12}/L); hemoglobin (Hgb) 9.4 g/dL (94 g/L; 5.83 mmol/L); hematocrit 28% (0.28); platelets 278×10^3 cells/mm^3 (278×10^9/L)

What signs and symptoms are consistent with anemia of CKD?

What additional information could you request to determine other causes of anemia in this patient?

Pharmacologic Therapy The first-line treatment for anemia of CKD involves replacement of iron stores with iron supplements. When iron supplementation alone is not sufficient to increase Hgb levels, ESAs are necessary to replace EPO. ESAs are synthetic formulations of EPO produced by recombinant human DNA technology. Use of ESAs increases the iron demand for RBC production and iron deficiency is common, requiring iron supplementation to correct and maintain adequate iron stores to promote RBC production. The approach to the management of anemia of CKD with iron supplementation and ESAs is illustrated in **Figure 26–2**.

Iron Supplementation. Use of ESAs can lead to iron deficiency if iron stores are not adequately maintained. According to the KDIGO guidelines, iron supplementation should be considered when:

- Serum ferritin levels less than 500 ng/mL (mcg/L; 1124 pmol/L)
- Transferrin saturation (TSat): less than 30% (0.30)[23]

Serum ferritin is an acute phase reactant that may become elevated with inflammation and infection. Thus when serum ferritin is normal or elevated in conjunction with TSat levels less than 30% (0.30), treatment should be based on the clinical picture of the patient. Iron supplementation may be indicated if Hgb levels are below the goal level, but avoided if the patient is infected.

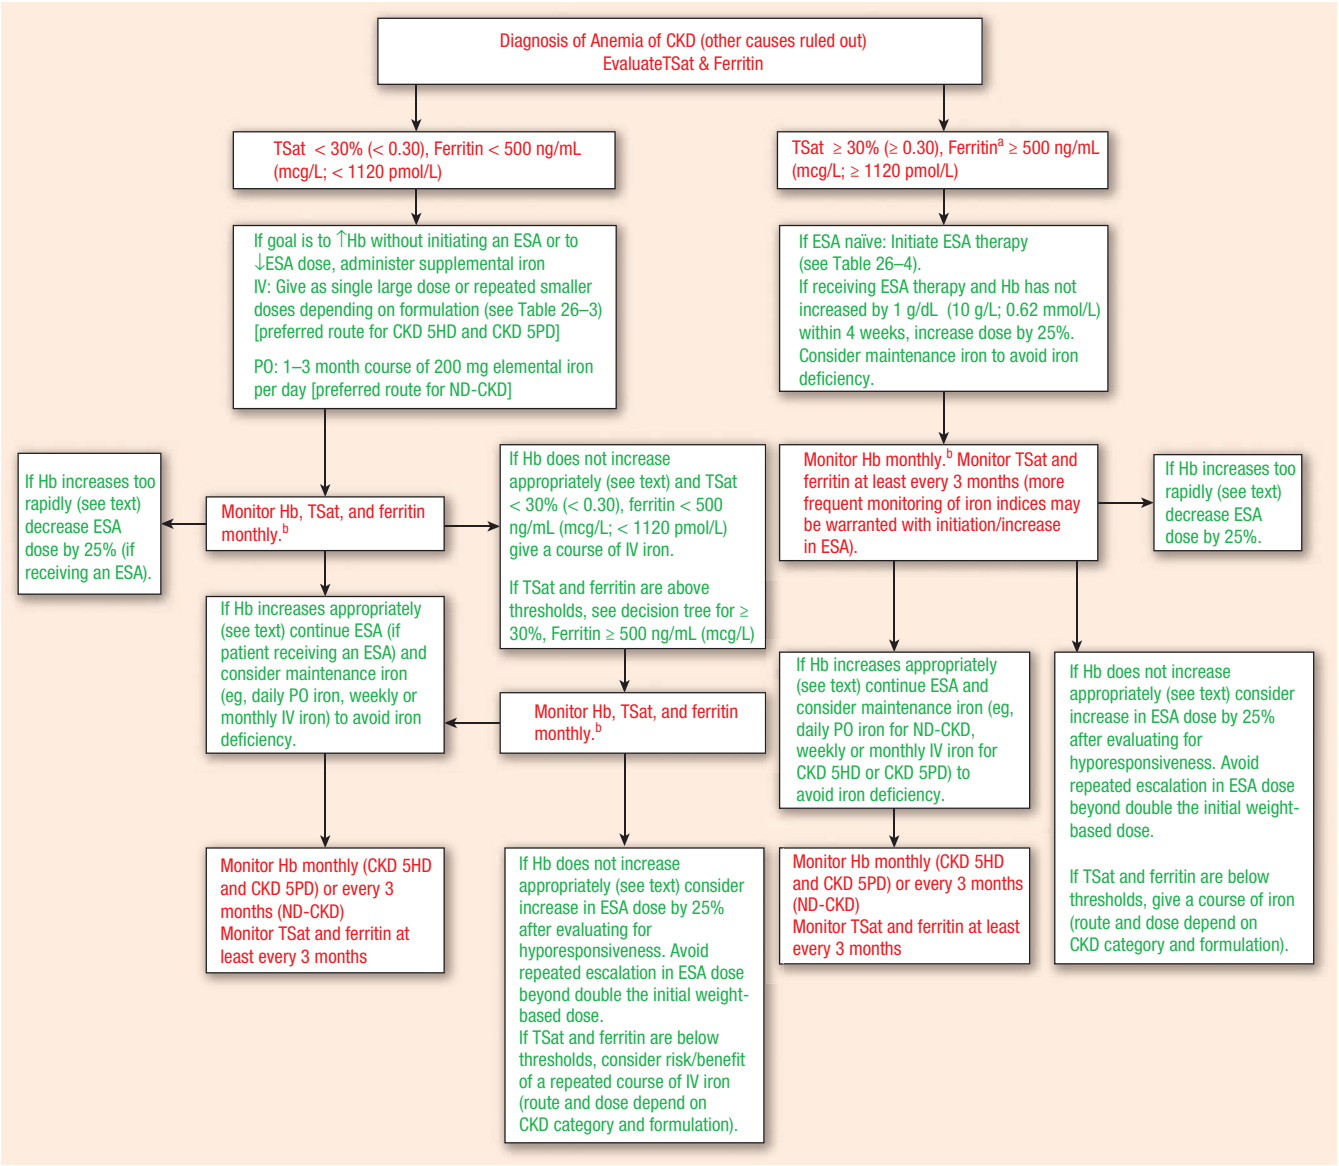

FIGURE 26–2. Algorithm for management of anemia of CKD. (CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agent; Hb, hemoglobin; ND-CKD, nondialysis CKD patients; TSat, transferrin saturation.) [a]Clinical judgement should be used to determine if iron supplementation should be given when ferritin > 500 ng/mL (mcg/L; 1,124 pmol/L). [b]Weekly monitoring of Hb may be warranted. Wait at least 1 week after an IV dose of iron to measure TSat and ferritin. (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill Education; 2017:626, with permission.)

Oral iron supplements are generally less costly than IV supplements and are generally the first-line treatment for iron supplementation for patients with CKD not receiving HD. When administering iron by the oral route, 200 mg of elemental iron should be delivered daily in divided doses to increase iron stores.[23]

When oral iron is not effective to increase iron stores or for patients receiving HD, IV iron should be administered. Table 26–3 lists the Food and Drug Administration (FDA)-approved doses of the currently available IV iron products. Patients receiving HD have ongoing blood losses with each HD session, which can lead to iron losses of 1 to 2 g per year. For HD, IV iron may be administered episodically based on routine surveillance of iron stores as a total of 1 g of IV iron, administered in small sequential doses to replete iron stores. An alternative method to administer IV iron is to give smaller maintenance doses of iron weekly or with each dialysis session (eg, iron dextran or iron sucrose 20–100 mg/week; sodium ferric gluconate 62.5–125 mg/week). The latter approach of giving smaller maintenance doses may result in lower cumulative doses of iron and lower doses of ESAs.[23]

IV iron preparations are equally effective in increasing iron stores. Anaphylaxis may occur with all IV preparations, but most notably with iron dextran, which can also cause delayed reactions, such as arthralgias and myalgias. A test dose of 25 mg iron dextran should be administered 30 minutes before the full dose to monitor for potential anaphylactic reactions, although anaphylactic reactions can occur in patients who safely received

Table 26–3

IV Iron Products

Iron Formulation (Product)	FDA-Approved Indications	FDA-Approved Dosing	Warnings	Dose Ranges[a]	How Supplied
Iron dextran (INFeD®, Dexferrum®)	Patients with iron deficiency in whom oral iron is unsatisfactory	IV push: 100 mg over 2 minutes (25 mg test dose required)	Black box (risk of anaphylactic reactions)	25–1000 mg	2-mL vials containing 50 mg elemental iron per mL
Ferric gluconate (Ferrlecit®, Sodium ferric gluconate)	Adult and pediatric HD patients age 6 years and older receiving ESA therapy	IV push (adult): 125 mg over 10 minutes IV infusion (adult): 125 mg in 100 mL of 0.9% NaCl over 60 minutes IV infusion (pediatric): 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 minutes; maximum dose 125 mg	General	6.25–500 mg	5-mL ampules containing 62.5 mg elemental iron (12.5 mg/mL)
Iron sucrose (Venofer®)	HD patients with CKD receiving ESA therapy	IV push: 100 mg over 2–5 minutes IV infusion: 100 mg in maximum of 100 mL of 0.9% NaCl over 15 minutes	General	25–500 mg	5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL)
	Nondialysis-CKD patients receiving or not receiving ESA therapy	IV push: 200 mg over 2–5 minutes on five different occasions within 14-day period			
	PD patients receiving ESA therapy	IV infusion: 2 infusions 14 days apart, of 300 mg in maximum of 250 mL of 0.9% NaCl over 1.5 hour, followed by 1 infusion 14 days later, of 400 mg in maximum of 250 mL of 0.9% NaCl over 2.5 hours			
Ferumoxytol (Feraheme™)	Adults with iron-deficiency anemia associated with CKD	IV infusion: 510 mg (17 mL) in 50–200 mL 0.9% NaCl or 5% Dextrose over at least 15 minutes, followed by a second 510-mg infusion 3–8 days after the initial infusion	General	1020 mg (2 doses of 510 mg separated by 3–8 days)	17 mL vials containing 510 mg (0 mg/mL)
Ferric carboxymaltose (Injectafer®)	Adults with nondialysis-dependent CKD	IV push: 750 mg over 10 minutes IV infusion: 750 mg in 100–250 mL of 0.9% NaCl over at least 15 minutes	General	1500 mg (2 doses of 750 mg separated by at least 7 days)	15-mL vials containing 750 mg elemental iron

[a]Small dosing ranges (eg, 25 to 100 mg/week) generally used for maintenance regimens. Larger doses (eg, 1 g) should be administered in divided doses.

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.

prior doses of iron dextran. Ferumoxytol also carries a warning for serious allergic reactions and should be closely monitored. Sodium ferric gluconate, iron sucrose, and ferric carboxymaltose are associated with fewer severe reactions and a much lower risk of anaphylaxis and do not require a test dose, making them the preferred agents in CKD. The most common side effects seen with these preparations include hypotension, flushing, nausea, and injection site reactions.

After administering a 1-g course of IV iron, iron status should be monitored to determine the effectiveness of the treatment. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron. If Hgb does not increase after a course of IV iron or serum ferritin is not greater than 500 ng/mL (mcg/L; 1124 pmol/L) and TSat greater than 30% (0.30), an additional 1 g of IV iron may be administered, based on the clinical situation.

Erythropoiesis-Stimulating Agents. ESAs may be considered if Hgb levels remain persistently low to improve symptoms of anemia. In patients not receiving dialysis, the decision to initiate ESAs should be based on the rate of Hgb decline, prior response to anemia treatment, risks associated with ESAs and the patient's symptoms. The KDIGO guidelines recommend considering initiating ESAs when Hgb is less than 10 g/dL

Table 26–4

Erythropoiesis Stimulating Agents in Chronic Kidney Disease

Drug	Brand Name	Starting Dose	Route of Administration	Half-Life (Hours)
Epoetin alfa	Epogen®, Procrit®	Adults: 50–100 units/kg three times per week Pediatrics: 50 units/kg three times per week	IV or SC	8.5 (IV) 24 (SC)
Darbepoetin alfa	Aranesp®	ND-CKD: 0.45 mcg/kg once every 4 weeks Dialysis: 0.45 mcg/kg once per week or 0.75 mcg/kg once every 2 weeks Pediatrics: 0.45 mcg/kg once weekly; may give 0.75 mcg/kg once every 2 weeks for nondialysis	IV or SC	25 (IV) 48 (SC)
Methoxy PEG-epoetin beta	Micera®	0.6 mcg/kg every 2 weeks; once Hgb stabilizes, double the dose and administer monthly (eg, if administering 0.6 mcg/kg every 2 weeks, give 1.2 mcg/kg every month)	IV or SC	134 (IV) 139 (SC)

CKD, chronic kidney disease; ND-CKD, nondialysis CKD; PEG, polyethylene glycol; SC, subcutaneous.

Adapted from Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill Education, 2017:624, with permission.

(100 g/L or 6.21 mmol/L).[23] However, the target for Hgb is unclear because use of ESAs to increase Hgb levels beyond 12 g/dL (120 g/L or 7.45 mmol/L) is associated with increased mortality.[23] The ESAs currently available in the United States are listed in Table 26–4. Epoetin α and epoetin β, which are available outside the United States, have the same biological activity as endogenous EPO. Darbepoetin alfa has two additional carbohydrate side chains that increase the half-life compared with epoetin alfa and endogenous EPO, allowing for less frequent dosing than that of epoetin alfa. Methoxy PEG-epoetin beta has the addition of an amide bond that produces a longer half-life than the other ESAs and is referred to as a continuous erythropoietin receptor activator (CERA). All ESAs are equivalent in their efficacy and have a similar adverse-effect profile.

The most common adverse effect seen with ESAs is increased blood pressure, which may require antihypertensive agents to control blood pressure. Caution should be used when initiating an ESA in patients with very high blood pressures (> 180/100 mm Hg). If blood pressures are refractory to antihypertensive agents, ESAs may need to be withheld. Seizures and pure red cell aplasia have also been reported in patients initiating ESA therapy, and have been reported more with the CERA product.

Subcutaneous (SC) administration of ESA is the preferred route of administration for all agents because it produces a more predictable and sustained response than IV administration, and lower doses of ESAs are generally needed. IV administration is often utilized in patients who have established IV access or are receiving HD. Starting doses of ESAs depend on the Hgb level, the target Hgb level, the rate of Hgb increase, and clinical circumstances. The initial increase in Hgb should be 1 to 2 g/dL (10–20 g/L or 0.62–1.24 mmol/L) per month.[23] The recommended starting doses of the ESAs are listed in Table 26–4.

When prescribing ESAs, clinicians should not attempt to target "normal" Hgb levels (ie, > 13 g/dL [130 g/L or 8.07 mmol/L] in males; > 12 g/dL [120 g/L or 7.45 mmol/L] in females). Several clinical trials have demonstrated that targeting Hgb levels greater than 13 g/dL (130 g/L or 8.07 mmol/L) resulted in more cardiovascular complications or death, compared with target Hgb levels less than 11 g/dL (110 g/L or 6.83 mmol/L).[23] Further studies are needed to evaluate the appropriate target level for Hgb. Nonetheless, based on these findings, the US FDA recommended addition of a black box warning to the product information for all ESAs indicating the maximum target Hgb should not exceed 11 g/dL (110 g/L or 6.83 mmol/L) and requires a medication guide be given to patients who are receiving ESAs. However, KDIGO suggests a maximum threshold of 11.5 g/dL (115 g/L or 7.14 mmol/L).[23]

▶ *Outcome Evaluation*

The outcomes to monitor for anemia of CKD include hemoglobin, iron status, and the need for blood transfusions. Hemoglobin should be monitored every 3 months in patients with CKD not on dialysis or receiving PD and monthly in patients receiving HD. Evaluate Hgb monthly when ESA therapy is initiated or the dose is adjusted to ensure Hgb does not exceed 11.5 g/dL (115 g/L or 7.14 mmol/L).[23] The ESA dose can increase monthly if Hgb is below goal. Once a stable Hgb is attained, evaluate Hgb every 3 months thereafter. While the patient is receiving

Patient Encounter 2, Part 2

The patient returns to your clinic in 1 week and states that her symptoms have not changed. She is asking about the results of her laboratory studies.

Labs: WBC 4.2×10^3 cells/mm^3 (4.2×10^9/L); RBC 2.7×10^6 cells/mm^3 (2.7×10^{12}/L); Hgb 9.2 g/dL (92 g/L; 5.71 mmol/L); hematocrit 27% (0.27); mean corpuscular volume (MCV) 86 fL; mean corpuscular hemoglobin concentration (MCHC) 31 g/dL (310 g/L); platelets 298×10^3 cells/mm^3 (298×10^9/L); iron 131 mcg/dL (23.4 µmol/L); total iron binding capacity (TIBC) 390 mcg/dL (69.8 µmol/L); ferritin 162 ng/mL (mcg/L; 364 pmol/L); transferrin saturation (TSat) 26% (0.26); stool guaiac negative × 3

What treatment would you recommend for this patient for treatment of anemia?

How would you evaluate the effectiveness of treatment of anemia?

ESA therapy, monitor iron stores at least every 3 months or more frequently when initiating or increasing the dose of ESAs, when monitoring response to a course of IV therapy, or when blood loss or other circumstances that may lead to depletion of iron stores occur.[23] When the goal Hgb is reached, monitor iron stores every 3 months. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron is administered.

CKD-Mineral and Bone Disorder and Secondary Hyperparathyroidism

▶ *Epidemiology and Etiology*

Increases in parathyroid hormone (PTH) occur early as kidney function begins to decline. The actions of PTH on bone turnover lead to CKD-mineral and bone disorders (CKD-MBD). The majority of patients with CKD G3-G5 have CKD-MBD.[25]

▶ *Pathophysiology*

As kidney function declines in patients with CKD, decreased phosphorus excretion disrupts the balance of calcium and phosphorus homeostasis. Decreased vitamin D activation in the kidney also decreases calcium absorption from the gastrointestinal (GI) tract. Fibroblast growth factor 23 (FGF-23) is a hormone produced by osteocytes and osteoblasts that is stimulated by increased phosphate and calcitriol. In CKD, elevated phosphate concentrations increase expression of FGF-23, which promotes phosphorus excretion and downregulates vitamin D activation in the kidney.[26] Each of these stimulates the parathyroid glands.

KEY CONCEPT The parathyroid glands release PTH in response to decreased serum calcium and increased serum phosphorus levels. The actions of PTH include the following:

- Increasing calcium resorption from bone
- Increasing calcium reabsorption from the proximal tubules in the kidney
- Decreasing phosphorus reabsorption in the proximal tubules in the kidney
- Stimulating activation of vitamin D by 1-α-hydroxylase to calcitriol (1,25-dihydroxyvitmin D_3) to promote calcium absorption in the GI tract and increased calcium mobilization from bone

All of these actions are directed at increasing serum calcium levels and decreasing serum phosphorus levels, although the activity of calcitriol also increases phosphorus absorption in the GI tract and mobilization from the bone, which can worsen hyperphosphatemia. Calcitriol also decreases PTH levels through a negative feedback loop. These measures are sufficient to correct serum calcium levels in the earlier stages of CKD.

As kidney function continues to decline and the GFR falls less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), phosphorus excretion continues to decrease and calcitriol production decreases,[26] causing PTH levels to begin to rise significantly, leading to sHPT. The excessive production of PTH leads to hyperplasia of the parathyroid glands, which decreases the sensitivity of the parathyroid glands to serum calcium levels and calcitriol feedback, further promoting sHPT. The most dramatic consequences of sHPT are vascular calcifications and alterations in bone turnover, which lead to renal osteodystrophy (ROD). The pathogenesis of sHPT and CKD-MBD is depicted in Figure 26–3.

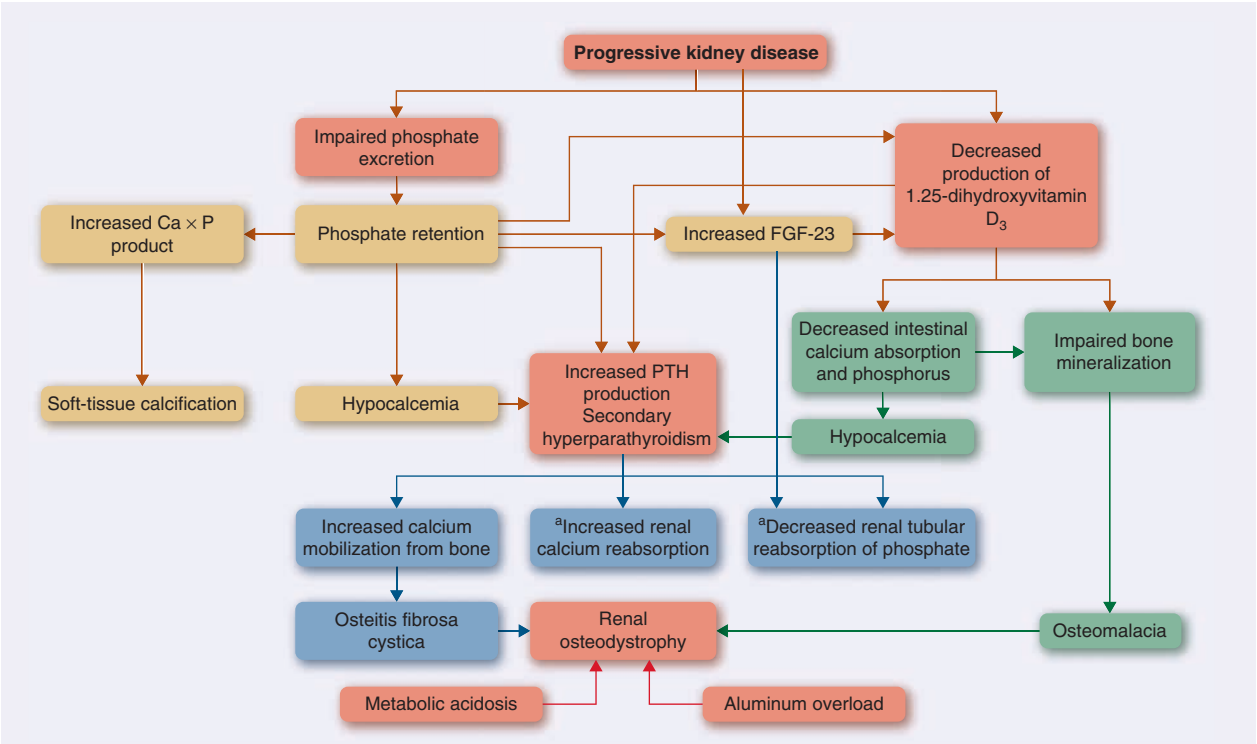

FIGURE 26–3. Pathogenesis of CKD-MBD. (Ca, calcium; FGF-23, fibroblast growth factor-23, PTH, parathyroid hormone.) [a]FGF-23 also increases in response to 1,25-dihydroxyvitamin D_3. [b]These adaptations are lost as kidney failure progresses. (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill Education; 2017:613, with permission.)

▶ *Treatment*

General Approach KEY CONCEPT Diagnosis and management of bone disease in CKD is based on corrected serum levels of calcium and phosphorus, and intact PTH levels (iPTH).[25,27] KDIGO guidelines recommend that hypercalcemia should be avoided in patients with CKD.[27] Phosphorus and PTH levels should be maintained as close to normal as possible.

Current recommendations suggest that treatment of CKD-MBD should take into consideration evaluations of calcium, phosphorus, and PTH level collectively and trends over time.[27] When phosphorus levels remain elevated, phosphorus-lowering treatment should be started. Management of sHPT often requires treatment with vitamin D analogs or cinacalcet in addition to phosphorus management.

Nonpharmacologic Therapy The first-line treatment for the management of hyperphosphatemia is dietary phosphorus restriction to 800 to 1000 mg/day in patients with CKD G3 or higher who have phosphorus levels at the upper limit of the normal range or elevated iPTH levels.[25,27] Many foods high in phosphorus are also high in protein, which can make it difficult to restrict phosphorus intake while maintaining adequate protein intake to avoid malnutrition. HD and peritoneal dialysis (PD) can remove up to 2 to 3 g of phosphorus per week. However, this is usually insufficient to control hyperphosphatemia, and pharmacologic therapy is necessary in addition to dialysis treatment.

Other nonpharmacologic strategies to manage sHPT and CKD-MBD include restriction of aluminum exposure and parathyroidectomy. Chronic ingestion of aluminum-containing antacids and other aluminum-containing products should be avoided in patients with CKD G4 and G5 (GFR less than 30 mL/min/1.73 m^2 [0.29 mL/s/m^2]) because of the risk of aluminum toxicity and potential uptake into the bone. Purification techniques for dialysate solutions also minimize the risk of exposure to aluminum.

Parathyroidectomy is a treatment of last resort for sHPT, but should be considered in patients with persistently elevated iPTH levels above 800 pg/mL (ng/L; 85.6 pmol/L) that is refractory to medical therapy to lower serum calcium and/or phosphorus levels.[25] A portion or all of the parathyroid tissue may be removed, and in some cases a portion of the parathyroid tissue may be transplanted into another site, usually the forearm for easy surgical access. After parathyroidectomy, serum calcium levels can decrease dramatically due to the low levels of PTH after the parathyroid tissue is removed, which decreases intestinal calcium absorption and bone resorption. Therefore, serum ionized calcium levels should be monitored frequently (every 4 to 6 hours for the first 48 to 72 hours) in patients receiving a parathyroidectomy. Calcium supplementation is usually necessary, administered IV initially, then orally (with vitamin D supplementation) once normal calcium levels are attained for several weeks to months after the procedure.

Clinical Presentation and Diagnosis of sHPT and ROD

General

Onset of sHPT and ROD is subtle and may not be associated with symptoms.

Symptoms

sHPT and ROD are usually asymptomatic in early disease. Calcification in the joints can be associated with decreased range of motion.

Conjunctival calcifications are associated with a gritty sensation in the eyes, redness, and inflammation.

Signs

Cardiovascular: Increased stroke index, heart rate, and diastolic and mean arterial pressures

Musculoskeletal: Bone pain, muscle weakness

Dermatologic: Pruritus

Laboratory Tests

Increased serum phosphorus levels

Low to normal serum calcium levels

Increased PTH levels

Decreased vitamin D levels

Diagnostic Tests

Radiographic studies show calcium–phosphate deposits in joints and/or cardiovascular system.

Bone biopsy of the iliac crest (not routinely performed)

Pharmacologic Therapy

Phosphate-Binding Agents. When serum phosphorus levels cannot be controlled by restriction of dietary intake, phosphate-binding agents are used to bind dietary phosphate in the GI tract to form an insoluble complex that is excreted in the feces. Phosphorus absorption is decreased, thereby decreasing serum phosphorus levels. The drugs used for binding dietary phosphate are listed in Table 26–5. The selection of the phosphate binding agent should be on sequential assessment of calcium and PTH levels in addition to the phosphorus level. These agents should be administered with each meal and can be tailored to the amount of phosphorus that is typically ingested during each meal. For example, patients can take a smaller dose with smaller meals or snacks, and a larger dose with larger meals. Although phosphate binders are not FDA approved for patients with CKD who are not receiving dialysis, they are used clinically when phosphorus levels are elevated, regardless of the GFR category.

Sevelamer and lanthanum phosphate binders do not contain calcium, iron, or aluminum. These agents are particularly useful in patients with hyperphosphatemia who have elevated serum calcium levels or who have vascular or soft tissue calcifications. Sevelamer is a cationic polymer that is not systemically absorbed and binds to phosphate in the GI tract, and it prevents absorption and promotes excretion of phosphate through the GI tract via the feces. Sevelamer has an added benefit of reducing LDL-C by up to 30% and increasing HDL-C levels.[25] The most common side effects of sevelamer are GI complaints including nausea, constipation, and diarrhea. However, some studies demonstrate that sevelamer may decrease mortality in patients receiving HD compared with CCPBs, primarily by decreasing the occurrence of calcifications in the coronary arteries.[25] Sevelamer carbonate may have added benefit to aid in the correction of metabolic acidosis.

Lanthanum is a naturally occurring trivalent rare earth element (atomic number 57). Lanthanum carbonate quickly dissociates in the acidic environment of the stomach, where the lanthanum ion binds to dietary phosphorus, forming an insoluble compound

Table 26–5

Phosphate-Binding Agents Used to Treat Hyperphosphatemia in CKD

Compound	Trade Name	Dosage Form	Compound Content (mg)	Elemental Compound Content (mg)	Starting Dose	Comments
Resin-based binders						
Sevelamer carbonate	Renvela®	Tablet, Powder for suspension	800		800 mg three times a day with meals	First-line agent; lowers LDL-C More expensive than calcium products; preferred in patients at risk for extraskeletal calcification May require large doses to control phosphorus levels
Elemental-based binders						
Lanthanum	Fosrenol®	Chewable tablet	500, 750, 1000	—	750–1500 mg three times a day with meals	Second-line agent; more expensive than calcium products; preferred in patients at risk for extraskeletal calcification Most patients require 1500–3000 mg/day to control phosphorus
Iron-based binders						
Sucroferric oxyhydroxide	Velphoro®	Chewable tablet	500	—	500 mg three times a day with meals	Do not use with levothyroxine; separate from doxycycline and alendronate by 1 hour
Ferric citrate	Auryxia®	Tablet	210	1 g ferric citrate	420 mg (2 tablets) three times a day with meals	Maximum dose is 12 tablets per day; iron is systemically absorbed
Calcium-containing binders						
Calcium carbonate (40% elemental calcium)	Tums®	Chewable tablet	500, 750, 1000; 1250	200, 300, 400, 500	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphorus-binding effect may vary from product to product; try to limit daily intake of elemental calcium to 1500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate
	Oscal®-500	Tablet	1250	500		
	Caltrate® 600	Tablet	1500	600		
	Nephro-Calci™	Tablet	1500	600		
	LiquiCal™	Liquid gelcap	1200	480		
	Calci-Chew®	Chewable tablet	1250	500		
Calcium acetate (25% elemental calcium)	PhosLo®	Capsule, Tablet	667	167	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with one-half the dose of elemental calcium; do not exceed 1500 mg elemental calcium intake per day Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only
	Phoslyra®	Solution	667/5 mL			
Aluminum-based binders						
Aluminum hydroxide	AlternaGel® Amphojel®	Suspension	Various	—	300–600 mg three times a day with meals	Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders

CKD, chronic kidney disease; LDL-C, low-density lipoprotein cholesterol.

that is excreted in the feces. Lanthanum has been shown to be as effective as other phosphate binders and may improve bone turnover, compared with calcium-containing products.[25] Side effects of lanthanum include nausea, peripheral edema, and myalgias.

Sucroferric oxyhydroxide and ferric citrate are iron-based phosphate binders that lower phosphate levels. Sucroferric oxyhydroxide is an insoluble form of iron that binds to phosphate in the GI tract and has been shown to be as effective as other phosphate binders with a lower pill burden.[28] Ferric citrate also lowers phosphate as effectively as other phosphate binders and can also increase serum ferritin and Tsat levels. The major side effects associated with both products are GI side effects, namely diarrhea. Sucroferric oxyhydroxide cannot be taken with levothyroxine and

must be taken 1 hour after doxycycline and alendronate.[28] This product was not studied in patients on PD, with significant liver or GI disease, or following major GI surgery.[28]

CCPBs, including calcium carbonate and calcium acetate, are effective in decreasing serum phosphate levels, as well as in increasing serum calcium levels. Calcium acetate binds more phosphorus than the carbonate salt, making it a more potent agent for binding dietary phosphate. Calcium carbonate can also aid in the correction of metabolic acidosis, another complication of kidney failure. Calcium citrate is usually not used as a phosphate-binding agent because the citrate salt can increase aluminum absorption. The dose of CCPBs should be limited because cardiovascular events and progression to dialysis are increased if calcium intake exceeds calcium losses.[27] In general, CCPBs should not be used if corrected serum calcium levels are near or above the upper end of the normal range or if arterial calcifications are present. Some evidence suggests that the use of CCPBs in CKD G3a-4 affects calcium balance, but does not decrease phosphorus balance.[29] Therefore, current guidelines recommend restricting the dose of CCPBs in all stages of CKD.[27] The most common adverse effects of CCPBs are constipation and hypercalcemia.

Aluminum-containing phosphate-binding agents are not recommended for chronic use in patients with CKD to avoid aluminum accumulation, leading to encephalopathy, bone disease, and anemia. These agents may be used for a short course of therapy (< 4 weeks) for significantly elevated phosphorus levels in AKI.

Vitamin D Therapy. Vitamin D regulates many processes in the body, including calcium and phosphorus absorption from the GI tract and kidney, PTH secretion, maintaining muscle, cardiovascular, immune and brain function, and glucose control. Vitamin D is activated in various tissues, with the liver and kidney being primary sites. In CKD, a decrease in renal metabolism of vitamin D decreases circulating concentrations of the activated form of vitamin D, calcitriol (1,25-dihydroxyvitamin D) and its precursor 25-hydroxyvitamin D. Vitamin D deficiency begins early in CKD and increases as kidney function declines.[30] PTH levels rise as early as CKD G3 as a result of low calcitriol concentrations.

Exogenous vitamin D compounds that mimic the activity of calcitriol act directly on the parathyroid gland to decrease PTH secretion by upregulation of the vitamin D receptor in the parathyroid gland, which decreases parathyroid gland hyperplasia and PTH synthesis and secretion. This is particularly useful when reduction of serum phosphorus levels does not sufficiently reduce PTH levels.

Vitamin D supplements (Table 26–6) can be used to lower serum PTH levels in patients with CKD. Ergocalciferol, cholecalciferol, and calcifediol have been shown to be effective in lowering PTH secretion in patients with CKD G3, and are useful in later stages of CKD to maintain adequate 25-hydroxyvitamin D levels for extrarenal functions.[27,30] In CKD G4 and G5, activated vitamin D analogs must be used to decrease PTH secretion in severe hyperparathyroidism.[27] Synthetic calcitriol has the same biologic activity as endogenous calcitriol. Doxercalciferol (1-α-hydroxyvitamin D_2) is another vitamin D analog that is hydroxylated in the liver to 1,25-dihydroxyvitamin D_2, which has the same biologic activity as calcitriol. Both calcitriol and doxercalciferol upregulate vitamin D receptors in the intestines, which increase calcium and phosphorus absorption, increasing the risk of hypercalcemia and hyperphosphatemia. It is important that serum calcium and phosphorus levels are within the normal range for the stage of CKD prior to starting either of these therapies. Paricalcitol (19-nor-1,25-dihydroxyvitamin D_2) is a vitamin D analog that has equal efficacy to calcitriol. Alfacalcidol (1-α-hydroxyvitamin D_3), falecalcitriol, and 22-oxacalcitriol (maxacalcitol) are only available outside the United States.

Calcimimetics. Cinacalcet and etelcalcetide are calcimimetics that increase the sensitivity of receptors on the parathyroid gland to serum calcium levels to reduce PTH secretion, but have no effect on intestinal absorption of calcium or phosphorus, and lower serum calcium levels.[25,31] Thus, calcimimetics are beneficial for patients with elevated PTH levels who have increased calcium or phosphorus levels or cannot use vitamin D therapy. Calcimimetics should also be used with caution in patients with seizure disorders because low serum calcium levels can lower the seizure threshold. Cinacalcet is an oral calcimimetic that is most widely used for sHPT. GI side effects, including nausea and vomiting, can decrease tolerability of cinacalcet for some patients. Etelcalcetide is an injectable agent that was recently developed to reduce GI side effects. It is administered as an IV three times a week after HD, which may improve adherence.[31]

Table 26–6

Available Treatments for Secondary Hyperparathyroidism

Generic Name	Trade Name	Dosage Range	Dosage Forms	Frequency of Administration
Vitamin D (prohormone)				
Ergocalciferol	Vitamin D_2	400–50,000 IU	PO	Daily (doses of 400–2000 IU) Weekly or monthly for higher doses (50,000 IU)
Cholecalciferol	Vitamin D_3			
Calcifediol	Rayaldee®	30–60 mcg	PO	Daily
Active vitamin D				
Calcitriol	Calcijex®	0.5–5 mcg	IV	Three times per week
	Rocaltrol®	0.25–5 mcg	PO	Daily, every other day, or three times per week
Vitamin D analogs				
Paricalcitol	Zemplar®	1–4 mcg	PO	Daily or three times per week
		2.5–15 mcg	IV	Three times per week
Doxercalciferol	Hectorol®	5–20 mcg	PO	Daily or three times per week
		2–8 mcg	IV	Three times per week
Calcimimetics				
Cinacalcet	Sensipar™	30–180 mg	PO	Daily
Etelcalcitide	Parsabiv™	2.5–15 mg	IV	Three times per week

Patient Encounter 3

A 58-year-old Caucasian man with a history of diabetes presents to your clinic for a routine follow-up. He has no complaints at this time.

PMH: Diabetes, diagnosed 5 years ago; hypertension, diagnosed 6 years ago; hyperlipidemia

Current meds: Aspirin 81 mg orally daily; atorvastatin 40 mg orally daily; carvedilol 12.5 mg orally twice daily; lisinopril 20 mg orally daily; glipizide 5mg orally twice daily; sitagliptin 25 mg orally daily

ROS: Unremarkable

PE:

VS: BP 136/84 mm Hg; P 70 beats/min; T 96.3°F (35.7°C); ht 6′1″ (185 cm); wt 277 lb (125.9 kg)

CV: RRR, normal S_1, S_2

Abd: No organomegaly, bruits, tenderness; (+) bowel sounds; heme (–) stool

Ext: 2+ edema bilaterally

Labs: Sodium 139 mEq/L (mmol/L); potassium 5.2 mEq/L (mmol/L); chloride 109 mEq/L (mmol/L); carbon dioxide 18 mEq/L (mmol/L); BUN 42 mg/dL (15 mmol/L urea); SCr 3.4 mg/dL (301 µmol/L); glucose 124 mg/dL (6.9 mmol/L); calcium 9.1 mg/dL (2.3 mmol/L); phosphate 7.2 mg/dL (2.33 mmol/L); intact parathyroid hormone (iPTH) 357 pg/mL (ng/L; 38.2 pmol/L); WBC 5.6×10^3 cells/mm^3 (5.6×10^9/L); RBC 3.9×10^6 cells/mm^3 (3.9×10^{12}/L); Hgb 9.8 g/dL (98 g/L; 6.08 mmol/L); Hct 29% (0.29); platelets 272×10^3 cells/mm^3 (272×10^9/L)

What signs are consistent with CKD mineral and bone disorder (MBD)?

What treatment would you recommend for CKD-MBD?

▶ *Outcome Evaluation*

KDIGO guidelines recommend monitoring serum calcium, phosphorus and PTH levels early in CKD, with increasing frequency as renal function declines. Calcium and phosphorus levels should be monitored every 6 to 12 months in CKD G3a-G3b; every 3 to 6 months in CKD G4, and every 1 to 3 months in CKD G5. PTH levels should be monitored every 6 to 12 months for CKD G3–G4 and every 3 to 6 months in CKD G5.[27]

Monitor serum calcium and phosphorus levels regularly in patients receiving phosphate-binding agents. When initiating therapy, monitor serum levels every 1 to 4 weeks, depending on the severity of hyperphosphatemia. Titrate doses of phosphate binders to maintain phosphorus levels near normal. Once target levels are achieved, monitor serum calcium and phosphorus levels every 1 to 3 months. Monitor intact PTH levels monthly while initiating vitamin D therapy, then every 3 months once stable iPTH levels are achieved. When starting or increasing the dose of cinacalcet, monitor serum calcium and phosphorus levels within 1 week; iPTH levels should be monitored within 1 to 4 weeks. Once target levels are achieved, decrease monitoring to every 3 months.

Impaired Electrolyte and Acid–Base Homeostasis

The kidney is responsible for regulating homeostasis for sodium, potassium, water, and acid–base. Reductions in the number of functioning nephrons decrease glomerular filtration regulation of electrolytes and acid secretion.

▶ *Pathophysiology*

As the number of functioning nephrons decreases, the remaining nephrons are able to increase excretion of sodium, water, potassium, and hydrogen ions. However, this is limited and as the number of functioning nephrons decreases as CKD progresses, total excretion of electrolytes and fluid eventually decreases.

Sodium and water balance is maintained by natriuretic peptides, namely atrial natriuretic peptide (ANP), which increases sodium excretion in the kidneys. The relative increase in sodium excretion by a smaller number of functioning nephrons results in an osmotic diuresis that promotes water excretion, but impairs the ability of the kidneys to concentrate and dilute urine. Thus, urine becomes fixed at an osmolality close to that of the plasma, approximately 300 mOsm/kg (mmol/kg), and presents as **nocturia**. Sodium and fluid retention increases intravascular volume and raises systemic blood pressure, which can present as early as CKD G3a-G3b.[32]

Potassium excretion occurs in both the distal tubules of the kidney and in the GI tract, which is mediated by aldosterone stimulation. Aldosterone increases in response to rising serum potassium, which then increases potassium excretion in both the functioning nephrons and GI tract. This maintains serum potassium concentrations within the normal range through CKD G1 to G4. Hyperkalemia begins to develop when GFR falls below 20% of normal, when the number of functioning nephrons and renal potassium secretion is so low that the capacity of the GI tract to excrete potassium has been exceeded.[33]

Medications can increase the risk of hyperkalemia in patients with CKD, including ACEI and ARBs, used for the treatment of proteinuria and hypertension. Potassium-sparing diuretics, used for the treatment of edema and chronic heart failure, can also exacerbate the development of hyperkalemia, and they should be used with caution in patients with CKD G3 or higher.

Hydrogen ions are excreted at the same rate of production by the kidney via buffers in the urine created by ammonia generation and phosphate excretion to maintain the pH of body fluids within a very narrow range. As kidney function declines, bicarbonate reabsorption is maintained, but hydrogen excretion is decreased because the ability of the kidney to generate ammonia is impaired. The positive hydrogen balance leads to metabolic acidosis, which is characterized by a serum bicarbonate level of 15 to 20 mEq/L (mmol/L), and an elevated anion gap greater than 17 mEq/L (mmol/L), resulting in a pH less than 7.35. Metabolic acidosis generally presents when the GFR declines below 25 mL/min/1.73 m^2 (0.24 mL/s/m^2).[34]

Metabolic acidosis contributes to various complications associated with CKD. Metabolic acidosis can directly cause bone disease, particularly in children, and contribute significantly to the bone disease induced by secondary hyperparathyroidism, as discussed previously. Metabolic acidosis also decreases hepatic albumin synthesis, which contributes to hypoalbuminemia and muscle wasting. Furthermore, metabolic acidosis can accelerate progression of CKD by causing tubular injury. Reversal of metabolic acidosis has been demonstrated to decrease progression of CKD, improve bone disease, and increase serum albumin concentrations.[34]

▶ *Treatment*

Nonpharmacologic treatment The kidney is unable to adjust to abrupt changes in sodium and potassium intake in patients

Clinical Presentation and Diagnosis of Electrolyte and Acid–Base Abnormalities

General

Alterations in sodium and water balance in CKD manifest as increased edema.

Hyperkalemia is generally asymptomatic in patients with CKD until serum potassium levels are greater than 5.5 mEq/L (mmol/L), when cardiac abnormalities present.

Metabolic acidosis is generally asymptomatic in patients with CKD.

Symptoms

Nocturia can present in CKD G3a-G3b.

Edema generally presents in CKD G4 or later.

Mild hyperkalemia and metabolic acidosis are generally not associated with overt symptoms.

Symptoms of hyperkalemia generally appear when GFR falls below 20 mL/min/1.73 m^2 (0.19 mL/s/m^2), such as muscle weakness, fatigue, nausea, and paresthesias.

Symptoms of chronic metabolic acidosis present as bone abnormalities and growth retardation in children.

Signs

Cardiovascular:

- Sodium: Worsening hypertension, edema
- Potassium: ECG changes (peaked T waves, widened QRS complex, loss of P wave)

Genitourinary: Sodium abnormalities result in change in urine volume and consistency.

Laboratory Tests

Sodium: Increased blood pressure; sodium levels remain within the normal range; urine osmolality is generally fixed at 300 mOsm/kg (mmol/kg)

Potassium: Increased serum potassium levels

Metabolic acidosis: Decreased serum bicarbonate levels (CO_2); decreased pH

with severe CKD. Electrolyte disorders resulting from an acute increase in intake can be more severe and prolonged.

Sodium and Water. Patients with CKD should be advised to refrain from adding salt to their diet but should not restrict sodium intake. Changes in sodium intake should occur slowly over a period of several days to allow adequate time for the kidney to adjust urinary sodium content. Sodium restriction produces a negative sodium balance, which causes fluid excretion to restore sodium balance. The resulting volume contraction can decrease perfusion of the kidney and hasten the decline in GFR. Saline-containing IV solutions should be used cautiously in patients with CKD because the salt load may precipitate volume overload.

Fluid restriction is generally unnecessary as long as sodium intake is controlled. The thirst mechanism remains intact in CKD to maintain total body water and plasma osmolality near normal levels. Fluid intake should be maintained at the rate of urine output to replace urine losses, usually fixed at approximately 2 L/day as urine concentrating ability is lost. Significant increases in free water intake orally or IV can precipitate volume overload and hyponatremia. Patients with CKD G5 require RRT to maintain normal volume status. Fluid intake is often limited in patients receiving HD to prevent fluid overload between dialysis sessions.

Diuretic therapy is often necessary to prevent volume overload in patients with CKD in those who still produce urine. When GFR falls below 30 ml/min/1.73 m^2 (0.29 mL/s/m^2), thiazide diuretics alone may not be effective in reducing fluid retention.[19] Loop diuretics are most frequently used to increase sodium and water excretion. As CKD progresses, higher doses, as much as 80 to 1000 mg/day of oral furosemide, or continuous infusion of loop diuretics may be needed, or combination therapy with loop and thiazide diuretics to increase sodium and water excretion.[19]

Potassium. Patients who develop hyperkalemia should restrict dietary intake of potassium to 50 to 80 mEq (mmol) per day. Potassium concentrations can also be altered in the dialysate for patients receiving HD and PD to manage hyperkalemia. Because GI excretion of potassium plays a large role in potassium homeostasis in patients with CKD G5, a good bowel regimen is essential to minimize constipation. Severe hyperkalemia is most effectively managed by HD.

Acute hyperkalemia can be managed medically until dialysis can be initiated. Diuretics, sodium polystyrene sulfonate, and fludrocortisone are useful in the management of hyperkalemia in patients with CKD. Acute hyperkalemia that results in cardiac abnormalities can be managed with calcium, insulin, and dextrose. The management of hyperkalemia is discussed in more detail in Chapter 27. Patiromer is a nonabsorbed potassium-binding polymer that is used for the treatment of hyperkalemia. Patiromer exerts its effect by exchanging calcium for potassium in the GI tract to enhance GI secretion of potassium. Serum potassium levels are significantly lowered within 7 hours of dosing.[35] Patiromer should be taken with food to enhance its effect and should be separated from all other oral medications by 3 hours.

Metabolic Acidosis. Pharmacologic therapy with sodium bicarbonate or citrate/citric acid preparations may be needed in patients with CKD G3 or higher to replenish body stores of bicarbonate. Calcium carbonate, used to bind phosphorus in sHPT, also aid in increasing serum bicarbonate levels, in conjunction with other agents. The management of acidosis is discussed in more detail in Chapter 28.

▶ *Outcome Evaluation*

Monitor serum electrolytes and bicarbonate levels regularly. Monitor edema after initiation of diuretic therapy. Monitor fluid intake to ensure obligatory losses are being met and avoid dehydration. If adequate diuresis is not attained with a single agent, consider combination therapy with another diuretic, such as a loop plus thiazide diuretic. In patients with cardiac abnormalities due to elevated potassium levels, monitor ECG continuously until serum potassium levels drop below 5 mEq/L (mmol/L) or cardiac abnormalities resolve. Evaluate serum potassium and glucose levels within 1 hour in patients who receive insulin and dextrose therapy. Evaluate serum potassium levels within 2 to 4 hours after treatment with patiromer, sodium polystyrene sulfonate (SPS), or diuretics. Repeat doses of diuretics or SPS if necessary until serum potassium levels fall below 5 mEq/L (mmol/L). Monitor blood pressure and serum potassium levels in 1 week after starting fludrocortisone. Correct metabolic acidosis slowly to prevent the development of metabolic alkalosis or other electrolyte abnormalities.

RENAL REPLACEMENT THERAPY

Patients who progress to ESKD require RRT. The modalities that are used for RRT are dialysis, including HD and PD, and kidney transplantation. The USRDS reported that the number of patients with ESKD was 703,243, with 124,114 new cases diagnosed in 2015.[2] The mortality rate of patients with ESKD was 13.6% in 2015, which is decreased from 20.4% in 1996.[2] The modality of RRT influences mortality considerably, with a 16.6% mortality rate with dialysis, compared to 3% mortality with transplant.[2] The improved survival makes kidney transplantation the preferred method of RRT; however, organ availability limits the number of patients who can receive a kidney transplant. Only 2.5% of patients with newly diagnosed ESKD receive kidney transplants each year.[2] Therefore, the most common form of RRT is dialysis, accounting for more than 97% of all patients with ESKD.[2] The principles and complications associated with dialysis are discussed later. Chapter 55 discusses the principles of kidney transplantation.

Indications for Dialysis

KEY CONCEPT Planning for dialysis should begin when GFR falls less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) (CKD G4),[1] when progression to ESKD is inevitable, to allow time to educate the patient and family on the treatment modalities and establish the appropriate access for the modality of choice. Ideally, initiation of dialysis should be done at a point when the patient is ready to undergo treatment, rather than when the patient is in emergent need of dialysis.

Initiation of dialysis depends on the patient's clinical status and not based solely on laboratory values. Symptoms that may indicate the need for dialysis include persistent anorexia, nausea, vomiting, fatigue, and pruritus. Other criteria that indicate the need for dialysis include declining nutritional status, declining serum albumin levels, electrolyte abnormalities, particularly hyperkalemia, and volume overload, which may manifest as chronic heart failure and uncontrolled hypertension. **Blood urea nitrogen** (BUN) and SCr levels may be used as a guide for the initiation of dialysis, but they should not be the absolute indicator. Dialysis is initiated in most patients after the GFR falls below 15 mL/min/1.73 m^2 (0.14 mL/s/m^2).[1] Patients should determine which modality of dialysis to use based on their own preferences. Advantages and disadvantages of HD and PD are listed in Tables 26–7 and 26–8, respectively.

The goals of dialysis are to remove toxic metabolites to decrease uremic symptoms, correct electrolyte abnormalities, restore acid–base status, and maintain volume status to ultimately improve quality of life and decrease the morbidity and mortality associated with ESKD.

Hemodialysis

HD is the most common method of RRT, initiated in 88% of US patients with newly diagnosed ESKD each year, with a total of 428,588 patients receiving HD in 2014.[2] Home HD is becoming increasingly more popular, but most patients continue to receive HD from a dialysis center.

▶ *Principles of HD*

KEY CONCEPT HD involves the exposure of blood to a semipermeable membrane (dialyzer) against which a physiologic solution (dialysate) is flowing (Figure 26–4). The dialyzer is composed of thousands of capillary fibers made up of the semipermeable membrane, which are enclosed in the dialyzer, to increase the surface area of blood exposure to maximize the efficiency of removing substances. The dialysate is composed of purified water and electrolytes, and it is run through the dialyzer countercurrent to the blood on the other side of the semipermeable membrane. The process allows for the removal of several substances from the bloodstream, including water, urea, creatinine, electrolytes, uremic toxins, and some drugs. Sterilization is not required for dialysate because the membrane prevents bacteria from entering into the bloodstream. However, if the membrane ruptures during HD, infection becomes a major concern for the patient.

Three types of membranes used for dialysis are classified by the size of the pores and the ability to remove solutes from the bloodstream: low flux, high efficiency, and high flux. Low flux membranes have small pores, which limit solute removal to relatively small molecules, such as creatinine and urea. High-efficiency membranes also have small pores but have a higher surface area that increases removal of small molecules, such as water, urea, and creatinine from the blood. The most widely used dialyzers are high-flux membranes which larger pores allow for the removal of substances with higher molecular weight, including some drugs, such as vancomycin.

Three primary processes are utilized for the removal of substances from the blood:

- Diffusion is the movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate). This process removes small molecules from the bloodstream, such as electrolytes. At times, solutes can be added to the dialysate that are diffused into the bloodstream. Changing the composition of the dialysate allows for control of the amount of electrolytes that are being removed.
- Ultrafiltration is the movement of solvent (plasma water) across the dialyzer membrane by applying hydrostatic or osmotic pressure, and it is the primary means for removing

Table 26–7

Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment.
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early.
3. The technique's failure rate is low.
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis.
5. In-center hemodialysis enables closer monitoring of the patient.

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient.
2. Dysequilibrium, dialysis, hypotension, and muscle cramps are common. May require months before patient adjusts to hemodialysis.
3. Infections in hemodialysis patients may be related to the choice of membranes; the complement-activating membranes are more deleterious.
4. Vascular access is frequently associated with infection and thrombosis.
5. Decline of residual renal function is more rapid compared with peritoneal dialysis.

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:640, with permission.

Table 26–8

Advantages and Disadvantages of Peritoneal Dialysis

Advantages

1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance
3. Better preservation of residual renal function
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well
6. Freedom from the "machine" gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis)
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron
8. Systemic heparin not required
9. Subcutaneous versus IV erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic

Disadvantages

1. Protein and amino acid losses through the peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition
2. Risk of peritonitis
3. Catheter malfunction, and exit site and tunnel infection
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed
5. Patient burnout and high rate of technique failure
6. Risk of obesity with excessive glucose absorption
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur
8. Extensive abdominal surgery may preclude peritoneal dialysis
9. No convenient access for IV iron administration

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:641, with permission.

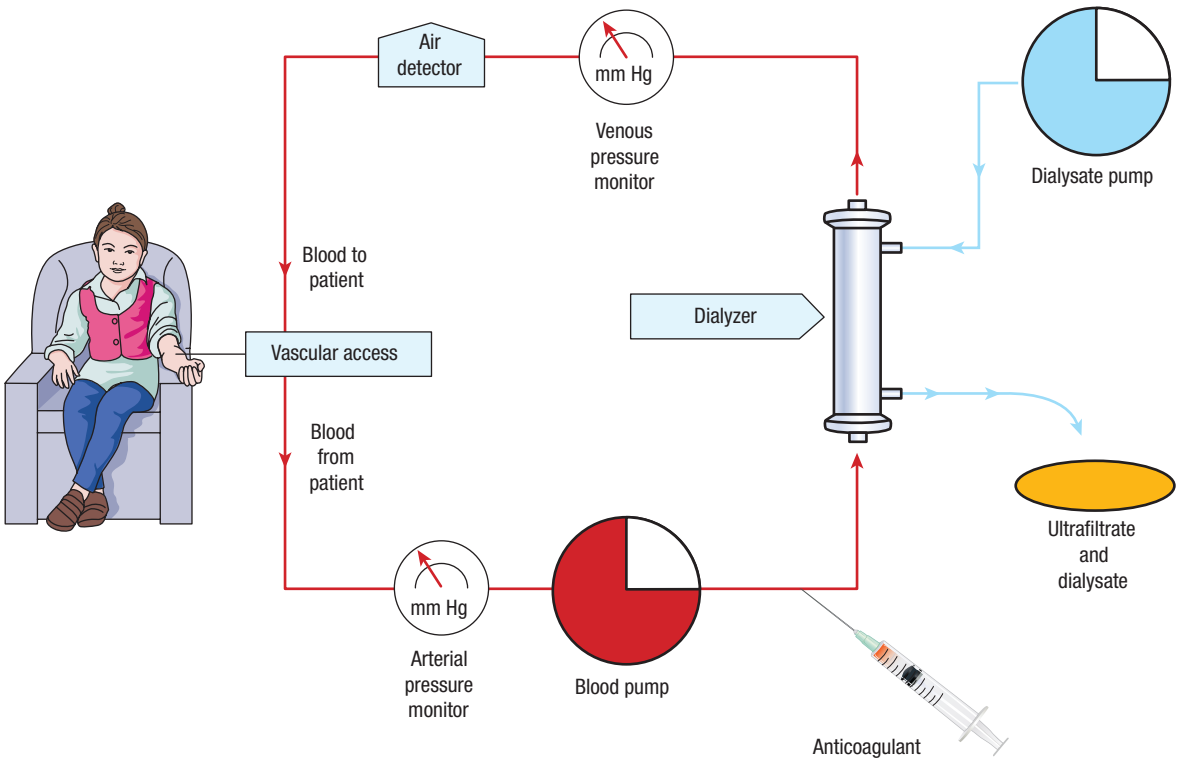

FIGURE 26–4. In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant (usually heparin) is administered to prevent clotting in the dialyzer. The dialysate is pumped at the rate of 500 to 1000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2014:642, with permission.)

Patient Encounter 4, Part 1

A 35-year-old Caucasian man with a history of IgA nephropathy presents to the clinic with complaints that he "feels awful." He has not felt like eating for several weeks and has lost 15 lb (6.8 kg) in the last 3 months.

PMH: IgA nephropathy; depression; hypertension; hyperlipidemia

Current medications: Bupropion 150 mg orally daily; vitamin D_3 1000 IU orally daily; escitalapram 10 mg orally daily; hydralazine 50 mg orally three times daily; labetalol 200 mg orally twice daily; calcium acetate 1334 mg orally three times daily with meals; pravastatin 40 mg orally daily

ROS: Lethargic male in mild distress

PE:

VS: BP 178/108 mm Hg; P 86 beats/min; T 97.2°F (36.2°C); ht 5'10" (178 cm); wt 186 lb (84.5 kg)

CV: RRR, normal S_1, S_2, present

Lungs: Crackles at bases; mild inspiratory wheezes

Ext: 4+ bilateral lower extremity edema present to mid-thigh

Labs: Sodium 138 mEq/L (mmol/L); potassium 6.3 mEq/L (mmol/L); chloride 106 mEq/L (mmol/L); carbon dioxide 15 mEq/L (mmol/L); BUN 52 mg/dL (18.6 mmol/L); SCr 6.2 mg/dL (548 µmol/L); glucose 62 mg/dL (3.4 mmol/L); calcium 9.8 mg/dL (2.45 mmol/L); phosphate 5.6 mg/dL (1.81 mmol/L); iPTH 315 pg/mL (ng/L; 33.7 pmol/L); WBC 6.8 × 10^3 cells/mm^3 (6.8 × 10^9/L); RBC 4.0 × 10^6 cells/mm^3 (4.0 × 10^{12}/L); Hgb 10.4 g/dL (104 g/L; 6.46 mmol/L); Hct 30% (0.30); platelets 278 × 10^3 cells/mm^3 (278 × 10^9/L)

What indications does the patient have for dialysis?

What alternatives for renal replacement therapy exist for the patient?

What are the advantages and disadvantages of each modality for renal replacement?

water from the bloodstream. Changing the hydrostatic pressure applied to the dialyzer or the osmotic concentration of the dialysate allows for control of the amount of water being removed.

- Convection is the movement of dissolved solutes across the dialyzer membrane by "dragging" the solutes along a pressure gradient with a fluid transport and is the primary means for larger molecules to be removed from the bloodstream, such as urea. Changing the pore size of the dialyzer membrane alters the efficiency of convection and allows for control of the amount of water removed in relation to the amount of solute being removed.

▶ *Vascular Access*

Long-term permanent access to the bloodstream is a key component of HD. There are three primary techniques used to obtain permanent vascular access in patients receiving HD: arteriovenous fistulas (AVFs), arteriovenous grafts (AVGs), and central venous catheters. An AVF is the preferred access method because it has the longest survival rate and the fewest complications. An AVF is made by creating an **anastomosis** between an artery and a vein, usually in the forearm of the nondominant arm (**Figure 26–5**). An AVG results in a similar access site but uses a synthetic graft, usually made of polytetrafluoroethylene, to connect the artery and vein in the forearm (Figure 26–5). The advantage of the AVG is that it is able to be used within 2 to 3 weeks, compared with 2 to 3 months for an AVF. However, AVGs are complicated by stenosis, thrombosis, and infections, which lead to a shorter survival time of the graft. Double-lumen venous catheters, placed in the femoral, subclavian, or jugular vein, are often used as temporary access while waiting for the AVF or AVG to mature. The catheters are tunneled beneath the skin to an exit site to reduce the risk of infection. Venous catheters can also be used as permanent access in patients in whom arteriovenous access cannot be established. However, venous catheters carry the greatest risk of complications, namely thrombosis and infections.

▶ *Complications of HD*

Complications associated with HD include hypotension, muscle cramping, thrombosis, infection, and vitamin depletion. The physiology of these complications is described below and the management is listed in **Table 26–9**.

Hypotension Hypotension is the most common complication seen during HD. It has been reported to occur with approximately 20% to 30% of dialysis sessions.[36]

Pathophysiology. Hypotension associated with HD manifests as a symptomatic decrease in systolic blood pressure of more than 20 mm Hg or a decrease in mean arterial pressure of more than 10 mm Hg during the dialysis session. The primary cause is fluid removal from the bloodstream. Ultrafiltration removes fluid from the plasma, which promotes redistribution of fluids from extracellular spaces into the plasma. However, decreased serum albumin levels and removal of solutes from the bloodstream reduce the osmotic pressure of the plasma relative to the extracellular spaces, slowing redistribution during HD. The decreased plasma volume causes hypotension. Other factors that can contribute to hypotension include antihypertensive medications prior to HD, a target "dry weight" (the target weight after HD session is complete) that is too low, diastolic or autonomic dysfunction, low dialysate calcium or sodium, high dialysate temperature, or ingesting meals prior to or during HD. Elderly age, diabetes, autonomic neuropathy, uremia, and cardiac disease also increase the potential for hypotension.[36] The symptoms associated with hypotension during dialysis include dizziness, nausea, vomiting, abdominal pain, and muscle cramping.

Muscle Cramps Muscle cramps are reported in as many as 35% to 86% of patients receiving HD.[37] The cause is often related to excessive ultrafiltration, which causes hypoperfusion of the muscles. Other contributing factors to the development of muscle cramps include hypotension, hypoosmolality, and electrolyte and acid–base imbalances that occur during HD sessions.[37]

Thrombosis Thrombosis associated with HD most commonly occurs in patients with venous catheter access for dialysis and is a common cause of catheter failure. However, thrombosis can occur in synthetic grafts and less frequently in AVFs.

Infection Infections are an important cause of morbidity and mortality in patients receiving HD. The cause of infection is usually related to organisms found on the skin, namely *Staphylococcus epidermidis* and *S. aureus*, including methicillin-resistant

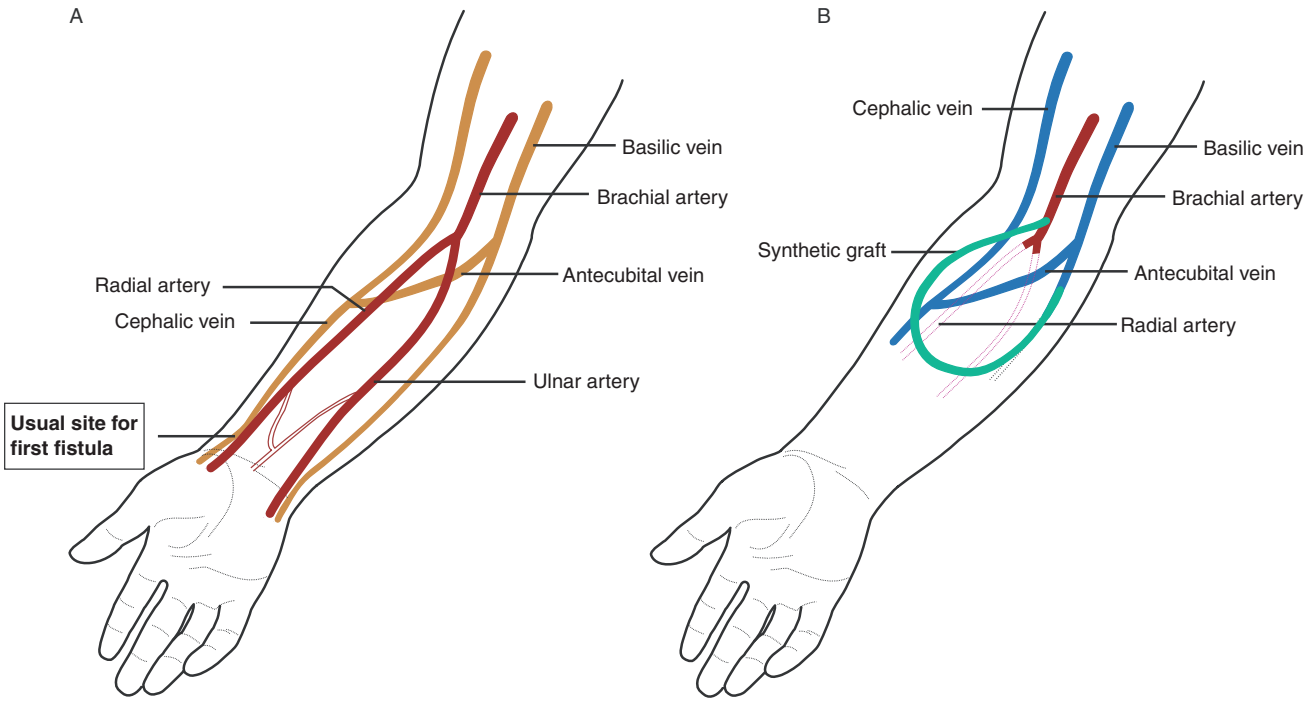

FIGURE 26–5. The predominant types of vascular access for chronic dialysis patients are (A) the arteriovenous fistula and (B) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries because it preferentially flows into the low pressure graft. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:642, with permission.)

S. aureus (MRSA). Gram-negative bacteria are more commonly associated with bacteremia. The greatest risk to patients receiving HD is the development of bacteremia, which is commonly associated with coagulase negative staphylococci and gram-negative bacteria. The risk of bacteremia is up to 10 times higher with venous catheters compared to AVF.[38]

Blood cultures should be obtained for any patient receiving HD who develops a fever. Nonpharmacologic management of

Table 26–9

Management of Complications Associated with Hemodialysis

Hypotension	Acute treatment	Place in Trendelenburg position (head lower than feet) Normal saline 100–200 mL Hypertonic saline (23.4%) 10–20 mL Mannitol 12.5 g
	Prevention	Accurate determination of "dry weight" Midodrine 2.5–10 mg 30 minutes prior to HD Other options with limited evidence: Levocarnitine 20 mg/kg IV after HD Sertraline 50–100 mg daily Fludrocortisone 0.1 mg before HD
Muscle cramps	Acute treatment	Normal saline 100–200 mL Hypertonic saline (23.4%) 10–20 mL Dextrose 50% 50 mL (for nondiabetic patients)
	Prevention	Decrease ultrafiltration rate Accurate determination of "dry weight" Stretching exercises, massage, flexing, compression devices Vitamin E 400 IU daily
Central venous catheter thrombosis	Acute treatment	Normal saline flush Alteplase 2 mg/2 mL per catheter lumen port Reteplase 0.4 units/0.4 mL per catheter lumen port
	Prevention	Heparin lock (1000–10,000 units/1 mL) Sodium citrate 4% lock
Vitamin depletion	Prevention	Multivitamin B complex with vitamin C supplement

infections involves preventive measures with sterile technique, proper disinfection, and minimizing the use and duration of venous catheters for HD access.

Pharmacologic management of infections should cover the gram-positive organisms that most frequently cause access-related infections. Patients who have positive blood cultures should receive treatment tailored to the organism isolated. Preventive measures for access-related infections include mupirocin at the exit site and povidone-iodine ointment. The recommendations of the National Kidney Foundation (NKF) for treatment of infections associated with HD are listed in Table 26–10.

Vitamin Depletion Water-soluble vitamins removed by HD contribute to malnutrition and vitamin deficiency syndromes. Patients receiving HD often require replacement of water-soluble vitamins to prevent adverse effects. The vitamins that may require replacement are ascorbic acid, thiamine, biotin, folic acid, riboflavin, and pyridoxine. Patients receiving HD should take a multivitamin B complex with vitamin C supplement, but they should not take supplements that include fat-soluble vitamins, such as vitamins A, E, or K, which can accumulate in patients with kidney failure.

Peritoneal Dialysis

PD is initiated in 9.6% of patients with newly diagnosed ESKD each year. In 2015, 49,205 patients were receiving PD.[2] PD is associated with improved survival compared with HD.[2] PD preserves residual renal function, which improves cardiovascular stability and may account for the improved survival. Thus, PD may be the preferred method of dialysis in patients with residual renal function.

Table 26–10

Management of Hemodialysis Access Infections[41]

AV Fistula	Treat as subacute bacterial endocarditis for 6 weeks Initial antibiotic choice should always cover gram-positive organisms (eg, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times per week) Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents (gentamicin 2 mg/kg IV with serum concentration monitoring)
Synthetic Grafts (AVG)	
Local infection	Empiric antibiotic coverage for gram-positive, gram-negative, and *Enterococcus* (eg, gentamicin plus vancomycin, then individualize after culture results become available); continue for 2–4 weeks
Extensive infection	Antibiotics as above plus total resection
Access less than 1-month old	Antibiotics as above plus removal of the graft
Tunneled Cuffed Catheters (Internal Jugular, Subclavian)	
Infection localized to catheter exit site	No drainage: topical antibiotics (eg, mupirocin ointment) Drainage present: Gram-positive coverage (eg, cefazolin 20 mg/kg IV three times a week)
Bacteremia with or without systemic signs or symptoms	Gram-positive coverage as above If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks

AV, arteriovenous.

Patient Encounter 4, Part 2

The patient returns to the dialysis center 1 month later for routine hemodialysis. Two hours after starting dialysis, he complains of dizziness.

PE:

VS: BP 95/68 mm Hg; P 108 beats/min; T 98.9° F (37.2° C); wt 184 lb (83.6 kg)

What is the most likely cause of his dizziness?

What treatment would you recommend?

► *Principles of PD*

PD utilizes similar principles as HD in that blood is exposed to a semipermeable membrane against which a physiologic solution is placed. In the case of PD, however, the semipermeable membrane is the peritoneal membrane, and a sterile dialysate is instilled into the peritoneal cavity. The peritoneal membrane is composed of a continuous single layer of mesothelial cells that covers the abdominal and pelvic walls on one side of the peritoneal cavity, and the visceral organs including the GI tract, liver, spleen, and diaphragm on the other side. The mesothelial cells are covered by microvilli that increase the surface area of the peritoneal membrane to approximate body surface area (1 to 2 m^2). Blood vessels that supply the abdominal organs, muscle, and mesentery serve as the blood component of the system.

The gaps between the mesothelial cells allow for large solutes to pass through into the bloodstream. Both the interstitium and endothelial cells of the blood vessels provide resistance to limit the solute size that is removed from the blood. Diffusion is the most important component of solute transport in PD, which is enhanced by the large surface area and volume of dialysate, as well as contact time with the peritoneal membrane. Ultrafiltration is achieved in PD by creating an osmotic pressure gradient between the dialysate and the blood. Traditionally, glucose has been used to create the osmotic gradient, but the solutions are not biocompatible with the peritoneal membrane, resulting in cytotoxicity of the cells. Polymeric glucose derivatives such as icodextrin may be used in place of glucose to create a colloid-driven osmosis that results in ultrafiltration and convection of solute removal, but are more expensive.

In PD, prewarmed dialysate is instilled into the peritoneal cavity where it "dwells" for a specified length of time (usually one to several hours, depending on the type of PD) to adequately clear metabolic waste products and excess fluids and electrolytes. At the end of the dwell time, the dialysate is drained and replaced with fresh dialysate. The continuous nature of PD provides for a more physiologic removal of waste products from the bloodstream, which mimics endogenous kidney function by limiting the fluctuations seen in serum concentrations of the waste products. Similarly, water is removed at a more constant rate, lessening the fluctuations in intravascular fluid balance and providing for more hemodynamic stability.

Several types of PD are used:

- Continuous ambulatory peritoneal dialysis (CAPD) is the most common. The patient exchanges 1 to 3 L of dialysate every 4 to 6 hours throughout the day with a longer dwell time overnight.

- Automated peritoneal dialysis (APD) procedures involve the use of a cycler machine that performs sequential exchanges overnight while the patient is sleeping.
- Continuous cycling PD (CCPD) performs three to five exchanges throughout the night. The final exchange remains in the peritoneal cavity to dwell for the duration of the day.
- Nightly intermittent PD (NIPD) performs six to eight exchanges throughout the night. The final exchange of dialysate is drained in the morning, and the peritoneal cavity remains empty throughout the day.
- Nocturnal tidal PD (NTPD) is similar to NIPD, with the exception that only a portion of the dialysate is exchanged throughout the night. The final exchange is drained in the morning, and the peritoneal cavity remains empty throughout the day.

▶ *Peritoneal Access*

Access to the peritoneal cavity requires placement of an indwelling catheter with the distal end of the catheter resting in the peritoneal cavity. The central portion of the catheter is generally tunneled under the abdominal wall and subcutaneous tissue where it is held in place by cuffs that provide stability and mechanical support to the catheter. The proximal portion of the catheter exits the abdomen near the umbilicus. Several types of indwelling catheters are available; the most common is the Tenckhoff catheter. Placement and handling of the catheter during PD exchanges requires a sterile environment to minimize the risk of infectious complications.

▶ *Complications of PD*

Complications associated with PD include mechanical problems related to the PD catheter, metabolic problems associated with the components of the dialysate fluid, damage to the peritoneal membrane, and infections (Table 26–11). Strategies to manage infectious complications of PD are discussed below.

Table 26–11

Common Complications during Peritoneal Dialysis

Mechanical Complications
Kinking in catheter
Catheter migration
Catheter adherence to peritoneal tissue
Excessive movement of catheter at exit site

Peritoneal Damage
Alterations in permeability of the peritoneal membrane
Sclerosis of the peritoneal membrane

Pain
Impingement of the catheter tip on visceral organs
Instillation pain
- Rapid inflow of dialysate
- Acidic pH of dialysate
- Chemical irritation from dialysate additives (eg, antibiotics)
- Low dialysate temperature

Infections
Peritonitis
Exit-site infections
Tunnel infections

Metabolic Complications
Exacerbation of diabetes mellitus from glucose load
Fluid overload
- Exacerbation of chronic heart failure
- Edema
- Pulmonary congestion

Electrolyte abnormalities

Malnutrition
- Albumin and amino acid loss
- Muscle wasting
- Increased adipose tissue
- Fibrin formation in dialysate

Weight gain

Peritonitis Peritonitis is a leading cause of morbidity in PD patients, which often leads to loss of the catheter and subsequent change to HD as the treatment modality. However, advances with connectors used during instillation and drainage of dialysate and delivery systems have dramatically decreased the incidence of peritonitis. Peritonitis can also be caused by chemical irritation or microorganisms.

Pathophysiology. Gram-positive organisms, namely *S. epidermidis*, are the most common cause of peritonitis. Other pathologic organisms include *S. aureus*, streptococcal species, enterococcus species, gram-negative organisms including *Escherichia coli* and *Pseudomonas* species, and fungal organisms. Peritonitis should be presumed if cloudy fluid is drained from the peritoneal cavity and the fluid should be evaluated by cultures. Antibiotic treatment should be initiated immediately, until cell counts and cultures prove otherwise.[39] Patients with peritonitis may also complain of abdominal pain, although pain may be absent in some cases.

Treatment. The International Society of Peritoneal Dialysis (ISPD) revised the recommendations for the treatment of PD-related infections in 2016.[39] Drug selection for empirical treatment of peritonitis should cover both gram-positive and gram-negative organisms specific to the dialysis center and be based on the protocols and sensitivity patterns of organisms known to cause peritonitis, as well as the history of infections in the patient. First-generation cephalosporins, such as cefazolin, or vancomycin are recommended for empirical coverage of gram-positive organisms. Appropriate coverage for gram-negative organisms includes third- or fourth-generation cephalosporins, such as ceftazidime or cefepime, or aminoglycosides. Alternatives for gram-negative coverage include oral fluoroquinolones and aztreonam. An example of an appropriate empiric treatment for peritonitis includes cefazolin in combination with ceftazidime, cefepime, or an aminoglycoside. If the patient has a β-lactam allergy, vancomycin in combination with an aminoglycoside or aztreonam is an alternative empirical treatment.[39] It should be noted that aminoglycosides can decrease residual renal function in patients receiving PD.

The preferred route of administration is intraperitoneal (IP) rather than IV to achieve maximum concentrations at the site of infection. Antibiotics can be administered IP intermittently as a single large dose in one exchange per day or continuously as multiple smaller doses with each exchange. Intermittent administration requires at least 6 hours of dwell time in the peritoneal cavity to allow for adequate systemic absorption and provides adequate levels to cover the 24-hour period. However, continuous administration is better suited for PD modalities that require more frequent exchanges (< 6-hour dwell time). See the ISPD guidelines for dosing recommendations for IP antibiotics in CAPD and automated PD patients.[39] The dose of the antibiotics should be increased by 25% for patients with residual kidney function who are able to produce more than 100 mL urine output per day.

Once the organism has been identified and sensitivities are known, drug selection should be adjusted to reflect the susceptibilities of the organism. Streptococcal, staphylococcal,

and enterococcal species sensitive to β-lactam antibiotics should be treated with continuous IP dosing to increase efficacy and minimize resistance.[39] Peritonitis caused by *S. aureus* or *P. aeruginosa* is often associated with catheter-related infections, which are difficult to treat and often require removal of the catheter. Two antibiotics are required for treatment of *P. aeruginosa* peritonitis.[39] If multiple organisms are cultured, treatment should cover all of the organisms, including anaerobic organisms, and the patient should be evaluated for other intra-abdominal pathologies.[39]

Peritonitis caused by fungal organisms is associated with mortality in 25% of patients,[39] which can be reduced by removing the catheter after fungal organisms are identified. If a fungal organism is identified, empirical treatment should include IP amphotericin B and flucytosine,[39] but alternative agents can be used based on susceptibilities. Although IP amphotericin administration is associated with chemical irritation and pain, penetration of amphotericin into the peritoneal cavity is poor with IV administration. Fluconazole, voriconazole, or caspofungin may be suitable alternatives, depending on culture results.

Catheter-Related Infections Catheter-related infections generally occur at the exit site or the portion of the catheter that is tunneled in the subcutaneous tissue. Previous infections increase the risk and incidence of catheter-related infections.

Pathophysiology. The major pathologic organisms responsible for causing catheter-related infections are *S. aureus* and *P. aeruginosa*. These organisms also cause the most serious catheter-related infections. *S. epidermidis* is found in less than 20% of catheter-related infections.[40]

Exit-site infections present with purulent drainage at the site. Erythema may or may not be present with an exit-site infection. Tunnel infections are generally extensions of exit-site infections and rarely occur alone. Symptoms of a tunnel infection may include tenderness, edema, and erythema over the tunnel pathway but are often asymptomatic. Ultrasound can be used to detect tunnel infections in asymptomatic patients. Exit-site infections caused by *S. aureus* and *P. aeruginosa* often spread to tunnel infections and are the most common causes of catheter-infection–related peritonitis.

Treatment. Exit-site infections may be treated immediately with empiric coverage, or treatment may be delayed until cultures return. Empiric treatment of catheter-related infections should cover *S. aureus* with a first-generation cephalosporin or penicillinase-resistant penicillin. Coverage for MRSA or *P. aeruginosa* should also be included if the patient has a history of infections with either organism. Vancomycin or clindamycin are used for empiric coverage of MRSA, while oral fluoroquinolones are used as first-line agents to treat *P. aeruginosa*.[40]

Cultures and sensitivity testing are particularly important in tailoring antibiotic therapy for catheter-related infections to ensure eradication of the organism and prevent recurrence or related peritonitis. Treatment of catheter-related infections should be continued until the exit site appears normal with no erythema or drainage. Generally, at least 2 weeks of therapy or longer are required to ensure complete eradication of the organism and prevent future recurrence, which is common with *S. aureus* and *P. aeruginosa*. Infections that do not resolve may require replacement of the PD catheter. Catheter-related

Patient Care Process: Chronic Kidney Disease

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements.
- Review the medical history, laboratory tests, and physical assessment.
- Speak with the patient and review records to identify socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Identify risk factors that increase the risk for CKD (Table 26–2).
- Determine whether the patient has any concomitant diseases that may hasten the progression of CKD or increase the risk of CVD.
- Identify medications the patient is taking that may cause nephrotoxicity or require adjustment for renal dysfunction.
- Review relevant laboratory tests to determine if patient is experiencing complications of CKD.
- Calculate GFR to determine the staging of CKD (Table 26–1).
- Determine if the patient is experiencing signs and symptoms associated with CKD, or complications of CKD (Figures 26–2 and 26–3).

Develop a Care Plan:

- Determine if pharmacotherapy is indicated for proteinuria or other concomitant disease states.
- Select appropriate medical treatments to control complications of CKD, including anemia (Figure 26–2, Tables 26–4 and 26–5); mineral and bone diseases (Figure 26–3, Tables 26–7 and 26–8); and electrolyte imbalances.
- Select medications and doses that are appropriately adjusted for the level of kidney function.

Implement the Care Plan:

- Educate the patient about changes in drug therapy.
- Address patient's concerns about CKD and its management.
- Educate the patient on dietary and lifestyle changes to treat complications of CKD.
- Stress the importance of adherence with the treatments for CKD and associated complications including lifestyle modifications and medications.
- Recommend a therapeutic regimen that is easy for the patient to accomplish.

Follow-up: Monitor and Evaluate:

- Follow-up at regular intervals to assess effectiveness and safety of therapy.
- Review physical examination and lab tests to assess changes in clinical status.

infections that present in conjunction with or progress to peritonitis with the same organism require removal of the PD catheter until the peritonitis is resolved.[40]

Prophylaxis of Peritonitis and Catheter-Related Infections. Prevention of peritonitis and catheter-related infections starts when the catheter is placed. The exit site should be properly cared for until it is well healed before it can be used for PD. Patients should receive proper instructions for care of the catheter during this time period, which can last up to 2 weeks. Patients should also be instructed on the proper techniques to use for dialysate exchanges to minimize the risk of infections during exchanges, which is the most common cause of peritonitis.

Topical antibiotics, including mupirocin, gentamicin, or ciprofloxacin cream or ointment should be applied daily around the exit site to prevent catheter-related infections.[40] Intranasal *S. aureus* increases the risk of *S. aureus* exit-site infections, tunnel infections, peritonitis, and subsequent catheter loss.[40]

Outcome Evaluation. Clinical improvement should be seen within 48 hours of initiating treatment for peritonitis or catheter-related infections. Perform daily inspections of peritoneal fluid or the exit site to determine clinical improvement. Peritoneal fluid should become clear with improvement of peritonitis and erythema, and discharge should remit with improvement of catheter-related infections. If no improvement is seen within 48 hours, obtain additional cultures and cell counts to determine the appropriate alterations in therapy.

Abbreviations Introduced in This Chapter

ACEI	Angiotensin-converting enzyme inhibitor
AGE	Advanced glycation end-product
AKI	Acute kidney injury
APD	Automated peritoneal dialysis
ARB	Angiotensin receptor blocker
AVF	Arteriovenous fistula
AVG	Arteriovenous graft
BUN	Blood urea nitrogen
CAPD	Continuous ambulatory peritoneal dialysis
CCPB	Calcium-containing phosphate binder
CCPD	Continuous cycling peritoneal dialysis
CKD	Chronic kidney disease
CKD-EPI	Chronic Kidney Disease Epidemiology Collaboration equation
CKD-MBD	Chronic kidney disease mineral and bone disease
CVD	Cardiovascular disease
DKD	Diabetic kidney disease
DM	Diabetes mellitus
ECG	Electrocardiogram
EPO	Erythropoietin
ESA	Erythropoiesis-stimulating agent
GFR	Glomerular filtration rate
HbA1c	Hemoglobin A1c
Hct	Hematocrit
HD	Hemodialysis
HDL-C	High-density lipoprotein cholesterol
Hgb	Hemoglobin
IP	Intraperitoneal
iPTH	Intact parathyroid hormone
ISPD	International Society of Peritoneal Dialysis
KDIGO	Kidney Disease: Improving Global Outcomes
LDL-C	Low-density lipoprotein cholesterol
LVH	Left ventricular hypertrophy
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular volume
MDRD	Modification of Diet in Renal Disease (study)
MRSA	Methicillin-resistant *Staphylococcus aureus*
NIPD	Nightly intermittent peritoneal dialysis
NKF	National Kidney Foundation
NTPD	Nocturnal tidal peritoneal dialysis
PD	Peritoneal dialysis
PTH	Parathyroid hormone
RBC	Red blood cell
ROD	Renal osteodystrophy
RRT	Renal replacement therapy
SC	Subcutaneous
SCr	Serum creatinine
sHPT	Secondary hyperparathyroidism
SPS	Sodium polystyrene sulfonate
TIBC	Total iron binding capacity
TSat	Transferrin saturation
USRDS	United States Renal Data Service

27 Fluids and Electrolytes

Mark A. Malesker and Lee E. Morrow

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Estimate the volumes of various body fluid compartments.
2. Calculate the daily maintenance fluid requirement for patients given their weight and gender.
3. Differentiate among currently available fluids for volume resuscitation.
4. Identify the electrolytes primarily found in the extracellular and intracellular fluid compartments.
5. Describe the unique relationship between serum sodium concentration and total body water (TBW).
6. Review the etiology, clinical presentation, and management for disorders of sodium, potassium, calcium, phosphorus, and magnesium.

BODY FLUID COMPARTMENTS

A thorough understanding of the fundamentals of fluid and electrolyte homeostasis is essential, given the frequency with which clinical disturbances are seen and the profound effects these disturbances can have on various aspects of patient care. However, the interplay of body fluids, serum electrolytes, and clinical monitoring is complex, and a thorough command of these issues is a challenging task even for advanced practitioners.[1] Practitioners must be familiar with the key concepts of body compartment volumes, calculation of daily fluid requirements, and the various types of fluid available for replacement. The management of disorders of sodium, potassium, calcium, phosphorus, and magnesium integrates these concepts with issues of dose recognition and patient safety.

The most fundamental concept to grasp is an assessment of total body water (TBW), which is directly related to body weight. KEY CONCEPT TBW constitutes approximately 50% of lean body weight in healthy females and 60% of lean body weight in males. For clinical purposes, most clinicians generalize that TBW accounts for 60% of lean body weight in adults, regardless of gender. The percentage of TBW decreases as body fat increases and/or with age (75%–85% of body weight is water for newborns). Unless the patient is obese (body weight > 120% of ideal body weight [IBW]), clinicians typically use a patient's actual body weight when calculating TBW.[2] In obese patients, it is customary to estimate TBW using lean body weight or IBW as calculated by the Devine–Devine method: males' lean body weight = 50 kg + (2.3 kg/in × [height in inches − 60]) and females' lean body weight = 45.5 kg + (2.3 kg/in × [height in inches − 60]).[3–5] Note that 1 kg is equivalent to 2.2 lb, 1 in is equivalent to 2.54 cm, and 1 L of water weighs 1 kg (2.2 lb).

LO 1

The intracellular fluid (ICF) represents the water contained within cells and is rich in electrolytes such as potassium, magnesium, phosphates, and proteins. KEY CONCEPT The ICF is approximately two-thirds of TBW regardless of gender. For a 70-kg person, this would mean that the TBW is 42 L and the ICF is approximately 28 L. Note that ICF represents approximately 40% of total body weight.

LO 1

The extracellular fluid (ECF) is the fluid outside the cell and is rich in sodium, chloride, and bicarbonate. KEY CONCEPT The ECF is approximately one-third of TBW (14 L in a 70-kg person) and is subdivided into two compartments: the interstitial fluid and the intravascular fluid. The interstitial fluid represents the fluid occupying the spaces between cells and is about 25% of TBW (10.5 L in a 70-kg person). The intravascular fluid (also known as plasma) represents the fluid within the blood vessels and is about 8% of TBW (3.4 L in a 70-kg person). Because the exact percentages are cumbersome to recall, many clinicians accept that the ECF represents roughly 20% of body weight (regardless of gender) with 15% in the interstitial space and 5% in the intravascular space.[6] Note that serum electrolytes are routinely measured from the ECF.

The transcellular fluid includes the viscous components of the peritoneum, pleural space, and pericardium, as well as the cerebrospinal fluid, joint space fluid, and the gastrointestinal (GI) digestive juices. Although the transcellular fluid normally accounts for about 1% of TBW, this amount can increase significantly during various illnesses favoring fluid collection in one of these spaces (eg, pleural effusions or ascites in the peritoneum). The accumulation of fluid in the transcellular space is often referred to as "third spacing." To review the calculations of the body fluid compartments in a representative patient, see Patient Encounter 1.

Fluid balance is assessed by several means each of which has its limitations. Blood pressure (BP) measurements estimate fluid status relative to the amount of blood volume pumped by the heart, but are affected by cardiac function and vascular pliability. Patients with significant volume deficiency may appear

Patient Encounter 1: Body Fluid Compartments

Calculate the TBW, ICF, and ECF in an 82-kg male.

hypotensive, but this is a late finding that may require greater than 20% of TBW to be lost. Patients with significant volume excess may appear edematous; however, third spacing may hide this finding until late in the course as well. The physical examination can indicate the presence of fluid deficits (dry mucous membranes) and fluid excess (peripheral edema, coarse breath sounds). Data suggest that dynamic assessments of volume status (pulse pressure variability, ultrasound-derived vena cava diameter variations, passive leg raising) are more accurate than either the bedside clinical examination or passive measurements of volume status (arterial catheter, central venous catheter, pulmonary artery catheter).

To maintain fluid balance, the total amount of fluid gained throughout the day (input, or "ins") must equal the total amount of fluid lost (output, or "outs"). Although most forms of the body's input and output can be measured, several cannot. For a normal adult on an average diet, ingested fluids are easily measured and average 1400 mL/day. Other fluid inputs, such as those from ingested foods and the water by-product of oxidation, are not directly measurable. Fluid outputs such as urinary and stool losses are also easily measured and referred to as sensible losses. Other sources of fluid loss, such as evaporation of fluid through the skin and/or lungs, are not readily measured and are called insensible losses. Table 27–1 shows the estimated ins and outs (I&Os) for a healthy 68-kg (150-lb) man.[6] The measurable I&Os are routinely measured in hospitalized patients and are used to estimate total fluid balance for each 24-hour period. It is important to realize that in hospitalized patients, multiple other forms of fluid loss must be considered. These include losses from enteric suctioning (most commonly, nasogastric [NG] tubes), from surgical drains (eg, chest tubes, nephrostomy tubes, and pancreatic drains), via fistulous tracts, and enhanced evaporative losses (burns and fever).

LO 2

LO 2

TBW depletion (often referred to as "dehydration") is typically a gradual, chronic problem. Because TBW depletion represents a loss of hypotonic fluid (proportionally more water is lost than sodium) from all body compartments, a primary disturbance of osmolality is usually seen. The signs and symptoms of TBW depletion include central nervous system (CNS) disturbances (mental status changes, seizures, and coma), excessive thirst, dry mucous membranes, decreased skin turgor, elevated serum sodium, increased plasma osmolality, concentrated urine, and acute weight loss. Common causes of TBW depletion include insufficient oral intake, excessive insensible losses, diabetes insipidus, excessive osmotic diuresis, and impaired renal concentrating mechanisms. Elderly long-term care residents are frequently admitted to the acute care hospital with TBW depletion secondary to lack of adequate oral intake, often with concurrent excessive insensible losses.

Table 27–1

Approximate I&Os for a Healthy 68-kg (150-lb) Man

Input	mL/day	Output	mL/day
Ingested fluid[a]	1400	Urine[a]	1500
Fluid in food	850	Skin losses	500
Water of oxidation	350	Respiratory tract losses	400
		Stool	200
Total	2600	Total	2600

[a]Readily quantifiable.

Table 27–2

Useful Calculations for the Estimation of Patient Maintenance Fluid Requirements

Neonate (1–10 kg) = 100 mL/kg
Child (10–20 kg) = 1000 mL + 50 mL for each kilogram > 10
Adult (> 20 kg) = 1500 mL + 20 mL for each kilogram > 20

LO 2

The volume of fluid required to correct TBW depletion equals the basal fluid requirement plus ongoing exceptional losses plus the fluid deficit. Basal daily fluid requirements are calculated using the formulas in Table 27–2. For an adult, this represents 1500 mL/day for the first 20 kg of body weight plus 20 mL/day for each additional kilogram. The volume of replacement fluids required for a given patient (the fluid deficit) can be estimated by the acute weight change in the patient (1 kg = 1 L of fluid). Because the precise weight change is not typically known, it is often calculated as follows: fluid deficit = normal TBW − present TBW. Normal TBW is estimated based on the patient's weight using the formulas in Table 27–2, and the present TBW is estimated based on the patient's current body weight. The choice of fluids used for replacement is guided by the presence of concurrent electrolyte abnormalities. The adequacy of replacement is guided by each patient's objective response to fluid replacement (improved skin turgor, adequate urine output, normalization of heart rate, BP, etc).

LO 2

Once TBW has been restored, the volume of "maintenance" fluid equals the basal fluid requirement plus ongoing exceptional losses. If the pathophysiologic process leading to TBW depletion has not been identified and corrected (or accounted for in the calculation of maintenance fluid requirements), TBW depletion will quickly recur. To review the concepts involved in the calculation of replacement fluids for a representative patient, see Patient Encounter 2.

Compared with TBW depletion, ECF depletion tends to occur acutely. In this setting, rapid and aggressive fluid replacement is required to maintain adequate organ perfusion. Because ECF depletion is generally due to the loss of isotonic fluid (proportional losses of sodium and water), major disturbances of plasma osmolality are not common. ECF depletion manifests clinically as signs and symptoms associated with decreased tissue perfusion: dizziness, orthostasis, tachycardia, decreased urine output, increased hematocrit, decreased central venous pressure, and/or hypovolemic shock. Common causes of ECF depletion include external fluid losses (burns, hemorrhage, diuresis, GI losses, and adrenal insufficiency) and third spacing of fluids (septic shock, anaphylactic shock, or abdominal ascites).

In clinical practice, the most commonly encountered problem is depletion of TBW and ECF. Accordingly, the fluid resuscitation strategy should address both of these compartments. As these compartments are repleted, serum electrolytes must be monitored closely as discussed in subsequent sections of this chapter.

Patient Encounter 2: Fluid Requirements

Calculate the daily fluid requirement for a 75-kg adult female.

THERAPEUTIC FLUIDS

Crystalloids

LO 3 KEY CONCEPT Therapeutic intravenous (IV) fluids include crystalloid solutions and colloidal solutions. Crystalloids are composed of water and electrolytes, all of which pass freely through semipermeable membranes and remain in the intravascular space for shorter periods of time. As such, these solutions are very useful for correcting electrolyte imbalances but result in smaller hemodynamic changes for a given unit of volume.

LO 3 Crystalloids can be classified further according to their tonicity. Isotonic solutions (ie, normal saline or 0.9% sodium chloride [NaCl]) have a tonicity equal to that of the ICF (approximately 310 mEq/L [mmol/L]) and do not shift the distribution of water between the ECF and the ICF. Because hypertonic solutions (ie, hypertonic saline or 3% NaCl) have greater tonicity than the ICF (> 376 mEq/L [mmol/L]), they draw water from the ICF into the ECF. In contrast, hypotonic solutions (ie, 0.45% NaCl) have less tonicity than the ICF (< 250 mEq/L [mmol/L]) leading to osmotic pressure gradient that favors shifts of water from the ECF into the ICF. The tonicity, electrolyte content, and glucose content of selected fluids are shown in Table 27–3.

The tonicity of crystalloid solutions is directly related to their sodium concentration. The most commonly used crystalloids include normal saline, dextrose/half-normal saline, hypertonic saline, and lactated Ringer's (LR) solution. Excessive administration of any fluid replacement therapy, regardless of tonicity, can lead to fluid overload, particularly in patients with cardiac or renal insufficiency. Glucose is often added to hypotonic crystalloids in amounts that result in isotonic fluids (D_5W, D5 ½ NS, and D5 ¼ NS). These solutions are often used as maintenance fluids to provide basal amounts of calories and water.

▶ *Normal Saline (0.9% NaCl or NS)*

LO 3 Normal saline is an isotonic fluid composed of water, sodium, and chloride. It provides primarily ECF replacement and can be used for virtually any cause of TBW depletion. Common uses of normal saline include perioperative fluid administration; volume resuscitation of shock, sepsis, hemorrhage, or burn patients; fluid challenges in hypotensive or oliguric patients; and hyponatremia. Normal saline can also be used to treat metabolic alkalosis (also known as contraction alkalosis). Large volumes of normal saline can cause a hyperchloremic metabolic acidosis.

▶ *Half-Normal Saline (0.45% NaCl or ½ NS)*

LO 3 Half-normal saline is a hypotonic fluid that provides free water in relative excess when compared with the sodium concentration. This crystalloid is typically used to treat patients who are hypertonic due to primary depletion of the ECF. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

▶ *5% Dextrose/Half-Normal Saline (D5 ½ NS)*

LO 3 D5 ½ NS is a hypotonic fluid that is commonly used as a maintenance fluid. This crystalloid is typically used once fluid deficits have been corrected with normal saline or LR solution. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

▶ *Hypertonic Saline (3% NaCl)*

LO 3 Hypertonic saline is obviously hypertonic and provides a significant sodium load to the intravascular space. This solution is used very infrequently given the potential to cause significant shifts in the water balance between the ECF and the ICF. It is typically used to treat patients with severe hyponatremia who have symptoms attributable to low serum sodium. Hypertonic

Table 27–3

Electrolyte and Dextrose Content of Selected Crystalloid Fluids

IV Solution	Osmolarity (mOsm or mmol)	Dextrose) (g/L) mmol/L	Sodium (mEq/L) mmol/L	Potassium (mEq/L) mmol/L	Calcium (mEq/L) mmol/L	Chloride (mEq/L) mmol/L	Lactate (mEq/L) mmol/L
D5%	250	50 / 2.78					
D10%	505	100 / 5.55					
0.9% NaCl	308		154			154	
0.45% NaCl	154		77			77	
3% NaCl	1025		512			512	
D5% and 0.45% NaCl	405	50 / 2.78	77			77	
D5% and 0.2% NaCl	329	50 / 2.78	34			34	
Ringer's injection	310		147	4	5 / 2.5	156	
Lactated Ringer's solution	274		130	4	3 / 1.5	109	28
Lactated Ringer's solution and D5%	525	50 / 2.78	130	4	3 / 1.5	109	28

D, dextrose; NaCl, sodium chloride.

saline in concentrations of 7.5% to 23.4% has been used to acutely lower intracranial pressure in the setting of traumatic brain injury and stroke. The literature is inconsistent for the optimal hypertonic concentration, dosing, timing of replacement, and goals for use in this population. Serum sodium and neurologic status must be very closely monitored whenever given.

▶ *Ringer's Lactate*

LO 3 This isotonic volume expander contains sodium, potassium, chloride, and lactate in concentrations that approximate the fluid and electrolyte composition of the blood. Ringer's lactate (also known as "Lactated Ringers") provides ECF replacement and is most often used in the perioperative setting and for patients with lower GI fluid losses, burns, or dehydration. The lactate component of LR works as a buffer to increase the pH. Accordingly, large volumes of LR may cause iatrogenic metabolic alkalosis. Because patients with significant liver disease are unable to metabolize lactate sufficiently, LR administration in this population may lead to accumulation of lactate with iatrogenic lactic acidosis.

▶ *5% Dextrose in Water (D_5W)*

LO 3 D_5W solution is a combination of free water and dextrose that provides a modest amount of calories but no electrolytes. Although it is technically isotonic, it acts as a hypotonic solution in the body. It is commonly used to treat severe hypernatremia. D_5W is also used in small volumes (100 mL) to dilute many IV medications or at a low infusion rate (10–15 mL/hour) to "keep the vein open" (KVO) for IV medications.

Colloids

LO 3 In contrast to crystalloids, colloids do not dissolve into a true solution and therefore do not pass readily across semipermeable membranes. As such, colloids effectively remain in the intravascular space and increase the oncotic pressure of the plasma. This effectively shifts fluid from the interstitial compartment to the intravascular compartment. In clinical practice, these theoretical benefits are generally short lived (given metabolism of colloidal proteins/sugars), and for most patients there is little therapeutic advantage of colloids over crystalloids or vice versa. Examples of colloids include 5% albumin, 25% albumin, the dextrans, hetastarch, and fresh-frozen plasma (FFP). Because each of these agents contains a substance (proteins and complex sugars) that will ultimately be metabolized, the oncotic agent will be ultimately lost and only the remaining hypotonic fluid delivery agent will remain. As such, use of large volumes of colloidal agents is more likely to induce fluid overload compared with crystalloids. Although smaller volumes of colloids have equal efficacy as larger volumes of crystalloids, they generally must be infused more slowly. Often the net result is that the time to clinical benefit is the same regardless of which class of fluid is utilized. For example, 500 mL of normal saline is required to increase the systolic BP to the same degree as seen with approximately 250 mL of 5% albumin; however, the normal saline can be administered twice as fast.

▶ *Albumin*

LO 3 Albumin is a protein derived from fractionating human plasma. Because albumin infusion is expensive and may be associated with adverse events, it should be used for acute volume expansion and *not* as a supplemental source of protein calories. Historically, albumin was used indiscriminately in the intensive care unit until anecdotal publications suggested that albumin might cause immunosuppression. However, the Saline Versus Albumin Fluid Evaluation (SAFE) trial found that the mortality for those who received albumin was the same as for those who received normal saline.[7] A subsequent post hoc analysis reported that patients with traumatic brain injury had higher mortality rates when given albumin for fluid resuscitation. These conflicting findings highlight the controversy and confusion surrounding the use of human albumin versus normal saline therapy for resuscitation of critically ill patients.[8,9] In 1818 patients with severe sepsis, albumin replacement with crystalloids as compared to crystalloids alone did not improve the rate of survival at 28 and 90 days.[10]

Based on limited availability, health systems and hospitals have had to define the appropriate albumin indications for their patients and ration albumin accordingly. Evidence-based indications for albumin include plasmapheresis/apheresis, large-volume paracentesis (> 4 L removed), hypotension in hemodialysis, and the need for aggressive diuresis in hypoalbuminemic hypotensive patients. Inappropriate uses of albumin include nutritional supplementation, impending hepatorenal syndrome, pancreatitis, alteration of drug pharmacokinetics, or acute normovolemic hemodilution in surgery. Practitioners can keep up with medication shortages by checking the American Society of Health-System Pharmacists (ASHP) website (www.ashp.org).

▶ *Hydroxyethyl Starch Solutions and Dextran*

While albumin is the most commonly used colloid, the other available products are not without their own risks and benefits.
LO 3 Hydroxyethyl starch (HES) solutions, including Hetastarch (various manufacturers) and Voluven, Hospira, contain 6% starch and 0.9% NaCl. Hextend, Hospira, is a comparable plasma expander that contains 6% hetastarch in lactated electrolyte solution. HES products have no oxygen-carrying capacity and are administered intravenously as plasma expanders. Limitations of these products include acquisition cost, hypersensitivity reactions, and bleeding. Dosing should be reduced in the presence of renal dysfunction. Clinical data linking HES solutions with an increased risk of mortality and renal injury requiring renal replacement therapy in critically ill patients prompted the US Food and Drug Administration (FDA) to issue a MedWatch safety communication in November 2013. FDA concluded these solutions should not be used in critically ill patients, including sepsis and those admitted to the intensive care unit, and a boxed warning to highlight the risk of mortality and severe renal injury is warranted. A list of recommendations for patients and healthcare providers to consider before use of HES solutions can be found on the FDA website (http://www.fda.gov/Safety/MedWatch/).

LO 3 Low molecular weight dextran (various manufacturers) and high molecular weight dextran (various manufacturers) are polysaccharide plasma expanders. Anaphylactic reactions and prolonged bleeding times have limited the use of these products. Potential mechanisms of colloid solution-induced bleeding include platelet inhibition or possible dilution of clotting factors via infusion of a large-volume colloid solution.

A Cochrane review regarding the use of colloids versus crystalloids for fluid resuscitation in critically ill patients found no evidence from randomized clinical trials that resuscitation with colloids reduces the risk of death in patients with trauma, burns, or following surgery. Additionally, the use of HES might be associated with mortality and given the lack of survival benefit and increased expense over crystalloids the continued use of colloids is limited.[11]

Fluid Management Strategies

LO 3

Classic indications for IV fluid include maintenance of BP, restoring the ICF volume, replacing ongoing renal or insensible losses when oral intake is inadequate, and the need for glucose as a fuel for the brain.[12] Although large volumes of fluid are given during the resuscitation of most trauma patients, a recent analysis reported uncertainty about the use of early large-volume fluid replacement in patients with active bleeding, calling into question our understanding of the need for fluids in various patient populations.[13]

When determining the appropriate fluid to be utilized, it is important to first determine the type of fluid problem (TBW vs ECF depletion), and start therapy accordingly. For patients demonstrating signs of impaired tissue perfusion, the immediate therapeutic goal is to increase the intravascular volume and restore tissue perfusion. The standard therapy is normal saline given at 150 to 500 mL/hour (for adult patients) until perfusion is optimized. Although LR is a therapeutic alternative, lactic acidosis may arise with massive or prolonged infusions. LR has less chloride content versus normal saline (109 mEq/L [mmol/L] vs 154 mEq/L [mmol/L]) and has the advantage of use when large volumes of normal saline produce acidosis during fluid resuscitation. In severe cases, a colloid or blood transfusion may be indicated to increase oncotic pressure within the vascular space. Once euvolemia is achieved, patients may be switched to a more hypotonic maintenance solution (D5 ½ NS or 0.45% NaCl) at a rate that delivers estimated daily needs.

The clinical scenario and the severity of the volume abnormality dictate monitoring parameters during fluid replacement therapy. These may include the subjective sense of thirst, mental status, skin turgor, orthostatic vital signs, pulse rate, weight changes, blood chemistries, fluid input and output, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. Fluid replacement requires particular caution in patient populations at risk of fluid overload, such as those with renal failure, cardiac failure, hepatic failure, or the elderly. Other complications of parenteral fluid therapy include IV site infiltration, infection, phlebitis, thrombophlebitis, and extravasation.

In summary, common settings for fluid resuscitation include hypovolemic patients (eg, sepsis or pneumonia), hypervolemic patients (eg, congestive heart failure [CHF], cirrhosis, or renal failure), euvolemic patients who are unable to take oral fluids in proportion to insensible losses (eg, the perioperative period), and patients with electrolyte abnormalities (see next).

ELECTROLYTES

LO 4

Normally, the number of anions (negatively charged ions) and cations (positively charged ions) in each fluid compartment are equal. Cell membranes play the critical role of maintaining distinct ICF and ECF spaces, which are biochemically distinct. Serum electrolyte measurements reflect the stores of ECF electrolytes rather than that of ICF electrolytes. Table 27–4 lists the chief cations and anions along with their normal concentrations in the ECF and ICF. The principal cations are sodium, potassium, calcium, and magnesium; the key anions are chloride, bicarbonate, and phosphate. In the ECF, sodium is the most common cation and chloride is the most abundant anion; in the ICF, potassium is the primary cation and phosphate is the main anion. Normal serum electrolyte values are listed in Table 27–5.

Osmolality is a measure of the number of osmotically active particles per unit of solution, independent of the weight or nature of the particle. Equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. Although the normal serum osmolality is 280 to 300 mOsm/kg (mmol/kg), multiple scenarios exist where this value becomes markedly abnormal. KEY CONCEPT The calculated serum osmolality helps determine deviations in TBW content. As such, it is often useful to calculate the serum osmolality as follows:

$$\text{Serum osmolality (mOsm/kg)} = 2\,(\text{Na mEq/L}) + (\text{glucose [mg/dL]})/18 + (\text{BUN [mg/dL]})/2.8$$

$$\text{Serum osmolality using SI units (mmol/kg)} = 2\,(\text{Na mmol/L}) + (\text{glucose mmol/L}) + (\text{BUN mmol/L})$$

LO 5

Because the body regulates water to maintain osmolality, deviations in serum osmolality are used to estimate TBW stores. Water moves freely across all cell membranes, making serum osmolality an accurate reflection of the osmolality within all body compartments. An increase in osmolality is equated with a loss of water greater than the loss of solute (TBW depletion). A decrease in serum osmolality is seen when water is retained in excess of solute (CHF or hepatic cirrhosis).

Table 27–4

Normal Cation and Anion Concentrations in the ECF and ICF

	ECF		ICF	
Ion Species	Plasma (mEq/L [mmol/L])	Interstitial Fluid (mEq/L [mmol/L])	Ion Species	mEq/L [mmol/L]
Cations			**Cations**	
Na^+	142 [142]	144 [144]	K^+	135 [135]
K^+	4 [4]	4 [4]	Mg^{2+}	43 [21.5]
Ca^{2+}	5 [2.5]	2.5 [1.25]		
Mg^{2+}	3 [1.5]	1.5 [0.75]		
Total	154 [150]	152 [150]	Total	178 [156.5]
Anions			**Anions**	
Cl^-	103 [103]	114 [114]	PO_4^{2-}	90 [45]
HCO_3^-	27 [27]	30 [30]	Protein	70 [70]
PO_4^{2-}	2 [1]	2 [1]	SO_4^{2-}	18 [9]
SO_4^{2-}	1 [0.5]	1 [0.5]		
Organic acid	5 [5]	5 [5]		
Protein	16 [16]	0		
Total	154 [152.5]	152 [150.5]	Total	178 [124]

ECF, extracellular fluid; ICF, intracellular fluid.

Table 27–5

Normal Ranges for Serum Electrolyte Concentrations

Sodium	135–145 mEq/L (mmol/L)
Potassium	3.5–5.0 mEq/L (mmol/L)
Chloride	98–106 mEq/L (mmol/L)
Bicarbonate	21–30 mEq/L (mmol/L)
Magnesium	1.4–2.2 mEq/L or 0.7–1.1 mmol/L
Calcium	
Total	4.4–5.2 mEq/L (9–10.5 mg/dL) or 2.2–2.6 mmol/L
Ionized	2.2–2.8 mEq/L (4.5–5.6 mg/dL) or 1.1–1.4 mmol/L
Phosphorus	3–4.5 mg/dL (1.0–1.5 mmol/L)

Patient Encounter 3: Calculate the Plasma Osmolality

A 22-year-old college student was at a tailgate party prior to a football game. He tripped on uneven pavement while staggering to the ticket gate. When attended by EMT personnel, he was agitated and complaining of a broken arm. Upon transfer to your emergency department, rapid respiration, tachycardia, and a BP of 90/60 mm Hg were noted. The sodium is 138 mEq/L (mmol/L), potassium 3.2 mEq/L (mmol/L), chloride 105 mEq/L (mmol/L), bicarbonate 12 mEq/L (mmol/L), glucose 200 mg/dL (11.1 mmol/L), and BUN 28 mg/dL (10.0 mmol/L). The measured osmolality was 340 mOsm/kg (mmol/kg).

Calculate the osmolality.

Calculate the osmolar gap.

What is the likely cause of an increased gap in this patient?

The difference between the measured serum osmolality and the calculated serum osmolality, using the equation just stated, is referred to as the **osmolar gap**. Under normal circumstances the osmolar gap should be 10 mOsm/kg (mmol/kg) or less. An increased osmolar gap suggests the presence of a small osmotically active agent and is most commonly seen with the ingestion of alcohols (ethanol, methanol, ethylene glycol, or isopropyl alcohol) or medications such as mannitol or lorazepam. Patient Encounter 3 illustrates the utility of serum osmolality in a clinical setting.

Many of the electrolyte disturbances discussed in the remainder of this chapter represent medical emergencies that call for aggressive interventions including the use of concentrated electrolytes. It is very difficult to immediately reverse the effects of concentrated electrolytes when they are administered improperly, and these solutions are a frequent source of medical errors with significant potential for patient harm. KEY CONCEPT As such, The Joint Commission recommends that concentrated electrolyte solutions (KCl, potassium phosphate, and NaCl > 0.9%) be removed from patient care areas. Hospitals should keep concentrated electrolytes in patient care areas only when patient safety necessitates their immediate use and precautions are used to prevent inadvertent administration. Collaborative cooperation among pharmacists, nurses, and physicians is essential.[14]

Sodium

LO 4

The body's normal daily sodium requirement is 1.0 to 1.5 mEq/kg (mmol/kg) (80–130 mEq [mmol]) to maintain a normal serum sodium concentration of 135 to 145 mEq/L (mmol/L). Sodium is the predominant cation of the ECF and largely determines ECF volume. Sodium is also the primary factor in establishing the osmotic pressure relationship between the ICF and ECF. All body fluids are in osmotic equilibrium, and changes in serum sodium concentration are associated with shifts of water into and out of body fluid compartments. When sodium is added to the intravascular fluid compartment, fluid is pulled intravascularly from the interstitial fluid and the ICF until osmotic balance is restored. As such, a patient's measured sodium concentration should *not* be viewed as an index of sodium need because this parameter reflects the balance between total body sodium content and TBW. Disturbances in the sodium concentration most often represent disturbances of TBW. Sodium imbalances cannot be properly assessed without first assessing body fluid status.

LO 4

KEY CONCEPT Hyponatremia is the most common electrolyte disorder in hospitalized patients and is defined as a serum sodium concentration below 135 mEq/L (mmol/L). Clinical signs and symptoms appear at concentrations below 120 mEq/L (mmol/L) and typically consist of irritability, mental slowing, unstable gait/falls fatigue, headache, and nausea. With profound hyponatremia (< 110 mEq/L [mmol/L]), confusion, seizures, stupor/coma, and respiratory arrest may be seen. Clinical practice guidelines regarding the diagnosis and treatment of hyponatremia have recently been published. Hyponatremia can be classified based on serum sodium concentration, rate of development, symptom severity, serum osmolality, and volume status.[15] Because therapy is also influenced by volume status, hyponatremia is further defined as (a) hypertonic hyponatremia, (b) hypotonic hyponatremia with an increased ECF volume, (c) hypotonic hyponatremia with a normal ECF volume, and (d) hypotonic hyponatremia with a decreased ECF volume.[16]

Hypertonic hyponatremia is usually associated with significant hyperglycemia. Glucose is an osmotically active agent that leads to an increase in TBW with little change in total body sodium. For every 60 mg/dL (3.3 mmol/L) increase in serum glucose above 200 mg/dL (11.1 mmol/L), the sodium concentration is expected to decrease by approximately 1 mEq/L (mmol/L). Appropriate treatment of the hyperglycemia will return the serum sodium concentration to normal.[15]

Hypotonic hyponatremia with an increase in ECF (hypervolemic hyponatremia) is also known as dilutional hyponatremia. In this scenario, patients have an excess of total body sodium and TBW; however, the excess in TBW is greater than the excess in total body sodium. Common causes include CHF, hepatic cirrhosis, and nephrotic syndrome. Treatment includes sodium and fluid restriction in conjunction with treatment of the underlying disorder; for example, salt and water restrictions are used in the setting of CHF along with loop diuretics, angiotensin-converting enzyme inhibitors, and spironolactone.

In hypotonic hyponatremia with a normal ECF volume (euvolemic hyponatremia), patients have an excess of TBW with relatively normal sodium content. In essence, there is a presence of excess free water. This is most frequently seen in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common causes of SIADH include carcinomas (eg, lung or pancreas), pulmonary disorders (eg, pneumonias or tuberculosis), CNS disorders (eg, meningitis, stroke, tumor, or trauma), and medications (eg, sulfonylureas, antineoplastic agents, barbiturates, morphine, antipsychotics, tricyclic antidepressants, nonsteroidal anti-inflammatory agents, selective serotonin reuptake inhibitors, dopamine agonists, and general anesthetics). These medications stimulate the release of antidiuretic hormone (ADH) from the pituitary gland resulting in water retention and dilution of the body's sodium stores.

LO 6

Short-term treatment of euvolemic hyponatremia includes fluid restriction, isotonic normal saline, hypertonic saline, or a vaptan. Initial treatment generally consists of fluid restriction alone. Hypertonic saline is used only when the sodium concentration is less than 110 mEq/L (mmol/L) and/or severe symptoms (eg, seizures) are present. Given the limitations associated with these treatment strategies (unpredictable therapeutic effects and side effects), the arginine vasopressin antagonist conivaptan (Vaprisol, Astellas Pharma) was developed for short-term treatment of

euvolemic hyponatremia. While conivaptan can also be used to manage hypervolemic hyponatremia in hospitalized patients, it should not be used for hypovolemic hyponatremia. Conivaptan is dosed 20 mg IV over 30 minutes, followed by a 20-mg continuous infusion over 24 hours for up to 4 days.

Long-term treatment options for euvolemic hyponatremia include fluid restriction, demeclocycline, loop diuretics, saline, lithium, urea, and tolvaptan. Demeclocycline (available as generic) is dosed at 600 to 1200 mg/day, takes days before clinical effect is realized, and can cause nephrotoxicity. Lithium (various generics) also has a slow onset of action and is limited by CNS side effects, GI disturbances, and cardiotoxicity. Furosemide (various generics) or other loop diuretics allow relaxation of fluid restriction but can cause significant volume depletion and electrolyte disturbances, and it has the potential for ototoxicity. No specific USP formulation exists for urea, and poor palatability and side effects limit its use. Tolvaptan (Samsca, Otsuka) is an oral alternative to IV conivaptan. This product is indicated for treatment of clinically significant hypervolemic and euvolemic hyponatremia (sodium < 125 mEq/L [mmol/L]) or less marked hyponatremia that is symptomatic and has resisted correction with fluid restriction. Patients with CHF, cirrhosis, and SIADH would be candidates for long-term use. Tolvaptan has a boxed warning for initiation of treatment in a hospital setting because of the need for close sodium monitoring. The initial dose is 15 mg orally daily and may be titrated up to a max of 60 mg. Concurrent use with potent CYP 3A4 inhibitors should be avoided: ketoconazole (available as generic), clarithromycin (available as generic), ritonavir (Norvir, Abbott), diltiazem (available as generic), verapamil (available as generic), fluconazole (available as generic), and grapefruit juice.

LO 5 In hypotonic hyponatremia with a decreased ECF volume (hypovolemic hyponatremia), patients usually have a deficit of both total body sodium and TBW, but the sodium deficit exceeds the TBW deficit. Common causes include diuretic use, profuse sweating, wound drainage, burns, GI losses (vomiting or diarrhea), hypoadrenalism (low cortisol and low aldosterone), and renal tubular acidosis. Treatment includes the administration

LO 6 of sodium to correct the sodium deficit and water to correct the TBW deficit. The sodium deficit can be calculated with the following equation[2]:

$$\text{Sodium deficit (mEq or mmol)} = (\text{TBW [in liters]})\,(\text{desired } Na^+ \text{ concentration [mEq/L or mmol/L]} - \text{current } Na^+ \text{ concentration})$$

Although both water and sodium are required in this instance, sodium needs to be provided in excess of water to fully correct this abnormality. As such, hypertonic saline (3% NaCl) is often used. One can estimate the change in serum sodium concentration after 1 L of 3% NaCl infusion using the following equation[16]:

$$\text{Change in serum } Na^+ \text{ (mEq/L or mmol/L)} = (\text{infusate } Na^+ - \text{serum } Na^+)/(\text{TBW} + 1)$$

In this formula, TBW is increased by 1 to account for the addition of the liter of 3% NaCl. Patient Encounters 4 and 5 illustrate the concepts of calculating and correcting the sodium deficit.

LO 4 Depending on the severity of the hyponatremia and acuity of onset, 0.9%, 3%, or 5% NaCl can be utilized. Most patients can be adequately managed with normal saline rehydration, which is generally the safest agent. Hypertonic saline (3% or 5% NaCl) is generally reserved for patients with severe hyponatremia (< 120 mEq/L [mmol/L]) accompanied by coma, seizures, or high urinary sodium losses. In general, a sodium replacement strategy should target a correction of 6 to 8 mEq/L (mmol/L) in serum per day. Overly aggressive correction of symptomatic hyponatremia (> 12 mEq/L [mmol/L] per day) can result in central pontine myelinolysis.[17] Given the potential for irreversible neurologic damage if untreated or if improperly treated, acute hyponatremia is an urgent condition that should be promptly treated with careful attention to monitoring serial sodium values and adjusting therapeutic infusions accordingly.[18]

Patient Encounter 4: Calculation of Serum Sodium Deficit

Calculate the sodium deficit for an 82-kg male with a serum sodium of 124 mEq/L (mmol/L).

Hypernatremia is a serum sodium concentration greater than 145 mEq/L (mmol/L) and can occur in the absence of a sodium deficit (pure water loss) or in its presence (hypotonic fluid loss).[19] The signs and symptoms of hypernatremia manifest with a serum sodium concentration greater than 160 mEq/L (mmol/L) and are usually the same as those found in TBW depletion: thirst, mental slowing, and dry mucous membranes. Signs and symptoms become more profound as hypernatremia worsens, with the patient eventually demonstrating confusion, hallucinations, acute weight loss, decreased skin turgor, intracranial bleeding, and/or coma. Many coexisting disorders and medications may complicate the diagnosis.

LO 5 The classic causes of hypernatremia are associated with TBW depletion. These include dehydration from loss of hypotonic fluid from the respiratory tract or skin, decreased water intake, osmotic diuresis (eg, mannitol, available as generic), and diabetes insipidus (eg, decreased ADH; phenytoin, available as generic; lithium, available as generic). Hypernatremia in hospitalized patients occurs secondary to inappropriate fluid management in patients at risk for increased free water losses and impaired

LO 6 thirst or restricted water intake.[20] Iatrogenic hypernatremia is occasionally caused by the administration of excessive hypertonic saline. Treatment of hypernatremia includes calculation of the TBW deficit followed by the administration of hypotonic fluids as previously described. The fluid volume should be replaced over 48 to 72 hours depending on the severity of symptoms and the degree of hypertonicity.[21] For asymptomatic patients, the rate of correction should not exceed 0.5 mEq/L/hour (mmol/L/hour). One rule of thumb is to reduce serum sodium by a maximum of 6 to 8 mEq (mmol) every 24 hours.[2,19] Excessively rapid correction of hypernatremia may lead to cerebral edema and death. Patient Encounters 6 and 7 reinforce the concepts of calculating TBW deficit and expected changes in serum sodium concentration with therapy.

Patient Encounter 5: Estimate the Anticipated Change in Serum Sodium

Estimate the anticipated change in serum sodium concentration after the infusion of 1 L of 3% NaCl in an 82-kg male with a serum sodium of 124 mEq/L (mmol/L).

Patient Encounter 6: Calculate Water Deficit

Calculate the water deficit in an 82-kg male with a serum sodium of 156 mEq/L (mmol/L).

Potassium

LO 4

The body's normal daily potassium requirement is 0.5 to 1 mEq/kg (mmol/kg) or 40 to 80 mEq (mmol) to maintain a serum potassium concentration of 3.5 to 5 mEq/L (mmol/L). Potassium is the most abundant cation in the ICF, balancing the sodium contained in the ECF and maintaining electroneutrality of bodily fluids. Because the majority of potassium is intracellular, serum potassium concentration is not a good measure of total body potassium; however, clinical manifestations of potassium disorders correlate well with serum potassium. The acid–base balance of the body affects serum potassium concentrations: hyperkalemia is routinely seen in patients with decreased pH (acidosis). Potassium regulation is primarily under the control of the kidneys with excess dietary potassium being excreted in the urine. Although mild abnormalities of serum potassium are considered a nuisance, severe hyperkalemia or hypokalemia can be life threatening.[22–24]

Hypokalemia (serum potassium < 3.5 mEq/L [mmol/L]) is a common clinical problem. While generally asymptomatic, signs and symptoms of hypokalemia include cramps, muscle weakness, polyuria, electrocardiogram (ECG) changes (flattened T waves and presence of U waves), and cardiac arrhythmias (bradycardia, heart block, atrial flutter, premature ventricular contractions, and ventricular fibrillation). Causes of hypokalemia include GI losses (vomiting, diarrhea, or NG tube suction), renal losses (high aldosterone and low magnesium), inadequate potassium intake (in IV fluids or oral), or alkalosis. Many medications can precipitate hypokalemia. β_2-Agonists (eg, albuterol, available as generic) and insulin (multiple product formulations) lower potassium via cellular redistribution. The use of loop diuretics (furosemide, Lasix, also available as generic), thiazide diuretics (hydrochlorothiazide, available as generic), high-dose antibiotics (penicillin, available as generic), and corticosteroids (prednisone, available as generic) causes renal potassium wasting. In addition, amphotericin B (available as generic), cisplatin (available as generic), and foscarnet (available as generic) can also produce hypokalemia secondary to depletion of magnesium. Hypomagnesemia diminishes intracellular potassium concentration and produces potassium wasting. Given the potential for significant morbidity and mortality, serum potassium concentrations should be monitored closely for patients with known (or suspected) hypokalemia.[2,24,25] Hypokalemia is a risk factor for digitalis toxicity.

Potassium repletion should be guided by close monitoring of serial serum concentrations instead of using empirically chosen amounts. Of the five potassium salts available, potassium acetate (10.2 mEq/K^+/g [mmol/K^+/g]) and KCl (13.4 mEq/K^+/g [mmol/K^+/g]) are the most commonly used forms. When hypokalemia occurs in the setting of alkalosis, KCl is the preferred agent; in acidosis, potassium should be provided in the form of acetate, citrate, bicarbonate, or gluconate salt. Table 27–6 outlines the potassium content of each potassium salt preparation, and Table 27–7 lists each of the oral potassium replacement products. Potassium acetate and chloride are available for IV infusions as premixed solutions. The usual dose of these agents is 10 to 20 mEq (mmol) diluted in 100 mL of normal saline.[2,25,26]

LO 6

Moderate hypokalemia is defined as a serum potassium of 2.5 to 3.5 mEq/L (mmol/L) without ECG changes. In this setting, potassium replacement can usually be given orally at a dose of 40 to 120 mEq/day (mmol/day). Anecdotally, oral potassium supplementation (see Table 27–7) is often more effective in repleting moderate hypokalemia. For patients with an ongoing source of potassium loss, chronic replacement therapy should be considered. The potassium deficit is a rough approximation of the amount of potassium needed to be replaced and can be estimated as follows:

$$\text{Potassium deficit (mEq or mmol/L)} = (4.0 - \text{current serum potassium}) \times 100$$

LO 6

Severe hypokalemia is defined as a serum potassium less than 2.5 mEq/L (mmol/L) or hypokalemia of any magnitude that is associated with ECG changes (eg, flattening of T wave or elevation of U wave) and cardiac arrhythmias. In these situations,

Table 27–6

Potassium Content in Various Potassium Salt Preparations

Potassium Salt	mEq/g (mmol/g)
Potassium gluconate[a]	4.3
Potassium citrate[a]	9.8
Potassium bicarbonate[a]	10.0
Potassium acetate[a]	10.2
Potassium chloride[b]	13.4

[a]Favored for hypokalemia and concurrent acidosis.

[b]Favored for hypokalemia and concurrent alkalosis.

Table 27–7

Oral Potassium Replacement Products

Product	Salt	Strength[a]
Extended/ controlled-release tablets	Chloride	10 mEq (750 mg) 20 mEq (1500 mg)
Effervescent tablets	Chloride and bicarbonate	10 mEq 20 mEq 25 mEq
Liquid	Chloride	20 mEq/15 mL (10%) 40 mEq/15 mL (20%)
Powder packets	Chloride	20 mEq 25 mEq

[a]For potassium, 1 mEq = 1 mmol.

Patient Encounter 7: Calculate the Anticipated Change in Serum Sodium

Calculate the anticipated change in serum sodium concentration after IV infusion of 1 L of 5% dextrose in an 82-kg male with a serum sodium of 156 mEq/L (mmol/L).

Table 27–8

Recommended Potassium Dosage/Infusion Rate

Clinical Scenario	Maximum Infusion Rate[a]	Maximum Concentration[a]	Maximum 24-Hour Dose[a]
K^+ > 2.5 mEq/L *and* No ECG changes of hypokalemia	10 mEq/hour	40 mEq/L	200 mEq
K^+ < 2.5 mEq/L *or* ECG changes of hypokalemia	40 mEq/hour	80 mEq/L	400 mEq

[a]For potassium, 1 mEq = 1 mmol.

IV replacement should be initiated urgently. KEY CONCEPT Potassium infusion at rates exceeding 10 mEq/hour (mmol/hour) requires cardiac monitoring given the potential for cardiac arrhythmias. Although the maximally concentrated solution for potassium replacement is 80 mEq/L (mmol/L), the maximum infusion rate is 40 mEq/hour (mmol/hour) and must be administered via a central line. Table 27–8 outlines current IV potassium replacement guidelines.

Caution must be exercised when repleting potassium with IV agents given possible vein irritation and/or thrombophlebitis. The risk of these complications is minimized by using less concentrated solutions and by giving infusions via central access if possible. Administration of potassium in vehicles containing glucose is discouraged because glucose facilitates the intracellular movement of potassium. Posttherapy improvements in serum potassium may be transient, and continuous monitoring is required. Patients with low serum magnesium will have exaggerated potassium losses from the kidneys and GI tract leading to refractory hypokalemia. In this situation, the magnesium deficit must be corrected in order to successfully treat the concurrent potassium deficiency. In the hypokalemic patient with concurrent acidosis, potassium is often given as the acetate salt, given that acetate is metabolized to bicarbonate. In the patient with depleted phosphorus and potassium, therapy with potassium phosphate is the natural choice.[22,27,28]

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L (mmol/L). Manifestations of hyperkalemia include muscle weakness, paresthesias, hypotension, ECG changes (eg, peaked T waves, shortened QT intervals, and wide QRS complexes), cardiac arrhythmias, and a decreased pH. Causes of hyperkalemia fall into three broad categories: (a) increased potassium intake, (b) decreased potassium excretion, and (c) potassium release from the intracellular space.

Increased potassium intake results from excessive dietary potassium (salt substitutes), excess potassium in IV fluids, and other select medications (potassium-sparing diuretics, cyclosporine [available as generic], angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, pentamidine [available as generic], unfractionated heparin, and low molecular weight heparins). Decreased potassium excretion results from acute renal failure, chronic renal failure, or Addison disease. Excess potassium release from cells results from tissue breakdown (surgery, trauma, hemolysis, or rhabdomyolysis), blood transfusions, and metabolic acidosis.

In addition to discontinuing all potassium supplements, potassium-sparing medications, and potassium-rich salt substitutes, management of hyperkalemia addresses three concurrent strategies: (a) agents to antagonize the proarrhythmic effects of hyperkalemia, (b) agents to drive potassium into the intracellular space and acutely lower the serum potassium, and (c) agents that will definitively (but more gradually) lower the total body potassium content.[29] If the serum potassium concentration is greater than 7 mEq/L (mmol/L) and/or ECG changes are present, IV calcium is administered to stabilize the myocardium. Depending on the acuity of the situation, 1 g of calcium chloride (13.5 mEq or 6.75 mmol) is administered by direct injection or diluted in 50 mL of D_5W and delivered IV over 15 minutes. Clinical effects are seen within 1 to 2 minutes of infusion and persist for 10 to 30 minutes. Repeat doses may be administered as necessary. Because most patients with clinically significant hyperkalemia receive multiple boluses of calcium directed by ECG findings, iatrogenic hypercalcemia is a potential complication of hyperkalemia treatment. As such, total calcium concentration is commonly checked with each potassium concentration measurement. Ionized calcium measurements should be obtained in patients who have comorbid conditions that would lead to inconsistency between total serum calcium and free calcium (abnormal albumin, protein, or immunoglobulin concentrations).

LO 6

Dextrose and insulin (with or without sodium bicarbonate) are typically given at the time of calcium therapy in order to redistribute potassium into the intracellular space. Dextrose 50% (25 g in 50 mL) can be given by slow IV push over 5 minutes or dextrose 10% with 20 units of regular insulin can be given by continuous IV infusion over 1 to 2 hours. The onset of action for this combination is 30 minutes; the duration of clinical effects is 2 to 6 hours. High-dose inhaled β_2-agonists (eg, albuterol, available as generic) may also be used to acutely drive potassium into the intracellular space.

LO 6

It is critically important to recognize that the treatments of hyperkalemia discussed thus far are transient, temporizing measures. They are intended to provide time to institute definitive therapy aimed at removing excess potassium from the body. Agents that increase potassium excretion from the body include sodium polystyrene sulfonate (Kayexalate, available as generic), loop diuretics, and hemodialysis or hemofiltration (used only in patients with renal failure). Sodium polystyrene sulfonate can be given orally, via NG tube, or as a rectal retention enema and is dosed at 15 to 60 g in four divided doses per day. In September 2009, MedWatch issued a safety alert that cases of colonic necrosis and other serious GI-adverse events (bleeding, ischemic colitis, perforation) had been reported in association with sodium polystyrene sulfonate (Kayexalate) suspension. The majority of these cases reported the concurrent use of sorbitol. Concurrent administration of sorbitol is no longer recommended. Medication safety alerts are available at www.fda.gov/MedWatch. Patiromer (Veltassa, Relypsa), a nonabsorbed cation exchange polymer, increases fecal potassium excretion and is utilized to manage hyperkalemia in nonemergent situations, primarily in outpatients.

LO 6

Calcium

LO 4

More than 99% of total body calcium is found in bone; the remaining less than 1% is in the ECF and ICF. Calcium plays a critical role in the transmission of nerve impulses, skeletal muscle contraction, myocardial contractions, maintenance of normal cellular permeability, and the formation of bones and teeth. There is a reciprocal relationship between the serum calcium concentration (normally 8.6–10.2 mg/dL [2.15–2.55 mmol/L]) and the serum phosphate concentration that is regulated by a

complex interaction between parathyroid hormone, vitamin D, and calcitonin. About one-half of the serum calcium is bound to plasma proteins; the other half is free ionized calcium. Given that the serum calcium has significant protein binding, the serum calcium measurement must be corrected in patients who have low albumin concentrations (the major serum protein). The most commonly used formula adds 0.8 mg/dL (0.2 mmol/L) of calcium for each gram of albumin deficiency as follows:

Corrected [Ca mg/dL] = Measured [Ca mg/dL] + [0.8 × (4 – measured albumin g/dL)][30–32]

Corrected [Ca mmol/L] = Measured [Ca mmol/L] + [0.02 × (40 – measured albumin g/L)]

Clinical manifestations of hypocalcemia are seen with total serum concentrations less than 6.5 mg/dL (1.63 mmol/L) or an ionized calcium less than 1.12 mmol/L and include tetany, circumoral tingling, muscle spasms, hypoactive reflexes, anxiety, hallucinations, hypotension, myocardial infarction, seizures, lethargy, stupor, and **Trousseau sign** or **Chvostek sign**.[24,33] Ionized calcium concentrations are typically used to assess calcium status in the critically ill as these patients often have concurrent hypoalbuminemia.

Causes of hypocalcemia include hypoparathyroidism, hypomagnesemia, alcoholism, hyperphosphatemia, blood product infusion (due to chelation by the citrate buffers), chronic renal failure, vitamin D deficiency, acute pancreatitis, alkalosis, and hypoalbuminemia. In the setting of hypocalcemia, magnesium concentration should be checked and corrected if low. Given that hypocalcemia may be caused by hypomagnesemia, clinicians should be aware that the serum calcium concentrations may not normalize until serum magnesium is replaced. Medications that cause hypocalcemia include phosphate replacement products, loop diuretics, phenytoin (Dilantin, available as generic), phenobarbital (available as generic), corticosteroids, aminoglycoside antibiotics, and acetazolamide (available as generic).[34–36]

Oral calcium replacement products include calcium carbonate (Os-Cal, GlaxoSmithKline and various generics; Tums, GlaxoSmithKline and various generics) and calcium citrate (Citracal, Mission Bayer and various generics). IV calcium replacement products include calcium gluconate and calcium chloride (both products available as generic). KEY CONCEPT Calcium gluconate is preferred for peripheral use because it is less irritating to the veins; it may also be given intramuscularly. Each 10 mL of a 10% calcium gluconate solution provides 90 mg (4.5 mEq or 2.25 mmol) of elemental calcium. KEY CONCEPT Calcium chloride is associated with more venous irritation and extravasation and is generally reserved for administration via central line. Each 10 mL of a 10% calcium chloride solution contains 270 mg (13.5 mEq or 6.75 mmol) of elemental calcium. IV calcium products are given as a slow push or added to 500 to 1000 mL of 0.9% normal saline for slow infusion.[33,36] In addition to hypocalcemia, IV calcium may also be used for massive blood transfusions, calcium channel blocker overdose, and emergent hyperkalemia and hypermagnesemia.

For acute symptomatic hypocalcemia, 200 to 300 mg of elemental calcium is administered IV and repeated until symptoms are fully controlled. This is achieved by infusing 1 g of calcium chloride or 2 to 3 g of calcium gluconate at a rate no faster than 30 to 60 mg of elemental calcium per minute. More rapid administration is associated with hypotension, bradycardia, or cardiac asystole. Total calcium concentration is commonly monitored in critically ill patients. Under normal circumstances, about half of calcium is loosely bound to serum proteins while the other half is free. Total calcium concentration measures bound and free calcium. Ionized calcium measures free calcium only. Under usual circumstances, a normal calcium concentration implies a normal free ionized calcium concentration. Ionized calcium should be obtained in patients with comorbid conditions that would lead to inconsistency between total calcium and free serum calcium (abnormal albumin, protein, or immunoglobulin concentrations). For chronic asymptomatic hypocalcemia, oral calcium supplements are given at doses of 2 to 4 g/day of elemental calcium. Many patients with calcium deficiency have concurrent vitamin D deficiency that must also be corrected in order to restore calcium homeostasis.[2,33,37]

Hypercalcemia is defined as a calcium concentration greater than 10.2 mg/dL (2.55 mmol/L). It may be categorized as mild if total serum calcium is 10.3 to 12 mg/dL (2.58–3.00 mmol/L), moderate if total serum calcium is 12.1 to 13 mg/dL (3.03–3.25 mmol/L), or severe when serum concentration is greater than 13 mg/dL (3.25 mmol/L). Causes of hypercalcemia include hyperparathyroidism, malignancy, Paget's disease, Addison disease, granulomatous diseases (eg, tuberculosis, sarcoidosis, or histoplasmosis), hyperthyroidism, immobilization, multiple bony fractures, acidosis, and milk-alkali syndrome. Multiple medications cause hypercalcemia and include thiazide diuretics, estrogens, lithium (available as generic), tamoxifen (Nolvadex, available as generic), vitamin A, vitamin D, and calcium supplements.[2,33,36,37]

Because the severity of symptoms and the absolute serum concentration are poorly correlated in some patients, institution of therapy should be dictated by the clinical scenario. All patients with hypercalcemia should be treated with aggressive rehydration: normal saline at 200 to 300 mL/hour is a routine initial fluid prescription. For patients with mild hypercalcemia, hydration alone may provide adequate therapy. The moderate and severe forms of hypercalcemia are more likely to have significant manifestations and require prompt initiation of additional therapy. These patients may present with anorexia, confusion, and/or cardiac manifestations (bradycardia and arrhythmias with ECG changes). Total calcium concentrations greater than 13 mg/dL (3.25 mmol/L) are particularly worrisome because these concentrations can unexpectedly precipitate acute renal failure, ventricular arrhythmias, and sudden death.

Once fluid administration has repleted the ECF, forced diuresis (with associated calcium loss) can be initiated with a loop diuretic. For this approach to be successful, normal kidney function is required. In renal failure patients, the alternative therapy is emergent hemodialysis. Other treatment options include bisphosphonates (zoledronic acid [Zometa, Novartis], pamidronate [Aredia, available as generic]), hydrocortisone (available as generic), calcitonin, and gallium. Given their efficacy and favorable side-effect profile, bisphosphonates are typically the agents of choice. Table 27–9 outlines the treatment options for hypercalcemia including time to onset of effect, duration of effect, and efficacy.[2,33,34,37]

Phosphorus

Phosphorus is primarily found in the bone (80% to 85%) and ICF (15% to 20%): the remaining less than 1% is found in the ECF. Note that phosphorus is the major anion within the cells. Given this distribution, serum phosphate concentration does not accurately reflect total body phosphorus stores. Phosphorus

Table 27–9

Selected Treatment Options for the Management of Hypercalcemia

Therapy	Dose	Onset	Duration	Efficacy[a]
Normal saline	3–6 L/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Furosemide (Lasix, available as generic)	80–160 mg/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Hydrocortisone (available as generic)	200 mg/day	Hours	Days	Mild/unpredictable
Calcitonin (Miacalcin, Novartis)	4–8 units/kg	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Pamidronate (Aredia, available as generic)	30–90 mg/week	Days	1–4 weeks	1–5 mg/dL(0.25–1.25 mmol/L)
Zoledronic acid (Zometa, Novartis)	4–8 mg	Days	Weeks	1–5 mg/dL (0.25–1.25 mmol/L

[a]Expected decrease in serum Ca^{2+}.

is expressed in milligrams (mg) or millimoles (mmol), not as milliequivalents (mEq). Because phosphorus is the source of phosphate for adenosine triphosphate (ATP) and phospholipid synthesis, manifestations of phosphorus imbalance are variable.

LO 6 Dietary intake, parathyroid hormone levels, and renal function are the major determinants of the serum phosphorus concentration, which is normally 2.7 to 4.5 mg/dL (0.87– 1.45 mmol/L).[2,33,38,39] Hypophosphatemia is defined by a serum phosphorus concentration less than 2.5 mg/dL (0.81 mmol/L); severe hypophosphatemia occurs when the phosphorus concentration is less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia can be caused by increased distribution to the ICF (hyperglycemia, insulin therapy, or malnourishment), decreased absorption (starvation, excessive use of phosphorus-binding antacids, vitamin D deficiency, diarrhea, or laxative abuse), or increased renal loss (diuretic use, diabetic ketoacidosis, alcohol abuse, hyperparathyroidism, or burns).[35,37] KEY CONCEPT Severe hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure. Medications that can cause hypophosphatemia include diuretics (acetazolamide [Diamox, available as generic], furosemide [Lasix, available as generic], hydrochlorothiazide [HydroDIURIL, available as generic]), sucralfate (Carafate, available as generic), corticosteroids, cisplatin (available as generic), antacids (aluminum carbonate, calcium carbonate, and magnesium oxide [antacids all available as generic]), foscarnet (available as generic), phenytoin (Dilantin, available as generic), phenobarbital (available as generic), and phosphate binders (sevelamer [Renvela, Genzyme Corp.] and calcium acetate [PhosLo, available as generic]).

LO 6 Signs and symptoms of hypophosphatemia include paresthesias, muscle weakness, myalgias, bone pain, anorexia, nausea, vomiting, red blood cell breakdown (hemolysis), acute respiratory failure, seizures, and coma.[37,40] For mild hypophosphatemia, patients should be encouraged to eat a high-phosphorus diet including eggs, nuts, whole grains, meat, fish, poultry, and milk products. For moderate hypophosphatemia (1–2.5 mg/dL, 0.32–0.81 mmol/L), oral supplementation of 1.5 to 2 g/day (30–60 mmol/day) is usually adequate. Diarrhea may be a dose-limiting side effect with oral phosphate replacement products.

LO 6 Injectable phosphate products are reserved for patients with severe hypophosphatemia or those in the intensive care unit.[41] The available agents are provided as sodium or potassium salts; however, unless concurrent hypokalemia is present, sodium phosphate is usually used. Empirically, for a mild serum phosphorus deficiency (2.3–3.0 mg/dL, 0.74–0.97 mmol/L), the corresponding IV phosphorus dose is 0.32 mmol/kg; for a moderate deficiency of serum phosphorus 1.6 to 2.2 mg/dL (0.52–0.71 mmol/L), the replacement dose is 0.64 mmol/kg; and the dose is 1 mmol/kg when the serum phosphorus is less than 1.5 mg/dL (0.48 mmol/L).[36] IV phosphorus preparations are usually infused over 4 to 12 hours. Table 27–10 compares the available phosphate replacement products.

LO 6 Hyperphosphatemia is defined by a serum phosphorus concentration greater than 4.5 mg/dL (1.45 mmol/L). The manifestations of hyperphosphatemia are similar to findings of hypocalcemia (see earlier), and include paresthesias, ECG changes (prolonged QT interval and prolonged ST segment), and metastatic calcifications. Causes of hyperphosphatemia include impaired phosphorus excretion (hypoparathyroidism or renal failure), redistribution of phosphorus to the ECF (acid–base imbalance, rhabdomyolysis, muscle necrosis, or tumor lysis during chemotherapy), and increased phosphorus intake (various medications).[37] Medications that can cause hyperphosphatemia include enemas containing phosphorus (eg, Fleet, Fleet), laxatives containing phosphate or phosphorus, parenteral or oral supplements (eg, K-Phos Neutral, Beach), vitamin D

Table 27–10

Phosphate Replacement Products

Product	Route	$mgPO_4^-$	$mmolPO_4^-$	mEq (mmol) Na^+	mEq (mmol) K^+
Potassium phosphate (KPO_4/mL), available as generic	IV	94	3	0	4.4
Sodium phosphate ($NaPO_4$/mL), available as generic	IV	94	3	4	0
Phos-NaK packets, Cypress	Oral	250	8	7.2	7
K-Phos Neutral tablets, Beach	Oral	250	8	13.1	1.4
K-Phos Original tablets, Beach	Oral	114	3.7	–	3.7

supplements, and the bisphosphonates (eg, pamidronate, various manufacturers).[42]

LO 6 Hyperphosphatemia is generally benign and rarely needs aggressive therapy. Dietary restriction of phosphate and protein is effective for most minor elevations. Phosphate binders such as aluminum-based antacids, calcium carbonate, calcium acetate (PhosLo, available as generic), sevelamer hydrochloride (Renagel, Genzyme), sevelamer carbonate (Renvela, Genzyme, Global), and lanthanum carbonate (Fosrenol, Shire) may be necessary for some patients (typically those with chronic renal failure).[43] Sucroferric oxyhydroxide (Velphoro, Fresenius Medical Care) is a noncalcium-based chewable phosphate binder administered with each meal. If patients exhibit findings of hypocalcemia (tetany), IV calcium should be administered empirically.

Magnesium

LO 4 The body's normal daily magnesium requirement is 300 to 350 mg/day to maintain a serum magnesium concentration of 1.5 to 2.4 mEq/L (0.75–1.20 mmol/L). Less than 1% of magnesium is found in the blood. Because magnesium is the second most abundant ICF cation, serum concentrations are a relatively poor measure of total body stores. Magnesium catalyzes and/or activates more than 300 enzymes, provides neuromuscular stability, and is involved in myocardial contraction. Magnesium is generally not part of standard chemistry panels and therefore must be ordered separately.[2,33,42,44,45]

LO 6 Hypomagnesemia is defined as a serum magnesium less than 1.5 mEq/L (0.75 mmol/L) and is most frequently seen in the intensive care and postoperative settings. Hypomagnesemia results from inadequate intake (alcoholism, dietary restriction, or inadequate magnesium in total parenteral nutrition [TPN]), inadequate absorption (steatorrhea, cancer, malabsorption syndromes, or excess calcium or phosphorus in the GI tract), excessive GI loss of magnesium (diarrhea, laxative abuse, NG tube suctioning, or acute pancreatitis), or excessive urinary loss of magnesium (primary hyperaldosteronism, certain medications, diabetic ketoacidosis, and renal disorders). Hypomagnesemia often occurs in the setting of hypokalemia and hypocalcemia. Clinicians should evaluate the magnesium concentration in these patients and correct if low. To evaluate magnesium status, both laboratory tests and clinical assessment are required. In order for calcium and potassium concentrations to normalize, magnesium supplementation is often required. Medications that potentially can cause hypomagnesemia include aminoglycoside antibiotics, amphotericin B (available as generic), cisplatin (available as generic), insulin, cyclosporine (available as generic), loop diuretics, and thiazide diuretics. There is also a strong correlation between hypokalemia and hypomagnesemia.[37,42,46,47] Clinicians should be alerted that the long-term use of proton pump inhibitors may be associated with unexplained hypomagnesemia, with subsequent hypokalemia or hypocalcemia.

LO 6 The findings of hypomagnesemia include muscle weakness, cramps, agitation, confusion, tremor, seizures, ECG changes (increased PR interval, prolonged QRS complex, peaked T waves, and increased QT interval), findings of hypocalcemia (see earlier), refractory hypokalemia (see earlier), metabolic alkalosis, and digoxin toxicity.[42,48,49]

LO 6 Asymptomatic mild magnesium deficiencies (1.0–1.5 mEq/L) (0.50–0.75 mmol/L) can be managed with increased oral intake of magnesium-containing foods or with oral supplementation. Magnesium oxide (Mag-Ox, Blaine Pharmaceuticals and various manufacturers) 400-mg tablets contain 241 mg (20 mEq or 10 mmol) of magnesium, and magnesium chloride hexahydrate tablets (Slow-Mag, Purdue) contain 64 mg of elemental magnesium. Diarrhea is often a dose-limiting side effect of oral supplementation. Severely deficient patients (< 1.0 mEq/L) (0.50 mmol/L) and all deficient critically ill patients should be managed with IV magnesium sulfate. Ten milliliters of a 10% magnesium sulfate solution contains 1 g of magnesium, which is equivalent to 98 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. IV magnesium supplementation may also be used in the setting of status asthmaticus, premature labor, and torsade de pointes. In May 2013, the FDA released a drug safety communication recommending against the prolonged use of magnesium sulfate to stop preterm labor due to bone changes in exposed babies. Administration of magnesium sulfate injection to pregnant women longer than 5 to 7 days may lead to low calcium levels and bone fractures in the developing baby or fetus (http://www.fda.gov/Safety/MedWatch/). Magnesium concentrations need to be monitored closely in these patients. KEY CONCEPT Because magnesium concentration does not correlate well with total body magnesium stores, magnesium is often administered empirically to critically ill patients.[2,33]

The most common causes of hypermagnesemia are renal failure, often in conjunction with magnesium-containing medications (cathartics, antacids, or magnesium supplements), and lithium therapy (available as generic). Hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mEq/L (1.20 mmol/L). Mild hypermagnesemia is present if the serum magnesium concentration is between 2.5 and 4 mEq/L (1.25–2.00 mmol/L) and manifests as nausea, vomiting, cutaneous vasodilation, and bradycardia. Moderate hypermagnesemia is present if the serum magnesium concentration is between 4 and 12 mEq/L (2–6 mmol/L) and may manifest with hyporeflexia, weakness, somnolence, hypotension, and ECG changes (increased QRS interval). Severe hypermagnesemia is present if the serum magnesium concentration is greater than 13 mEq/L (6.5 mmol/L) and can manifest as muscle paralysis, complete heart block, asystole, respiratory failure, refractory hypotension, and death.[2,50]

LO 6 All patients with hypermagnesemia should have all magnesium supplements or magnesium-containing medications discontinued.[2,33] Iatrogenic hypermagnesemia has been observed after IV magnesium therapy for refractory asthma or preeclampsia. Mild hypermagnesemia and moderate hypermagnesemia without cardiac findings can be treated with normal saline infusion and furosemide therapy (assuming the patient has normal renal function). Moderate hypermagnesemia with cardiac irritability and severe hypermagnesemia require concurrent IV calcium gluconate to reverse the neuromuscular and cardiovascular effects. Calcium gluconate given at typical doses of 1 to 2 g IV will have transient effects and can be repeated as clinically indicated. Hemodialysis may be necessary for those with severely compromised renal function.

CONCLUSION

Because disturbances in fluid balance are routinely encountered in clinical medicine, it is essential to have a thorough understanding of body fluid compartments and the therapeutic use of fluids. Similarly, disturbances in serum sodium, potassium, calcium, phosphorus, and magnesium are ubiquitous and must be mastered by all clinicians. Dysregulation of fluid and/or electrolyte status has serious implications regarding the concepts of drug absorption, volumes of distribution, and toxicity. Similarly, many medications can disrupt fluid and/or electrolyte balance as an unintended consequence.

Patient Encounter 8: Putting It All Together

JW, a 67-year-old female nursing home resident, is admitted to the hospital with a 3-day history of altered mental status. The patient was unable to give a history or review of systems. On physical examination, the vital signs revealed a BP of 100/60 mm Hg, pulse 110 beats per minute, respirations 14 per minute, and a temperature of 38.3°C (101°F). Rales and dullness to percussion were noted at the posterior right base. The cardiac examination was significant for tachycardia. No edema was present. Laboratory studies included sodium 160 mEq/L (mmol/L), potassium 4.6 mEq/L (mmol/L), chloride 120 mEq/L (mmol/L), bicarbonate 30 mEq/L (mmol/L), glucose 104 mg/dL (5.8 mmol/L), BUN 34 mg/dL (12.1 mmol/L), and creatinine 2.2 mg/dL (194 µmol/L). The CBC was within normal limits. Chest x-ray indicated right lower lobe pneumonia. The patient is 5′7″ (170 cm) tall and currently weighs 65 kg (143 lb). Her normal weight is 70 kg (154 lb).

What are the likely causes for the increased sodium concentration in this patient?

Calculate the TBW, ICF, and ECF for this patient.

Calculate DM's fluid deficit if one is present.

In the next 24 hours, the medical team wants to replace 50% of the fluid deficit plus an extra 240 mL to account for increased insensible losses in addition to the patient's maintenance needs. Using the equation (1500 mL + 20 mL for each kilogram > 20 kg), calculate the rate of fluid administration for the total fluids needed in this 24-hour period and over the next 48 hours.

Calculate JW's daily maintenance fluids.

Calculate JW's fluid administration rate for the first 24 hours (hospital day 1).

Calculate JW's fluids for the subsequent 48 hours (hospital days 2 and 3) if the goal is to replete the remaining fluid deficit during that time.

What type of fluid should be used to treat JW's fluid disorder?

Abbreviations Introduced in This Chapter

ADH	Antidiuretic hormone
ASHP	American Society of Health-System Pharmacists
ATP	Adenosine triphosphate
BP	Blood pressure
BUN	Blood urea nitrogen
Ca^{+}	Calcium
CHF	Congestive heart failure
Cl	Chloride
D_5W	Dextrose 5% water
ECF	Extracellular fluid
ECG	Electrocardiogram
FFP	Fresh-frozen plasma
IBW	Ideal body weight
ICF	Intracellular fluid
I&Os	Ins and outs
IV	intravenous
K^{+}	Potassium
KPO_4	Potassium phosphate
KVO	Keep the vein open
LR	Lactated Ringer's (solution)
Mg^{++}	Magnesium
Na^{+}	Sodium
NaCl	Sodium chloride
$NaPO_4$	Sodium phosphate
NG	Nasogastric
NS	Normal saline
SI	Standardized international units
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
TBW	Total body water
TPN	Total parenteral nutrition

28 Acid–Base Disturbances

Lee E. Morrow and Mark A. Malesker

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Compare and contrast the four primary acid–base disturbances within the human body.
2. Apply simple formulas in a systematic manner to determine the etiology of simple acid–base disturbances and the adequacy of compensation.
3. Integrate the supplemental concepts of the anion gap and the excess gap to further assess for complex acid–base disturbances.
4. Discuss the most common clinical causes for each primary acid–base abnormality.
5. Describe the potential clinical complications of altered acid–base homeostasis.
6. Propose an appropriate treatment plan for patients with deranged acid–base physiology.

INTRODUCTION

Given its reputation for complexity and the need to memorize innumerable formulas, acid–base analysis intimidates many health care providers. In reality, acid–base disorders always obey well-defined biochemical and physiological principles. The pH determines a patient's acid–base status and an assessment of the bicarbonate (HCO_3^-) and arterial carbon dioxide ($PaCO_2$) values identifies the underlying process. Rigorous use of a systematic approach to arterial blood gases (ABGs) increases the likelihood that derangements in acid–base physiology are recognized and correctly interpreted. This chapter outlines a clinically useful approach to acid–base abnormalities and then applies this approach in a series of increasingly complex clinical scenarios.

Disturbances of acid–base equilibrium occur in a wide variety of illnesses and are among the most frequently encountered disorders in critical care medicine. The importance of a thorough command of this content cannot be overstated given that acid–base disorders are remarkably common and may result in significant morbidity and mortality. Although severe derangements may affect virtually any organ system, the most serious clinical effects are cardiovascular (arrhythmias, impaired contractility), neurologic (coma, seizures), pulmonary (dyspnea, impaired oxygen delivery, respiratory fatigue, respiratory failure), and/or renal (hypokalemia). Changes in acid–base status also affect multiple aspects of pharmacokinetics (clearance, protein binding) and pharmacodynamics.

PHYSIOLOGY OF ACID–BASE HOMEOSTASIS

Acid–base homeostasis is responsible for maintaining blood hydrogen ion concentration [H^+] near normal despite the daily acidic and/or alkaline loads derived from the intake and metabolism of foods. Acid–base status is traditionally represented in terms of pH, the negative logarithm of [H^+]. Because [H^+] is equal to 24 times the ratio of $PaCO_2$ to HCO_3^-, the pH can be altered by a change in either the bicarbonate concentration or the dissolved carbon dioxide (CO_2). A critically important concept is that [H^+] depends only on the *ratio* of $PaCO_2$ to HCO_3^- and not the absolute amount of either. As such, a normal $PaCO_2$ or HCO_3^- alone does not guarantee that the pH will be normal. Conversely, a normal pH does not imply that either the $PaCO_2$ or HCO_3^- will be normal.[1]

KEY CONCEPT Acid–base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum HCO_3^- concentration through the excretion or reabsorption of filtered HCO_3^-, the excretion of metabolic acids, and synthesis of new HCO_3^-. The lungs control arterial CO_2 concentrations through changes in the depth and/or rate of respiration. The net result is tight regulation of the blood pH by these three distinct mechanisms working in harmony: extracellular HCO_3^- and intracellular protein buffering systems; pulmonary regulation of $PaCO_2$, effectively allowing carbonic acid to be eliminated by the lungs as CO_2; and renal reclamation or excretion of HCO_3^- and excretion of acids such as ammonium.

Because the kidneys excrete less than 1% of the estimated 13,000 mEq (mmol) of H^+ ions generated in an average day, renal failure can be present for prolonged periods before life-threatening imbalances occur. Conversely, cessation of breathing for minutes results in profound acid–base disturbances.[1]

The best way to assess a patient's acid–base status is to review the results of an ABG specimen. ABG analyzers directly measure the pH and $PaCO_2$, while the HCO_3^- value is calculated using the Henderson–Hasselbalch equation. A more direct measure of serum HCO_3^- is obtained by measuring the total venous carbon dioxide (tCO_2). Because dissolved CO_2 is almost exclusively in the form of HCO_3^-, tCO_2 is essentially equivalent to the measured serum HCO_3^- concentration. This value (HCO_3^-) is routinely reported on basic chemistry panels. In the remainder of this chapter, the pH and $PaCO_2$ values should be assumed to come from an ABG while HCO_3^- values should be considered to be the measured serum concentration.

BASIC PATHOPHYSIOLOGY

LO 1 Under normal circumstances, the arterial pH is tightly regulated between 7.35 and 7.45. Acidemia is an abnormally low arterial blood pH (< 7.35) while acidosis is a pathologic process that acidifies body fluids. Similarly, alkalemia is an abnormally high arterial blood pH (> 7.45) while alkalosis is a pathologic process that alkalinizes body fluids. As such, although a patient can simultaneously have acidosis *and* alkalosis, the end result will be acidemia *or* alkalemia.

LO 1 Changes in the arterial pH are driven by changes in the $PaCO_2$ and/or the serum HCO_3^-. CO_2 is a volatile acid regulated by the depth and rate of respiration. Because CO_2 can be either "blown off" or "retained" by the respiratory system, it is referred to as being under respiratory control. KEY CONCEPT Respiratory acidosis and alkalosis result from primary disturbances in the arterial CO_2 concentration. Metabolic compensation for respiratory disturbances is a slow process, often requiring days for the serum HCO_3^- to reach the steady state. KEY CONCEPT Respiratory acidosis is caused by respiratory insufficiency resulting in an increased arterial CO_2 concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum HCO_3^-. KEY CONCEPT Respiratory alkalosis is caused by hyperventilation resulting in a decreased arterial CO_2 concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum HCO_3^-.

LO 1 A respiratory acid–base disorder is a pH disturbance caused by pathologic alterations of the respiratory system or its central nervous system (CNS) control. Such an alteration may result in the accumulation of $PaCO_2$ beyond normal limits (> 45 mm Hg [6.0 kPa]), a situation termed *respiratory acidosis*, or it may result in the loss of $PaCO_2$ beyond normal limits (< 35 mm Hg or 4.7 kPa), a condition termed *respiratory alkalosis*. Variations in respiratory rate and/or depth allow the lungs to achieve changes in the $PaCO_2$ very quickly (within minutes).

HCO_3^- is a base regulated by renal metabolism via the enzyme carbonic anhydrase. As such, HCO_3^- is often referred to as being under metabolic control. KEY CONCEPT Metabolic acidosis and alkalosis result from primary disturbances in the serum HCO_3^- concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours. KEY CONCEPT Metabolic acidosis is characterized by a decrease in serum HCO_3^-. The anion gap is used to narrow the differential diagnosis because metabolic acidosis may be caused by the addition of acids (increased anion gap) or loss of HCO_3^- (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial CO_2. KEY CONCEPT Metabolic alkalosis is characterized by an increase in serum HCO_3^-. This disorder requires loss of fluid that is low in HCO_3^- from the body or addition of HCO_3^- to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial CO_2.

LO 1 A metabolic acid–base disorder is a pH disturbance caused by derangement of the pathways responsible for maintaining a normal HCO_3^- concentration. This may result in a pathologic accumulation of HCO_3^- (> 26 mEq/L [mmol/L]), a condition termed *metabolic alkalosis*, or it may result in the loss of HCO_3^- beyond normal (< 22 mEq/L [mmol/L]), a condition termed *metabolic acidosis*. In contrast to the lungs' rapid effects on CO_2, the kidneys change the HCO_3^- very slowly (hours to days).

Respiratory and metabolic derangements can occur in isolation or in combination. If a patient has an isolated primary acid–base disorder that is not accompanied by another primary acid–base disorder, a simple (uncomplicated) disorder is present. The most common clinical disturbances are simple acid–base disorders. If two or three primary acid–base disorders are simultaneously present, the patient has a mixed (complicated) disorder. More complex clinical situations lead to mixed acid–base disturbances. Because CO_2 is a volatile acid, it can rapidly be changed by the respiratory system. If a respiratory acid–base disturbance is present for minutes to hours, it is considered an acute disorder, while if it is present for days or longer, it is considered a chronic disorder. By definition, the metabolic machinery that regulates HCO_3^- results in slow changes, and all metabolic disorders are chronic.

Changes that follow the primary disorder and attempt to restore the blood pH to normal are referred to as compensatory changes. It should be stressed that compensation never normalizes the pH. Because all metabolic acid–base disorders are chronic and the normal respiratory system can quickly alter the $PaCO_2$, essentially all metabolic disorders are accompanied by some degree of respiratory compensation.[2,3] Similarly, chronic respiratory acid–base disorders are typically accompanied by attempts at metabolic compensation.[4,5] However, with acute respiratory acid–base disorders there is insufficient time for the metabolic pathways to compensate significantly.[6] As such, acute respiratory derangements are essentially uncompensated.

The amount of compensation (metabolic or respiratory) can be reliably predicted based on the degree of derangement in the primary disorder. Table 28–1 outlines the simple acid–base disorders and provides formulas for calculating the expected compensatory responses.[7] Although it is not mandatory to memorize these formulas in order to interpret acid–base problems, they can be helpful tools. If the measured values differ markedly from the calculated values (the measured serum HCO_3^- is > 2 mEq/L [mmol/L] from the calculated value or the measured $PaCO_2$ is > 4 mm Hg [0.5 kPa] from the calculated value), a second acid–base disorder is present as outlined in Table 28–2.

Table 28–1

The Six Simple Acid–Base Disorders

Type of Disorder	pH	$PaCO_2$[a]	HCO_3^-
1. Metabolic acidosis	↓	Decreased[b] $PaCO_2 = (1.5 \times HCO_3^-) + 8$	Decreased[c]
2. Metabolic alkalosis	↑	Increased[b] $PaCO_2 = (0.9 \times HCO_3^-) + 15$	Increased[c]
3. Acute respiratory acidosis	↓	Increased[c]	Approximately normal $\Delta HCO_3^- = 0.1 \times \Delta PaCO_2$[a]
4. Chronic respiratory acidosis	↓	Increased[c]	Increased[d] $\Delta HCO_3^- = 0.35 \times \Delta PaCO_2$[a]
5. Acute respiratory alkalosis	↑	Decreased[c]	Approximately normal $\Delta HCO_3^- = 0.2 \times \Delta PaCO_2$[a]
6. Chronic respiratory alkalosis	↑	Decreased[c]	Decreased[d] $\Delta HCO_3 = 0.4 \times \Delta PaCO_2$[a]

[a] $PaCO_2$ in mm Hg and is calculated from kPa by dividing by 0.133.

[b] Respiratory compensation: If inappropriate, see Table 28–2.

[c] Primary disorder.

[d] Metabolic compensation: If inappropriate, see Table 28–2.

Table 28–2

Diagnosis of Concurrent Acid–Base Disturbances When Compensation Is Inappropriate

Primary Acid–Base Disturbance	Assessment of Compensation	Concurrent Acid–Base Disturbance
Metabolic acidosis	$PaCO_2$ too low[a]	Respiratory alkalosis
	$PaCO_2$ too high[a]	Respiratory acidosis
Metabolic alkalosis	$PaCO_2$ too low[a]	Respiratory alkalosis
	$PaCO_2$ too high[a]	Respiratory acidosis
Respiratory acidosis	HCO_3^- too low[b]	Metabolic acidosis
	HCO_3^- too high[b]	Metabolic alkalosis
Respiratory alkalosis	HCO_3^- too low[b]	Metabolic acidosis
	HCO_3^- too high[b]	Metabolic alkalosis

[a]Measured $PaCO_2$ more than 4 mm Hg (0.5 kPa) from the calculated value.

[b]Measured HCO_3^- more than 2 mEq/L (mmol/L) from the calculated value.

DIAGNOSIS

LO 2

When given an ABG for interpretation, it is essential to use an approach that is focused yet comprehensive.[8] An algorithm illustrating this concept is shown in Figure 28–1. Using this algorithm, step 1 is to identify all abnormalities in the pH, $PaCO_2$, and/or HCO_3^- and then decide which abnormal values are primary and which are compensatory. This is best done by initially looking at the pH. Whichever side of 7.40 the pH is on, the process that caused it to shift to that side is the primary abnormality. If the arterial pH is lower than 7.40 (acidemia), an elevated $PaCO_2$ (> 45 mm Hg [6.0 kPa], **respiratory acidosis**) or a lowered HCO_3^- (< 22 mEq/L [mmol/L], **metabolic acidosis**) would be the primary abnormality. If the arterial pH is higher than 7.40 (alkalemia), a decreased $PaCO_2$ (< 35 or 4.7 kPa, **respiratory alkalosis**) or an increased HCO_3^- (> 25 mEq/L [mmol/L], **metabolic alkalosis**) would be the primary abnormality. Once the primary disorder is established, step 2 is to apply the formulas from Table 28–1 to assess whether the observed compensation is appropriate for the primary disorder and to look for concurrent processes.[7]

An alternative to a diagnostic algorithm is use of a graphic nomogram.[9] Nomograms are plots of the pH, $PaCO_2$, and HCO_3^- that allow the user to rapidly determine whether ABG

Patient Encounter 1

An unconscious 27-year-old Afghanistan war veteran is brought to the emergency department by his wife who found him unconscious when she returned home from work. She reports that he is on disability and that the pain clinic has been making "lots of changes to all his pain pills" for the veteran's chronic low back pain. The initial ABG has a pH of 7.20 with a $PaCO_2$ of 65 mm Hg (8.6 kPa), and the serum HCO_3 is 27 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 2

The next patient is a 39-year-old man with advanced emphysema due to α_1 antitrypsin deficiency who is undergoing evaluation for lung transplantation. An ABG drawn as a routine part of the transplant workup shows a pH of 7.34, a $PaCO_2$ of 70 mm Hg (9.3 kPa), and an HCO_3^- of 35 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 3

A healthy 19-year-old undergraduate student is having an ABG drawn as part of a clinical trial she is participating in as a control. Her ABG shows a pH of 7.50, a $PaCO_2$ of 29 mm Hg (3.9 kPa), and an HCO_3^- of 22 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 4

An 87-year-old man has small vessel ischemic cardiomyopathy and chronic congestive heart failure as a complication of mantle field radiation he received for lymphoma in the early 1960s. He requires daily furosemide (Lasix) therapy to remain euvolemic. An ABG was drawn for increasing dyspnea and shows the following: pH of 7.50, a $PaCO_2$ of 47 mm Hg (6.3 kPa), and an HCO_3^- of 36 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 5

The final patient in this section is a 46-year-old woman with end-stage renal disease who was sent to the emergency room (ER) from the dialysis center for evaluation of hypotension. Upon arrival to dialysis she complained of several days of diarrhea and dizziness when standing. When her physical examination confirmed orthostatic changes in her blood pressure, she was sent to the ER without initiation of dialysis. Her ABG in the ER shows a pH of 7.20, a $PaCO_2$ of 20 mm Hg (2.7 kPa), and an HCO_3^- of 8 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

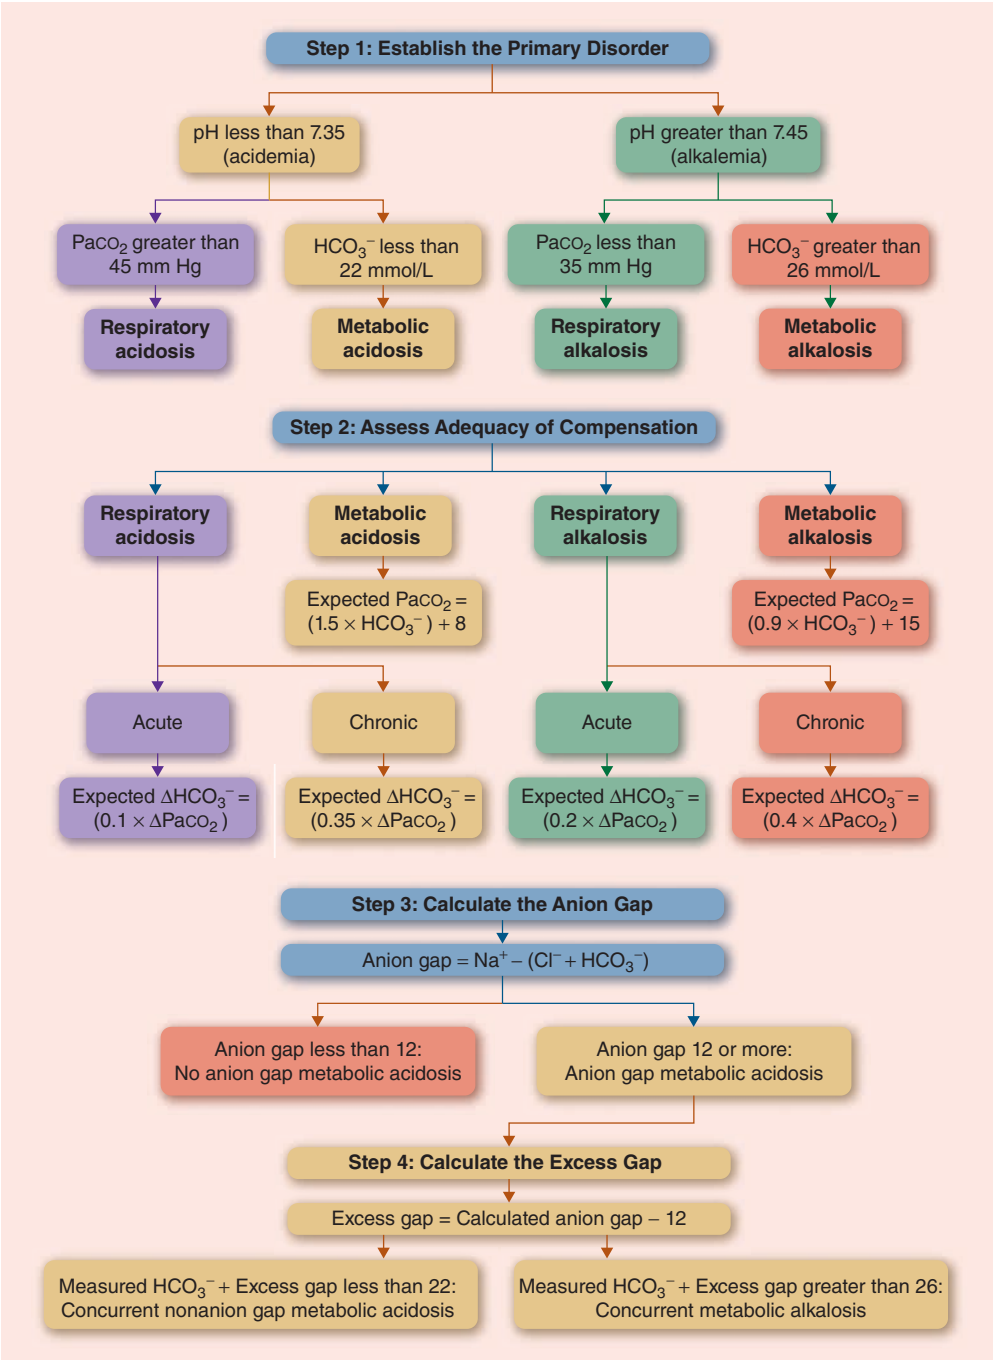

FIGURE 28–1. An algorithmic approach to acid–base disorders. Normal values: pH 7.35 to 7.45, $PaCO_2$ 35 to 45 mm Hg (4.7 to 6.0 kPa), HCO_3^- 22 to 26 mEq/L (mmol/L), anion gap less than 12 mEq/L (mmol/L). Note that $PaCO_2$ should be in units of mm Hg to use the equations in the figure. To convert $PaCO_2$ in units of kPa to mm Hg, divide by 0.133. (Cl^-, chloride ion; HCO_3^-, bicarbonate; Na^+, sodium ion; $PaCO_2$, partial pressure of arterial carbon dioxide.)

values are consistent with one of the six simple primary acid–base disturbances. Although nomograms are commonly used to identify acid–base disturbances in clinical practice, only individuals who fully comprehend the fundamental concepts of acid–base assessment should use these tools. Also, appreciate that nomograms have limited utility when dealing with complex acid–base derangements.

Acid–base disturbances are always manifestations of underlying clinical disorders. It is useful to specifically define the primary acid–base abnormality because each disorder is caused by a limited number of disease processes. Establishing the specific disease process responsible for the observed acid–base disorder is clinically important because treatment of a given disorder will only be accomplished by correcting the underlying disease process.

ADVANCED PATHOPHYSIOLOGY

LO 3

The concepts in this section are used to further expand on steps 3 and 4 of the diagnostic algorithm shown in Figure 28–1. Under normal circumstances, the serum is in the isoelectric state. This

means that the positively charged entities reported in a standard chemistry panel (cations: sodium [Na^+] and potassium [K^+]) should be exactly balanced by the negatively charged entities (anions: chloride [Cl^-] and bicarbonate [HCO_3^-]). However, this relationship is consistently incorrect because the measured cations are higher than the measured anions by 10 to 12 mEq/L (mmol/L). This discrepancy results from the presence of unmeasured anions (eg, circulating proteins, phosphates, and sulfates). This apparent difference in charges, the serum **anion gap**, is calculated as follows:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

LO 3 Because the serum K^+ content is relatively small and is very tightly regulated, it is generally omitted from the calculation.[10]

It is important to realize that the serum HCO_3^- concentration may be affected by the presence of unmeasured endogenous acids (lactic acid or ketoacids). HCO_3^- will attempt to buffer these acids, resulting in a 1 mEq (mmol) loss of serum HCO_3^- for each 1 mEq (mmol) of acid titrated. Because the cation side of the equation is not affected by this transaction, the loss of serum HCO_3^- results in an increase in the calculated anion gap. Identification of an increased anion gap is very important because a limited number of clinical scenarios lead to this unique acid–base disorder. A mnemonic to recall the differential diagnosis for an anion gap acidosis is shown in Table 28–3. The concept of the increased anion gap is applied later in Patient Encounters 6 through 10.

Step 3 in Figure 28–1 suggests that any time an ABG is analyzed it is wise to concurrently inspect the serum chemistry values and to calculate the anion gap. The body does not generate an anion gap to compensate for a primary disorder. As such, if the calculated anion gap exceeds 12 mEq/L (mmol/L), there is a primary metabolic acidosis regardless of the pH or the serum HCO_3^- concentration. The anion gap may be artificially lowered by decreased serum albumin, multiple myeloma, lithium intoxication, or a profound increase in the serum potassium, calcium, or magnesium.[11]

LO 3 Step 4 in Figure 28–1 shows how calculation of the anion gap also facilitates determination of the **excess gap** or the degree to which the calculated anion gap exceeds the normal anion gap. The excess gap is calculated as follows:

$$\text{Excess gap} = \text{calculated anion gap} - \text{normal anion gap}$$
$$= [Na^+ - (Cl^- + HCO_3^-)] - 12$$

Table 28–3

Mnemonics for the Differential Diagnoses of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
M—Methanol, metformin	U—Ureteral diversion
U—Uremia	S—Saline infusion
D—Diabetic (or alcoholic) ketoacidosis	E—Exogenous acid
	D—Diarrhea
P—Paraldehyde, phenformin	C—Carbonic anhydrase inhibitors
I—Isoniazid, iron	A—Adrenal insufficiency
L—Lactic acidosis	R—Renal tubular acidosis
E—Ethylene glycol, ethanol	
S—Salicylates	

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

LO 3 The excess gap represents the amount of HCO_3^- that has been lost due to buffering unmeasured cations. The excess gap can be added back to the measured HCO_3^- to determine what the patient's HCO_3^- would be if these endogenous acids were not present. This is a very valuable tool that can be used in narrowing the differential diagnosis of certain acid–base disorders as well as in uncovering occult or mixed acid–base disorders.

In summary, the approach to assessment of acid–base status involves four key steps as outlined in Figure 28–1: step 1 = initial inspection of the pH, $PaCO_2$, and HCO_3^-; step 2 = assessment of the adequacy of compensation; step 3 = calculation of the anion gap; and step 4 = calculation of the excess gap.

ETIOLOGY AND TREATMENT

KEY CONCEPT *ABGs*, serum electrolytes, physical examination findings, the clinical history, and the patient's recent medications must be reviewed in order to establish the etiology of a given acid–base disturbance. Tables 28–3 through 28–7 outline the most commonly encountered causes for each of the primary acid–base disorders. The therapeutic approach to each of these acid–base derangements should emphasize a search for the cause, as opposed to immediate attempts to normalize the pH.

KEY CONCEPT It is critical to treat the underlying causative process to effectively resolve most observed acid–base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.[12,13]

All patients with significant disturbances in their acid–base status require continuous cardiovascular and hemodynamic monitoring. Because frequent assessment of the patient's response to treatment is critical, an arterial line is often placed to minimize patient discomfort with serial ABG collections. If the anion gap was initially abnormal, serial chemistries should be followed to ensure that the anion gap resolves with treatment. Specific treatment decisions depend on the underlying pathophysiologic state (eg, dialysis for renal failure, insulin for diabetic ketoacidosis, or improving tissue perfusion and oxygenation for lactic acidosis).

Metabolic Acidosis

Metabolic acidosis is characterized by a reduced arterial pH, a primary decrease in the HCO_3^- concentration, and a compensatory reduction in the $PaCO_2$. The etiologies of metabolic acidosis are divided into those that lead to an increase in the anion gap and those associated with a normal anion gap and are listed in Table 28–4. Although there are numerous mnemonics to recall the differential diagnosis of the metabolic acidosis, two simple ones are shown in Table 28–3. High anion gap metabolic acidosis is most frequently caused by lactic acidosis, ketoacidosis, and/or renal failure. Although there is considerable variation, the largest anion gaps are caused by ketoacidosis, lactic acidosis, and methanol or ethylene glycol ingestion.[14]

LO 4

LO 5 Symptoms of metabolic acidosis are attributable to changes in cardiovascular, musculoskeletal, neurologic, or pulmonary functioning. Respiratory compensation requires marked increases in minute ventilation and may lead to dyspnea, respiratory fatigue, and respiratory failure. Acidemia predisposes to ventricular arrhythmias and reduces cardiac contractility, each of which can result in pulmonary edema and/or systemic hypotension.[15] Neurologic symptoms range from lethargy to coma and are usually proportional to the severity of the pH derangement. Chronic metabolic acidosis leads to a variety of musculoskeletal problems including impaired growth, rickets,

LO 5

Table 28–4

Common Causes of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
Intoxications	Bowel fistula
Methanol	Diarrhea
Ethylene glycol	Dilutional acidosis
Salicylates	Drugs
Paraldehyde	Acetazolamide[b]
Isoniazid	Ammonium chloride[b]
Ketoacidosis	Amphotericin B[b]
Diabetic	Arginine hydrochloride[c]
Ethanol	Cholestyramine[b]
Starvation	Hydrochloric acid[b]
Lactic acidosis	Lithium[b]
Carbon monoxide poisoning	Parenteral nutrition[b]
Drugs	Topiramate[b]
IV lorazepam (due to vehicle)[c]	Zonisamide[b]
Metformin[b]	Lead poisoning
Nitroprusside (due to cyanide accumulation)[b]	Renal tubular acidosis
	Surgical drains
Nucleoside reverse transcriptase inhibitors[b]	Ureteral diversion
	Villous adenomas (some)
Propofol[c]	
Seizures	
Severe hypoxemia	
Shock	
Renal failure	

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

[b]May be observed with therapeutic doses or overdoses.

[c]Typically observed with overdoses or prolonged, high-dose infusions (the so-called propofol infusion syndrome).

osteomalacia, or osteopenia. These changes are believed to be caused by the release of calcium and phosphate during bone buffering of excess H^+ ions.

As previously discussed, in anion gap metabolic acidosis, the isoelectric state is maintained because unmeasured anions are present. With a *normal* anion gap metabolic acidosis, the isoelectric state is maintained by an increase in the measured chloride. Because of this, normal anion gap metabolic acidosis is often referred to as hyperchloremic acidosis.

Patient Encounter 6

A 19-year-old woman with Prader-Willi Syndrome and hyperphagia is admitted to the intensive care unit after ingesting an unknown quantity of aspirin tablets. Her presenting labs show a pH of 7.50, a $PaCO_2$ of 20 mm Hg (2.7 kPa), an HCO_3^- of 16 mEq/L (mmol/L), a sodium concentration of 140 mEq/L (mmol/L), and a chloride level of 103 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 7

A 56-year-old man is brought to the emergency room by his family. Because he has not felt well for the past week, he skipped his last three routine hemodialysis sessions. He had the onset of vomiting and confusion 2 days ago but consistently refused medical evaluation. When family members found him unresponsive today they called 911. Lab analyses show: pH of 7.40, $PaCO_2$ of 40 mm Hg (5.3 kPa), HCO_3^- of 24 mEq/L (mmol/L), sodium concentration of 145 mEq/L (mmol/L), and chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 8

A boisterous, intoxicated 44-year-old woman is brought to the ER by rescue squad after police found her disrupting traffic by blocking multiple lanes of a very busy city street with her bicycle and personal belongings. Shortly after arrival in the ER she has multiple episodes of bloody emesis with an obvious aspiration event. She is transferred to the ICU where she becomes progressively hypoxic and requires intubation and mechanical ventilation during the ensuing hours. Her ABG immediately postintubation shows a pH of 7.50, a $PaCO_2$ of 20 mm Hg (2.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 9

A frail, 69-year-old man is being evaluated for altered mental status. His wife says he has suffered from "stomach flu" for several days and has experienced frequent bouts of bilious emesis. He is a poorly controlled diabetic and his wife states that she stopped giving him his insulin since he has not been able to eat. He became more somnolent yesterday but she was unable to bring him to the ER because she was hosting a bridge party. She called an ambulance today when she noticed his breathing was very slow and shallow. The blood work drawn prior to urgent intubation shows a pH of 7.10, a $PaCO_2$ of 50 mm Hg (6.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

In patients with a normal anion gap metabolic acidosis, it is often helpful to calculate the urine anion gap (UAG).[16] The UAG is calculated as follows:

$$UAG = (Urine\ Na^+ + Urine\ K^+) - Urine\ Cl^-$$

The normal UAG ranges from 0 to 5 mEq/L (mmol/L) and represents the presence of unmeasured urinary anions. In metabolic acidosis, the excretion of NH_4^+ and concurrent Cl^- should increase markedly if renal acidification capacity is intact. This results in UAG values from −20 to −50 mEq/L (mmol/L). This occurs because the urinary Cl^- concentration now markedly exceeds the urinary Na^+ and K^+ concentrations. LO 4 Diagnoses consistent with an excessively negative UAG include proximal (type 2) renal tubular acidosis, diarrhea, or administration of acetazolamide or hydrochloric acid (HCl). Excessively positive values of the UAG suggest a distal (type 1) renal tubular acidosis.

In order to effectively treat metabolic acidosis, the *causative process* must be identified and treated.[17] The precise role of adjunctive therapy with sodium bicarbonate ($NaHCO_3$) is not universally agreed upon. However, most practitioners accept that LO 6 $NaHCO_3$ is indicated when renal dysfunction precludes adequate regeneration of HCO_3^- or when severe acidemia (pH < 7.15) is present. The metabolic acidosis seen with lactic acidosis and ketoacidosis generally resolves with therapy targeted at the underlying cause, and $NaHCO_3$ may be unnecessary regardless of the pH. The metabolic acidosis of renal failure, renal tubular acidosis, or intoxication with ethylene glycol, methanol, or salicylates is much more likely to require $NaHCO_3$ therapy.

If $NaHCO_3$ is used, the plasma HCO_3^- should not be corrected entirely. Instead, aim at increasing HCO_3^- above an absolute value of 10 mEq/L (mmol/L). The total HCO_3^- deficit can be calculated from the current bicarbonate concentration ($HCO_{3\ curr}^-$), the desired bicarbonate concentration ($HCO_{3\ post}^-$), and the body weight (in kilograms) as follows:

$$HCO_3^-\ deficit = [(2.4/HCO_{3\ curr}^-) + 0.4] \times weight \times (HCO_{3\ curr}^- - HCO_{3\ post}^-)$$

No more than half of the calculated HCO_3^- deficit should be given initially to avoid volume overload, hypernatremia, hyperosmolarity, overshoot alkalemia, hypocalcemia, and/or hypokalemia. The calculated HCO_3^- deficit reflects only the present situation and does not account for ongoing H^+ production and HCO_3^- loss. When giving HCO_3^- therapy, serial blood gases are needed to monitor therapy.

Historically, another option for patients with severe acidemia has been tromethamine (tris-hydroxymethyl aminomethane or THAM).[18] This inert amino alcohol buffers acids and CO_2 through its amine ($-NH_2$) moiety:

$$THAM - NH_2 + H^+ = THAM - NH_3^+$$
$$THAM - NH_2 + H_2O + CO_2 = THAM - NH_3^+ + HCO_3$$

Protonated THAM (with Cl^- or HCO_3^-) is excreted in the urine at a rate that is slightly higher than creatinine clearance. As such, THAM augments the buffering capacity of the blood without generating excess CO_2. THAM is less effective in patients with renal failure, and toxicities may include hyperkalemia, hypoglycemia, and possible respiratory depression. THAM is particularly useful in patients with volume overload because it does not contain sodium.

THAM is often administered as an empiric dose of 18 g (150 mEq [mmol]) in 500 mL water via slow intravenous (IV) infusion. Additional infusions are given as dictated by the severity and progression of acidosis. Unfortunately, the only US manufacturer of THAM discontinued its production in 2016 and no future production is anticipated.

LO 6 Chronic metabolic acidosis can successfully be managed using potassium citrate/citric acid (Polycitra-K, Cytra-K) or sodium citrate/citric acid (Bicitra, Oracit).

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increased arterial pH, a primary increase in the HCO_3^- concentration, and a compensatory increase in the $PaCO_2$. Patients will always hypoventilate to compensate for metabolic alkalosis—even if it results in profound hypoxemia. For a metabolic alkalosis to persist there must concurrently be a process that elevates serum HCO_3^- concentration (gastric or renal loss of acids) and another that impairs renal HCO_3^- excretion (hypovolemia, hypokalemia, or mineralocorticoid excess). The etiologies of metabolic alkalosis are listed in Table 28–5.

LO 4 Patients with metabolic alkalosis rarely have symptoms attributable to alkalemia. Rather, complaints are usually related to volume depletion (muscle cramps, positional dizziness, weakness) or to hypokalemia (muscle weakness, polyuria, polydipsia).

LO 5 In order to effectively treat metabolic alkalosis, the *causative process* must be identified and treated. The major causes of metabolic alkalosis are often readily apparent after carefully reviewing the patient's history and medication list. In hospitalized patients, always look for administration of compounds such as citrate in blood products and acetate in parenteral nutrition that can raise the HCO_3^- concentration. If the etiology of the metabolic alkalosis is still unclear, measurement of the urinary chloride may be useful. Some processes leading to metabolic alkalosis (eg, vomiting, nasogastric suction losses, factitious diarrhea) will have low urinary Cl^- concentrations (< 25 mEq/L [mmol/L]) and are likely to respond to administration of saline. Other causes (eg, diuretics, hypokalemia, and mineralocorticoid excess) will have higher urinary Cl^- concentrations (> 40 mEq/L [mmol/L]) and are less likely to correct with saline infusion.

In general, contributing factors such as diuretics, nasogastric suction, and corticosteroids should be discontinued if possible. Any fluid deficits should be treated with IV normal saline. Again, patients with metabolic alkalosis and high urine Cl^- (while relatively

Table 28–5

Common Causes of Metabolic Alkalosis

IV bicarbonate therapy	Corticosteroid therapy
Oral alkali therapy	Diuretics
Parenteral nutrition with acetate	Hypokalemia
"Contraction alkalosis" postdiuretic use	Mineralocorticoid excess
Decreased chloride intake	Hyperaldosteronism
Loss of gastric acid	Bartter syndrome
Vomiting	Cushing syndrome
Nasogastric suction	
Posthypercapnia	
Villous adenomas (some)	

[a]May be observed with therapeutic doses or overdoses.

uncommon) are generally resistant to saline loading. Potassium supplementation should always be given if it is also deficient.

LO 6 In patients with mild or moderate alkalosis who require ongoing diuresis but have rising HCO_3^- concentrations, the carbonic anhydrase inhibitor acetazolamide can be used to reduce the HCO_3^- concentration. Acetazolamide is typically dosed at 250 mg every 6 to 12 hours as needed to maintain the pH in a clinically acceptable range. This agent results in gradual changes in the serum HCO_3^- and is not used to acutely correct a patient's acid–base status. If alkalosis is profound and potentially life threatening (due to seizures or ventricular tachyarrhythmias), hemodialysis or transient HCl infusion can be considered. The hydrogen ion deficit (in mEq or mmol) can be estimated from the current bicarbonate concentration ($HCO_{3\ curr}^-$), the desired bicarbonate concentration ($HCO_{3\ post}^-$), and the body weight (in kg) as follows:

$$H^+ \text{ deficit} = 0.4 \times \text{weight} \times (HCO_{3\ curr}^- - HCO_{3\ post}^-)$$

After estimating the H^+ deficit, 0.1 to 0.2 N HCl is infused at 20 to 50 mEq/h (mmol/h) into a central vein. Arterial pH must be monitored at least hourly and the infusion stopped as soon as clinically feasible. Ammonium chloride and arginine hydrochloride, agents that result in the formation of HCl, are not commonly prescribed because they may lead to significant toxicity. Ammonium chloride may cause accumulation of ammonia leading to encephalopathy while arginine hydrochloride can induce life-threatening hyperkalemia through unclear mechanisms.

Respiratory Acidosis

Respiratory acidosis is characterized by a reduced arterial pH, a primary increase in the arterial $PaCO_2$ and, when present for sufficient time, a compensatory rise in the HCO_3^- concentration. Because increased CO_2 is a potent respiratory stimulus, respiratory acidosis represents ventilatory failure or impaired central control of ventilation as opposed to an increase in CO_2 production. As such, most patients will have hypoxemia in addition to hypercapnia. The most common etiologies of respiratory acidosis are listed in Table 28–6.

LO 5 Severe, acute respiratory acidosis produces a variety of neurologic abnormalities. Initially these include headache, blurred vision, restlessness, and anxiety. These may progress to tremors, asterixis, somnolence, and/or delirium. If untreated, terminal manifestations include peripheral vasodilation leading to hypotension and cardiac arrhythmias. Chronic respiratory acidosis is typically associated with cor pulmonale and peripheral edema.

LO 6 In order to effectively treat respiratory acidosis, the *causative process* must be identified and treated. If a cause is identified, specific therapy should be started. This may include naloxone for opiate-induced hypoventilation or bronchodilator therapy for acute bronchospasm. Because respiratory acidosis represents ventilatory failure, an increase in alveolar ventilation is required. This can often be achieved by controlling the underlying disease (eg, bronchodilators and corticosteroids in asthma) and/or physically augmenting ventilation.

LO 6 Although their precise role and mechanisms of action are unclear, agents such as medroxyprogesterone, theophylline, and doxapram stimulate respiration and have been used to treat mild to moderate respiratory acidosis. Of these, only doxapram is approved by the US Food and Drug Administration (FDA) for this indication. Doxapram is administered IV, typically 0.5 to 1 mg/kg repeated every 5 minutes to a maximum dose of 3 g per 24 hours. Patients given doxapram required monitoring of their blood pressure, pulse, and deep tendon reflexes as this drug can cause cardiac excitation and spasticity. Moderate or severe respiratory acidosis requires assisted ventilation. This can be provided to spontaneously breathing patients via bilevel positive airway pressure (BiPAP) delivered via a tight-fitting mask or by intubation followed by mechanical ventilation. In mechanically ventilated patients, respiratory acidosis is treated by increasing the minute ventilation. This is achieved by increasing the respiratory rate and/or tidal volume.

As with the treatment of metabolic acidosis, the role of $NaHCO_3$ therapy is not well defined for respiratory acidosis. Realize that administration of $NaHCO_3$ can paradoxically result in increased CO_2 generation ($HCO_3^- + H^+ \rightarrow H_2O + CO_2$) and worsened acidemia. Careful monitoring of the pH is required if $NaHCO_3$ therapy is started for this indication. The use of tromethamine in respiratory acidosis (see Metabolic Acidosis section earlier) has unproven safety and benefit.

LO 6 The goals of therapy in patients with chronic respiratory acidosis are to maintain oxygenation and to improve alveolar ventilation if possible. Because of the presence of metabolic compensation it is usually not necessary to treat the pH, even in patients with severe hypercapnia. Although the specific treatment varies with the underlying disease, excessive oxygen and sedatives should be avoided because they can worsen CO_2 retention.

Respiratory Alkalosis

Respiratory alkalosis is characterized by an increased arterial pH, a primary decrease in the arterial $PaCO_2$ and, when

Table 28–6

Common Causes of Respiratory Acidosis

- CNS disease
  - Brainstem lesions
  - Central sleep apnea
  - Infection
  - Intracranial hypertension
  - Trauma
  - Tumor
  - Vascular
- Drugs[a]
  - Aminoglycosides
  - Anesthetics
  - β-Blockers
  - Botulism toxin
  - Hypnotics
  - Narcotics
  - Neuromuscular blocking agents
  - Organophosphates
  - Sedatives
- Neuromuscular disease
  - Guillain-Barré syndrome
  - Muscular dystrophy
  - Myasthenia gravis
  - Polymyositis
- Pulmonary disease
  - Lower airway obstruction
  - Foreign body
  - Status asthmaticus
  - Chronic obstructive pulmonary disease
  - Pneumonia
  - Pneumonitis
  - Pulmonary edema
- Restrictive lung disease
  - Ascites
  - Chest wall disorder
  - Fibrothorax
  - Kyphoscoliosis
  - Obesity
  - Pleural effusion
  - Pneumoconiosis
  - Pneumothorax
  - Progressive systemic sclerosis
  - Pulmonary fibrosis
  - Spinal arthritis
- Smoke inhalation
- Upper airway obstruction
  - Foreign body
  - Laryngospasm
  - Obstructive sleep apnea
- Others
  - Abdominal distention
  - Altered metabolic rate
  - Congestive heart failure
  - Hypokalemia
  - Hypothyroidism
  - Inadequate mechanical ventilation

[a]May be observed with therapeutic doses or overdoses.

Table 28–7

Common Causes of Respiratory Alkalosis

CNS disease	Pulmonary disease
Infection	Early restrictive lung disease
Trauma	Infection
Tumor	Pneumothorax
Vascular	Pulmonary edema
Drug or toxin induced[a]	Pulmonary embolism
Catecholamines	Tissue hypoxia
Doxapram	Burn injury
Methylphenidate	Excessive mechanical ventilation
Methylxanthines	Fever
Nicotine	Hepatic failure
Progesterone	Hypoxemia
Salicylates	Pain
Psychiatric disease	Postmetabolic acidosis
Anxiety	Pregnancy
Hyperventilation	Severe anemia
Hysteria	Thyrotoxicosis
Panic disorder	

[a]May be observed with therapeutic doses or overdoses.

present for sufficient time, a compensatory fall in the HCO_3^- concentration. Respiratory alkalosis represents hyperventilation and is remarkably common. The most common etiologies of respiratory alkalosis are listed in Table 28–7 and range from benign (anxiety) to life threatening (pulmonary embolism). Some causes of hyperventilation and respiratory acidosis are remarkably common (hypoxemia or anemia).

LO 5

The symptoms produced by respiratory alkalosis result from increased irritability of the central and peripheral nervous systems. These include light-headedness, altered consciousness, distal extremity paresthesias, circumoral paresthesia, cramps, carpopedal spasms, and syncope. Various supraventricular and ventricular cardiac arrhythmias may occur in extreme cases, particularly in critically ill patients. An additional finding in many patients with severe respiratory alkalosis is hypophosphatemia, reflecting a shift of phosphate from the extracellular space into the cells. Chronic respiratory alkalosis is generally asymptomatic.

LO 6

It is imperative to identify serious causes of respiratory alkalosis and institute effective treatment. In spontaneously breathing patients, respiratory alkalosis is typically only mild or moderate in severity and no specific therapy is indicated. Severe alkalosis generally represents respiratory alkalosis imposed on metabolic alkalosis and may improve with sedation or rebreathing maneuvers (rebreathing mask, paper bag). Patients receiving mechanical ventilation are treated with reduced minute ventilation achieved by decreasing the respiratory rate and/or tidal volume. If the alkalosis persists in the ventilated patient, high-level sedation or paralysis is effective.

SUMMARY

Acid–base disturbances are common clinical problems that are not difficult to analyze if approached in a consistent manner. The pH, $PaCO_2$, and HCO_3^- should be inspected to identify all abnormal values. This should lead to an assessment of which deviations represent the primary abnormality and which represent compensatory changes. The serum electrolytes should always be used to calculate the anion gap. In cases in which the anion gap is increased, the excess anion gap should be added back to the measured HCO_3^-. The anion gap and the excess gap are useful tools that can identify hidden disorders. This rigorous assessment of the patient's acid–base status, incorporated with the available clinical data, increases the likelihood that the clinician will successfully determine the cause of each identified disorder. Although supportive therapy is often required for profound acid–base disturbances, definitive therapy must target the underlying process that has led to the observed derangements.

Patient Care Process

Collect Information:

- Every patient with a suspected acid–base disturbance should have an arterial blood gas and a serum chemistry panel drawn concurrently. The results of these tests should be reviewed using a systematic approach to ensure proper interpretation.

Assess the Information:

- What is the primary disorder? Has compensation occurred?
- Is the anion gap excessively large? If so, does calculation of the excess gap identify another acid–base disorder?

Develop a Care Plan and Implement the Care Plan:

- Continuous cardiovascular and hemodynamic monitoring should be used for significant pH disturbances because the most serious sequelae of acid–base disorders include electrolyte abnormalities, cardiac dysrhythmias, and hypotension.
- All acid–base abnormalities result from underlying disease processes. Definitive therapy for these disturbances requires treatment of the illness that has disrupted the pH equilibrium.
- Review each patient's history, physical examination, and current medication list for clues regarding potential causes of the observed acid–base disorder.

Follow-up: Monitor and Evaluate:

- Serial arterial blood gases and serum chemistries should be compared because every patient's acid–base status is continuously changing based on the underlying disease state and any therapy initiated.

Abbreviations Introduced in This Chapter

ABG	Arterial blood gas
BiPAP	Bilevel positive airway pressure
Cl^-	Chloride ion
CO_2	Carbon dioxide
Δ (delta)	Change
ER	Emergency room
IV	intravenous
H^+	Hydrogen ion
HCl	Hydrochloric acid
HCO_3^-	Bicarbonate
$HCO_{3\ curr}^-$	Current bicarbonate
$HCO_{3\ post}^-$	Posttherapy bicarbonate
Hg	Mercury
K^+	Potassium ion
Na^+	Sodium ion
$NaHCO_3$	Sodium bicarbonate
NH_2	Terminal amine group
NH_4^+	Ammonium

pH	Logarithm of the hydrogen ion concentration
$PaCO_2$	Partial pressure of arterial carbon dioxide
tCO_2	Total venous carbon dioxide
THAM	Tromethamine
UAG	Urine anion gap

29 Alzheimer Disease

Megan J. Ehret and Kevin W. Chamberlin

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology of Alzheimer disease (AD) and its effects on society.
2. Describe the pathophysiology, including genetic and environmental factors that may be associated with AD.
3. Detail the clinical presentation of the typical patient with AD.
4. Describe the clinical course of the disease and typical patient outcomes.
5. Explain how nonpharmacologic therapy is combined with pharmacologic therapy for patients with AD.
6. Recognize and recommend treatment options for disease-specific symptoms as well as behavioral/noncognitive symptoms associated with AD.
7. Educate patients and/or caregivers about the expected outcomes for patients with AD, and provide contact information for support/advocacy agencies.

INTRODUCTION

KEY CONCEPT

Alzheimer disease (AD) is characterized by progressive cognitive decline including memory loss, disorientation, and impaired judgment and learning. Currently, it is diagnosed by exclusion of other potential causes for dementias. There is no single symptom unique to AD; therefore, diagnosis relies on a thorough patient history. The exact pathophysiologic mechanism underlying AD is not entirely known, although certain genetic and environmental factors may be associated with the disease. There is no cure for AD; however, drug treatment can slow symptom progression.

Family members of AD patients can be profoundly affected by the increased dependence of their loved ones as the disease progresses. Advocacy organizations, such as the Alzheimer Association, can provide early education and social support for both the patient and family. The Alzheimer Association has developed a list of common warning signs, which include memory loss, difficulty completing familiar tasks, disorientation, problems with word finding, misplacing things, impaired judgment, social withdrawal, and changes in mood.[1]

EPIDEMIOLOGY AND ETIOLOGY

LO 1

AD is the most common type of dementia, affecting an estimated 5.5 million Americans in 2017.[2] The majority (5.3 million) are 65 years and older. Various classifications of dementia include dementia of the Alzheimer type, vascular dementia, and dementia due to human immunodeficiency virus (HIV) disease, head trauma, Parkinson disease, Huntington disease, Pick disease, or Creutzfeldt-Jakob disease.[3] This chapter addresses only Alzheimer type dementia.

The prevalence of AD increases with age. Of those affected, one in ten are 65 years of age or older, and one in three are 85 years of age or older.[2] It is projected that by 2050, there will be a threefold increase in prevalence due to a population increase in persons older than 65 years.[2] The severity of AD also correlates with increasing age and is classified as mild, moderate, or severe. Other risk factors for AD include family history, female gender, and vascular risk factors such as diabetes, hypertension, heart disease, and current smoking.[4] It is unknown how factors such as environment contribute and interact with the genetic predisposition for AD.

The mean survival time of persons with AD is approximately 4 to 8 years from symptom onset. However, age at diagnosis, severity of AD, and other medical conditions affect survival time.[5] Although AD does not directly cause death, it is associated with an increase in risk factors that often contribute to death, such as senility, sepsis, stroke, pneumonia, dehydration, and decubitus ulcers.

The etiology of AD is unknown; however, genetic factors may contribute to errors in protein synthesis resulting in the formation of abnormal proteins involved in pathogenesis.[6] Early onset (AD prior to age 60) accounts for approximately 1% of all AD. This type is usually familial and follows an autosomal dominant pattern in approximately 50% of cases. Mutations in three genes, presenilin 1 on chromosome 14, amyloid precursor protein (APP) on chromosome 21, and presenilin 2 on chromosome 1, lead to an increase in the accumulation of amyloid beta (Aβ) in the brain, resulting in oxidative stress, neuronal destruction, and the clinical syndrome of AD.[7,8]

In late-onset AD, genetic susceptibility is more sporadic, and it may be more dependent on environmental factors.[6] The apolipoprotein E (apo E) gene on chromosome 19 has been identified as a strong risk factor for late-onset AD. Of the three variants of apo E, carriers of two or more of the apo E4 allele have an earlier onset of AD (~6 years earlier) compared with noncarriers.[6] Only 50% of AD patients have the apo E4 allele, thus indicating it is only a susceptibility marker.

PATHOPHYSIOLOGY

LO 2

KEY CONCEPT Pathologic hallmarks of the disease in the brain include **neurofibrillary tangles** (NFTs) (made up of abnormally phosphorylated tau (τ) protein) and **neuritic plaques** (primarily composed of insoluble forms of Aβ). Accumulation of these toxic forms results in neurodegeneration. In early stages of the disease, neurodegeneration of areas responsible for cholinergic transmission results in a cholinergic deficit. As the disease progresses, widespread neurodegeneration causes imbalance in all neurotransmitter systems. These are primarily located in brain regions involved in learning, memory, and emotional behaviors such as the hippocampus within the medial temporal lobe of the cerebral cortex, basal forebrain, and amygdala.[9]

Tangles

NFTs interfere with neuronal function and their presence has been correlated with the severity of dementia.[10] Unfortunately, NFTs are insoluble even after cell death and they cannot be removed once established, thus prevention is key. The neurons that provide most of the cholinergic innervation to the cortex are prominently affected.[11]

Plaques

The Aβ protein is present in neuritic plaques in a nontoxic, soluble form in human brains. In AD, conformational changes occur that render it insoluble and cause it to deposit into amorphous diffuse plaques associated with dystrophic neuritis.[12] Over time, these deposits become compacted into plaques, and the Aβ protein becomes fibrillary and neurotoxic. Inflammation occurs secondary to clusters of astrocytes and microglia surrounding these plaques.

Acetylcholine

In AD, the plaques and tangles damage **acetylcholine** (Ach) pathways, leading to a shortage of Ach and learning and memory impairment.[13] The basis of current pharmacologic treatment of AD has been to improve cholinergic neurotransmission in the brain. Blocking acetylcholinesterase, the enzyme that degrades Ach in the synaptic cleft, leads to an increased level of Ach with a goal of stabilizing neurotransmission.[13] This process is flawed as cholinergic cell loss appears to be a secondary consequence of AD pathology and not the disease producing event. Cholinergic neurons are only one of the many neuronal pathways affected in AD.

Glutamate

Glutamate is the primary excitatory neurotransmitter in the central nervous system; it is involved in memory, learning, and neuronal plasticity. It affects cognition through facilitation of connections with cholinergic neurons in the cerebral cortex and basal forebrain.[14] In AD, one type of glutamate receptor, *N*-methyl-D-aspartate (NMDA), is less prevalent than normal. There also appears to be overactivation of unregulated glutamate signaling. This results in a rise in calcium ions that induce secondary cascades, which lead to neuronal death and an increased production of APP.[13] The increased production of APP is associated with higher rates of plaque development and hyperphosphorylation of τ protein.[14] Current treatment of AD includes selective inhibition of NMDA receptor-mediated excitotoxicity.

Cholesterol

Increased cholesterol concentrations have also been associated with AD. Cholesterol increases β-amyloid protein synthesis, which can lead to plaque formation.[13] Also, the apo E4 allele is thought to be involved in cholesterol metabolism and is associated with higher cholesterol levels.[13]

Cerebrovascular Pathologies

Cerebrovascular pathologies are common pathologies with age-related cognitive decline along with AD pathologies. Although criteria are still being evaluated to understand the levels of cerebrovascular pathologies that contribute to cognitive impairment, epidemiological studies have found that the presence of vascular and metabolic risk factors during midlife are most strongly associated with risk of cognitive impairment and dementia.[15] Studies have found that antihypertensive treatment can be beneficial in reducing the risk of dementia.[16] Longitudinal studies are needed to study the evolution of cerebrovascular pathologies in those at higher risk of cardiovascular disease starting at midlife.

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT The diagnosis of AD is established following an extensive history and physical examination, and by ruling out other potential causes of dementia. Currently, there are biological

Clinical Presentation and Diagnosis of Alzheimer Disease

General

The diagnosis of AD is primarily made by medical and psychiatric history, neurological examination, formal memory testing, interview of caregivers and family members, and laboratory and imaging data.

Signs and Symptoms

- Cognitive, which occur gradually: memory loss, problems with language, disorientation to time and place, poor or decreased judgment, problems with learning and abstract thinking, misplacing things
- Noncognitive: Changes in mood, behavior, or personality, or loss of initiative
- Functional: Difficulty performing familiar tasks

Tests

- Neuropsychological tests such as the Folstein Mini-Mental State Examination
- MRI or CT to measure changes in brain size and volume in the medial temporal lobe/hippocampus and rule out stroke, brain tumor, or cerebral edema

Laboratory Tests

- Tests to exclude possible causes of dementia: depression screen, vitamin B_{12} and folate levels, thyroid function tests (thyroid-stimulating hormone and free triiodothyronine and thyroxine), complete blood count, and chemistry panel[17]
- Other diagnostic tests to consider for differential diagnosis: erythrocyte sedimentation rate, urinalysis, toxicology, chest x-ray, heavy metal screen, HIV testing, and CSF examination

Table 29–1

***DSM-5* Diagnostic Criteria for Major Neurocognitive Disorders**

A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
   1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function and
   2. A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment
B. Cognitive deficits interfere with independence in everyday activities
C. Cognitive deficits do not occur exclusively in the contest of delirium
D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013:602–603, with permission.

markers available to assist in diagnosis, but they are not currently used in routine practice. Further research is needed to improve brain, imagining, cerebrospinal fluid (CSF), and other AD biomarkers for routine clinical diagnostic use. The clinical presentation and diagnosis of AD is based on history, signs and symptoms, and laboratory and/or imaging tests.

LO 3

AD is a progressive disease that, over time, affects multiple areas of cognition. The American Psychiatric Association recently updated the criteria for AD in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*). See Tables 29–1, 29–2, and 29–3 for full criteria.[3]

Table 29–2

***DSM-5* Diagnostic Criteria for Mild Neurocognitive Disorder**

A. Evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
   1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a mild decline in cognitive function and
   2. A modest impairment in cognitive performance, preferably documented by standardized neuropsychological testing, or in its absence, another quantified clinical assessment
B. Cognitive deficits do not interfere with capacity for independence in everyday activities
C. Cognitive deficits do not occur exclusively in the context of delirium
D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013;605; with permission.

Table 29–3

***DSM-5* Diagnostic Criteria for Major or Mild Neurocognitive Disorder Due to Alzheimer Disease**

A. Criteria are met for major or mild neurocognitive disorder
B. Insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, at least two domains must be impaired)
C. Criteria are met for either probable or possible Alzheimer disease as follows:
   For Major Neurocognitive Disorder:
   Probable Alzheimer disease is diagnosed if either of the following is present; otherwise possible Alzheimer disease should be diagnosed.
   1. Evidence of a causative Alzheimer disease genetic mutation from family history or genetic testing
   2. All three of the following are present:
      a. Clear evidence of decline in memory and learning and at least one other cognitive domain
      b. Steadily progressive gradual decline in cognition, without extended plateaus
      c. No evidence of mixed etiology

   For Mild Neurocognitive Disorder:
   Probable Alzheimer disease: diagnosed if there is evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history
   Possible Alzheimer disease: diagnosed if there is no evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history, and all three of the following are present:
   1. Clear evidence of decline in memory and learning
   2. Steadily progressive, gradual decline in cognition, without extended plateaus
   3. No evidence of mixed etiology
D. Disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systematic disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013;611; with permission.

Patient Encounter Part 1

A man presents at the clinic with his 75-year-old mother complaining that his mother's memory is worsening. He complains that his mother is continuing to forget things, including paying the bills and emptying the cat's litter box. Three months ago, she was started on rivastigmine 4.6 mg/24 hours, which was titrated to 9.5 mg/24 hours. Her son organizes a weekly pillbox and helps administer the medications. The son asks if there is anything else his mother could take to help her memory.

What education points about Alzheimer disease would you provide to the son?

Where would you recommend the son find more information about Alzheimer disease?

How would you address the son's question regarding the pharmacologic management of his mother's Alzheimer disease?

Clinical Course and Typical Patient Outcomes

LO 4

AD has a gradual onset and is slowly progressive, with episodic memory, executive function, visuospatial function, and word-finding difficulties being affected early on. Impairment in motor, behavioral, and sensory functioning occurs later in the illness. During the final stages, patients are not aware of the events occurring around them and are dependent on others.

TREATMENT

Desired Outcomes

KEY CONCEPT Treatment is focused on delaying disease progression and preservation of functioning as long as possible. Secondary goals include treating psychiatric and behavioral symptoms that may occur during the course of the disease.

General Approach to Treatment

KEY CONCEPT The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a cholinesterase (ChE) inhibitor and/or an NMDA antagonist. There are four agents approved for the treatment of AD, but none are curative or known to directly reverse the disease process, donepezil, rivastigmine, galantamine, and memantine. Additionally, psychiatric and behavioral symptoms that occur during the course of the disease should be treated as they occur.

Treatment of AD includes education, communication, and planning with the patient's family/caregiver. Treatment options, legal and financial decisions, and course of the illness should be discussed with the patient and family members. The clinician's emphasis should be on helping to maintain a therapeutic living environment while minimizing the burden of care resulting from the disease.

Nonpharmacologic Therapy

LO 5

The life of a patient with AD must become progressively more simple and structured as the disease progresses, and the caregiver must learn to keep requests and demands on the patient simple. Basic principles in the treatment of patients with AD are shown in Table 29–4.

Pharmacologic Therapy

▶ *Conventional Pharmacologic Treatment for Cognitive Symptoms*

ChE Inhibitors (Donepezil, Rivastigmine, and Galantamine) Guidelines recommend the use of ChE inhibitors as a valuable treatment for AD and the use of memantine for moderate to severe AD.[17] The few head-to-head studies comparing the ChE inhibitors conclude that there are no major differences in clinical outcomes. The selection of one ChE over another should be based on differences in mechanisms of action, adverse reactions, titration schedules, potential drug interactions, and patient and caregiver preference.[18] ChE inhibitors provide only modest benefit which should be communicated to the patient and caregiver.

Table 29–4

Basic Principles in the Management of Patients with AD

- Using a gentle, calm approach to the patient
- Giving reassurance when needed
- Empathizing with the patient's concerns
- Using distraction and redirection
- Maintaining daily routines
- Providing a safe environment
- Providing daytime activities
- Avoiding overstimulation
- Using familiar decorative items in the living area
- Bringing abrupt declines in function and the appearance of new symptoms to professional attention

Table 29–5

Treatment Algorithm for Cognitive Symptoms of AD

1. Patient diagnosed with AD
2. Assess all comorbid medical disorders and drug therapies that may affect cognition
3. Rule out comorbid depression
4. Evaluate for pharmacotherapy based on illness stage
   a. Mild AD: Cholinesterase inhibitor
   b. Moderate to severe AD: Cholinesterase inhibitor, memantine, or combination cholinesterase inhibitor and memantine
3. Deteriorating Mini Mental State Exam (MMSE) score > 2–4 points after 1 year: Change to a different cholinesterase inhibitor
4. Stable MMSE: Continue regimen
5. Treat behavioral/noncognitive symptoms associated with AD as they arise

Treatment should begin as early as possible after diagnosis.[19] Table 29–5 provides a recommended treatment algorithm. Patients should be switched to another ChE inhibitor from their initial ChE inhibitor if they show an initial lack of efficacy, initially respond but then lose clinical benefit, or experience safety/tolerability issues. This switch should not be attempted until the patient has been on a maximally tolerated dose for 3 to 6 months. The switch should also be based on realistic expectations of the patient and/or caregiver.[20] ChE inhibitor should be discontinued in patients who experience poor tolerance or adherence, who do not improve after 6 months at optimal dosing, who fail attempts at monotherapy with at least two agents or combination therapy, who continue to deteriorate at the pretreatment rate, who have dramatic clinical deterioration following initiation of treatment, or who deteriorate to the point where there is no significant effect on quality of life. Patients with an MMSE score less than 10 may also benefit from discontinuation of medication; however, this has not been substantially proven in clinical studies.[21]

LO 6

Donepezil Donepezil is a piperidine ChE inhibitor that reversibly and noncompetitively inhibits centrally active acetylcholinesterase.[22] A dose of 10 mg/day has demonstrated efficacy in patients with either mild to moderate or moderate to severe forms of AD, while the 23-mg dose is also approved for patients with moderate to severe disease. The 23-mg dose showed a small improvement in cognitive symptoms compared to the 10 mg/day dose; however, there was no improvement in overall functioning, and there was a higher incidence of adverse effects.[23] Table 29–6 describes dosing strategies for all of the approved agents for AD. The most frequent adverse effects are mild to moderate gastrointestinal symptoms.[22,24–27] Others include headache, dizziness, syncope, bradycardia, and muscle weakness. Table 29–7 compares their major side effects and monitoring parameters.[1,22,24–29]

Only a small number of drug interactions have been reported with donepezil. Monitoring for increased peripheral side effects is advised when adding a cytochrome P450 (CYP) 2D6 or 3A3/4 inhibitor to donepezil treatment. Also, inducers of CYP2D6 and 3A4 could increase the rate of elimination of donepezil.[22]

Table 29–6

Dosing Strategies for Cognitive Agents

	Donepezil (Aricept)	Rivastigmine (Exelon)	Galantamine (Razadyne)	Memantine (Namenda)[a]
Starting dose	5 mg daily in the evening	1.5 mg twice daily or 4.6 mg/24 hour applied daily (patch)	4 mg twice daily or 8 mg daily in the morning	5 mg daily or 7 mg daily (ER formulation)
Maintenance dose	5–23 mg daily	3–6 mg twice daily or 9.5 mg/24 hour applied daily (patch)	8–12 mg twice daily or 16–24 mg daily	10 mg twice daily or 28 mg daily (ER formulation)
Time between dose adjustments	4–6 weeks between 5 and 10 mg increment; 3 months between 10 and 23 mg increment	2 weeks for oral and 4 weeks for patch	4 weeks	1 week
Dosage adjustments for renal or hepatic impairment	None	Moderate to severe renal impairment, mild to moderate hepatic impairment, or low body weight (< 50 kg): consider maximum dose of 4.6 mg/24 hour	Do not exceed 16 mg for moderately impaired hepatic or renal function; do not administer in severe renal or hepatic impairment	Severe renal impairment: target maintenance dose of 5 mg twice daily or 14 mg daily

[a]Forest Pharmaceuticals, Inc. has discontinued the sale of all configurations of Namenda. They will continue to sell oral solution of Namenda as well as once-daily Namenda XR. Namzaric, a fixed-dose combination of extended-release memantine and donepezil (14/10 mg and 28/10 mg), was recently approved.

Rivastigmine Rivastigmine, approved for the treatment of mild to moderate AD, has central activity for both acetylcholinesterase and butyrylcholinesterase, which could potentially lead to broader efficacy.[27]

Rivastigmine is available as an oral formulation and a patch. If the patient is taking less than 6 mg/day orally, the 4.6 mg/24 hour patch is recommended if switching from oral form to the patch. If the patient is taking 6 to 12 mg/day orally, the 9.5 mg/24 hour patch is recommended. The first patch should be applied on the day following the last oral dose.[24]

Cholinergic side effects are common, but they are usually well tolerated if the recommended dosing schedule is followed. If side effects cause intolerance, several doses can be held, and then dosing can be restarted at the same or next lower dose. Drugs that induce or inhibit CYP450 metabolism are not expected to alter rivastigmine metabolism.[24]

Galantamine Galantamine, approved for the treatment of mild to moderate AD, is a ChE inhibitor, which elevates Ach in the cerebral cortex.[27] It also modulates the nicotinic Ach receptors to increase Ach release from surviving presynaptic nerve terminals. Galantamine may also increase glutamate and serotonin levels, but whether this brings additional benefit is unknown.

CYP3A4 and 2D6 are the major metabolizing enzymes, and pharmacokinetic studies with inhibitors of these enzymes have shown increased galantamine concentrations or reductions in clearance. Similar to donepezil, if inhibitors are given concurrently with galantamine, increased cholinergic side effects should be monitored.[27]

NMDA Receptor Antagonist Memantine is a noncompetitive antagonist of the NMDA type of glutamate receptors that are located throughout the brain. NMDA receptors regulate activity throughout the brain by controlling the amount of calcium that enters the nerve cell, a process essential for establishing an environment required for information storage. Overstimulation of the NMDA receptor by excessive glutamate allows too much calcium into the cell, disrupting information processing. Blocking NMDA receptors with memantine may protect neurons from the effects of excessive glutamate without disrupting normal neurotransmission.[22,27]

Memantine is approved to treat moderate to severe AD. It can be given as monotherapy or in combination with ChE inhibitors. Only modest benefit can be anticipated with the utilization of memantine. Memantine is not indicated for mild AD, and current evidence does not support its use in mild AD.[30] Adverse reactions associated with memantine include constipation, confusion, dizziness, headache, coughing, and hypertension. Closer monitoring should be done if memantine is given concurrently with a ChE inhibitor.

In vitro studies have shown that memantine produces minimal inhibition of CYP450 enzymes CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4, and that no pharmacokinetic interactions with drugs metabolized by these enzymes should be expected.[26,27]

Future Therapies KEY CONCEPT Future therapies for AD may include disease-modifying therapies. Current investigations involving the amyloid hypothesis are evaluating various compounds in the secondary prevention of AD. Mechanisms by which these compounds are thought to work include[7]:

- Reducing levels of brain Aβ or manipulating its configuration
- Targeting τ proteins
- Targeting inflammatory approaches
- Addressing insulin resistance in the brain

Recent studies of bapineuzumab and solanezumab, humanized monoclonal antibody targeting the Aβ, failed to demonstrate a significant change in the Alzheimer Disease Assessment Scale (ADAS-cog11) in phase 3 clinical trials.[31,32]

Patient Encounter Part 2

The patient returns to the clinic in 6 months. She has been receiving 9.5 mg/24 hours of rivastigmine. Her memory symptoms have slowed in their decline, but recently she has been agitated at bedtime and talking to her deceased sister. The son is particularly concerned about the symptoms and wants to know what he could do to help. The patient's record is as follows:

PMH: Diabetes mellitus since age 51, it was well controlled until last year when she became confused about when to take her medication; hypertension treated for 23 years and well controlled; has been hypotensive on a few occasions recently during physicals; osteopenia, last bone mineral density test 12 months ago (T-score = –1.2); on therapy; hypercholesterolemia, last cholesterol panel 12 months ago showed well-controlled levels in normal range; on therapy

FH: Father died of myocardial infarction at age 76; mother died of breast cancer at age 79

SH: Lives with wheelchair-bound husband; son lives across street and checks in daily; denies drinking alcohol or smoking

Meds: Metformin 500 mg orally twice daily; insulin glargine 18 units subcutaneously at bedtime; hydrochlorothiazide 25 mg orally once daily in the morning; lisinopril 20 mg orally once daily in the morning; calcium carbonate and vitamin D 600 mg/200 international units orally twice daily with lunch and dinner; atorvastatin 10 mg orally once daily with dinner; rivastigmine 9.5 mg/24 hours

ROS: (+) Weight loss of 6.3 kg (14 lb) since last visit; (–) N/V/D, change in appetite, heartburn, chest pain, or shortness of breath

PE:

VS: BP 111/72 mm Hg supine, P 79 beats/min, RR 16 breaths/min, T 37°C (98.6°F)

Gen: Poorly groomed, thin woman looks stated age

Neuro: Folstein Mini-Mental State Exam score 20/30; disoriented to month, date, and day of week, clinic name and floor; poor registration with impaired attention and short-term memory; good language skills but problems with commands

CT Scan: Mild-to-moderate generalized cerebral atrophy

What do you recommend with regard to her current rivastigmine treatment?

What nonpharmacologic and pharmacologic interventions could be recommended for the agitation and psychosis?

► *Nonconventional Pharmacologic Treatment*

Nonconventional treatments have historically been used as adjunctive treatments of AD. Vitamin E was previously

recommended because of its antioxidant properties, but a meta-analysis suggested that greater than 400 IU/day should be avoided due to an increased all-cause mortality.[33] There is insufficient data supporting efficacy for nonsteroidal anti-inflammatory drugs (NSAIDs); gastritis, GI bleeds, and increased cardiovascular events are associated with their use.[34] Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) should be reserved for those who have other indications for their use.[35] Until Ginkgo biloba has a more standardized manufacturing process and its long-term safety and efficacy are established, it should be recommended with caution.[36] The medical food caprylidene (AC-1202, Axona) is a medium chain triglyceride approved for the dietary management of metabolic processes associated with mild to moderate AD.[37] Reduced neuronal metabolism of glucose has been associated with AD, and ketone bodies can potentially be used as an alternative energy source for AD patients.[37] Caprylidene is converted by the liver into the ketone body β-hydroxybutyrate (BHB). BHB crosses the blood–brain barrier and can be utilized by neurons as a potential energy source to generate adenosine triphosphate (ATP) and increase pools of Ach.[38] Tramiprosate (homotaurine), or Alzhemed, demonstrated early promise in the treatment of AD, but phase III trials were disappointing. Homotaurine is naturally occurring in seaweed and thought to interfere with amyloid plaque formation and subsequent degeneration of neuronal cells. It is available as a dietary supplement Vivimind™ or ActiveMind™ for age-associated memory impairment.[39]

With the growing body of evidence that brain vascular disease plays a role in the progression of dementia, guidelines support monitoring blood pressure, glucose, cholesterol, and homocysteine, and initiation of appropriate interventions.[40] Adherence to the Mediterranean Diet or Dietary Approaches to Stop Hypertension diet may reduce the risk of cognitive impairment or decline.[41] Additionally, physical activity is an important component of vascular brain health and has been shown in some short-term studies to be associated with a reduced risk of cognitive impairment as well.[41]

Treatment of Behavioral Symptoms

LO 6

KEY CONCEPT Treatment of behavioral symptoms should begin with nonpharmacologic treatments but may also include antipsychotic agents and/or antidepressants. Nonpharmacologic recommendations for treatment include[42]:

- Music
- Videotapes of family members
- Audiotapes of the voices of caregivers
- Walking and light exercise
- Sensory stimulation and relaxation

Clinical trials have reported modest benefit in managing behavioral symptoms with ChE inhibitors and memantine, although the long-term benefits have not been demonstrated to date. Antipsychotics are also frequently used for neuropsychiatric symptoms associated with AD. A meta-analysis concluded that only 17% to 18% of dementia patients demonstrated treatment response to atypical antipsychotics.[43] A double-blind, placebo-controlled trial of olanzapine, quetiapine, or risperidone for the treatment of psychosis, aggression, or agitation in patients with AD showed that adverse effects offset the benefits in the efficacy of atypical antipsychotics.[44]

In April 2005, the US Food and Drug Administration (FDA) issued a statement requiring black-box warnings on all antipsychotics stating that elderly people with dementia-related psychosis treated with an antipsychotic are at an increased risk of death compared with those treated with placebo. Fifteen of 17 trials investigating olanzapine, aripiprazole, quetiapine, and risperidone in elderly demented patients with behavioral disorders showed an increase in mortality compared with the placebo-treated groups (1.6–1.7 times increased risk of death). Causes for these deaths were heart-related events (heart failure and sudden death) and infections (mostly pneumonia). Readers are referred to Chapter 37 for additional information on antipsychotics.

Antipsychotics are not approved for the treatment of elderly patients with dementia-related psychosis. Therefore, it is important to individually assess and balance the risk versus benefit of antipsychotic use in this population. Both the American Society of Consultant Pharmacists and the American Psychiatric Association have published statements regarding the use of antipsychotics to treat agitation and psychosis in dementia.[45,46]

Depressive symptoms occur in as many as 50% of patients with AD and can be difficult to differentiate from symptoms of dementia. Symptoms of depression should be documented for several weeks prior to initiating therapy for depression with AD.[7] The selective serotonin reuptake inhibitors are most commonly used based on their side-effect profile and evidence of efficacy.[7] Indications for the use of antidepressants include depression characterized by poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, and agitation. A recent trial suggested a lack of benefit of sertraline and mirtazapine compared with placebo and an increased risk of adverse effects.[47] Readers are referred to Chapter 38 for more information on antidepressants.

Other miscellaneous therapies for AD include benzodiazepines for anxiety, agitation, and aggression. However, their routine use is not advised because of the increase in falls.[7] Mood stabilizer anticonvulsants, carbamazepine, valproic acid, or gabapentin may be used as alternatives, but the current evidence is conflicting.[48] Buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.[49] In open-label and controlled studies, selegiline decreased anxiety, depression, and agitation.[50] Finally, trazodone has been shown to decrease insomnia, agitation, and dysphoria, and it has been used to treat sundowning in AD patients.

GENOMICS

KEY CONCEPT At this time, there are no specific recommendations regarding the choice of medications or dosing regimens for the current treatments for AD based on genotype or other biomarkers.

Patient Encounter Part 3

The patient returns to the clinic for follow-up 1 year later. Her son states her memory has continued getting worse. Her current MMSE is 16/30. The addition of risperidone 0.5 mg at bedtime helped with her agitation. Her son would like to know if there are any other choices to help treat his mom.

What changes to the patient's current medications would you recommend?

Patient Care Process

Collect Information:

- Assess the type, frequency, and duration of cognitive and noncognitive symptoms.
- Review any available diagnostic data from the medical and psychiatric history including interviews from family, neuropsychologic testing, CT and MRI, and other labs (ie, vitamin deficiencies, thyroid function tests, complete blood counts, and chemistry panel).
- Obtain a thorough history of prescription, nonprescription, and natural drug product use.
- Identify allergies to medications and other substances.

Assess the Information:

- Determine whether the patient has any other disease state (ie, depression) or is taking any medications that could contribute to cognitive changes in the elderly.
- Document current cognitive and noncognitive symptoms present in the patient.
- Assess the current regimen for appropriateness, effectiveness, adverse effects, drug interactions, appropriate dosing, and medication adherence (see Table 29–7).

Develop a Care Plan:

- Select an appropriate ChE inhibitor to avoid drug–drug interactions and adverse effects and in consideration of cost and patient preference (see Tables 29–6 and 29–7).
- Develop a plan to monitor cognitive response to treatment over time.
- Select appropriate medications for behavior symptoms if lifestyle modifications do not achieve goals.

Implement the Care Plan:

- If needed, provide patients and caregivers information about lifestyle modification, and refer them to support when needed.
- Be a resource and give continuous support to the patient and caregivers throughout the long course of the disease.
- Educate patient and caregivers on what to expect from pharmacotherapy.

Follow-up: Monitor and Evaluate:

- Follow up at needed intervals to assess effectiveness and safety of therapy. Review medical history and physical examination findings, lab tests, and results of other diagnostic tests.
- Monitor pharmacotherapy initiation (see Table 29–6), and regularly evaluate the patient for the presence of adverse drug reactions, drug allergies, drug–drug and drug–disease interactions, and adherence.
- If symptoms progress, consider stopping/switching the ChE inhibitor. Switch if there is initial lack of efficacy, loss of clinical benefit, or if poor tolerability develops. Discontinue if there is poor adherence, 6 months with no clinical improvement, or if there is continued deterioration at pretreatment rates.
- Continue to offer support to the patient and caregiver.

OUTCOME EVALUATION

- The success of therapy is measured by the degree to which the care plan decreases the pretreatment rate of cognitive deterioration, preserves the patients' functioning, and treats psychiatric and behavioral symptoms. The primary outcome measure is thus subjective information from the patient and the caregiver, although the MMSE can be a helpful tool. There are no physical examination or laboratory parameters to evaluate the success of therapy.
- Develop a plan to assess the effectiveness of the ChE inhibitor in slowing the deterioration of cognitive functioning after an appropriate interval (every 3–6 months).
- Assess improvement in quality-of-life measures such as ability to function independently and for slowing of memory deterioration (every 3–6 months).
- Evaluate functional performance, mood, and behaviors.
- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions at appropriate intervals (soon after drug initiation or change and every 3–6 months).

CONCLUSION

AD is a progressive deterioration of cognitive abilities usually with behavioral disturbances and personality changes in the later stages of the disease. In an effort to help prepare patients and their caregivers for the inevitable, the Alzheimer Association has developed 10 quick tips on "Living with Alzheimer disease" and they can also provide many resources for patients and caregivers. LO 7

Abbreviations Introduced in This Chapter

Ach	Acetylcholine
Aβ	Amyloid beta
AD	Alzheimer disease
apo E	Apolipoprotein E
APP	Amyloid precursor protein
BHB	β-Hydroxybutyrate
ChE	Cholinesterase
CSF	Cerebrospinal fluid
CYP	Cytochrome P450
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
HIV	Human immunodeficiency virus
MMSE	Mini-Mental State Examination
NMDA	*N*-Methyl-D-aspartate
NFTs	Neurofibrillary tangles
NSAID	Nonsteroidal anti-inflammatory drug
τ	Tau protein

30 Multiple Sclerosis

Melody Ryan

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for multiple sclerosis (MS).
2. Distinguish between forms of MS based on patient presentation and disease course.
3. Compare and contrast MS disease-modifying treatment choices for a given patient.
4. Determine appropriate symptomatic treatment choices for a given patient.
5. Develop a monitoring plan for a patient placed on specific medications.

INTRODUCTION

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS). *Multiple* describes the number of CNS lesions, and *sclerosis* refers to the demyelinated lesions, today called plaques.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

LO 1

Approximately 2.3 million people worldwide have MS.[1] Diagnosis usually occurs between 20 and 50 years, affecting at least twice as many women as men.[1] Whites and people of northern European heritage are more likely to develop MS.[1] Risk factors include family history of MS, autoimmune diseases, or migraine; personal history of autoimmune diseases or migraine; and cigarette smoke exposure.

Etiology

The cause of MS is unknown, but may be genetic, environmental, or both. Genetic risks may explain up to 35% of cases.[2] Environmental theories involve infectious agents or decreased patient or maternal vitamin D serum concentrations or other infectious exposures.[2,3]

PATHOPHYSIOLOGY

While the causative agent of MS is unclear, the result is the development of an autoimmune disorder with areas of CNS inflammation and degeneration.

Inflammation

An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T-cells to become autoreactive (Figure 30–1). Autoreactive T-cells enter lymphatic tissues to expand. Upon a signal involving sphingosine-1-phosphate, T-cells reenter the circulation.[4] Once activated, T-cells cause blood–brain barrier breakdown and enter the CNS. These T-cells come into contact with antigen-presenting cells (APCs) and proliferate and differentiate. Th1 cells secrete cytokines that enhance macrophage and microglial cells that attack myelin.[4]

B-cells cross damaged sections of the blood–brain barrier where autoreactive T-cells trigger B-cells to form myelin autoantibodies. These inflammatory processes probably cause relapses.[4]

Degeneration

Axonal injury and transection disrupts nerve signals. Growing evidence suggests cytotoxic T-cells cause axonal injury early in disease.[4] Axonal loss is likely responsible for MS progression.[4]

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

LO 2

Clinically isolated syndrome (CIS) is a focal demyelinating event in the CNS, often optic neuritis or myelopathy, in a patient not known to have MS.[7] CIS has approximately 60% rate of conversion to clinically definite MS over 4 years.[8] This definite diagnosis is made when dissemination in time and space is demonstrated. KEY CONCEPT The McDonald criteria are used to show dissemination in time by more than one clinical attack and dissemination in space by an attack at a different body site.[9] Evidence from magnetic resonance imaging (MRI) and/or **oligoclonal immunoglobulin G bands** can help fulfill these time and space criteria and facilitate earlier diagnosis and treatment (Figure 30–2).[9] KEY CONCEPT MS is classified into relapsing and progressive disease (Figure 30–3). Progressive MS diagnosis is more difficult because there are often no clinical attacks. Diagnosis requires 1 year of disease progression and two of the following: dissemination in space on MRI of the brain, dissemination in space on MRI of the spinal cord, and positive cerebrospinal fluid (CSF) (oligoclonal immunoglobulin G bands or elevated immunoglobulin G index).[9] MS is the most common cause of young adult disability (impaired walking, fine motor movements, sight, cognitive dysfunction, mood disorders, pain) and reduces life expectancy by 10 to 12 years.[10]

TREATMENT

Desired Outcomes and General Approach to Treatment

The goal of treatment is preventing permanent neurologic damage. There are three approaches to treatment. KEY CONCEPT First, treat acute relapses with corticosteroids to speed recovery.

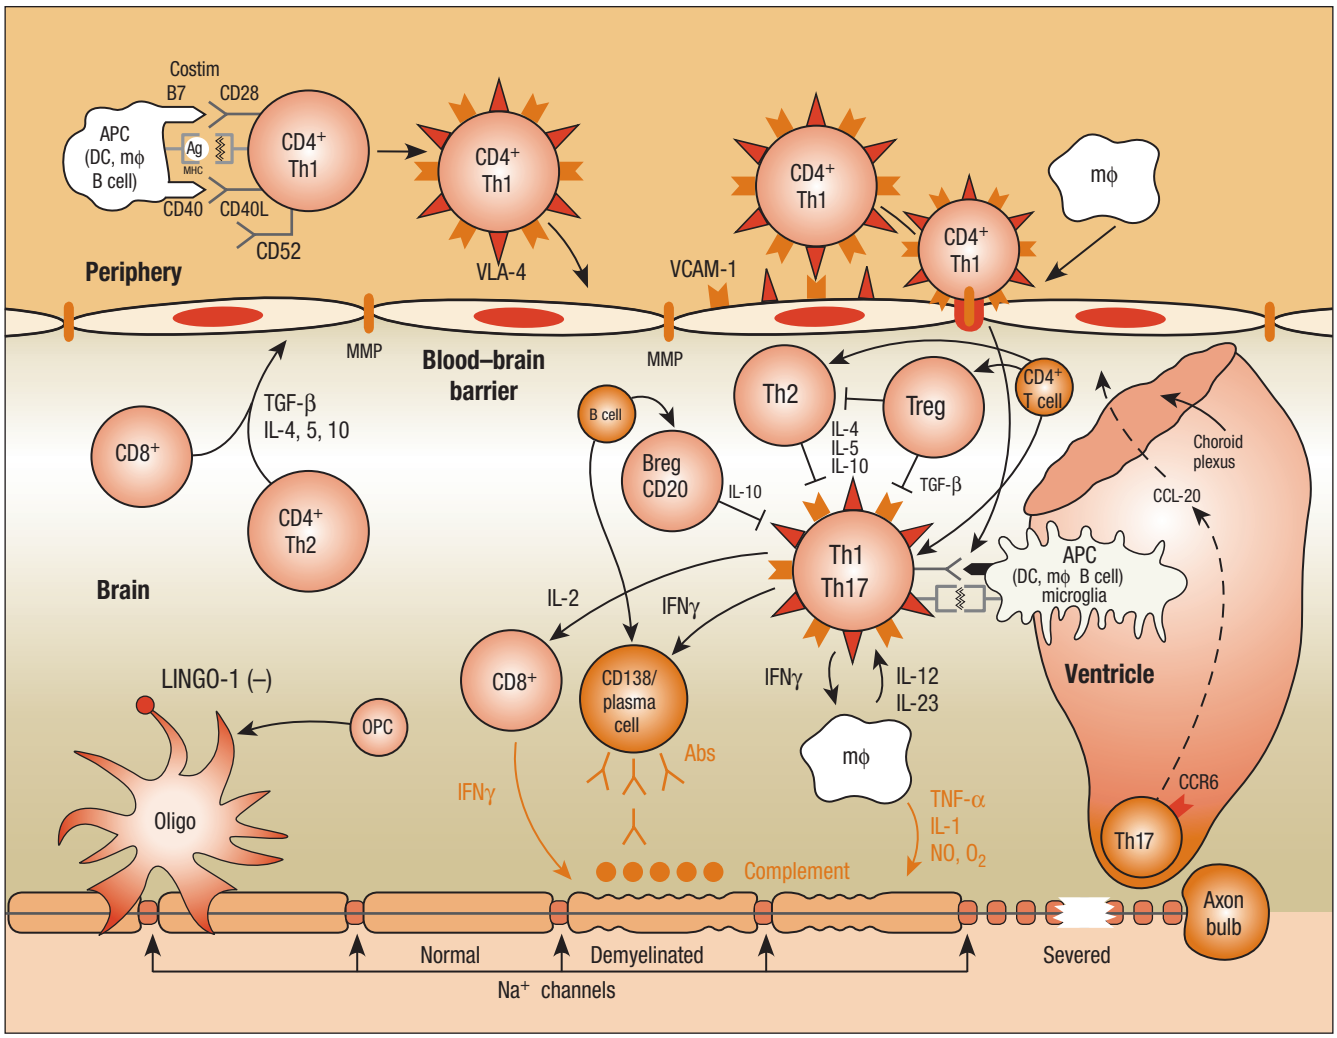

FIGURE 30–1. Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells ($CD4^+$) appear to be key initiators of myelin destruction in MS. These autoreactive $CD4^+$ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection. The activation of T- and B-cells requires two signals. The first signal is the interaction between MHC and APC (macrophage, dendritic cell, and B-cell). The second signal consists of the binding between B7 on the APC and CD28 on the T-cell for T-cell activation. Similarly, CD40 expressed on APCs and CD40L expressed on T-cells interact to signal the proliferation of B-cells within the blood–brain barrier following the entry to T-cells. The T-cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood–brain barrier. The activated T-cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T-cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T-cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B-cells, complement, macrophages, and antibodies. The T-cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of $CD4^+$, $CD8^+$, and Th1-cells. New pathogenic mechanisms involve, but are not limited to, receptor-ligand mediated T-cell entry via choroid plexus (CCR6-CCL20 axis), coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75 or TROY complex, Jagged-Notch signaling). (Ag, antigens; APC, antigen presenting cell; DC, dendrite cell; IgG, immunoglobulin G; MΦ, macrophage; Na^+, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.) (From Bainbridge JL, Miravalle A, Wong PS. Multiple sclerosis. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 10th ed. New York, NY: McGraw-Hill; 2017, with permission.)

Clinical Presentation of MS[5,6]

MS symptoms depend on the location of lesions within the CNS and thus can be nonspecific. Myelin increases the speed of nerve impulse transmission; demyelination slows the speed. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. The secondary symptoms of MS result from the primary symptoms.

Primary Symptoms	Frequency of Occurrence (%)	Related Secondary Symptoms
Urinary symptoms	70	
Incontinence		Decubitus ulcers
Urinary retention		Urinary tract infections
Spasticity	70–80	Falls, care difficulties, pain, gait problems
Visual symptoms		
Optic neuritis	70	Falls, care difficulties
Bowel symptoms	39–73	
Incontinence		Decubitus ulcers
Constipation		Pain
Depression	50	Suicide
Anxiety	36	
Cognitive deficits	43–70	Decline in work or social performance, care difficulties
Fatigue	92	Effects on employment and social roles
Uhthoff phenomenon	80	
Sexual dysfunction		
Erectile dysfunction	50–90	
Female sexual dysfunction	40–85	
Tremor	80	Inability to perform activities of daily living
Pain	86	
Trigeminal neuralgia		
Lhermitte sign		
Dysesthetic pain	14–29	
Impaired gait	64	

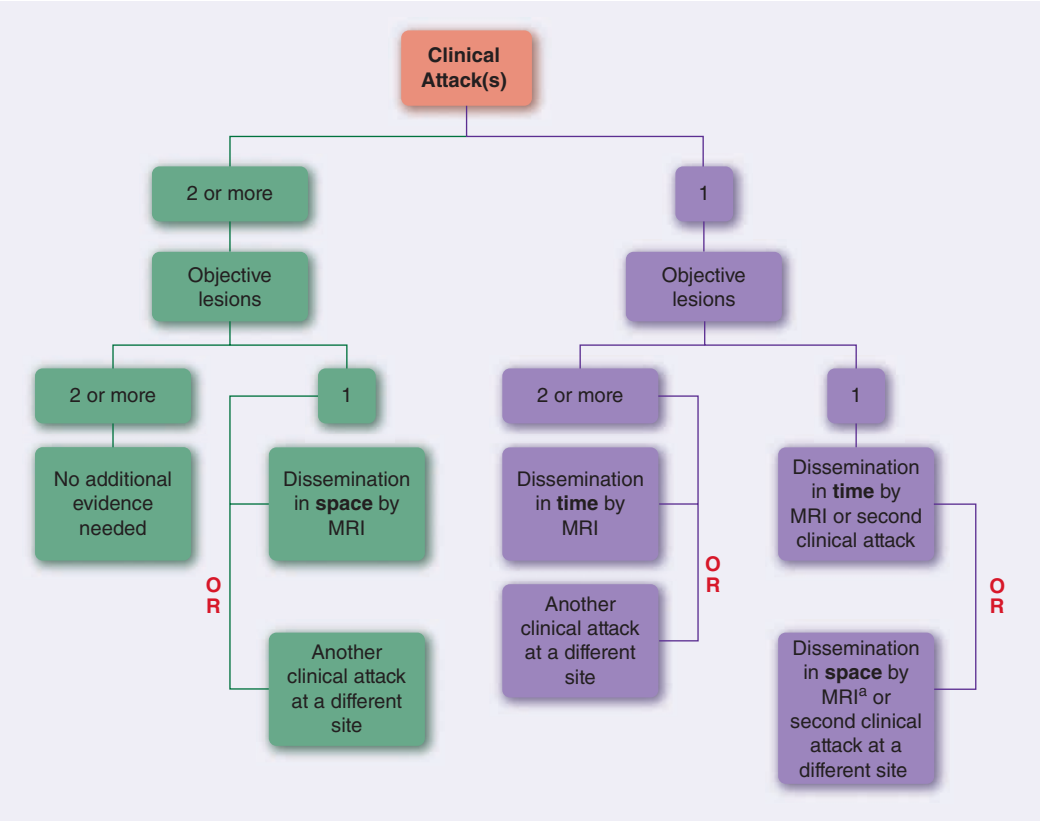

FIGURE 30–2. McDonald diagnostic criteria for MS.[9] An attack is defined as a patient-reported or objectively observed event typical of an acute inflammatory demyelinating event in the CNS with a duration of at least 24 hours in the absence of fever or infection. MRI evidence of dissemination over time is a new T2-weighted lesion after the initial clinical event or the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time. [a]Dissemination in space by MRI evidence of one or more T2-weighted lesions in at least two of the following areas: periventricular, juxtacortical, infratentorial, spinal cord.

MS Type	Definition	Patients Affected	Example
Relapsing remitting	Episodes of acute worsening of neurologic function (relapses) followed by a varying degree of recovery, with a stable course between attacks (remissions)	85%	Primary progressive	Gradual, nearly continuous, worsening with minor fluctuations but no distinct relapses	10%	Secondary progressive	Initial relapsing-remitting disease course followed by progression with or without occasional relapses, minor remissions, and plateaus	50% of relapsing remitting patients within 10 years of diagnosis	Progressive relapsing	Progressive disease from onset, with clear acute relapses, with or without recovery, with periods between relapses characterized by continuing progression	5%	
FIGURE 30–3. Clinical patterns of MS.

KEY CONCEPT Second, disease-modifying therapies decrease the number of relapses, prevent permanent neurologic damage, and prevent disability. KEY CONCEPT Third, symptomatic treatments improve quality of life by minimizing problematic symptoms.

Pharmacologic Treatment

▶ *Treatment of Acute Relapses with Corticosteroids*

Pharmacology and Mechanism of Action Corticosteroids prevent inflammatory cytokine activation, inhibit T- and B-cell activation, and prevent immune cells from entering the CNS.[11] Corticosteroids hasten functional recovery.[11] Equivalence of IV and oral dosage forms has been demonstrated.[12]

Adverse Effects The most common adverse effects are taste change, flushing, gastrointestinal upset, insomnia, and mood disturbance.[13]

Dosing and Administration Methylprednisolone is given 1000 mg/day IV or orally as one dose for 3 days.[12] Oral prednisone 1250 mg/day provides an equivalent dose. Recovery is equivalent with or without a subsequent oral corticosteroid taper.[14]

▶ *Outcome Evaluation*

- Monitor for symptom improvement
- Educate regarding adverse effects

Disease-Modifying Therapies

LO 3

Agents indicated for MS are shown in Table 30–1. These immunomodulators reduce annualized relapse rates (ARRs) 30% to 70%.[15–30] Almost all agents are indicated for relapsing forms of MS and many may be used for CIS. Ocrelizumab is the first agent approved for primary progressive MS. KEY CONCEPT There is no consensus on the best medication for initial therapy. Figure 30–4 suggests a treatment approach. Agents below are ordered according to place in therapy.

▶ *β-Interferons*

Pharmacology and Mechanism of Action β-Interferons decrease T-cell activation, thereby decreasing cytokine secretion;

Patient Encounter Part 1

A 33-year-old white woman visits the emergency department today with complaints of decreased sensation on the right side of her body that developed over several hours. She reports over the last 2 to 3 years she has had periodic changes in her visual acuity that resolve spontaneously over weeks. She has also noticed heat intolerance that seems to lead to stumbling when she walks and a few falls.

What information is suggestive of multiple sclerosis (MS)?

What risk factors does she have for MS?

What additional information or testing would assist in making the diagnosis of MS?

What treatment could be provided to her for the current acute event?

Table 30–1

Disease-Modifying Therapies

Drug	Dose	Route	Frequency	Selected Adverse Effects	Black Box Warnings
Interferon β-1a (Avonex)	Initial 7.5 mcg for 1 week, then 15 mcg for 1 week, then 22.5 mg for 1 week, then 30 mcg	IM	Weekly	Flu-like symptoms 61% Anemia 8% Neutralizing antibody formation 2%–18.9%	None
Interferon β-1a (Rebif)	22 mcg or 44 mcg Initial 20% increase over 4 weeks to final dose	SQ	Three times/week	Flu-like symptoms 28% Injection site reactions 66% Leukopenia 22% Increased AST/ALT 17%–27% Neutralizing antibody formation 16.5%–35.4%	None
Interferon β-1b (Betaseron, Extavia)	Initial 0.0625 mg, increase over 6 weeks to 0.25 mg	SQ	Every other day	Flu-like symptoms 60%–76% Injection site reactions 50%–85% Asthenia 49% Menstrual disorder 17% Leukopenia 10%–16% Increased AST/ALT 4%–19% Neutralizing antibody formation 27.3–53.3%	None
Peginterferon β-1a (Plegridy)	Initial 63 mcg, 94 mcg day 15, 125 mcg day 29	SQ	Every 2 weeks	Injection site reactions 62% Flu-like symptoms 47% Neutralizing antibody formation < 1%	None
Glatiramer acetate (Copaxone, Glatopa)	20 mg 40 mg (Copaxone only)	SQ SQ	Daily Three times/week	Injection site reaction 90% Systemic reaction 15% Alopecia 61% Menstrual disorders 61% Urinary tract infection 32% Leukopenia 19% GGT increase 15% Injection site atrophy 2%	None
Teriflunomide (Aubagio)	7 or 14 mg	By mouth	Daily	Increased AST 12%–14% Alopecia 10%–13% Diarrhea 15%–18% Decreased white blood cell and platelet counts 10%–15%	Hepatotoxicity Teratogenicity
Dimethyl fumarate (Tecfidera)	Initial 120 mg for 1 week, then 240 mg	By mouth	Twice daily	Flushing 30% Gastrointestinal effects 25% Leucopenia/lymphopenia 4%–10% Influenza viral infections 13% Diarrhea 12% Cough 10% Bradycardia 4%	None
Fingolimod (Gilenya)	0.5 mg	By mouth	Daily	ALT/GGT/AST elevations 15% Hypertension 8% Lymphopenia 7%	None
Natalizumab (Tysabri)	300 mg	IV	Every 4 weeks	Headache 38% Fatigue 27% Arthralgia 19% Urinary tract infection 20%	Progressive multifocal leukoencephalopathy

(*Continued*)

Table 30–1

Disease-Modifying Therapies (*Continued*)

Drug	Dose	Route	Frequency	Selected Adverse Effects	Black Box Warnings
Ocrelizumab (Ocrevus)	Course 1: 300 mg Other courses: 600 mg	IV	Course 1: once, then once 2 weeks later Other courses: every 6 months	Infection 58%–70% Infusion reactions 34%–40%	None
Alemtuzumab (Lemtrada)	Course 1: 12 mg/day Course 2: 12 mg/day	IV	Course 1: Daily for 5 days Course 2: Daily for 3 days 12 months after course 1	Infusion reaction 92% Infections 71% Thyroid disorders 34% Diarrhea 12% Blood in urine 8% Dyspnea 8%	Autoimmunity Infusion reactions Malignancies
Mitoxantrone (Novantrone)	12 mg/m^2 up to 140 mg/m^2 (maximum lifetime dose)	IV	Infuse over 30 minutes every 3 months	Nausea 76% Arrhythmia 3%–18% Cardiotoxicity 2.7% Alopecia 61% Menstrual disorders 61% Urinary tract infection 32% Leukopenia 19% Increased GGT 15%	Bone marrow suppression Cardiotoxicity Secondary acute myelogenous leukemia

Govindappa K, Sathish J, Park K, Kirkham J, Pirmohamed M. Development of interferon beta-neurtralising antibodies in multiple sclerosis-a systematic review and meta-analysis. Eur J Clin Pharmacol. 2015;72:1287–1298.

Subei AM, Ontaneda D. Risk mitigation strategies for adverse reactions associated with the disease modifying drugs in multiple sclerosis. CNS Drugs 2015;29:759–771.

prevent upregulation of adhesion molecules on activated T-cells, limiting T-cells access to the CNS; suppress matrix metalloproteinases (MMPs), maintaining the integrity of the blood–brain barrier; decrease microglial proliferation, preserving myelin; promote formation of Th2 cells rather than Th1 cells, decreasing inflammation; and increase neural growth factor production, assisting in repair of the CNS.[15,34]

Efficacy in Patients with Relapsing Remitting MS (RRMS) β-Interferons reduce relapses by about one-third versus placebo.[15] CIS treatment resulted in fewer patients developing clinically definite MS compared with placebo.[15]

Efficacy in Patients with Secondary Progressive MS Who Experience Relapses β-Interferons reduce the risk of relapses, but do not slow progression.[16] Treatment is most effective if clinical relapses or MRI inflammatory activity are present.[16]

Adverse Effects Adverse effects are common with β-interferons (Tables 30–1). Flu-like symptoms (fever, fatigue, muscle aches, malaise, and chills) begin a few hours postinjection and dissipate within 24 hours.[17] Injection site reactions range from redness to necrosis. There are preventive and treatment measures for these reactions (Table 30–2). Because of conflicting data, it is difficult to determine if β-interferons cause depression; however, providers should monitor and assess for depression because patients with MS do commonly develop depression during the course of the disease.[33] Antibodies to β-interferons can reduce effect.[15] **Neutralizing antibodies** develop 6 to 18 months after initiation, can form against any β-interferon, and are cross-reactive (Table 30–3).[15,34] There are no standardized recommendations for neutralizing antibody testing.[15]

▶ *Glatiramer Acetate*

Pharmacology and Mechanism of Action Glatiramer acetate binds to MHC class II, blocking the activation of T-cells, and activates Th2 cells, preventing inflammation. Activated Th2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective.[19]

Efficacy Glatiramer acetate reduces relapses by 28% compared with placebo, but does not prevent sustained progression of RRMS.[20] It is used in CIS to prevent conversion to clinically definite MS.[19]

Adverse Effects Patients report injection site reactions (see Table 30–2). Icing the injection site preinjection and postinjection and/or topical anesthetics improve these reactions. A postinjection reaction may yield a systemic effect (flushing, chest tightness, palpitations, anxiety, and shortness of breath). If this occurs, it is self-limited to 15 minutes, close in time to the injection and recurrence is infrequent. Doses may be reduced by

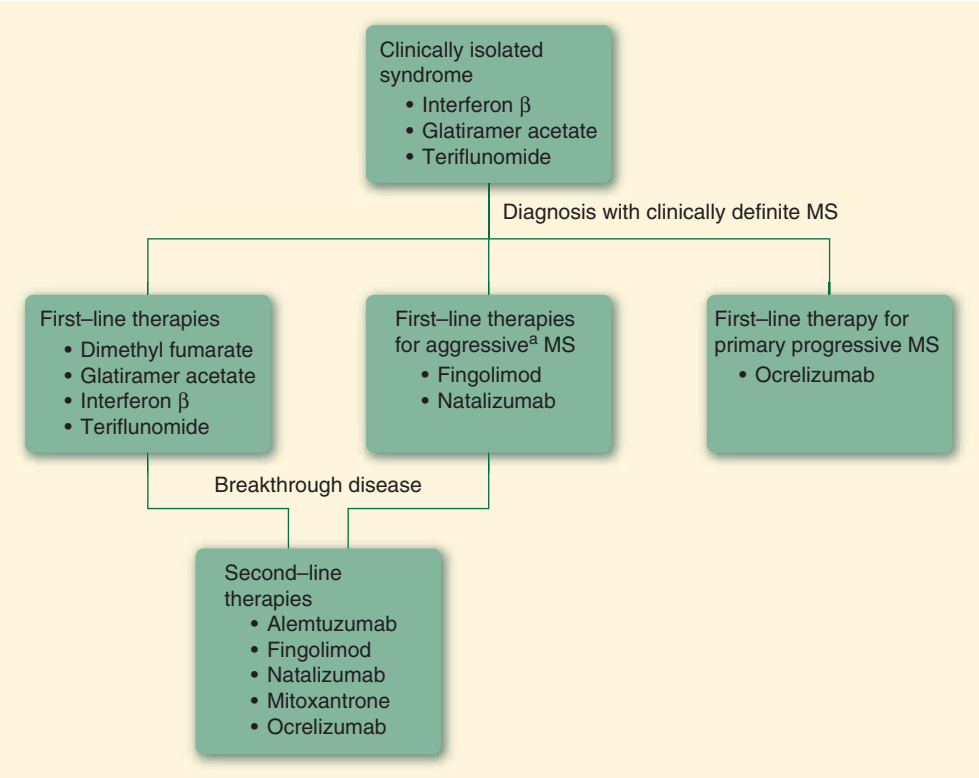

FIGURE 30–4. Treatment algorithm for CIS and MS.[31] [a]A definition of aggressive multiple sclerosis has been proposed as follows: two or more relapses in the preceding year and two or more gadolinium-enhancing lesions on brain MRI scans or a significant T2 lesion burden.[32]

75% for the week following the reaction, then increased by 25% per week to the full dose.[17]

▶ *Teriflunomide*

Pharmacology and Mechanism of Action Teriflunomide has a cytostatic effect on rapidly dividing B- and T-cells by inhibiting *de novo* pyrimidine synthesis and it inhibits T-cell activation, entry to the CNS, and secretion of proinflammatory cytokines.[21]

Pharmacokinetics Half-life of teriflunomide is 2 weeks, taking 3 months to achieve steady-state concentrations. Teriflunomide inhibits CYP2C8 and induces CYP1A2 and CYP2C9.

Table 30–2

β-Interferon Adverse Effects Prevention or Treatment Strategies

Flu-Like Symptoms	Injection Site Reaction
Inject dose in the evening Begin at ¼ dose for 2 weeks of treatment, then increase by 25% every 2 weeks to full dose Use ibuprofen 200 mg or acetaminophen 325–650 mg before and 6 and 12 hours after injection	Bring medication to room temperature Ice injection site before and after injection Rotate injection sites Inject in buttocks or abdomen Use an autoinjection device If severe, use hydrocortisone 1% cream If necrotic: temporarily discontinue; consult dermatologist; do not use topical corticosteroids

Efficacy Teriflunomide reduces relapse rate and progression of disease for relapsing forms of MS.[21] It also prevents CIS from converting to clinically definite MS.[22]

Adverse Effects Teriflunomide is generally well tolerated. Rare, but serious, adverse effects include hepatotoxicity, skin reactions, peripheral neuropathy, infections, and teratogenicity.[21]

▶ *Dimethyl Fumarate*

Pharmacology and Mechanism of Action Dimethyl fumarate shifts cytokine production from a proinflammatory state to an anti-inflammatory state, prevents macrophage entry into the CNS by an unknown mechanism, and stabilizes transcription factor nuclear (erythroid-derived 2) related factor which may reduce oxidative stress.[23]

Efficacy Dimethyl fumarate reduced relapses approximately 50% compared to placebo. It slowed RRMS progression in some studies.[23]

Adverse Effects Dimethyl fumarate causes a transient, dose-dependent flushing sometimes with itching that is likely due to histamine release. The incidence of this reaction decreases after the first month and may be improved by slower dose titration, administration with food, and/or H2-blocking antihistamines.[23] Gastrointestinal adverse effects may be lessened with a slow dose increase and administration with food.[23]

▶ *Fingolimod*

Pharmacology and Mechanism of Action Fingolimod is a sphingosine 1-phosphate receptor modulator. It retains T-cells in lymphoid tissues, depleting peripheral blood and CNS lymphocytes. Fingolimod binds to brain sphingosine 1-phosphate receptors, reducing inflammatory cytokines.[24]

Table 30–3

Monitoring Disease-Modifying Therapies

Therapy	Tests	Frequency
All Therapies	EDSS, MSFC, neurologic examination	Baseline, every 3 months for 2 years; then every 6 months
β-Interferons	CBC with differential, bilirubin, electrolytes, AST, ALT, GGT, alkaline phosphatase, depression/suicidal ideation	Baseline, 1, 3, and 6 months; then every 3 months
	Thyroid function tests	Baseline and every 6 months in patients with a history of thyroid dysfunction
Teriflunomide	CBC, screen for tuberculosis, pregnancy testing	Baseline
	ALT, AST, bilirubin	Baseline and monthly for first 6 months
	Blood pressure	Baseline; then periodically
Dimethyl fumarate	CBC, ALT, AST, alkaline phosphatase, bilirubin	Baseline and every 6 months
Fingolimod	Varicella zoster immunity evaluation and/or vaccination and FEV_1, pregnancy test	Baseline
	CBC, ALT, AST, bilirubin	Baseline and every 6 months
	Pulse and blood pressure	Baseline; observe in clinical area for 6 hours after initial dose with hourly monitoring
	Ophthalmology evaluation	Baseline; 3–4 months; then as needed
	Dermatologic evaluation	Baseline; then as needed
	Electrocardiogram	Baseline and 6 hours after initial dose
Natalizumab	HIV, CBC, AST, ALT, MRI	Baseline; repeat MRI at 6 months; then yearly
	MRI, CSF JC virus	Periodically and at onset of new neurologic symptoms
	Anti-JC virus antibody index	Baseline and every 6 months
Ocrelizumab	Hepatitis B screening	Baseline
	Infection assessment	Prior to every infusion
Alemtuzumab	Thyroid function	Baseline, every 3 months until 48 months after last infusion
	CBC with differential, serum creatinine, urinalysis with cell counts	Baseline, monthly until 48 months after last infusion
	Varicella zoster immunity evaluation and/or vaccination, tuberculosis screening, hepatitis B and C screening	Baseline
	Vital signs	Baseline, during, and 2 hours after infusion
	Skin examination	Baseline and yearly
Mitoxantrone	CBC, bilirubin, AST, ALT, alkaline phosphatase, pregnancy test	Before each infusion
	Echocardiogram/MUGA scan	Baseline; prior to each infusion, and yearly after stopping mitoxantrone

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CSF, cerebrospinal fluid; EDSS, expanded disability status scale; FEV_1, forced expiratory volume during one second; GGT, gamma-glutamyl transferase; HIV, human immunodeficiency virus; JC, John Cunningham; MRI, magnetic resonance imaging scan; MSFC, multiple sclerosis functional composite; MUGA, multigated acquisition scan.

Subei AM, Ontaneda D. Risk mitigation strategies for adverse reactions associated with the disease modifying drugs in multiple sclerosis. CNS Drugs 2015;29:759–771.

Pharmacokinetics Fingolimod has a half-life of 8 to 9 days (steady-state concentrations achieved in 1–2 months).[24]

Efficacy Treatment reduced the ARR to 0.18 compared with 0.40 for placebo. It also slowed RRMS progression.[24]

Adverse Effects Fingolimod reduces circulating lymphocytes by about 75%; therefore, infections and malignancies are concerns.[24] Sphingosine 1-phosphate receptors modulation causes first-dose bradycardia, macular edema, and reduced forced vital capacity.[24] Fingolimod is contraindicated in patients with myocardial infarctions, unstable angina, stroke, transient ischemic attacks, or some types of congestive heart failure within the past 6 months or in patients with many types of atrioventricular block, prolonged QT interval, or who are taking class Ia or III antiarrhythmic medicines.[24] Baseline and first-dose monitoring is required (see Table 30–3); monitoring must be repeated if therapy is interrupted.[24]

▶ *Natalizumab*

Pharmacology and Mechanism of Action Natalizumab is a α_4-integrin antagonist. It binds to $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, preventing lymphocyte migration into the CNS and inflammation, and inhibits binding of α_4-positive leukocytes to fibronectin and osteopontin, decreasing the activation of leukocytes within the CNS.[25]

Efficacy Treatment with natalizumab reduced relapses in RRMS by 68% at 1 year and disability by 42% at 2 years versus placebo.[25]

Adverse Effects Hypersensitivity reactions (itching, dizziness, fever, rash, hypotension, dyspnea, chest pain, and anaphylaxis) may occur within 2 hours of administration and requires treatment discontinuation. A separate infusion reaction (headache, dizziness, fatigue, nausea, sweats, and rigors) may occur within 2 hours of dosing.[17] Histamine 1 and 2 receptor blockers prevent these symptoms, and discontinuation is not required. A serious, but rare, adverse effect is progressive multifocal leukoencephalopathy (PML). PML, caused by the John Cunningham (JC) polyomavirus virus, is rapidly progressive and often results in death or permanent disability. Though most associated with natalizumab, PML has been reported in patients treated with dimethyl fumarate, fingolimod, and alemtuzumab.[17] Specific recommendations are to test for JC virus, avoid natalizumab in immunocompromised patients; carefully assess for immune compromise in patients previously treated with immunosuppression, radiation therapy, or chemotherapy; use only as monotherapy, and carefully monitor patients.[17] Vigilance is paramount because PML can mimic MS symptoms.[25]

KEY CONCEPT These concerns lead to the recommendation that natalizumab be reserved for patients with rapidly advancing disease who have failed other therapies.

Antinatalizumab antibodies develop in 9% to 12% of patients. If patients have antibodies 6 months after start of therapy, relapse rates, disability, and hypersensitivity reactions increase.[25]

▶ *Ocrelizumab*

Pharmacology and Mechanism of Action Ocrelizumab is a monoclonal antibody approved for treatment of relapsing or primary progressive MS. Ocrelizumab depletes B-cells.[26]

Efficacy In RRMS, ocrelizumab treatment lowered ARR and disability progression compared with interferon β.[27] In primary-progressive MS, fewer patients had confirmed disability progression compared with placebo.[28]

Adverse Effects Infusion reactions (pruritus, rash, erythema, bronchospasm, dyspnea, flushing, hypotension, pyrexia, headache, nausea, and tachycardia) are seen in 34% to 40% of patients given ocrelizumab.[27,28] Premedication with corticosteroids and antihistamines is required and antipyretics considered before each infusion. Ocrelizumab is contraindicated in patients with active hepatitis B infections.

▶ *Alemtuzumab*

Pharmacology and Mechanism of Action Alemtuzumab is a monoclonal antibody that eliminates circulating B- and T-cells. Repopulation of these cells takes 8 to 35 months.[29]

Efficacy Treatment reduced relapse rates compared to interferon β with 77% of patients relapse-free for 2 years.[29]

Adverse Effects Infusion-associated reactions (headache, rash, pyrexia, nausea, itching, and fatigue) occur in more than 90% of patients, requiring pretreatment with methylprednisolone and often antihistamines and antipyretics.[33] Acyclovir co-treatment is required due to risk of herpesvirus infections. Secondary autoimmune diseases can also develop.[29] Because of these safety concerns, alemtuzumab is generally reserved for patients who have failed two therapies. Neutralizing antibodies are present in up to 94% of patients, but do not seem to decrease efficacy.

▶ *Mitoxantrone*

Pharmacology and Mechanism of Action Mitoxantrone is an anthracenedione antineoplastic. It causes apoptosis in T-cells and APCs, preventing initial T-cell activation; inhibits DNA and RNA synthesis, decreasing proliferation of T-cells, B-cells, and macrophages; decreases cytokine release, preventing inflammation; and inhibits macrophages, preventing myelin degradation.[30]

Efficacy Mitoxantrone reduces the relapse rate and attack-related MRI outcome measures and MS progression.[30] KEY CONCEPT Because of its potential for significant toxicities, mitoxantrone is reserved for patients with rapidly advancing disease who have failed other therapies.

Adverse Effects Bluish discoloration of the sclera and urine lasts 24 hours or more postinfusion.[17] Amenorrhea may be permanent and lead to infertility.[30] Cardiotoxicity is a serious adverse effect. Mitoxantrone is contraindicated in patients with cardiomyopathy, even if asymptomatic. Cyclooxygenase-2 inhibitors potentially worsen cardiac toxicity and should be avoided.[30] Maximum lifetime dose of mitoxantrone is 140 mg/m^2.

▶ *Issues with Self-Injected Disease-Modifying Therapies*

Adherence KEY CONCEPT Adherence to injectable medications is a significant problem, with 22% to 59% discontinuation. Realistic therapy expectations, higher educational levels, and higher self-efficacy improve adherence; depression and cognitive problems lower adherence.[35]

Patient Education Refer to Table 30–4 for patient self-injection education.

▶ *Other Therapy Considerations*

Pregnancy Because MS affects women of childbearing age, the teratogenicity of medications is concerning. Although none of the disease modifying therapies is recommended for use during pregnancy, pregnancy registry analysis demonstrates no adverse outcomes with interferon β, glatiramer acetate, and natalizumab.[36] Sphingosine 1-phosphate receptors are important

Table 30–4

Self-Injection Patient Education

Keep supplies together and out of reach of children/pets
Allow medication to warm to room temperature
Wash hands
Choose injection site, rotating among sites
Ice area (≤ 15 minutes) prior to injection, if desired
Clean site with alcohol or soap/water
Administer injection
Ice site (≤ 15 minutes) after injection, if desired

in fetal formation; thus fingolimod should be discontinued for at least 2 months before conception. Mitoxantrone and teriflunomide are contraindicated during pregnancy, and teriflunomide is contraindicated for men who have sexual intercourse with women who may become pregnant.[36] Because of the long half-life of teriflunomide, accelerated elimination with cholestyramine or activated charcoal is recommended for women who wish to become pregnant.[36]

Vaccinations Patients taking alemtuzumab, fingolimod, mitoxantrone, ocrelizumab, or teriflunomide should not receive live attenuated virus vaccines.[21,25,37] Vaccines may be less effective while on several disease-modifying therapies; they should be given 6 weeks before therapy starts. Vaccines should be held for 4 to 6 weeks after a mitoxantrone dose.[21,25]

▶ *Outcome Evaluation*

LO 5

- Assess symptom changes periodically (every 3–12 months).
- In β-interferon-treated patients with frequent relapses, test for neutralizing antibodies.
- Monitor medication-specific adverse effects (see Tables 30–1 and 30–3).
- Assess adherence.
- Assess disability with the Expanded Disability Status Scale[38] or the Multiple Sclerosis Functional Composite Score.[39]

▶ *Symptomatic Therapies*

LO 4

Symptoms most unique to MS are fatigue, spasticity, impaired ambulation, and pseudobulbar affect. Treatment of other symptoms such as urinary incontinence, pain, depression, cognitive impairment, and sexual dysfunction is addressed elsewhere in this text and does not differ in MS.

Fatigue There are nonpharmacologic and pharmacologic strategies for coping with fatigue (Table 30–5).[40]

Spasticity Spasticity treatment goals are patient specific. For ambulatory patients, reducing spasticity may improve mobility and decrease pain. For bed-bound patients, treating spasticity may relieve pain and facilitate care. Physical therapy is a nonpharmacologic treatment for spasticity.[41]

KEY CONCEPT MS patients must be treated with agents specific for upper motor neuron spasticity (Table 30–6).[41] MS spasticity is classified as focal (one muscle group) or generalized. Botulinum toxin may benefit focal spasticity.[41] Systemic medications are used for generalized spasticity. No conclusion can be reached regarding efficacy superiority of one agent.[41]

Patient Encounter Part 2

PMH: She reports over the last 2 to 3 years she has had periodic changes in her visual acuity that resolve spontaneously over weeks. She has also noticed heat intolerance that seems to lead to stumbling when she walks and a few falls.

FH: Both parents alive and well. Younger sister with an episode of optic neuritis.

SH: Elementary school teacher. Divorced. She smokes 1 pack/day. She drinks 2 to 3 alcoholic beverages/week. She does not use illicit drugs.

Allergies: NKDA

Meds: None

ROS: (–) HA, SOB, chest pain, cough

PE:

VS: 122/76, P 76, RR 20, T 36°C (96.8°F)

Skin: Warm, dry

HEENT: Right pupillary response to light is sluggish, decreased visual acuity right eye

CV: RRR, normal S1 and S2, no m/r/g

Chest: CTA

Abd: Soft, NT/ND

Neuro: A & O × 3; CN II-XII intact.

Motor: Paresthesia to touch and decreased pin sensation on right side. Mild vibratory sense loss in distal right leg. Tandem gait mildly unstable.

Labs: WNL

Imaging: T2-weighted MRI shows two enhancing T2-weighted lesions in left cortex and a nonenhancing T2-weighted lesion on the right optic nerve.

Given this additional information, what is your assessment of this patient's condition?

Identify your treatment goals for this patient.

What pharmacologic alternatives are available for this patient?

Impaired Ambulation Nonpharmacological treatment includes assistive devices, physical therapy, and/or exercise. Extended-release dalfampridine is indicated for improvement in walking speed. This potassium channel blocker prolongs action potentials, improving conduction in demyelinated neurons.[42] Not all patients

Patient Encounter Part 3

Based on the information available, create a care plan for this patient's MS. The plan should include (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

Table 30–5

Pharmacologic and Nonpharmacologic Fatigue Treatments

Nonpharmacologic	Pharmacologic	Renal Dosing
Appropriate rest-to-activity ratio Use assistive devices to conserve energy Environmental modifications to make activities efficient	*First-line therapy:* Amantadine 100 mg orally every morning and early afternoon	CrCl 30–50 mL/min (0.50–0.84 mL/s): 100 mg/day CrCl 15–29 mL/min (0.25–0.49 mL/s): 100 mg every other day CrCl < 15 mL/min (0.25 mL/s): 200 mg every 7 days
Cooling strategies to avoid fatigue caused by elevations in core body temperature	*Second-line therapy:* Methylphenidate 10–20 mg every morning and noon	
Regular aerobic exercise Lower extremity muscle resistance training Stress management		

CrCl, creatinine clearance.

From Asano M, Finlayson ML. Meta-analysis of three different types of fatigue management interventions for people with multiple sclerosis: exercise, education, and medication. Mult Scler Int. 2014;2014:798285.

respond to this agent; response can be assessed at 2 months.[42] Urinary tract infections, insomnia, dizziness, headache, nausea, asthenia, back pain, and balance disorder all occur frequently with dalfampridine.[42] Seizures are an uncommon adverse effect; therefore, patients with seizure disorders should not receive dalfampridine.[42]

Pseudobulbar Affect Ten percent of patients with MS develop pseudobulbar affect, which is characterized by inappropriate laughing or crying and can lead to social isolation.[43] A combination of dextromethorphan and quinidine is a treatment for pseudobulbar affect. Dextromethorphan prevents the release of excitatory neurotransmitters. Low-dose quinidine blocks first-pass metabolism of dextromethorphan and increases serum concentrations. Episodes decrease 49% with this treatment.[43]

LOS

▶ *Outcome Evaluation*

- Assess symptom improvement/recurrence.
- Assess quality of life.
- Monitor adverse effects.
- Monitor adherence.

Table 30–6

Antispasticity Agents

Place in Therapy	Medication	Mechanism of Action	Dose
First-line	Baclofen	Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist	5 mg orally three times daily; increase by 5 mg/dose every 3 days; maximum 80 mg/day *Renal dysfunction:* Dose reduction
	Tizanidine	Centrally acting α_2-receptor agonist	2 mg orally three times daily; increase gradually by 2 mg at each dose every 1–4 days; maximum 36 mg/day *Hepatic and renal dysfunction:* Dose reduction
Second-line	Dantrolene	Direct inhibitor of muscle contraction by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum	25 mg orally daily; increase to 25 mg three to four times daily after 7 days; then increase by 25 mg every 4–7 days; maximum 400 mg/day
	Diazepam	γ-aminobutyric acid agonist	2–10 mg orally three to four times daily *Cirrhosis:* Reduce dose by 50%
Third-line	Intrathecal baclofen	Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist	Titrated individually; usual range: 62–749 mcg/day
Focal spasticity	Botulinum toxin	Prevents release of acetylcholine in the neuromuscular junction	Individualized

Data from Gold R, Oreja-Guevera C. Advances in the management of multiple sclerosis spasticity: multiple sclerosis spasticity guidelines. Expert Rev Neurother. 2013;13(suppl 12):55–59.

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review the medical history and physical assessment findings.
- Speak with the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and care.

Assess the Information:

- Based on physical examination and review of systems, determine whether patient is experiencing an MS exacerbation currently. Determine presence of symptoms such as urinary incontinence.
- Based on the medical history and MRI findings, determine the following. Does the patient have CIS? Has the patient had MS relapses? Does patient have aggressive MS (Figure 30–4)? Is patient pregnant? Does patient want to become pregnant?
- Review available laboratory tests.
- Based on the medication history, has patient been treated with any MS medications or immunosuppressants previously? Is patient experiencing adverse effects from current therapy?
- If patient is receiving disease-modifying or symptomatic pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

Develop a Care Plan:

- If patient is having relapses, select corticosteroids.
- Select disease-modifying therapy (Table 30–1, Figure 30–4), considering:
  - Route of administration
  - Frequency of administration
  - Adverse effect profile
  - Cost, including insurance preauthorization needs

Implement the Care Plan:

- Obtain baseline laboratory studies (Table 30–2).
- Educate patient regarding self-injection, if necessary (see Table 30–4), and adherence.
- Initiate needed symptomatic treatments.
- Address any concerns about MS and management.
- Refer patient to the National MS Society for information, newsletters, and local support groups (www.nationalmssociety.org).
- Instruct patient to contact clinician for any sudden symptom changes indicating relapse or adverse effects.

Follow-up: Monitor and Evaluate:

LOS

- Monitor patient for efficacy and adverse effects of disease-modifying and symptomatic therapies (Table 30–2).
- Obtain MRI annually or more frequently as dictated by symptoms and selected therapy.
- Assess adherence with medications.
- Monitor quality of life, disability, and further symptom development.

Abbreviations Introduced in This Chapter

ALT	Alanine aminotransferase
APC	Antigen-presenting cell
ARR	Annualized relapse rate
AST	Aspartate aminotransferase
CBC	Complete blood count
CIS	Clinically isolated syndrome
CNS	Central nervous system
CrCl	Creatinine clearance
CSF	Cerebrospinal fluid
DC	Dendrite cell
EDSS	Expanded Disability Status Scale
FEV_1	Forced expiratory volume in 1 second
HIV	Human immunodeficiency virus
IgG	Immunoglobulin G
IL	Interleukin
INF	Interferon
MHC	Major histocompatibility complex
MMP	Matrix metalloproteinase
Mϕ	Macrophage
MRI	Magnetic resonance imaging
MS	Multiple sclerosis
MSFC	Multiple Sclerosis Functional Composite
MUGA	Multiple-gated acquisition
OPC	Oligodendrocyte precursor cell
PML	Progressive multifocal leukoencephalopathy
RRMS	Relapsing remitting multiple sclerosis
TGF	Transforming growth factor
Th1	T-helper-1 cells
Th2	T-helper-2 cells
TNF	Tumor necrosis factor
VCAM	Vascular cell adhesion molecule
VLA	Very late antigen

31 Epilepsy

Timothy E. Welty and Edward Faught

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures and epilepsy.
4. Differentiate and classify seizure types given a description of the clinical presentation of the seizure and electroencephalogram.
5. Identify key therapeutic decision points and therapeutic goals in the treatment of epilepsy.
6. Discuss nonpharmacologic treatments for epilepsy.
7. Recommend an appropriate pharmacotherapeutic regimen with monitoring parameters for the treatment of epilepsy.
8. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
9. Manage potential drug interactions with antiepileptic drugs (AEDs).
10. Determine when and how to discontinue AED therapy.
11. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

EPIDEMIOLOGY

LO 1

Epilepsy is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted prevalence of approximately 4 to 7 cases per 1000 persons.[1] The incidence of epilepsy in the United States is estimated at 35 to 75 cases per 100,000 persons per year.[2,3] In developing countries, the incidence is higher at 100 to 190 cases per 100,000 persons per year. About 8% of the US population will experience a **seizure** during their lifetime. New-onset seizures occur most frequently in infants younger than 1 year and in adults after age 55.[2]

SOCIAL IMPACT

LO 1

Epilepsy has a profound impact on a patient's life. Due to restrictions on driving, individuals who have recently had a seizure face major impediments to engaging in simple activities.[4] Fifty percent of patients with epilepsy report cognitive and learning difficulties.[5,6] Underemployment and unemployment are major concerns for individuals with epilepsy, due to limited transportation options, cognitive and learning difficulties, and seizures, resulting in problems paying for health care. Additionally, the social stigma of embarrassment or injury due to seizures in public results in isolation of the patient.[7]

Patients with epilepsy often depend on caregivers to assist with medications, transportation, and ensuring the patient's safety, so they should be informed about treatments and managing seizures.

ETIOLOGY

In approximately 80% of patients with epilepsy, the underlying etiology is unknown.[8] The most common causes of epilepsy are head trauma and stroke. Developmental and identifiable genetic defects cause about 5% of cases. Genetic causes are presumed in up to 25% of patients but are often unproven. Brain tumors, central nervous system (CNS) infections, and neurodegenerative diseases are other common causes. Human immunodeficiency virus infection and neurocysticercosis infection are also important causes.

Isolated seizures can be caused by stroke, CNS trauma, CNS infections, metabolic disturbances (eg, hyponatremia, hypoglycemia), and hypoxia. Failure to correct these causes may lead to the development of epilepsy. Drugs commonly associated with causing seizures are tramadol, bupropion, theophylline, select antidepressants and antipsychotics, amphetamines, cocaine, imipenem, lithium, excessive doses of penicillins or cephalosporins, and sympathomimetics or stimulants.

PATHOPHYSIOLOGY

Seizures

LO 3

Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In individual patients, it is usually impossible to identify which neurochemical factors are responsible.

Neurotransmitters

The primary excitatory neurotransmitter is glutamate.[9] When glutamate is released from a presynaptic neuron, it attaches to postsynaptic receptors. The result is opening of membrane

channels allowing sodium or calcium to flow into the neuron, depolarizing it and transmitting an excitatory signal.[10] Many antiepileptic drugs (AEDs) (eg, phenytoin, carbamazepine, lamotrigine) work by blocking the release of glutamate or blocking sodium or calcium channels.[11] At usual doses, these drugs only halt the excessive rapid neuronal firing characteristic of seizures, and do not affect normal brain function.

The primary inhibitory neurotransmitter is **γ-*aminobutyric acid* (GABA)**. It attaches to neuronal membranes and opens chloride channels. Chloride flow into the neuron causes hyperpolarization and less excitability. This mechanism is probably critical for suppressing seizure activity. Barbiturates and benzodiazepines primarily enhance the action of GABA.

Cortical function is modulated by many other neurotransmitters, but their role in epilepsy is poorly understood.

Neuronal Mechanisms

Seizures originate in a group of neurons with abnormal electrical behavior, presumably due to an imbalance of neurotransmitter function.[11] In individual neurons, firing is excessively prolonged and repetitive. Instead of firing a single action potential, these neurons stay depolarized too long, firing many action potentials. This long, abnormal depolarization is called a *paroxysmal depolarizing shift (PDS)*.

Excessive electrical discharges can spread to adjacent neurons or distant ones connected by fiber tracts.[12] The seizure spreads to other areas by recruiting neurons into uncontrolled firing patterns. Recruited neurons may be normal but are diverted from their normal functioning to participate in the excessive discharges. The area of spread determines the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously, because inhibitory mechanisms overcome abnormal excitation.

Epilepsy

LO 2

Epilepsy is a disease where individuals have at least 2 unprovoked seizures more than 24 hours apart, 1 unprovoked seizure with at least a 60% probability of another seizure in the next 10 years, or diagnosis of an epilepsy syndrome.[13] Practically, this implies a permanent change in cortical function, rendering neurons more likely to participate in a seizure discharge, epileptogenesis.

Epilepsy may develop days, months, or years after a brain insult. A small group of abnormal neurons causes adjacent or connected normal neurons to gradually become abnormal. When a network of abnormal neurons becomes sufficiently large, it causes an excessive firing pattern for at least several seconds: a seizure. This hyperexcitable network of neurons is the seizure focus.

If the change in cortical electrical characteristics is permanent, why do seizures not occur all the time? The occurrence of an individual seizure depends on an interplay of environmental and internal brain factors that intermittently result in loss of the normal mechanisms that control abnormal neuronal firing. It is impossible to determine what triggers a specific seizure.

Epilepsy may remain stable, decrease in severity, or worsen over time. Repeated seizures may cause further damage to the cortex and loss of neurons. Reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections.

Epilepsy is associated with an increased mortality rate, from injuries with seizures or sudden death.[14] Early control of epileptic seizures may reduce permanent changes in brain function, although this hypothesis is unproven.

Genetic Factors

Patients with seizures may be concerned that their children or other family members will inherit epilepsy. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit epilepsy. Most patients with inherited epilepsy have generalized onset epilepsy, and develop seizures during childhood.[15,16] Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to occur in offspring. Most patients can be reassured that their children and siblings are unlikely to develop epilepsy.

SEIZURE CLASSIFICATION AND PRESENTATION

General Principles

Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. The International League Against Epilepsy (ILAE) recently revised the classification of seizures (**Table 31–1**).[17] The new system integrates the concept of onset of seizures with their clinical presentation. Classification of epileptic seizures emphasizes electroencephalographic (EEG) findings combined with the clinical symptoms of the seizure events. Clinical presentation of seizures varies widely depending on the region and the amount of brain involved in the seizure.

LO 4

Generalized Seizures

If the entire cerebral cortex is involved in the seizure from the onset, the seizure is classified as **generalized seizures**. There are multiple types of generalized seizures. Two major categories of generalized seizures are motor, seizures that involve involuntary muscle activity, and nonmotor, seizures without involuntary muscle activity. In these seizures, the EEG demonstrates involvement of the entire brain from the onset of the seizure.

Focal Seizures

When the seizure begins in a localized area of the brain, it is defined as **focal seizures**. There are two main types of focal seizures, aware or impaired awareness. Focal seizures can be further categorized as motor and nonmotor. The EEG demonstrates that the seizure begins in a small region of the brain. Additionally, focal seizures can spread to involve the entire brain.

Unknown-Onset Seizures

Individuals whose seizures are classified as **unknown-onset** have seizures where the distinction between generalized and focal cannot be made. In these seizures, the EEG is unclear as to the start of the seizure.

Epilepsy Syndromes

Currently, there are no officially recognized epilepsy syndromes. Epilepsy syndromes that are often described in publications include **juvenile myoclonic epilepsy (JME)**, **Lennox–Gastaut syndrome (LGS)**, **mesial temporal lobe epilepsy (MTLE)**, **severe myoclonic epilepsy of infancy (SMEI)**, and **infantile spasms (West syndrome)**.

Table 31–1

ILAE 2017 Classification of Seizure Types[17]

Focal Onset[a,b]				
Aware[c]	Impaired Awareness[d]	Generalized Onset[a,g]	Unknown Onset	Unclassified
Motor		**Motor**	**Motor**	
Automatisms		Tonic-clonic	Tonic-clonic	
Atonic[e]		Clonic	Epileptic spasms	
Clonic		Tonic	**Nonmotor**

[a]The word "onset" is assumed when the seizure type begins with focal, generalized, or absence.

[b]Formerly partial seizures.

[c]Formerly simple partial seizures.

[d]Formerly complex partial seizures.

[e]Do not have a level of awareness specified.

[f]Formerly secondary generalized seizures.

[g]Formerly primary generalized seizures.

[h]Formerly absence seizures.

DIAGNOSIS

A correct and accurate diagnosis is essential prior to starting pharmacotherapy. KEY CONCEPT A distinction between a single seizure and epilepsy must be made, and other seizure-like disorders (eg, syncope, psychogenic, nonepileptic events, anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic attacks, tics, and complicated migraine headaches) should be ruled out. Seizures are typically brief spells, lasting less than 5 minutes. However, prolonged seizures lasting greater than or equal to 5 minutes or occurring one after another without recovery in between are status epilepticus, which requires immediate medical attention (Chapter 32).

A proper diagnostic workup of a patient presenting with seizures includes the following elements:

- Complete neurologic examination
- EEG
- Laboratory tests (complete blood count [CBC], complete serum chemistry which includes liver function tests [LFTs])
- Neuroimaging (preferably magnetic resonance imaging [MRI])

Many of the tests are done to rule out other causes of seizures (eg, infection, electrolyte imbalance), and in most patients will be normal. Often the EEG appears normal between seizures. Sleep deprivation, photic stimulation, prolonged (> 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation can be done to capture seizure or seizure-like activity on the EEG.

TREATMENT

Desired Outcomes

LOS The ultimate outcome goal for any patient with epilepsy is the elimination of all seizures without adverse effects from treatment. An effective treatment plan allows the patient to live a normal lifestyle with complete control of seizures. The treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, 30% to 50% of patients are not able to fully achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure frequency and/or severity and medication adverse effects, enabling the individual to have a lifestyle as nearly normal as possible.

General Approach to Treatment

Once it is concluded that the patient has epilepsy, the type of seizure must be determined.

KEY CONCEPT Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types. Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

KEY CONCEPT Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure. If there is an underlying treatable cause, such as hyponatremia or a CNS infection, the risks of another seizure and the development

Clinical Presentation and Diagnosis of Epilepsy

General

Typically, health care providers are not able to observe a patient's seizures, and for most types of seizures, the patient has no memory of the event. It is important to obtain a careful history from the patient and any individuals who witness the seizures.

Common Descriptions of Seizures

The clinical presentation of seizures varies from patient to patient depending on the portion of brain involved in the seizure. Events tend to be stereotypical for an individual patient.

Patients who experience seizures may complain of paroxysmal spells of

- Blanking-out spells, lapses in memory, periods of altered consciousness
- Warnings or auras consisting of various sensations or automatic, uncontrolled movements
- Daydreaming
- Jerks, shoulder shrugs, sudden chills of spine
- Falling out

Associated Symptoms

- Incontinence, usually of urine
- Tongue biting
- Traumatic injuries, usually associated with falling during a seizure

Diagnosis

Description of events: The patient and any witnesses to the seizures should be carefully interviewed to obtain a full and complete description of typical seizures.

Neurologic examination: Usually, the neurologic physical examination is completely normal. Any neurologic deficits identified should be fully investigated because seizures do not usually cause permanent, detectable neurologic deficits.

Electroencephalogram (EEG): A routine EEG can be helpful if epileptiform discharges are seen. However, the EEG may be normal between seizures, and most routine EEGs are not performed during a seizure. Maneuvers such as sleep deprivation, photic stimulation, hyperventilation, or prolonged monitoring can help expose EEG changes consistent with epilepsy.

Neuroimaging (preferably an MRI of the brain): Imaging of the brain is important to rule out obvious causes of seizures such as stroke or tumors. An MRI scan is also helpful in detecting mesial temporal sclerosis, a finding often associated with mesial temporal epilepsy and predictive of positive surgical outcomes.

Video EEG monitoring: A procedure consisting of continuous video monitoring of the patient with a simultaneous EEG. Usually a patient is monitored in the hospital for 4 to 5 days. This procedure is used to determine if the patient is truly having seizures, to determine the specific type of seizures the patient is having, and to localize the area of the brain that is the origin of the seizures.

of epilepsy are very small. In these cases, the only necessary pharmacotherapy is to correct the underlying problem and possibly use an AED short-term. Risk factors for repeated seizures in patients without an underlying disorder include[18]

- Structural CNS lesion
- Abnormal EEG
- Partial seizure type
- Positive family history
- Postictal motor paralysis

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%. If the estimated risk is over 70%, an epilepsy diagnosis is plausible. When sufficient evidence is available to determine the patient has seizures and is at risk for another seizure, pharmacotherapy is usually started (Table 31–2). The patient or caregiver should be in agreement with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects. KEY CONCEPT Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential drug interactions are key elements in selecting a medication. Other patient factors such as gender, concomitant drugs, age, economic factors, and lifestyle also need to be considered.

Nonpharmacologic Therapy

LO 6

Nonpharmacologic treatments for epilepsy include surgery, vagal nerve stimulation, and dietary modifications. For some patients, surgery is the treatment approach with the greatest probability of eliminating seizures. The most common surgery for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure free.[19] Other surgical procedures that are less likely to make a patient seizure free include corpus callosotomy and extratemporal lesion removal.

Vagal nerve stimulation is another nonpharmacologic approach to treating all types of seizures.[20] The unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck and delivers a small electrical stimulus to the vagus nerve. This efficacy of this treatment is essentially equivalent to starting a new medication, with fewer than 10% of refractory patients becoming seizure free. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates. Finally, deep brain stimulation devices are approved for individuals with seizures refractory to other treatments. Some AED therapy is usually continued in patients with devices.

Another nonpharmacologic treatment is the ketogenic diet.[21] This diet produces a keto-acidotic state through the elimination of nearly all carbohydrates. The diet consists of high dietary fats (eg, butter, heavy cream, fatty meats) and low protein with no added sugar. Daily urinalysis for ketones is performed to ensure the patient remains in ketosis. Any inadvertent consumption of sugar results in the diet needing to be reinitiated. Clinicians must be vigilant in maintaining the diet, by determining the sugar or

Table 31–2

Evidence-Based Selection of Antiepileptic Drugs for Initial Monotherapy Treatment of Epilepsy[a]

Seizure Type	Drugs
Generalized onset: Motor	Carbamazepine (except myoclonic) Lamotrigine Levetiracetam Oxcarbazepine (except myoclonic) Perampanel Phenobarbital Phenytoin Topiramate Valproate
Generalized onset: Nonmotor (Absence)	Clobazam Clonazepam Ethosuximide (preferred) amotrigine Topiramate Valproate Zonisamide
Focal onset: Motor and nonmotor	Carbamazepine Gabapentin Lamotrigine Levetiracetam Oxcarbazepine Phenobarbital Phenytoin Topiramate Valproate

Efficacy and tolerability of the new antiepileptic drugs I: treatment of new onset epilepsy report of the Therapeutics and Technology Assessment Subcommittee and Quality Standards Subcommittee of the American Academy of Neurology and the American Epilepsy Society. Neurology. 2005;62:1252–1260.

carbohydrate content of medications the patient is taking. This diet is typically used only in children with difficult-to-control seizures. In certain patients, the diet can be extremely effective, resulting in complete seizure control and reduction of AEDs. However, it is difficult to maintain, and palatability of the diet, growth retardation, and hypercholesterolemia are concerns. Less stringent diets, such as a modified Adkins diet, may produce seizure control similar to a rigorous ketogenic diet.

Pharmacologic Therapy

▶ *Special Considerations*

Use of AEDs presents some unique challenges due to their pharmacokinetic and pharmacodynamic properties.

Michaelis–Menten Metabolism Phenytoin metabolism is capacity limited. Michaelis–Menten pharmacokinetics occurs when the maximum capacity of hepatic enzymes to metabolize the drug is reached within the normal dose range. The clinical significance is that small changes in doses result in large changes in serum concentrations. Too large a dose change may result in concentration-related toxicity or breakthrough seizures. Individual differences in metabolism result in differing relationships between dose and serum concentrations. These differences can be defined only by careful use of serum concentration and dosing data. There are numerous schemes for determining appropriate dosage adjustments of phenytoin, but for routine clinical practice, dosage adjustments for adults with normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan:

- For serum concentrations less than 7 mcg/mL (mg/L; 28 μmol/L), the total daily dose is increased by 100 mg.
- For serum concentrations of 7 to 12 mcg/mL (mg/L; 28–48 μmol/L), the total daily dose is increased by 50 mg.
- For serum concentrations more than 12 mcg/mL (mg/L; 48 μmol/L), the total daily dose is increased by no more than 30 mg.[22]

Protein Binding Some AEDs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember the value represents the total (ie, bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different.

Normally, 88% to 92% of phenytoin is bound to plasma protein, leaving 8% to 12% as unbound. The unbound component produces the clinical effect in the CNS, produces dose-related side effects in the CNS and at other sites, distributes to other peripheral sites, and gets metabolized. Certain patient groups have decreased protein binding, resulting in an increased unbound percentage of drug. These patient groups include:

- Those with kidney failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care settings

Due to the Michaelis–Menten metabolism of phenytoin, alterations in its protein binding result in increased concentration-related adverse effects. In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is less compared with phenytoin. Michaelis–Menten metabolism is not a factor with valproate, so hepatic enzymes are able to efficiently metabolize the additional unbound portion.

Autoinduction Carbamazepine is a potent inducer of hepatic microsomal enzymes. It increases the rate of metabolism for many other drugs, and the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (Table 31–3). Most dosage regimens for carbamazepine use a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg/day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose reduces the risk for severe dose-related adverse effects.

▶ *Drug Selection and Seizure Type*

LO 7 The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment

Patient Encounter 1: New-Onset Seizures

MN, a 22-year-old man, is seen by his physician due to a series of unexplained episodes. He has no memory of these events. Friends say that he stares, speaks incoherently, and fumbles with his clothes.

His physical examination is completely normal, and no focal neurologic deficits were observed. An MRI was ordered and reported as left mesial temporal sclerosis. An EEG shows occasional left frontal temporal spike waves.

What additional information is needed to make a decision about pharmacotherapy?

How should this information be used to make choices concerning AED therapy?

He remembers several weeks ago that when he woke up in the morning, his muscles ached all over and there was some blood in his mouth and on his pillow.

Is pharmacotherapy indicated?

If it is indicated, what drug should be used and how should it be started?

What adverse effects are important to monitor?

Six months later, he still is having 1 to 2 episodes a month of similar symptoms.

What adjustments in pharmacotherapy should be made at this point?

Is it possible for him to discontinue AED therapy at some time in the future?

guidelines from the Scottish Intercollegiate Guidelines Network (SIGN), the National Institute for Clinical Excellence (NICE) in the United Kingdom, the American Academy of Neurology (AAN), and ILAE all link seizure type to the selection of pharmacotherapy (Table 31–2).[23–26] Table 31–2 summarizes recommendations from these treatment guidelines and US Food and Drug Administration (FDA) approved indications.

For initial treatment of absence seizures, ethosuximide is preferred. In absence and myoclonic seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided due to association with worsening of these seizure types.

KEY CONCEPT AED therapy should usually be initiated carefully using a titration schedule to minimize adverse events. Moderate target doses are chosen until the patient's response can be further evaluated in the clinic. If seizures continue, the dose is increased gradually until the patient becomes seizure free or adverse effects appear. For some drugs like lamotrigine, specific titration guidelines are established by the manufacturer.

Treatment of refractory seizures (ie, unresponsive to at least two first-line AEDs) is somewhat different. Combinations of drugs may be useful in patients with difficult to control seizures. All AEDs, except ethosuximide, are effective in combination therapy for partial seizures.

▶ Complications of Pharmacotherapy

LO 10

Adverse effects of AEDs are frequently dose limiting or cause a drug to be discontinued. Two types of adverse effects occur with AEDs: serum concentration-related and idiosyncratic (Table 31–3). Concentration-related adverse effects occur with increasing frequency and severity as the dose or serum concentration of a drug is increased. Common concentration-related adverse effects include sedation, ataxia, and diplopia. Adverse effects should be considered in the selection of AED. For example, if a patient has a job that requires mental alertness, it is best to choose an AED that is less likely to cause sedation (eg, lamotrigine, levetiracetam).

Idiosyncratic adverse effects are not dose or concentration related and almost always result in the AED being discontinued. Typically, these types of reactions will occur during the first 6 to 12 months of taking the AED. Rash is the most common of these. Prior to initiating carbamazepine, genetic testing for human leukocyte antigen (HLA) HLA-B*1502 and HLA-A*3101 should be done. Polymorphisms of these HLA genes are associated with increased risk of severe skin reactions in patients of Asian descent. Likewise with phenytoin, genetic polymorphisms of HLA-B*1502 and the CYP 2C9*3 have been associated with increased risk of severe skin reactions. Severe skin, hepatic, or hematological reactions occur rarely, but are potentially life-threatening. The AED should be discontinued immediately when these reactions occur. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause reactions. There is a possibility of cross-reactivity for these adverse effects, especially for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine.

▶ Chronic Adverse Effects

Because AEDs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects associated with AEDs include peripheral neuropathy and cerebellar atrophy. Other chronic adverse effects are extensions of acute adverse effects, for example, weight gain.

Osteoporosis is a major chronic adverse effect of several drugs.[27,28] Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate decrease bone mineral density, after 6 months of treatment. The risk of osteoporosis due to chronic AED use is comparable to the risk with chronic use of glucocorticosteroids. Patients taking carbamazepine, oxcarbazepine, phenytoin, phenobarbital, or

Patient Encounter 2: Managing Chronic Adverse Reactions

JP, a 45 year-old woman, has been taking oxcarbazepine 600 mg/day for 15 years. Her seizures are well controlled on this regimen, and she works as a public health nurse. She expresses concern about taking the oxcarbazepine for so long.

What chronic adverse effects are important to monitor in this patient?

How should monitoring for these adverse effects be done?

What measures can be taken to prevent these adverse effects?

Table 31–3

Characteristics of Common AEDs

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Brivaracetam (Briviact)	Modulate synaptic vesicle protein 2A	*Maintenance Dose*: 50–100 mg twice daily	*Half-life*: 9 hours *Apparent volume of distribution*: 0.5 L/kg *Protein binding*: 17.5% *Primary elimination route*: Hepatic	Not established	Ataxia, dizziness, fatigue, somnolence	Angioedema, bronchospasm, suicidal behavior and ideation,
Carbamazepine (Tegretol and generic, Tegretol XR, generic), Carbatrol, Epitol, Equetro	Fast sodium channel inactivation	*Maintenance dose*: Titrate dosage to target over 3–4 weeks Adults: 800–1200 mg/day in divided doses Children: 20–30 mg/kg/day as a divided dose Intravenous: Indicated for oral replacement therapy at 70% of the total oral maintenance dose divided into four equal doses given every 6 hours	*Half-life*: 10–25 hours with chronic dosing *Apparent volume of distribution*: 0.8–1.9 L/kg *Protein binding*: 67%–81% *Primary elimination route*: Hepatic	4–12 mcg/mL (mg/L; 17–51 µmol/L)	Diplopia, drowsiness, nausea, sedation	Aplastic anemia, hyponatremia, leukopenia, osteoporosis, rash
Clobazam (Onfi)	Enhance GABA	Weight < 30 kg, start 5 mg/day, titrate to 20 mg/day in divided doses Weight > 30 kg start 10 mg/day in divided doses, titrate to 40 mg/day in divided doses CYP 2C19 poor metabolizers: start 5 mg/day, titrate to 10–20 mg/day, maximum dose 40 mg/day	*Half-life*: 10–50 hours *Apparent volume of distribution*: ~0.9 L/kg *Protein binding*: ~90% *Primary elimination route*: Hepatic; metabolized to active metabolite that is further metabolized by CYP 2C19	Not established	Sedation, somnolence, lethargy, pyrexia, irritability, drooling, aggression	
Clonazepam (Klonopin, generic)	Enhance GABA activity	*Maintenance dose*: Initiate at 0.5 mg one to three times daily, titrate dose to effectiveness, usually 3–5 mg daily in two or three divided doses Pediatric dosing in children < 10 years or < 30 kg: Initiate at 0.01–0.03 mg/kg/day in 2–3 divided doses, titrate dose to effectiveness	*Half-life*: 30–40 hours *Apparent volume of distribution*: 3.2 L/kg *Protein binding*: 47%–80% *Primary elimination route*: Hepatic	Not established	Ataxia, memory impairment, sedation, slowed thinking	
Eslicarbazepine (Aptiom)	Fast sodium channel inactivation	*Maintenance dose*: Adults: Initiate at 400 mg daily and titrate in increments of 400–600 mg daily to a maintenance dose of 800–1600 mg daily Pediatrics: Initial, incremental increases, and maintenance dose based on body weight	*Half-life*: 13–20 hours in adults *Apparent volume of distribution*: 0.85–0.9 L/kg *Protein binding*: < 40% *Primary route of elimination*: Renal	Not established	Ataxia, dizziness, diplopia, drowsiness, sedation, nausea, vomiting	

(*Continued*)

Table 31–3

Characteristics of Common AEDs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Ethosuximide (Zarontin, generic)	Modulate calcium channels	*Maintenance dose*: Initiate at 250 mg twice daily and titrate to 500–1000 mg twice daily	*Half-life*: 60 hours *Apparent volume of distribution*: 0.6–0.7 L/kg *Protein binding:* None *Primary elimination route*: Hepatic	40–100 mcg/mL (mg/L; 283–708 µmol/L)	Ataxia, sedation	Hepatotoxicity, neutropenia, rash
Felbamate (Felbatol)	Inhibit glutamate activity	*Maintenance dose*: 1200–3600 mg/day in three or four divided doses	*Half-life*: Monotherapy: 20 hours Concurrent enzyme inducers: 11–16 hours *Apparent volume of distribution*: 0.7–0.8 L/kg *Protein binding*: 25%–35% *Primary elimination route*: Hepatic	Not established	Anxiety, insomnia, nausea	Anorexia, aplastic anemia, headache, hepatotoxicity, weight loss
Gabapentin (Neurontin, generic)	Modulate calcium channels and enhance GABA activity	*Maintenance dose*: Adults: 900–3600 mg/day in three or four divided doses Pediatrics: Age 3–4 Initial dose 10–15 mg/kg/day, titrate to a maximum of 50 mg/kg/day divided in divided three doses; age 5–11 initial dose 10–15 mg/kg/day titrate to maximum of 50 mg/kg/day in three divided doses; age > 12 Initial dose 300 mg thrice daily titrate to a maximum of 360 mg/day divided in three doses Renal dosing: CrCl 30–50 mL/min (0.50–0.84 mL/s) decrease by 25% and give twice daily; CrCl 10–29 mL/min (0.17–0.49 mL/s) decrease dose by 25% and give once daily; CrCl < 10 mL/min (0.17 mL/s) decrease dose 25% and give every other day	*Half-life*: 5–7 hours (proportional to creatinine clearance) *Apparent volume of distribution*: 0.6–0.8 L/kg *Protein binding*: < 10% *Primary elimination route*: Renal	Not established	Drowsiness, sedation	Peripheral edema, weight gain

Lacosamide (Vimpat)	Slow sodium channel inactivation; modulate collapsin response; mediator protein-2	*Maintenance dose*: 200–400 mg/day; start at 100 mg/day in two divided doses and titrate upward according to response	*Half-life*: Approximately 13 hours *Volume of distribution*: 0.6 L/kg *Protein binding*: < 15% *Primary elimination route*: 40% renal 60% hepatic	Not established	Ataxia, dizziness, diplopia, headache, nausea, vomiting	PR interval prolongation
Lamotrigine (Lamictal, Lamictal XR, generic)	Fast sodium channel inactivation	*Initial dose*: With valproate 25 mg every other day for 2 weeks, then 25 mg daily for 2 weeks, then 25 mg twice daily for a week, increase by 25 mg/day every week until maintenance dose of 150 mg/day is achieved; without enzyme inhibitor or inducer 25 mg daily for 2 weeks, then 25 mg twice daily for 2 weeks, then increase by 25 mg daily every week maintenance dose of at least 200 mg/day is achieved; with enzyme inducer 25 mg twice daily for 2 weeks, then 50 mg twice daily for 2 weeks, then increase by 100 mg/day every week until maintenance dose of 300–500 mg/day is achieved *Maintenance dose*: 150–800 mg/day in two or three divided doses Pediatric: age 2–12 with valproate 0.15 mg/kg/day for 2 weeks, then 0.3 mg/kg/day for 2 weeks, then increase by 0.3 mg/kg/day every week until maintenance dose of 1–5 mg/kg/day achieved; without inhibitor or inducer 0.3 mg/kg/day for 2 weeks, then 0.6 mg/kg/day for 2 weeks, then increase by 0.6 mg/kg/day weekly until maintenance dose of 4.5–7.5 mg/kg/day achieved; with inducer 0.6 mg/kg/day in two divided doses for 2 weeks, then 1.2 mg/kg/day in two divided doses for 2 weeks, then increase by 1.2 mg/kg/day weekly until maintenance dose of 5–15 mg/kg/day is achieved	*Half-life*: Monotherapy: 24 hours Concurrent enzyme inducers: 12–15 hours Concurrent enzyme inhibitors: 55–60 hours *Apparent volume of distribution*: 1.1 L/kg *Protein binding*: 55% *Primary elimination route*: Hepatic	Not established	Ataxia, drowsiness, headache, insomnia, sedation	Rash

(*Continued*)

Table 31–3

Characteristics of Common AEDs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Levetiracetam (Keppra, Keppra XR, generic)	Modulate synaptic vesicle protein	*Adult Maintenance dose*: 1000–3000 mg/day. Start at 1000 mg/day and titrated upward as indicated by response *Pediatric*: 1–6 months 7 mg/kg twice daily titrate by 7 mg/kg twice daily every 2 weeks to maintenance dose of 21 mg/kg twice daily; 6 months to 4 years 10 mg/kg twice daily then increase by 10 mg/kg twice daily every 2 weeks to maintenance dose of 25 mg/kg twice daily; 4–16 years 10 mg/kg twice daily then increase by 30 mg/kg twice daily Renal failure: CrCl 50–80 mL/min (0.84–1.33 mL/s) 500–1000 mg twice daily, CrCl 30–50 mL/min (0.50–0.84 mL/s) 250–750 mg twice daily, CrCl < 30 mL/min (0.50 mL/s) 250–500 mg twice daily, End stage on dialysis 500–1000 mg daily	*Half-life*: 6–8 hours *Apparent volume of distribution*: 0.5–0.7 L/kg *Protein binding*: < 10% *Primary elimination route*: 70% renal 30% hepatic	Not established	Somnolence, dizziness	Depression
Perampanel (Fycompa)	Antagonist of glutamate receptors on postsynaptic neurons	*Maintenance dose*: without CYP3A4 inducers 8–12 mg once daily. Start at 2 mg once daily, increase by 2 mg/day increments to desired response With CYP3A4 inducers Start at 4 mg once daily, increase by 2 mg/day increments to desire response with maximum dose of 12 mg daily	*Half-life*: 105 hours *Apparent volume of distribution*: 0.7–1.5 L/kg *Protein binding*: 95%–96% *Primary elimination route*: Hepatic	Not established	Ataxia, dizziness, drowsiness, somnolence	Suicidal behavior and ideation, agitation, hostility, aggression, hypersensitivity reactions
Oxcarbazepine (Trileptal, generic)	Fast sodium channel inactivation	*Maintenance dose*: 600–1200 mg/day. Start at 300 mg twice daily and titrated upward as indicated by response Pediatric dosing *Maintenance dose*: 20 kg 300–450 mg twice daily; 25–30 kg 450–600 mg twice daily; 35–40 kg 450–750 mg twice daily; 40–50 kg 600–750 mg twice daily; 50–55 kg 600–900 mg twice daily; 60–65 kg 600–1050 mg twice daily Renal failure dosing CrCl < 30 mL/min (0.50 mL/s) starting dose of 150 mg twice daily and titrate at a slower rate to desired effect	*Half-life*: *Parent drug*: Approximately 2 hours *10-monohydroxy metabolite*: Approximately 9 hours *Apparent volume of distribution*: 0.5–0.7 L/kg *Protein binding*: 40% *Primary elimination route*: Hepatic	Not established	Diplopia, dizziness, somnolence	Hyponatremia, 25%–30% cross-sensitivity in patients with hypersensitivity to carbamazepine

Phenobarbital (Luminal, generic) Primidone (Mysoline, generic) gets metabolized to phenobarbital	Fast sodium channel inactivation	*Loading dose*: 10–20 mg/kg as single or divided IV infusion or orally in divided doses over 24–48 hours *Maintenance dose*: Adults: 1–4 mg/kg/day as a single or divided dose Children: 3–6 mg/kg/day as divided dose Neonates: 1–3 mg/kg/day as divided dose	*Half-life*: Adults: 49–120 hours Children: 37–73 hours Neonates: approximately 115 hours *Volume of distribution*: 0.7–1 L/kg *Protein binding*: Approximately 50% *Primary elimination route*: Hepatic	15–40 mcg/mL (mg/L; 65–172 µmol/L)	Ataxia, drowsiness, sedation	Attention deficit, cognitive impairment, hyperactivity, osteoporosis, passive-aggressive behavior
Phenytoin (Dilantin, Phenytek, generic)	Fast sodium channel inactivation	*Loading dose*: Adults: 15–20 mg/kg single IV dose or divided oral dose Infants younger than 3 months: 10–15 mg/kg single IV dose Neonates: 15–20 mg/kg single IV dose *Maintenance dose*: Adults: 5–7 mg/kg/day, as single or divided dose Children: 6–15 mg/kg/day, as divided dose Neonates: 3–8 mg/kg/day, as divided dose	*Half-life*: Follows capacity-limited or Michaelis–Menten pharmacokinetics. Half-life increases as the dose and serum concentration increases. *Volume of distribution*: Adults: 0.7 L/kg Children: 0.8 L/kg Neonates: 1.2 L/kg *Protein binding*: adults, children: 88%–92% Neonates: 65% *Primary elimination route*: Hepatic	10–20 mcg/mL (mg/L; 40–79 µmol/L) total concentration 1–2 mcg/mL (mg/L; 4–8 µmol/L) unbound concentration	Ataxia, diplopia, drowsiness, sedation	Anemia, gingival hyperplasia, hirsutism, lymphadenopathy, osteoporosis, rash
Pregabalin (Lyrica)	Modulate calcium channels	*Maintenance dose*: Initiate at 150 mg/day in two or three divided doses and titrate to a maximum dose of 600 mg/day Renal failure dosing CrCl > 60 mL/min (1.0 mL/s) 150–600 mg / day in 2–3 divided doses; CrCl 30–60 mL/min (0.50–1.0 mL/s) 75–300 mg/day in 2–3 divided doses; CrCl 15–30 mL/min (0.25–0.50 mL/s) 25–150 mg/day in 1–2 divided doses; CrCl < 15 mL/min (0.25 mL/s) 25–75 mg/day	*Half-life*: 6.3 hours, proportional to creatinine clearance *Apparent volume of distribution*: 0.5 L/kg *Protein binding*: Negligible *Primary elimination route*: Renal	Not established	Ataxia, blurred vision, dizziness, dry mouth, somnolence	Edema, weight gain

(*Continued*)

Table 31–3

Characteristics of Common AEDs *(Continued)*

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Rufinamide (Banzel)	Unknown, may enhance inactivation of sodium channels	*Maintenance dose*: Adults: 3200 mg/day; start at 400–800 mg/day in two divided doses and titrate upward according to response Children: 45 mg/kg/day or 3200 mg/day; start at 10 mg/kg/day in two divided doses and titrate upward according to response	*Half-life*: 6–10 hours *Apparent volume of distribution*: Approximately 0.7 L/kg, varies with dose *Protein binding*: 34% (27% to albumin) *Primary elimination route*: Hepatic	Not established	Dizziness, fatigue, headache, nausea, somnolence, vomiting	
Tiagabine (Gabitril, generic)	Enhance GABA activity	*Maintenance dose*: With concomitant hepatic enzyme inducers Initiate with 4 mg/day for 1 week, increase weekly by 4–8 mg/day in 2–3 divided doses with maximum dose of 56 mg/day Without concomitant hepatic enzyme inducers Initiate with 2–4 mg/day for 1 week, increase weekly by 2–4 mg/day to maintenance dose of 12–22 mg/day in 2–3 divided doses Pediatric dosing Age > 12 Initiate with 4 mg/day for 1 week, then 4 mg twice daily for 1 week, then titrate by 4–8 mg/day in 2–4 divided doses with maximum dose of 32 mg/day	*Half-life*: Monotherapy: 7–9 hours Concurrent enzyme inducers: 2.5–4.5 hours *Apparent volume of distribution*: 0.6–0.8 L/kg *Protein binding*: 96% *Primary elimination route*: Hepatic	Not established	Dizziness, somnolence, irritability, slowed thinking	
Topiramate (Topamax, generic) Qudexy, Trokendi, Topiragen	Fast sodium channel inactivation, inhibit glutamate activity, enhance GABA activity	*Maintenance dose*: 100–400 mg/day in two or three divided doses. Doses should be started at 25–50 mg/day and gradually titrated upward over 3–6 weeks to avoid excessive adverse effects Pediatric dosing Ages 2–16 Initiate at 5–9 mg/kg/day in two divided doses for 1 week, then titrate by 1–3 mg/kg/day every 1–2 weeks to desired response maximum dose of 400 mg/day	*Half-life*: Monotherapy: 21 hours Concurrent enzyme inducers: 11–16 hours *Apparent volume of distribution*: 0.55–0.8 L/kg *Protein binding*: 13%–17% *Primary elimination route*: 60% renal 40% hepatic	Not established	Ataxia, dizziness, drowsiness, slowed thinking	Acute glaucoma, metabolic acidosis, oligohidrosis, paresthesia, renal calculi, weight loss

Valproic acid/ divalproex sodium (Depakene, Depakote, Depakote ER, Depacon, generic), Stavzor	Fast sodium channel inactivation	*Loading dose*: 20–40 mg/kg *Maintenance dose*: Adults: 15–45 mg/kg/day in two to four divided doses Pediatric dosing: 5–60 mg/kg/day in two to four divided doses Do not administer to children < 2 years of age Doses of extended release products should be 8%–20% higher than immediate release products	*Half-life*: Adults: 8–15 hours Children: 4–15 hours Infants younger than 2 months: 65 hours *Volume of distribution*: 0.1–0.5 L/kg *Protein binding*: 90% (decreases with increasing serum concentrations) *Primary elimination route*: Hepatic	50–100 mcg/mL (mg/L; 346–693 µmol/L) Children may require concentrations up to 150 mcg/mL (mg/L; 1040 µmol/L)	Drowsiness, nausea, sedation, tremor	Hepatotoxicity, osteoporosis, pancreatitis, weight gain
Vigabatrin (Sabril)	Inhibits GABA transaminase	*Adults*: Initiate at 1000 mg/day in two divided doses, titrate up to 3000 mg/day *Children*: 1 month–2 years: 50 mg/kg/day in two divided doses *Renal failure*: CrCl 50–80 mL/min (0.84–1.33 mL/s), decrease dose by 25%; CrCl 30–50 mL/min (0.50–0.84 mL/s), decrease dose by 50%; CrCl 10–30 mL/min (0.17–0.50 mL/s), decrease dose by 75%	*Half-life*: 7.5 hours, proportional to creatinine clearance *Volume of distribution*: 1.1 L/kg *Protein binding*: negligible *Primary route of elimination*: Renal	Not established	Convulsion, dizziness, headache, nasopharyngitis, somnolence, weight gain	Vision loss and blindness
Zonisamide (Zonegran, generic)	Modulate sodium and calcium channels	*Maintenance dose*: 100–600 mg/day; start at 100 mg/day and titrated upward as indicated by response	*Half-life*: Approximately 63 hours *Apparent volume of distribution*: 1.45 L/kg *Protein binding*: 40% *Primary elimination route*: Hepatic	Not established	Dizziness, somnolence	Metabolic acidosis, oligohidrosis, paresthesia, renal calculi

GABA, γ-aminobutyric acid.

valproate more than 6 months should take supplemental calcium and vitamin D. Routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

▶ *Practical Issues*

Comorbid Disease States Patients with epilepsy often have comorbid disease states. Care must be taken when treating comorbid conditions, as numerous drugs can interact with AED. These interactions necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an AED is added or removed. Patients with headaches need special attention in the selection of an AED. Agents known to prevent headache (eg, valproate and topiramate) may be preferred, and agents associated with increased headaches (eg, lamotrigine and felbamate) may be secondary or tertiary alternatives.

Depression is common in patients with epilepsy. Approximately 30% have symptoms of major depression at some point.[29] Patients with epilepsy should be routinely assessed for depression using a validated screening tool, and treatment initiated if necessary. Most AEDs can exacerbate depression, and patients should be warned to watch for mood changes. Some AEDs (eg, lamotrigine, carbamazepine, oxcarbazepine) may be useful in treating depression. If treatment for depression is necessary, an agent that is unlikely to increase seizures and does not interact with AEDs should be chosen. However, treatment with an appropriate antidepressant should not be withheld because of a small risk of increasing seizure frequency.

LO 8

Switching Drugs Changing from one AED to another can be a complex process. If the first drug is stopped too abruptly, breakthrough seizures may occur. KEY CONCEPT Changes in AED regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs. Typically, the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

LO 10

Stopping Therapy Epilepsy is generally considered to be a lifelong disorder requiring ongoing treatment. However, some patients who are seizure free may desire to discontinue their medications.[30,31] Patients who become seizure free following surgery for epilepsy may have medications slowly tapered starting 1 to 2 years after surgery. Many patients will choose to stay on at least one medication, following successful surgery, to ensure they remain seizure free. KEY CONCEPT Discontinuation of AEDs should be done gradually, only after the patient has been seizure free for 2 to 5 years and with careful consideration of factors predictive of seizure recurrence. They are

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of partial or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 61% chance of remaining seizure free after AEDs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom with medications and the chance of remaining seizure free after medications are withdrawn. Withdrawal of AEDs is done slowly, usually with a tapering dose over at least 1 to 3 months.

▶ *Dosing*

Dosing of AEDs is determined by general guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges that are often quoted are broad guidelines for dosing, but should never replace careful evaluation of the patient's response. In ambulatory patients, it is usually best to obtain AED concentrations immediately before a dose, preferably the first morning dose. Sufficient time should have elapsed for the AED to be at steady state when a concentration is measured. In acute care, concentrations may be measured more frequently to ensure proper dosing and check for alterations in AED pharmacokinetics (eg, altered protein binding, poor oral absorption, increased metabolism).

▶ *Drug Interactions*

LO 9

AEDs are associated with many different drug interactions.[32–35] Most interactions occur due to alterations in absorption, metabolism, and protein binding. Tube feedings and antacids are known to reduce the absorption of phenytoin and carbamazepine. Phenytoin, carbamazepine, and phenobarbital are potent inducers of various CYP450 isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 31–4). In contrast, valproate is a CYP450 and UDP-glucuronosyltransferase (UGT) isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein bound and can be displaced when taken together or with other highly protein-bound drugs. For example, when phenytoin and valproate are taken together, there may be increased dose-related adverse effects within several hours of dosing. This can be avoided by staggering doses or giving smaller doses more frequently during the day. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in dose of AEDs be made.

▶ *Special Populations*

KEY CONCEPT Children and women with epilepsy have unique problems related to the use of AEDs. In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child, it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. AED doses are increased rapidly, and frequent changes in the regimen are made to maximize seizure control. Due to rapid metabolic rates seen in children, doses of AEDs are typically higher on a milligram per kilogram basis compared with adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, breastfeeding, interactions between AEDs and hormonal contraceptives, and reduced fertility.[36–38] Recommendations are developed for managing women of childbearing potential and who are pregnant (Table 31–5). Several AEDs are implicated in causing birth defects.[39] Neural tube defects (eg, spina bifida, microcephaly, anencephaly) are associated most commonly with valproate and possibly carbamazepine. Additionally, valproate is associated with impaired cognitive development in children born to women taking valproate during pregnancy. Use of valproate should be

Table 31–4

Cytochrome P450 and AED Interactions

Enzyme	Substrate	Common Inducers	Common Inhibitors
CYP 1A2	Carbamazepine Perampanel	Carbamazepine Phenytoin Phenobarbital Rifampin	Cimetidine Ciprofloxacin Erythromycin Clarithromycin
CYP 2C9	Brivaracetam Phenobarbital[a] Phenytoin[a] Carbamazepine Valproate	Carbamazepine Phenytoin Phenobarbital Rifampin	Amiodarone Cimetidine Fluconazole Valproate
CYP 2C19	Brivaracetam[a] Phenobarbital Phenytoin Valproate Lacosamide		Felbamate Omeprazole Ticlopidine Topiramate Zonisamide
CYP 2D6	Zonisamide	Carbamazepine	
CYP 3A4	Carbamazepine[a] Perampanel[a] Tiagabine[a] Zonisamide[a]	Carbamazepine Phenytoin Phenobarbital Rifampin	Amiodarone Erythromycin Ketoconazole
Uridine diphosphate glucuronyl-transferase	Lamotrigine[a] Carbamazepine Valproate	Lamotrigine Phenobarbital Phenytoin Hormonal contraceptives	Valproate

[a]Primary route of metabolism.

avoided, if possible, in women of childbearing potential. All women of childbearing potential who take AEDs should take 1 to 4 mg daily of supplemental folic acid to reduce the risk of birth defects. Many AEDs are excreted in breast milk. However, infants were exposed to higher concentrations of AED in utero, so it is unclear if drugs in breast milk are harmful to the child. Decisions about breastfeeding are made on an individual basis.

Many AEDs induce hepatic microsomal enzyme systems and reduce the effectiveness of hormonal contraceptives. Women taking AEDs that may reduce the effectiveness of hormonal contraceptives should also use other forms of birth control. In contrast to these interactions, hormonal contraceptives induce glucuronidation of lamotrigine and valproate, and cause reductions in serum concentrations of these drugs during days of the cycle when hormones are taken; serum concentrations increase during days when hormones are not taken. Serum concentrations of many AEDs drop during pregnancy and dose increases based on frequent serum concentration monitoring is necessary. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone-binding globulin, some AEDs reduce fertility. Valproate has been associated with a drug-induced polycystic ovarian syndrome.

Table 31–5

Management of AEDs During Pregnancy

- Give supplemental folic acid 1–4 mg daily to all women of childbearing potential
- Use monotherapy whenever possible
- Use lowest doses that control seizures
- Continue pharmacotherapy that best controls seizures prior to pregnancy
- Monitor AED serum concentrations at start of pregnancy and monthly thereafter
- Adjust AED doses to maintain baseline serum concentrations
- Administer supplemental vitamin K during eighth month of pregnancy to women receiving enzyme-inducing AEDs
- Monitor postpartum AED serum concentrations to guide adjustments of drug doses
- Avoid valproate, if possible

Patient Encounter 3: Pregnancy

TC is a 22-year-old woman with epilepsy who comes to clinic for a routine visit. Her medications consist of oxcarbazepine and nonprescription antihistamines. She is sexually active and asks about birth control and concerns about becoming pregnant. Her seizures are well controlled and overall she is in good health.

What advice should be given regarding birth control?

What is the risk of birth defects if she gets pregnant while taking AEDs?

What can be done to limit the risk of birth defects?

What AEDs should generally be avoided in women of childbearing potential?

How should oxcarbazepine be managed when she becomes pregnant and after delivery?

Patient Encounter 4: Seizures in Older Adults

WB is a 78-year-old man who had several seizures after a stroke 2 years ago. He was started on levetiracetam at that time and continues to take it. His MRI is consistent with an old stroke and his EEG is reported as normal.

Should pharmacotherapy be continued in this patient?

If pharmacotherapy is discontinued, how should it be stopped?

How should the efficacy and toxicity be monitored in this patient?

Women who experience difficulties with fertility should seek the advice of health care professionals with expertise in fertility.

KEY CONCEPT Older adults have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment. The highest incidence of seizures and epilepsy is in individuals older than 65 years. Cerebrovascular disease, tumors, trauma, and neurodegenerative diseases are the primary causes of epilepsy in this age group. Diagnosis of epilepsy in older adults is difficult. This is due to the subtle symptoms of seizures, often compromised memory in the elderly, and the fact that many elderly live alone. Carbamazepine, lamotrigine, levetiracetam, topiramate, and gabapentin are effective in controlling seizures in older adults. Elderly patients are more sensitive to adverse events, so smaller doses tend to be used in this age group. Additionally, patients in this age group are at a greater risk for drug interactions due to the likelihood they are taking concomitant medications for other disease states.

OUTCOME EVALUATION

LO 10

KEY CONCEPT Patients receiving AEDs for seizures should be instructed on and have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, comorbid conditions, and possible drug interactions.

Efficacy

- Seizure counts are the standard way to evaluate the efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day a seizure occurs and the type of seizure. Compare seizure counts on a monthly basis to determine the level of seizure control.

Toxicity

- Monitor acute toxicity of AEDs at every clinic visit.
- Question patients about common adverse effects of the AEDs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control. If it is determined, the adverse effects negatively impact the patient more than the extent of seizure control benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of AEDs.

Comorbid Conditions

Routinely evaluate patients for signs and symptoms of depression.

Patient Care Process

Collect Information:

- Description of seizure events
- EEG report
- Neuroimaging report
- Laboratory results (eg, serum chemistry, complete blood count, renal function, hepatic function, toxicology screen, AED serum concentrations)
- History of prematurity or difficult delivery at birth, febrile seizures, head injury, infections of the central nervous system
- Family history of seizures or other neurological disorders
- Medication history
- Adherence to medications
- Allergies
- Social history (eg, employment, driving, living situation, recreational activities)

Assess the Information:

- Type of seizure
- Risk of a recurrent seizure
- Impact of potential pharmacotherapy on lifestyle
- Ability to adhere to medication regimen
- Need for modifying lifestyle (eg, ability to drive, modifications at work, avoidance of recreational activities that could result in harm with a seizure)

Develop a Care Plan:

- Determine optimal goals of pharmacotherapy
- Select medication that is effective for the seizure type, and minimizes the risk of adverse effects that negatively impact the patient's lifestyle; evaluate the risk of important drug interactions
- Design a dosing schedule to optimize adherence
- Identify important patient education points (eg, driving, safety, pregnancy, birth control, adherence)

Implement the Care Plan:

- Select and initiate the best medication for the patient at an appropriate starting dose
- Provide a medication titration schedule, if needed
- Assist patient to determine the best ways to monitor efficacy (eg, seizure frequency and severity) and adverse events
- Instruct patient on important patient education points (eg, driving, safety, pregnancy, birth control, adherence)

Follow-up: Monitor and Evaluate:

- Seizure frequency and severity
- Adverse events (eg dose-related, idiosyncratic, chronic)
- Serum concentrations, when appropriate
- Possible drug interactions
- Adherence

Abbreviations Introduced in This Chapter

AAN	American Academy of Neurology
AED	Antiepileptic drug
CBC	Complete blood count
CNS	Central Nervous System
CYP	Cytochrome P 450
EEG	Electroencephalograph
GABA	γ-aminobutyric acid
HLA	Human leukocyte antigen
ILAE	International League Against Epilepsy
JME	Juvenile myoclonic epilepsy
LFT	Liver function tests
LGS	Lennox-Gastaut syndrome
MRI	Magnetic resonance imaging
MTLE	Mesial temporal lobe epilepsy
NICE	National Institute for Clinical Excellence in the United Kingdom
PDS	Paroxysmal depolarizing shift
SIGN	Scottish Intercollegiate Guidelines Network
SMEI	Severe myoclonic epilepsy in infancy
UGT	Uridine 5′-diphospho-glucuronosyltransferase

32 Status Epilepticus

Eljim P. Tesoro and Gretchen M. Brophy

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of status epilepticus.
2. Explain the urgency of diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment goals for a patient in status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

INTRODUCTION

KEY CONCEPT **Status epilepticus** (SE) is a neurologic emergency that can lead to permanent brain damage or death. KEY CONCEPT SE is defined as continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.[1] Refractory status epilepticus (RSE) is unresponsive to emergent (first-line) or urgent (second-line) therapy.

SE can present as nonconvulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by persistent impaired consciousness without clinical seizure activity and is diagnosed with **electroencephalography** (EEG). GCSE is characterized by full-body motor seizures and involves the entire brain.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of SE in the United States is 12.5/100,000/year, with an in-hospital mortality rate of 9.2%,[2] and an estimated annual direct cost for inpatient admissions of $4 billion.[3] It occurs most frequently in males, African Americans, children, and the elderly.

KEY CONCEPT It is important to evaluate etiologies of SE for timely and optimal seizure control. Causes of SE include metabolic disturbances (eg, hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia); central nervous system (CNS) disorders, infections, injuries; **hypoxia**; and drug toxicity (eg, theophylline, isoniazid, cyclosporine, cocaine). Chronic causes of SE include preexisting **epilepsy**, chronic alcoholism (withdrawal seizures), CNS tumors, and strokes.[4] In epileptics, the common causes of SE are anticonvulsant withdrawal or subtherapeutic levels.

PATHOPHYSIOLOGY

LO 1 Status epilepticus occurs when the brain fails to stop isolated seizures, due to a mismatch of neurotransmitters. **Glutamate**, the primary excitatory neurotransmitter, stimulates postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, causing neuronal depolarization. Sustained depolarization causes neuronal injury and death.[5] The primary inhibitory neurotransmitter, **γ-aminobutyric acid** (GABA), opposes excitation by stimulating $GABA_A$ receptors, producing hyperpolarization and inhibition of the postsynaptic cell membrane. GABA-mediated inhibition diminishes with continuous seizure activity, causing a decreased response to GABA-receptor agonists.[6] Seizures lasting more than 30 minutes cause significant injury and neuronal loss because of excessive electrical activity and cerebral metabolic demand. Decreased $GABA_A$-receptor response and increasing neuronal injury with prolongation of seizure activity necessitates rapid control of SE.

LO 2

Systemic changes appear in two phases during SE. Phase I occurs during the first 30 minutes, and phase II occurs after 30 to 60 minutes.[7]

Phase I

LO 3 During phase I, autonomic activity increases, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow increases to preserve oxygen supply to the brain. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can cause ventricular arrhythmias, severe acidosis, and rhabdomyolysis which can lead to hypotension, shock, hyperkalemia, and acute kidney injury.

Phase II

After 30 to 60 minutes of continuous seizure activity, loss of cerebral autoregulation, decreased cerebral blood flow, increased intracranial pressure (ICP), and systemic hypotension occur. LO 7 Cerebral metabolic demand remains high; however, the body is unable to compensate, resulting in hypoglycemia, hyperthermia, respiratory failure, hypoxia, respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and uremia. Motor activity may not be clinically evident during prolonged seizures, but electrical activity may still exist (ie, NCSE) requiring prompt recognition and aggressive treatment.

Patient Encounter 1, Part 1

A 79-year-old woman with a history of hypertension, diabetes, and arthritis was admitted with traumatic subdural hematoma after falling down a flight of stairs. She underwent surgery 2 days ago to evacuate the hematoma and is currently recovering in the intensive care unit (ICU). She was started on fosphenytoin for seizure prophylaxis upon admission along with her home medications. She has only one peripheral IV line and has very poor vascular access. Her nurse reports that a few minutes ago, she was alert and awake, but now she is unarousable and is having jerky, convulsive movements on both sides of her body. The doctor evaluates her and the jerky activity stops, but then starts again about 1 minute later. She never regained consciousness between these episodes. Her diagnosis is status epilepticus. Ht 165 cm (5'5"), Wt 147 kg (323 lbs).

What initial assessments should be performed?

What are some possible etiologies for her seizure?

What nonpharmacologic interventions are needed at this time?

CLINICAL PRESENTATION AND DIAGNOSIS

History

KEY CONCEPT When a patient presents with seizures, a thorough history is needed to determine the type and duration of previous seizure activity. This will help guide therapy and clarify necessary laboratory and diagnostic tests. Emergent treatment should not be delayed if seizure activity is diagnosed or is suspected based on the patient's family or emergency response personnel.

Physical Examination

Once clinical seizures are halted, a neurologic examination should evaluate the level of consciousness (coma, lethargy, or somnolence), motor function and reflexes (rhythmic contractions, rigidity, spasms, or posturing), and pupillary response. A physical examination can identify secondary injuries.

Clinical Symptoms

LO 3

Patients with SE usually present with generalized, convulsive, tonic-clonic seizures. They may also be hypertensive, tachycardic, febrile, and diaphoretic which resolve after seizure termination. A loss of bowel or bladder function, respiratory compromise, and nystagmus may also be observed. When seizure activity exceeds 30 to 60 minutes, muscle contractions may no longer be visible, necessitating an EEG to diagnosis SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures.

Laboratory Parameters

KEY CONCEPT It is important to obtain a serum chemistry profile to help identify possible causes of SE, such as hypoglycemia, hyponatremia or hypernatremia, hypomagnesemia, and hypocalcemia; patients with renal and liver failure are at high risk as well. In febrile patients with elevated white blood count (WBC) counts, active infections should be considered and treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be collected once seizures are controlled. Computed tomography (CT) or magnetic resonance imaging (MRI) can rule out CNS abscesses, bleeding, or tumors, all of which may be a source of seizures. Order a blood alcohol level and urine toxicology screen to determine if SE is caused by alcohol withdrawal, illicit drug use, or a drug overdose. Serum drug levels should be obtained in an overdose situation to rule out toxicity. KEY CONCEPT Knowing the cause of SE will guide initial antiepileptic therapy and increase the probability of seizure termination.

In patients taking anticonvulsants, a baseline serum concentration can help determine if the concentration is below the desired range and whether a loading dose (LD) is needed. Albumin levels, and renal and liver function tests should also be utilized to assess therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Pulse oximetry and arterial blood gas (ABG) measurements are used to assess pulmonary status and determine the need for protection or supplemental oxygen. Metabolic acidosis may resolve without treatment after termination of clinical seizures.

Clinical Presentation of Status Epilepticus

General

- The patient may present with or without clinically noticeable seizures.

Symptoms

- Impaired consciousness, from lethargy to coma
- Disorientation after GCSE cessation
- Pain from associated injuries (eg, tongue lacerations, dislocated shoulder, head/facial trauma)

Signs

Phase I (≤ 30 minutes of SE):
Generalized convulsions
Hypertension, tachycardia
Fever and sweating
Muscle contractions, spasms
Respiratory compromise
Incontinence

Phase II (> 30 minutes of SE):
Respiratory failure with pulmonary edema
Cardiac failure (arrhythmias, shock)
Hypotension
Hyperthermia
Rhabdomyolysis and multiorgan failure

Laboratory Tests

- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE
- The white blood cell (WBC) count may slightly increase
- Abnormal arterial blood gases (ABGs) due to hypoxia and respiratory or metabolic acidosis
- Elevated serum creatinine will be present in renal failure patients
- Myoglobinuria can occur in patients with continuous seizures

Diagnostic Tests

EEG to confirm seizure activity

CT or MRI may reveal mass lesions or hemorrhage

Diagnostic Tests

EEG is required to identify SE in a comatose patient. Continuous EEG monitoring should be used in patients who remain unconscious after initial antiepileptic treatment, those receiving long-acting paralytic agents, or those requiring prolonged RSE therapy. Treatment should not be delayed while awaiting EEG results. CT and MRI scans are useful to identify traumatic injury, mass lesions, or evidence of infection as the cause of SE.

TREATMENT

Desired Outcomes

LO 4

KEY CONCEPT The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent recurrence, and minimize adverse drug events. Poor outcomes are associated with prolonged SE and refractory SE.[8] Complications of SE should also be treated.

General Approach

LO 5

The initial approach to SE involves removing the patient from harmful surroundings and ensuring maintenance of airway, breathing, and circulation. Benzodiazepines are the preferred initial drugs to stop acute seizure activity (emergent therapy), followed by an anticonvulsant (urgent therapy) for suppression of seizures. Medications are given intravenously (IV) for immediate onset of action, but if IV access is not available, select medications may be given rectally, intramuscularly (IM), buccally, or nasally. After seizures stop, clinicians must identify and treat underlying causes of the seizures, such as toxins, hypoglycemia, or brain injury. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications, noncompliance, or drug interactions. Recent guidelines provide treatment algorithms for SE.[1,9]

Nonpharmacologic Treatment

Oxygen administration or intubation for mechanical ventilation should be performed in cases of hypoxia, and temperature management should be considered for febrile seizures. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an intensive care unit (ICU) allows for aggressive treatment and monitoring.

Pharmacologic Treatment

▶ *Initial Treatment*

Hypoglycemia-induced SE is treated with IV dextrose. IV thiamine is given to alcoholics prior to administering any dextrose-containing solutions to prevent encephalopathy.

▶ *Benzodiazepines*

LO 5

KEY CONCEPT Initial or emergent drug therapy begins with IV administration of a benzodiazepine. This class of agents is highly effective in terminating seizures.[10,11] Intravenous bolus doses of diazepam, lorazepam, and midazolam have been used in SE because of their rapid effects on GABA receptors. Lorazepam is the preferred agent of most clinicians. When treating patients on chronic benzodiazepine therapy, consider using higher doses to overcome tolerance. Diazepam and lorazepam should be diluted 1:1 with normal saline before parenteral administration via peripheral veins to avoid vascular irritation from the propylene glycol diluent.

Diazepam Being extremely lipophilic, diazepam penetrates the CNS quickly, but rapidly redistributes into body fat and muscle. This results in a rapid decline in CNS levels and early recurrence of seizures. Doses can be given every 5 minutes until seizure activity stops or toxicities are seen (eg, respiratory depression). Diazepam can be administered as a rectal gel enabling nonmedical personnel to provide timely therapy at home or in public areas.[12] IM administration of diazepam is not recommended because of erratic absorption.

Lorazepam Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and decreased need for repeated doses. Both lorazepam and diazepam are effective in stopping seizures,[13] but lorazepam is currently preferred due to a longer duration of action. It can be redosed every 5 to 10 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. IM administration is not preferred due to slow and unpredictable absorption.

Midazolam Midazolam is water-soluble and can be administered intramuscularly,[14] buccally,[15,16] and nasally.[17,18] Compared to diazepam and lorazepam, it has less respiratory

Patient Encounter 1, Part 2

Physical examination, chart review, and recent laboratory studies reveal the following information:

PE:

VS: BP 178/92 mm Hg, HR 109 beats/min, RR 26 breaths/min, T 39.0°C (102.2°F)

CNS: Unresponsive, unarousable

CV: Sinus tachycardia; normal S1, S2; no murmurs, rubs, gallops

Pulm: Tachypneic; oxygen saturation 88% (0.88) on room air; no rhonchi, wheezes, rales

Abd: Deferred

Exts: Rhythmic tonic-clonic movements of all extremities

GU: Incontinent of urine and stool

HEENT: Persistent upward gaze

Current Medications: Fosphenytoin 100 mg PE IV every 8 hours; Famotidine 20 mg IV every 12 hours; Metoprolol 50 mg PO every 12 hours; Insulin glargine 25 units SQ at bedtime; Insulin aspart 5 units SQ with meals; Acetaminophen/hydrocodone 325 mg/5 mg tablet PO; Every 4 hours as needed for pain; Morphine 2 mg IVP every 2 hours as needed for pain

Labs: Sodium 129 mEq/L (mmol/L), potassium 4.1 mEq/L (mmol/L), phenytoin 2.7 mcg/mL (11 µmol/L), albumin 3.5 g/dL (35 g/L), chloride 105 mEq/L (mmol/L), carbon dioxide 12 mEq/L (mmol/L), blood urea nitrogen 10 mg/dL (3.6 mmol/L), serum creatinine 0.9 mg/dL (80 µmol/L), glucose 54 mg/dL (3.0 mmol/L); WBC $15 \times 10^3/mm^3$ ($15 \times 10^9/L$), hemoglobin 9.6 g/dL (96 g/L or 5.96 mmol/L), hematocrit 28% (0.28 volume fraction), platelets $235 \times 10^3/mm^3$ ($235 \times 10^9/L$), prothrombin time 12 seconds; international normalized ratio 1.1, activated partial thromboplastin time 28 seconds.

What is your assessment of the cause of this patient's condition?

What pharmacologic interventions are needed at this time?

Identify goals of therapy for this patient.

What therapies must be instituted next?

and cardiovascular side effects. Its short half-life requires that it be redosed frequently or administered as a continuous IV infusion. Liquid or injectable formulations can be given buccally or intranasally (0.3 mg/kg) in pediatric patients. Rapid breathing and increased secretions can interfere with nasal administration. A recent study in adults and children showed that IM midazolam was as safe and effective as IV lorazepam for prehospital termination of seizures.[18]

▶ *Anticonvulsants*

LO 5 KEY CONCEPT After administering the first dose of benzodiazepine, an anticonvulsant such as phenytoin, valproate sodium, or phenobarbital should be started to prevent further seizures (urgent therapy). Anticonvulsants must not be given as first-line therapy since they are infused relatively slowly to avoid adverse effects, delaying their onset of action. If the underlying cause of the seizures has been corrected (eg, hypoglycemia) and seizure activity has ceased, an anticonvulsant may be unnecessary. This may be reasonable when patients become alert and oriented or if an EEG confirms absence of seizure activity.

After the LD of the anticonvulsant is administered, maintenance doses should be initiated to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects and potential drug interactions should be considered if the patient continues anticonvulsant therapy. Drugs should be adjusted for any hepatic or renal dysfunction. Table 32–1 summarizes the doses used in SE, and Table 32–2 is an example algorithm for treatment of patients in SE.

Phenytoin The most widely used anticonvulsant for urgent treatment of SE is phenytoin. It is available in its original form or as a prodrug, fosphenytoin, which is the most commonly used dosage form. Doses are infused no faster than 50 mg/min due to risks of hypotension or arrhythmias. Continuous monitoring of electrocardiogram (ECG) and blood pressure is recommended. Maintenance doses can be started 12 hours after the LD. Phenytoin should not be infused with other medications because of stability concerns (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given IM due to its alkalinity.

LO 7

Patient Encounter 2, Part 1

A 19-year-old man admitted for two reported episodes of intermittent jerking in his left arm that were witnessed by his mother this morning. He is nonresponsive at the time of these episodes and does not remember anything during that period of time. He does not take any medications and has no drug allergies. One week ago, he was seen in the emergency department for confusion and difficulty walking after being hit in the head with a soccer ball. At that time, a head CT scan showed no hemorrhage and he was diagnosed with a mild traumatic brain injury. While the nurse is taking his vital signs, he becomes confused and then unarousable with jerky movements on the left side of his body. His diagnosis is status epilepticus after this seizure activity does not stop over the next 5 minutes.

VS: BP 111/75 mm Hg, HR 108 beats/min, RR 21 breaths/min, T 37.0°C (98.6°F), Wt 68 kg (150 lb), Ht 178 cm (5′10″).

What is the most likely cause of this patient's SE?

What are possible treatment options at this time?

How would you optimize his outcome?

LO 7 **Extravasation** of phenytoin can cause local tissue discoloration, edema, pain, and sometimes necrosis (purple glove syndrome). Oral loading is not recommended due to the limitations of single dose absorption (ie, doses > 400 mg are not fully absorbed) and delayed peak concentrations when given orally. Obese patients require larger LDs due to a larger volume of distribution (V_d).[19] A dosing weight (DW) can be calculated using total body weight (TBW) and ideal body weight (IBW): DW = IBW + 1.33(TBW – IBW). V_d can be calculated as follows: V_d = 0.7 L/kg × DW (in kg). An LD can then be calculated using V_d and a target concentration: LD = $C_{target} \times V_d$.

Fosphenytoin Fosphenytoin is a water-soluble, phosphoester prodrug that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions. It is dosed in phenytoin equivalents (PEs), and it can be infused up to 150 mg PE/min. Although it has fewer cardiovascular side effects than phenytoin, clinicians should continuously monitor blood pressure, ECG, and heart rate. **Paresthesias**, especially around the lips and groin, are common, but typically resolve within a few minutes and should not necessitate stopping the infusion. If a postload serum level is desired, it should be obtained 2 hours after an IV load; if subtherapeutic, an LD is indicated.

LO 7

Valproate Sodium Valproate sodium has been successfully used IV in various types of SE including generalized tonic-clonic, myoclonic, and NCSE.[20] It is particularly useful in patients with cardiorespiratory compromise and/or those allergic to phenytoin and phenobarbital.[21]

Phenobarbital If phenytoin or valproate sodium fails to prevent seizure recurrence, phenobarbital can be considered. However, emerging evidence suggests that phenobarbital may not be effective if SE persists despite benzodiazepines and phenytoin. This may be due to progressive resistance of the $GABA_A$ receptor, where barbiturates also act.[22] Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients receiving a rapid IV LD of phenobarbital should have hemodynamic monitoring and be mechanically ventilated if at high risk of respiratory compromise. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy or as adjunct therapy to prevent withdrawal seizures when weaning refractory SE patients off pentobarbital infusions.

LO 7

Treatment of Refractory Status Epilepticus

KEY CONCEPT Seizure activity unresponsive to emergent and urgent therapy is considered RSE.[23] Refractory SE can occur in up to 30% of patients with SE and has a mortality rate approaching 50%. Patients in RSE are unlikely to regain independent function, even if seizures are controlled. Clinical signs may become subtle and an EEG may be required to detect ongoing seizure activity. KEY CONCEPT Even SE patients without clinical signs of seizing are at risk for brain damage or death.

LO 8

Optimal therapy for RSE is undetermined.[24] Clinicians must aggressively investigate and treat possible causes including infection, tumors, drugs or toxins, metabolic disorders, liver failure, or fever. In general, patients with RSE are managed in an ICU with hemodynamic and respiratory support and frequent monitoring. Continuous EEG monitoring is essential and should not be delayed. Any anticonvulsants initiated before treatment for RSE should be continued, and their serum levels optimized to prevent breakthrough or withdrawal seizures. KEY CONCEPT Treatment of RSE consists of intensive monitoring, supportive care, and a continuous intravenous infusion of midazolam, propofol, or pentobarbital to suppress clinical and EEG evidence

LO 6

Table 32–1

Medications Used in Adult Status Epilepticus

Drug Name (Brand Name)	Loading Dose and RSE Maintenance Dose (If Applicable)	Administration Rate	Therapeutic Level	Side Effects	Comments
Diazepam (Valium)	0.15 mg/kg (up to 10 mg per dose); may repeat in 5 minutes	5 mg/min (IVP)	N/A	Hypotension, respiratory depression	Rapid redistribution rate; can be given rectally
Lorazepam (Ativan)	0.1 mg/kg (up to 4 mg per dose); repeat in 5–10 minutes	2 mg/min (IVP)	N/A	Hypotension, respiratory depression	May be longer acting than diazepam
Midazolam (Versed)	0.2 mg/kg IM up to 10 mg per dose RSE: 0.2 mg/kg (2 mg/min) IV then 0.05–2 mg/kg/hour		N/A	Sedation, respiratory depression	Can also be given buccally, intranasally
Phenytoin (Dilantin)	20 mg/kg	Up to 50 mg/min	Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 µmol/L) Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 µmol/L)	Arrhythmias, hypotension	Hypotension, especially in older adults
Fosphenytoin (Cerebyx)	20 mg PE/kg	Up to 150 mg PE/min	Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 µmol/L) Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 µmol/L)	Paresthesias, hypotension	Less CV adverse effects than phenytoin
Phenobarbital (Luminal)	20 mg/kg	50–100 mg/min	15–40 mcg/mL (mg/L; 65–172 µmol/L)	Hypotension, sedation, respiratory depression	Long-acting
Valproate sodium (Depacon)	20–40 mg/kg	3–6 mg/kg/min	50–150 mcg/mL (mg/L; 347–1040 µmol/L)		Less CV adverse effects than phenytoin
Levetiracetam (Keppra)	1000–3000 mg IV or 60 mg/kg (max 4500 mg)	2–5 mg/kg/min			Minimal drug interactions
Lacosamide (Vimpat)	200–400 mg IV	Over 15 minutes		PR prolongation, hypotension	
Topiramate (Topamax)	200–400 mg NG/PO every 6 hours		2–20 mcg/mL (mg/L; 6–59 µmol/L)	Metabolic acidosis	
Propofol (Diprivan)	Bolus: 1–2 mg/kg RSE: 30–250 mcg/kg/min	Approximately 40 mg every 10 seconds	N/A (typically titrated to EEG)	Hypotension, respiratory depression, PRIS	Requires mechanical intubation; high lipid load (increased calories)
Pentobarbital (Nembutal)	Bolus: 10–15 mg/kg RSE: 0.5–4 mg/kg/hour	Up to 50 mg/min	10–20 mcg/mL (mg/L; 44–89 µmol/L) (typically titrated to EEG)	Hypotension, respiratory depression, cardiac depression, infection, ileus	Requires mechanical intubation, vasopressors, hemodynamic monitoring
Ketamine (Ketalar)	RSE: 0.5–4.5 mg/kg IV bolus, then infusion up to 5 mg/kg/hour		N/A	Hypertension, arrhythmias	Associated cerebral atrophy

CV, cardiovascular; EEG, electroencephalogram; IM, intramuscular; IV, intravenous; IVP, intravenous push; N/A, not applicable; NG, nasogastric; PE, phenytoin equivalents; PO, by mouth; PR, per rectum; PRIS, propofol-related infusion syndrome; RSE, refractory status epilepticus.

LO 8

of seizures (Tables 32–1 and 32–2).[25] These agents are typically titrated to achieve **burst suppression** on the EEG, although this practice lacks strong evidence. Patients should be intubated and mechanically ventilated before initiating treatment for RSE. Seizure control per EEG should be maintained for 24 to 48 hours before considering tapering therapy. Consultation with neurologists or epileptologists is highly recommended.

▶ *Midazolam*

Midazolam infusions must be adjusted, especially in patients with renal impairment, as the active metabolite can accumulate.[26] Breakthrough seizures are common with midazolam infusions and usually respond to boluses and a 20% increase in infusion rate. Despite this, tachyphylaxis can occur, and patients should be switched to another agent if seizures continue.

Table 32–2

Algorithm for Treatment of Status Epilepticus in Adult

Time (minutes)	Assessment/Monitoring	Treatment
0	Vital signs (HR, RR, BP, T) Assess airway Monitor cardiac function (ECG) Pulse oximeter Check blood glucose Check laboratory tests: complete blood count, serum chemistries, liver function tests, arterial blood gas, blood cultures, serum anticonvulsant levels, urine drug/alcohol screen	Stabilize airway (intubate if necessary) Administer oxygen Secure IV access and start fluids Give IV thiamine (100 mg), then IV dextrose (50 mL of 50% solution) if hypoglycemic
0–10	Vital signs Physical examination Patient history including medications (prescription, OTC, and herbals)	Lorazepam 0.1 mg/kg (maximum 4 mg) IVP at 2 mg/min (may repeat in 5–10 minutes to maximum of 8 mg if no response) If no IV access, can give: diazepam 10 mg PR (may repeat in 10 minutes if no response); midazolam 0.2 mg/kg IM (maximum 10 mg; may repeat in 10 minutes if no response) Anticonvulsant may not be necessary if underlying cause is corrected and seizures have ceased
10–20	Vital signs Review laboratory results and correct any underlying abnormalities CT scan (if seizures controlled)	Phenytoin 15–20 mg/kg IV at a maximum rate of 50 mg/min (or fosphenytoin 15–20 mg PE/kg IV at a maximum rate of 150 mg PE/min) In patients allergic to phenytoin, give valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min Treat for possible infection
20–30	Vital signs Consult neurologist/epileptologist Consider admission to ICU Consider EEG	If seizures continue: additional phenytoin bolus 5–10 mg/kg (or fosphenytoin 5–10 mg PE/kg) **OR** start phenobarbital at 20 mg/kg IV at a maximum rate of 100 mg/min **OR** start valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min in patients who are not intubated
> 30–60 *refractory status epilepticus*	Vital signs Transfer to ICU Obtain EEG Consider MRI when controlled	Midazolam 0.2 mg/kg IV bolus followed by 0.05–2 mg/kg/hour CI **OR** propofol 1 mg/kg bolus followed by 30–250 mcg/kg/min CI **OR** pentobarbital 10–15 mg/kg bolus over 1–2 hours followed by 0.5–4 mg/kg/hour Consider intubation and/or vasopressor support if needed Optimize anticonvulsant levels: repeat boluses of phenobarbital 10 mg/kg **OR** valproate sodium 20 mg/kg at 6 mg/kg/min max
> 24 hours *super refractory status epilepticus*	Vital signs Continuous EEG	Optimize anticonvulsant therapy Consider ketamine infusion, immunomodulation (eg, steroids, IV immunoglobulin), inhaled anesthetics, ketogenic diet

BP, blood pressure; CI, continuous infusion; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalograph; HR, heart rate; ICU, intensive care unit; IM, intramuscular; IV, intravenous; IVP, intravenous push; MRI, magnetic resonance imaging; OTC, over the counter; PE, phenytoin equivalents; PR, per rectum; RR, respiratory rate; T, temperature.

Patient Encounter 2, Part 2

Over the next hour, he is treated with your recommendations for emergent and urgent treatment of SE as above. His jerky movements stopped, but he remains comatose.

VS: BP 95/62 mm Hg, HR 120 beats/min, RR 14 breaths/min, T 37.1°C (98.8°F)

A continuous EEG is started and reveals the patient is in SE.

What is your assessment of the patient's current condition?

What do you recommend for further nonpharmacologic and pharmacologic therapy?

How would you optimize his outcomes?

▶ *Propofol*

LDs of the anesthetic propofol can be given every 3 to 5 minutes until clinical response, after which an infusion can be initiated. Propofol causes hypotension, especially with LDs; therefore, some clinicians avoid LDs and quickly titrate with a continuous infusion. Long-term, high-dose (> 80 mcg/kg/min) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol-related infusion syndrome), especially in children.[27] It has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. Propofol infusions are a source of calories (1 kcal/mL [4.2 kJ/mL]), so nutritional support must be adjusted accordingly.

LO7

▶ *Pentobarbital*

Barbiturate infusions are reported to be highly effective in treating RSE[28] and decreasing elevated ICP, but they cause significant hypotension, myocardial and respiratory depression,

LO6 LO7

ileus, and infections. Therefore, patients require mechanical ventilation and invasive hemodynamic monitoring. Patients often require IV vasopressor therapy and total parenteral nutrition.

LO 6 A meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) compared to midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher with pentobarbital.[28] This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol should be switched to pentobarbital.

LO 6

▶ *Levetiracetam*

LO 6 Levetiracetam does not have the cardiopulmonary, hepatic, and sedative side effects seen with the other agents; nor does it have potentially harmful drug interactions. Both IV[29] and oral[30] formulations have been used in RSE patients as add-on therapy with some success, although it is unclear if levetiracetam would be effective as monotherapy.[31] LDs up to 2000 mg over 15 to 30 minutes in the critically ill have been given with very little toxicity.[32]

▶ *Other Agents*

Ketamine,[33] topiramate, and inhaled anesthetics have also been used for RSE. Ketamine is an NMDA receptor antagonist that has been given orally[34] and intravenously[35] for pediatric RSE. Topiramate is an oral anticonvulsant with multiple mechanisms of action in RSE. The oral dose in adults ranges from 300 to 1600 mg/day.[36] Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg/day and titrated to a maintenance dose of 5 to 6 mg/kg/day.[16] Topiramate can induce metabolic acidosis, requiring careful monitoring. The inhaled anesthetics, desflurane and isoflurane,[37] require special equipment for administration in an ICU. Lacosamide, an enhancer of slow inhibition of sodium channels, has limited drug interactions.[38] It has been used orally[39] and intravenously[40] in the setting of refractory partial SE.

LO 7

Special Populations

Certain patients require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects.[41] Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies in terms of immediate care, assessment, and drugs (see Table 32–2).

▶ *Pediatrics*

The treatment approach for SE in children is similar to that in adults with a few exceptions (see Table 32–3). The doses are also weight-based but are typically higher than those used in adults due to faster hepatic clearance. Timely IV access in children may be difficult, so alternate routes of administration have been used, including intranasal, buccal, rectal, and IM. Early administration of benzodiazepines and reduced time to hospital admission are important in decreasing prolonged seizures.[42]

▶ *Geriatrics*

Older adults are often vulnerable because of multiple disease states and polypharmacy. Seizures in older adults often arise from metabolic disorders, drug interactions, or incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding. Clinicians treating older adult patients with SE should investigate drug- and disease state–induced causes, since treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and anticonvulsants is no different in older adults, but they may experience more profound sedative and cardiorespiratory side effects. Phenytoin/fosphenytoin LDs should be carefully calculated in older adults whose weights may be overestimated, and who may not tolerate high doses. They should also be infused more slowly to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in older adults, especially after benzodiazepines. Clinicians should consider using smaller doses and evaluate for renal and hepatic insufficiency if repeated doses are to be given.

LO 7

Table 32–3

Medications Used in Pediatric Status Epilepticus

Drug	Dose	Comments
Diazepam (Valium injection, Diastat rectal gel)	IV: 0.2–0.3 mg/kg over 2–5 minutes	Maximum dose in children < 5 years: 5 mg Maximum dose in children > 5 years: 15 mg
	PR: 2–5 years: 0.5 mg/kg 6–11 years: 0.3 mg/kg > 12 years: 0.2 mg/kg	A second rectal dose can be given 4–12 hours after the first dose if necessary
Lorazepam (Ativan)	0.05–0.1 mg/kg IV over 2–4 minutes	May redose twice in 10–15 minutes if necessary
Midazolam (Versed)	0.2 mg/kg IV bolus followed by 0.05–0.6 mg/kg/hour continuous infusion	Bolus dose may also be given intranasally, buccally, or intramuscularly
Phenytoin (Dilantin)	15–20 mg/kg IV at 1–3 mg/kg/min *max*	
Fosphenytoin (Cerebyx)	15–20 mg PE/kg IV at 3 mg PE/kg/min *max*	
Phenobarbital (Luminal)	15–20 mg/kg IV at 100 mg/min *max*	
Levetiracetam (Keppra)	20–60 mg/kg IV at 2 mg/kg/min	Few drug interactions
Valproate sodium (Depacon)	15–20 mg/kg IV at 1.5–3 mg/kg/min	May have fewer cardiovascular side effects than other agents
Propofol (Diprivan)		Not recommended due to adverse events (eg, propofol-related infusion syndrome)
Pentobarbital (Nembutal)	10–15 mg/kg IV over 1–2 hours followed by continuous infusion at 1 mg/kg/hour	Titrated to EEG

EEG, electroencephalograph; IV, intravenous; PE phenytoin equivalent; PR, per rectum.

Patient Care Process

Collect Information:

- Review time of onset of seizure activity and past medical/surgical history.
- Obtain vital signs and relevant laboratory testing.
- Perform a medication history of prescription and nonprescription medications and identify medication allergies.
- Obtain patient weight.

Assess the Information:

- Determine airway patency, breathing status, and circulatory status.
- Determine precipitating factors or etiology of SE.
- Identify drug interactions.
- Assess efficacy of and adherence to anticonvulsants if appropriate.
- Review laboratory results for electrolyte and glucose abnormalities and anticonvulsant serum levels.

Develop a Care Plan:

- Correct reversible causes of SE.
- Select initial benzodiazepine agent and dose appropriate for patient based on access and vital signs.
- Select initial anticonvulsant for patient based on access and vital signs.
- If patient is taking anticonvulsants that can be monitored, evaluate for subtherapeutic serum levels and calculate appropriate LDs.

Implement the Care Plan:

- Administer therapeutic doses within the appropriate time frame (see Tables 32–1 and 32–2). Provide maintenance dosing of anticonvulsants when indicated.
- Identify potential drug interactions and adjust as needed.
- Obtain expertise of neurologist or epileptologist when appropriate.

Follow-up: Monitor and Evaluate:

- Determine if physical seizures have stopped and the patient regains consciousness. If not, consider continuous EEG monitoring for at least 24 to 48 hours to identify possible nonconvulsive SE.
- Obtain trough serum anticonvulsant levels at steady state, or sooner if seizures continue. Adjust anticonvulsants based on levels, maximizing seizure control and minimizing adverse effects.

▶ *Pregnancy*

The main concern in the treatment of pregnant females in SE is the safety of the fetus which is at risk of hypoxia during periods of prolonged seizures. Although many drugs used in SE are teratogenic, clinicians should still use them acutely to stop seizures, but consider alternative agents for maintenance therapy.[43] The volume of distribution and clearance of many drugs are increased during pregnancy, and this must be considered when calculating doses.

OUTCOME EVALUATION

Start pharmacologic treatment as soon as possible.

- First-line (emergent) treatment for SE should halt seizure activity within minutes of administration.
- In patients who are unarousable following treatment, confirm termination of seizures with an EEG.
- Perform a physical examination and evaluate laboratory results to help determine if the cause or complications of seizure activity are being appropriately treated.
- Once seizure activity has ceased and the patient has stabilized, review the patient's therapeutic regimen.
- Evaluate and monitor serum trough concentrations of anticonvulsants with defined target ranges to determine patient-specific therapeutic goals.
- In patients with RSE on multiple anticonvulsants, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity.
- Continue to monitor anticonvulsant serum trough concentrations approximately every 3 to 5 days until the anticonvulsants have reached steady-state concentrations.
- Monitor for signs of drug toxicity and seizures until drug concentrations have stabilized.
- Closely evaluate medication profiles, and change drugs or doses to minimize any drug interactions, if possible.

Abbreviations Introduced in This Chapter

ABG	Arterial blood gas
CNS	Central nervous system
CSF	Cerebrospinal fluid
CT	Computed tomography
ECG	Electrocardiogram
EEG	Electroencephalography
GABA	γ-aminobutyric acid
GCSE	Generalized convulsive status epilepticus
ICP	Intracranial pressure
ICU	Intensive care unit
IM	Intramuscular
IV	Intravenous
LD	Loading dose
MRI	Magnetic resonance imaging
NCSE	Nonconvulsive status epilepticus
NMDA	*N*-methyl-D-aspartate
PE	Phenytoin equivalent
RSE	Refractory status epilepticus
SE	Status epilepticus
WBC	White blood cell

33 Parkinson Disease

Thomas R. Smith and Mary L. Wagner

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Describe the pathophysiology of Parkinson disease (PD) related to neurotransmitter involvement and targets for drug therapy.
2. Recognize the cardinal motor symptoms of PD and determine a patient's clinical status and disease progression based on the Movement Disorder Society Unified Parkinson Disease Rating Scale (MDS UPDRS).
3. For a patient initiating therapy for PD, recommend appropriate drug therapy and construct patient-specific treatment goals.
4. Recognize and recommend appropriate treatment for nonmotor symptoms.
5. Formulate a plan to minimize patient "off-time" and maximize "on-time" including timing, dosage, and frequency of medications.
6. Recognize and treat various motor complications in PD.
7. Construct appropriate patient counseling regarding medications and lifestyle modifications for PD.
8. Develop a monitoring plan to assess effectiveness and adverse effects of treatment.

INTRODUCTION

LO1 KEY CONCEPT Parkinson disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the **substantia nigra** are primarily affected, and degeneration of these neurons causes a disruption in smooth motor control. Cardinal features of PD include tremor at rest, rigidity, **akinesia**/bradykinesia, and postural instability. There is no cure, and treatment aims at controlling symptoms and maintaining quality of life (QOL) or functioning.

LO2

EPIDEMIOLOGY AND ETIOLOGY

PD affects approximately 1 million Americans, and a lifetime risk of developing the disease is 1.5%. Median age of the onset is 60 years, but about 10% of people with PD are younger than 45 years. The average time span from diagnosis to death is about 15 years. Approximately 15% of patients with PD have a first-degree relative with the disease.[1,2]

The etiology of neuron degeneration in PD remains unknown, but aging is a primary risk factor. Thus, as the fraction of the population that is elderly continues to increase, this disease may see a subsequent increase in prevalence. Cell death may be caused by oxidative stress, mitochondrial dysfunction, increased excitotoxic amino acids and inflammatory cytokines, immune system disorders, signal-mediated **apoptosis**, and environmental toxins. Oxidative stress may result from increased monoamine oxidase-B (MAO-B) metabolism or decreased glutathione clearance of free radicals.[2–5]

Genetic mutations such as those in *LRRK2* have been linked to PD, and particular mutations may predict early versus late onset of the disease.[2,3] Most likely, a combination of inducers of cell death and genetic mutations are involved in PD.[2] Pigmented cells in the substantia nigra that make and store dopamine are lost. At the time of diagnosis, 50% to 60% of dopamine neurons located here may be dysfunctional. Neurons have lost about 80% of their activity in the striatum at the onset of PD. Cortical **Lewy bodies** along with Lewy neurites in the central nervous system (CNS) and the gastrointestinal (GI) system may explain some of the nonmotor symptoms (e.g., psychiatric, autonomic symptoms) of PD.[2,4,5]

Interestingly, patients with a history of smoking or who drink coffee or tea have demonstrated decreased risk of PD through unknown mechanisms.[2]

PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through pathways and nerve tracts that connect the cerebral cortex, **basal ganglia**, thalamus, cerebellum, reticular formation, and spinal neurons. The substantia nigra, where dopamine neurons in PD are lost, sends nerve fibers to the corpus striatum. The corpus striatum is composed of the caudate nucleus and the lentiform nuclei that consist of the pallidum (globus pallidus) and putamen (**Figure 33–1**). As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain, and patients develop motor symptoms. A variety of other neurotransmitters active in the basal ganglia lose concentration as well. These deficits possibly explain specific nonmotor symptoms seen in PD as loss of dopamine and norepinephrine in the limbic system correlates with depression and anxiety, while losses of neurotransmitters, acetylcholine and serotonin in the limbic system are associated with cognitive impairment.[2,3,5,6]

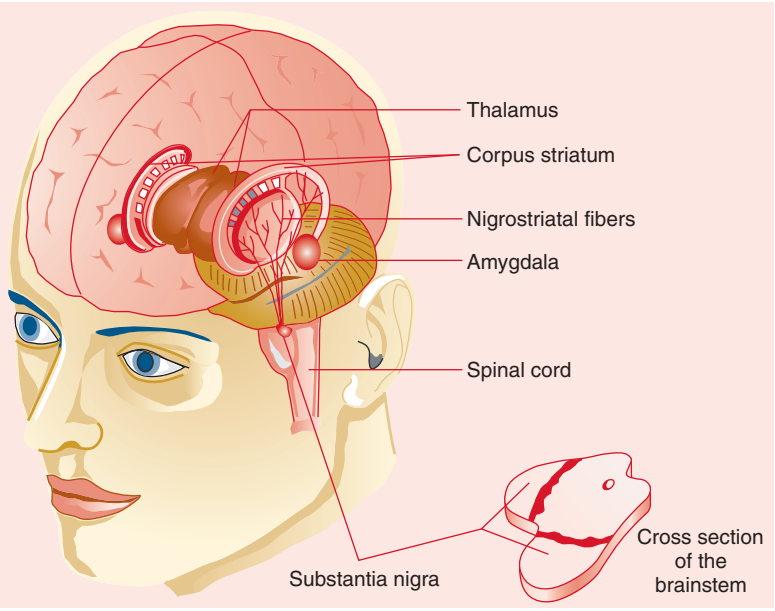

FIGURE 33–1. Anatomy of the extrapyramidal system. The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD have a loss of dopamine neurons in the substantia nigra in the brainstem that leads to depletion of dopamine in the corpus striatum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that are made up of the putamen and the globus pallidus.

Theorized to begin in the autonomic system, olfactory system, or vagus nerve in the lower brainstem, the disease may then spread to the upper brainstem and cerebral hemisphere affecting dopamine pathways later.[2] It is essential to rule out drug-induced pseudoparkinsonism due to dopamine antagonists such as antipsychotics, metoclopramide, and antiemetics (prochlorperazine) before diagnosis. Removing the offending agent generally resolves symptoms.[1,7]

Clinical Presentation of PD

Motor Symptoms (TRAP)

T = Tremor at rest ("pill rolling")

R = Rigidity (stiffness and cogwheel rigidity)

A = Akinesia or bradykinesia

P = Postural instability and gait abnormalities

Nonmotor Symptoms (SOAP)

S = Sleep disturbances (insomnia, REM sleep behavioral disorder, [RLS])

O = Other miscellaneous symptoms (nausea, fatigue, speech, pain, dysesthesias, vision problems, seborrhea)

A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)

P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

Response Fluctuations (MAD)

M = Motor fluctuations (delayed peak, wearing off, random off, freezing)

A = Akathisia

D = Dyskinesias (eg, chorea, dystonia, diphasic dyskinesia)

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of PD is based substantially on signs and symptoms rather than diagnostic tests or imaging; however, this can be difficult as other illnesses have characteristics similar to PD and patients' presentations vary initially and through time. DaTscan, a radiopharmaceutical contrast agent, may help differentiate PD from other disorders such as essential tremor, but not from similar Parkinson-plus syndromes.[8] Therefore, a thorough patient history and detailed description of symptoms are essential.

Patient Encounter Part 1: Initial Visit—Medical History

A 63-year-old woman presents to the movement disorder clinic on suspicion of new-onset PD. She complained to her physician that "for the past few months, I've had a tremor in my left arm most of the time and have noticed that my muscles in my arms seem to be stiff. I must have a problem with cramping." She reports nothing that worsens symptoms or any acute changes in severity recently. She cares for her 1-year-old granddaughter three times per week but has found that her symptoms disrupt her ability to fully care for the child as she has trouble picking her up and feeding her. She reports that her tremor somewhat affects her ability to feed the child when she uses a spoon. Other complaints include worsening of eyesight, feeling more tired than usual, constipation, decreased libido, and sadness.

What test could be ordered to aid in the diagnosis of PD?

What assessments should be completed at this time?

Identify this patient's motor and nonmotor symptoms of PD.

What additional information would you collect before creating this patient's treatment plan?

Motor Symptoms

KEY CONCEPT PD is a slow, progressive neurodegenerative disease of the extrapyramidal motor system with classic motor symptoms of tremor, rigidity, akinesia/bradykinesia, and postural/gait instability (TRAP).

The onset of PD is gradual, and movement impairment may initially go unnoticed. Tremor occurs during rest and disappears with purposeful movement. Hand tremor may mimic a patient rolling a pill between his or her fingers. Rigidity manifests as stiffness with uniform muscle resistance on examination. Examiners may notice cogwheel rigidity on extension or flexion of extremities and feel rhythmical jerking as if hitting a series of teeth on the rim of a wheel. Bradykinesia manifests as hesitancy in movement initiation, slowness in movement, or rapid fatiguing. Decreased automatic activity (e.g., eye blinking, **hypomimia**, minimal arm swing while walking) is common. Rigidity and bradykinesia may make handwriting difficult as **micrographia** is common. Loss of reflexes to maintain balance as well as stooped posture causes postural instability and unsteadiness. This, combined with gait abnormalities such as slow shuffling, leg dragging, **festination**, or **freezing**, increases the risk of falls.[2,9–13]

Nonmotor Symptoms

Nonmotor symptoms in PD may precede the onset of motor symptoms by many years and result from PD itself or medications. Sleep disturbances, autonomic impairment, psychological disturbances, and sensory disturbances (**anosmia**) are common.[2,6,9,14-17]

Speech problems manifest as **hypophonia**, slurring, monotone speech, rapid speech, or stammering. When ocular muscles are impaired, difficulty reading, double vision, decreased blinking, and burning or itchy eyes are possible.[2,6,9–13]

Autonomic nervous system disruption may produce orthostatic hypotension as well as GI, urinary, sexual, and dermatologic symptoms. Orthostatic hypotension may cause dizziness, lightheadedness, fainting, or falls. Constipation is very common and **dysphagia** may lead to weight loss, **sialorrhea**, and aspiration.[14,15] Genitourinary symptoms include incontinence, urgency, and frequency causing nocturia. Sexual dysfunction includes libido or inability to achieve orgasm and erectile or ejaculatory dysfunction. Dermatologic symptoms include sweating and intolerance to temperature changes.[2,6,9,14,15]

Psychological symptoms of psychosis, dementia, impaired cognitive function, depression, and anxiety may result from PD, during symptom exacerbation, or from medications. Psychosis occurs in nearly 60% of PD patients. Depression is common, but decreased facial expression and bradykinesia may give a false appearance of depression in the PD patient; thus a proper assessment of mood is necessary. Often comorbid with depression, anxiety has been noted in over half of patients with motor fluctuations.[2,6,14,16–18]

Sleep disorders may be due to PD itself or medication adverse effects. Excessive daytime sleepiness, insomnia, and abnormal sleep events, such as rapid eye movement sleep behavior disorder (REM SBD), may occur.[6,9,14]

Motor Complications

Motor complications appear with either disease progression or as a complication of treatment, particularly with levodopa. Motor complications include **delayed peak response**, early and unpredictable "wearing off," freezing, and **dyskinesias**—namely **chorea** and **dystonia**. Risk factors for developing motor complications include younger age at diagnosis, high dosage of levodopa, and longer duration and severity of disease. Wearing off occurs when the therapeutic window of levodopa—the minimum effective concentration required to control PD symptoms ("on" without dyskinesia) through the maximum concentration before experiencing side effects from excessive levodopa ("on" with dyskinesia)—narrows over time. Although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect in early PD lasts about 5 hours, and the patient experiences no dyskinesias. This is due to supplemental dopamine production in the CNS. As PD progresses, this endogenous supply is lost, the therapeutic window narrows, and each dose of levodopa acts less functionally, with the effect decreasing to only 2 to 3 hours. Additionally, dyskinesias occur more frequently during the on state, particularly as the dose of levodopa is increased.[5,19,20]

KEY CONCEPT The Unified Parkinson Disease Rating Scale (MDS UPDRS) describes total symptom burden, tracks disease progression, and assesses treatment efficacy. This clinician and patient-rated scale has four parts, which allow for evaluation of nonmotor symptoms, activities of daily living (ADL), motor symptoms, and complications of therapy. Each symptom is given a numerical score from 0 to 4 (none to severe) to describe severity.[21]

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of treatment include:

- maintaining patient independence, ADL, and QOL
- minimizing the development of response fluctuations
- limiting medication-related adverse effects

General Approach to Treatment

KEY CONCEPT Treatment of PD is categorized into three types: (1) lifestyle changes, nutrition, and exercise; (2) pharmacologic intervention; and (3) surgical treatments after pharmacologic interventions fail.

LO 3

Initial treatment depends on the patient's age, risk of adverse effects, degree of physical impairment, and readiness to initiate therapy (Figure 33–2).[22,24]

The 2002 American Academy of Neurology (AAN) guidelines suggest that pharmacologic treatment be delayed until the patient experiences functional disability.[23] However, 2017 guidelines by the National Institute for Health and Care Excellence (NICE) differ and recommend dopamine agonists, levodopa, or MAO-B inhibitors be offered to patients even before QOL is affected.[24] While some data do suggest that earlier treatment may delay the progression of disease, many studies examining this have design flaws and inconsistent results.[12,14,25] One must weigh the pros and cons of delaying pharmacotherapy or starting medications early on an individual patient basis.[23,26,27]

Nonpharmacologic Therapy

▶ *Lifestyle Modifications*

Nonpharmacologic therapy and patient education is ideally implemented early and continued throughout treatment for PD. The most common interventions include maintaining

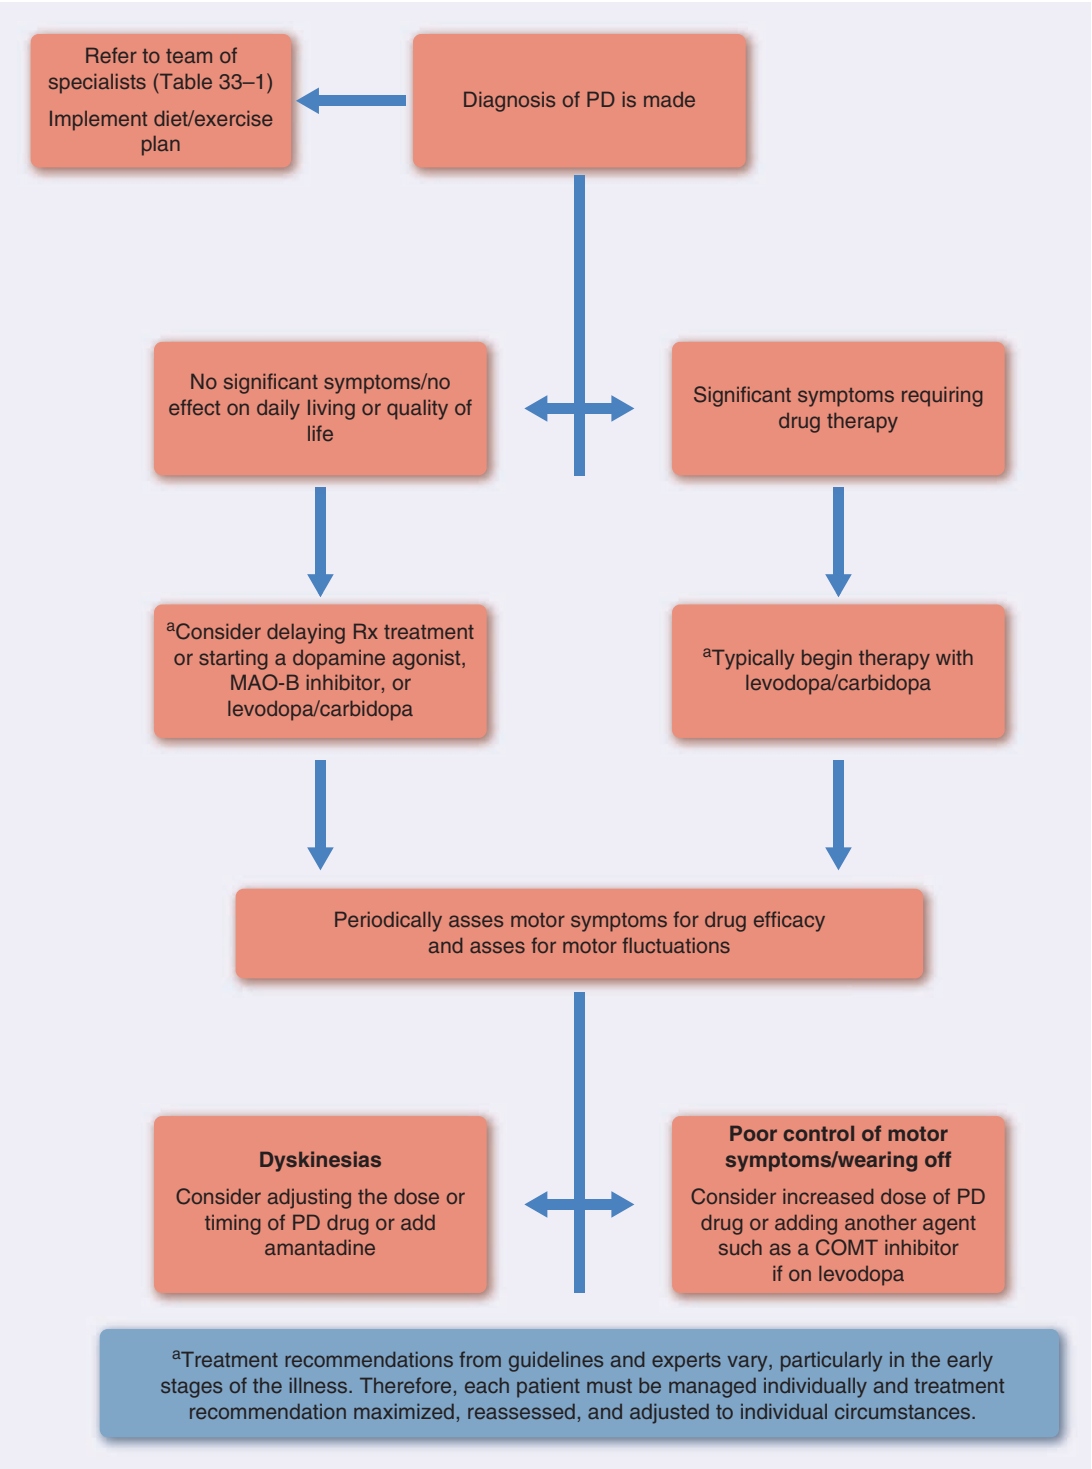

FIGURE 33–2. Algorithm for diagnosis and management of Parkinson disease.[1,19,24]

good nutrition, physical condition, and social interactions.[1,10] These treatments may improve ADLs, gait, balance, and mental health. Coordinated care with multiple health care professionals maximizes patient outcomes as each specialist plays a necessary role in the treatment team (Table 33–1).

Surgery

Consider surgery with deep brain stimulation (DBS) when inadequate control of motor symptoms develop despite pharmacotherapy. This procedure electrically stimulates the subthalamic nucleus (STN) or globus pallidus interna. DBS may significantly reduce motor symptoms and complications and improve QOL compared to medication management. Targeting the STN is preferred when a decrease in PD medication use is desired while targeting the globus pallidus may better treat dyskinesias.[28,29] Thalamic stimulation is available for those with severe tremor who are unsuitable for STN stimulation. These surgeries carry risks and are generally utilized after suboptimal response to drug therapy.[24]

Patient Encounter Part 2: Initial Visit—Physical Examination and Diagnostic Tests

Chief Complaint: New onset unilateral tremor and upper body muscle stiffness; decreased sleep quality

PMH: Constipation for greater than 10 years, osteoporosis, cataracts, mild anemia

SH: Retired. Lives alone but provides childcare for her granddaughter. Denies alcohol use. Smoked 0.5 PPD in her 20s and 30s but has since quit.

Meds: Alendronate 70 mg orally once weekly, ferrous sulfate 325 mg orally twice daily

ROS: (–) Psychosis or agitation; reports depression; denies nausea, vomiting, diarrhea, HA, dizziness, or pain

PE:

Gen: Flat affect, looks older than stated age, speaks softly and often difficult to hear, handwriting when completing the intake forms is difficult to read

VS: BP: sitting 115/75, P 63 beats/min, RR 18/min, Wt 59 kg (130 lb), Ht 165 cm (65 in)

HEENT: Decreased eye blinking and facial expression, CN II-XII intact, PERRLA, TMs intact

CV: RRR, normal S1, S2; no murmurs, rubs, gallop

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

Skin: Some dryness on the back of her neck, otherwise normal

Exts: Mild to moderate tremor in her left arm most noticeable at rest. Mild cogwheel rigidity bilateral elbows

Neuro: Slow, sensory function intact, normal muscle strength, normal reflexes, alert, mental status examination normal

Rating Scales: Patient Health Questionnaire (PHQ-9) = 10; Mini Mental State Exam (MMSE) = 29/30; UPDRS = 58 at current visit; no prior history to compare to

Labs: Normal metabolic profile and CBC

Given this additional information, what is your assessment of the patient's condition?

Identify treatment goals for the patient.

Describe nonpharmacologic treatments that should be started for the patient.

List options for initial pharmacologic treatments that are available for the patient and differentiate between their appropriateness.

Table 33–1

Specialist Care for Patients with PD

Provider	Reason for Referral
Dentist	PD medications may decrease saliva flow and increase the risk of dental caries
Dietician	Recommend appropriate caloric intake, meal selection, and protein consumption which may: • improve constipation and nausea • decrease weight loss and aspiration • minimize erratic drug absorption
Speech therapist	Improved swallowing, articulation, and force of speech
Physical therapy	Improve strength, activity, sleep quality, and reduce fall risk May provide neuroprotection
Occupational therapist	Educate on adaptive environment of home, specialized clothing, and personal training to evaluate and maximize: • Independence • Safety • ADLs • Handwriting • Driving ability
Social worker	Arrange for community assistance programs and family counseling Increase engagement in family activities

Nutt JG, Wooten GF. Diagnosis and initial management of Parkinson's disease. N Engl J Med. 2005;353:1021–1027.[1]

Anonymous. Drugs for Parkinson's disease. Treat Guidel Med Lett. 2011;9(101):1–6.[27]

Pharmacologic Therapy of Motor Symptoms

KEY CONCEPT Drug therapy aims to enhance dopaminergic activity in the substantia nigra. When to initiate dopaminergic therapy is controversial and patient specific. Medications minimize motor symptoms and improve QOL and ADLs but are not curative (Table 33–2).[1,2,30] Even with pharmacotherapy, PD patients have greater mortality and morbidity than the general population.[1] KEY CONCEPT Choice of pharmacologic agent should be individualized based on patient-specific parameters, and dose regimens based on individual response to maximize "on time" and minimize "off time."

Pharmacologic options for PD include anticholinergics (Ach), amantadine, MAO-B inhibitors, dopamine agonists, levodopa/carbidopa, and catechol-*O*-methyltransferase (COMT) inhibitors. Most pharmacologic treatments in PD aim to avoid degeneration of the dopaminergic nigrostriatal pathway and increase dopamine concentrations (Figure 33–3). The AAN and the Movement Disorder Society recommend most patients initiate treatment with either levodopa/carbidopa or a dopamine agonist.[10–14] The 2017 NICE guidelines slightly differ and recommend levodopa/carbidopa for patients once motor symptoms begin to affect QOL.[24]

Choice between drugs varies based on clinical experience and patient preference. Starting with a dopamine agonist may delay the onset of dyskinesias and response fluctuations seen with long-term levodopa use; however, less motor benefit and greater risk of hallucinations or somnolence may occur. Levodopa causes the greatest motor improvement and should be used as initial therapy in the elderly, but may increase the risk of motor fluctuations over time.[26] Data are insufficient to recommend initiating treatment with combined drug classes. Initiating treatment with anticholinergic medications, amantadine, or MAO-B inhibitors is recommended only for patients who have mild symptoms because they are not as effective as dopamine agonists or levodopa.[1,2,10–14,30]

Table 33–2

Dosing of Medications Used to Treat PD[1,2,32,34]

Generic Name (Trade Name)	Initial Dose	Titration and Maintenance Dose	Available Formulations	Hepatic or Renal Adjustments
Levodopa Formulations				
Levodopa with carbidopa (Sinemet)	Half tablet (100 mg LD, 25 mg CD) twice daily for 1 week, then half tablet three times daily	Increase by half tablet daily every week; usual MD is 300–2000 mg daily; because the duration of LD is 2–3 hours, patients may require doses every 2 hours.	Stalevo—CD/LD/Entacapone tablet	
Sinemet CR	One tablet (100 mg LD, 25 mg CD) two to three times daily	Increase to 200 mg LD tablet two to four times daily; usual MD is 200–2200 mg daily.	Sustained-release tablet	
Rytary (extended-release levodopa with carbidopa)	In levodopa naïve patients: 23.75 mg/95 mg taken orally three times a day for the first 3 days	On the fourth day of treatment, the dosage may be increased to 36.25 mg/145 mg taken three times a day. Individual doses may be increased and doses may be given up to five times a day based on individual response; patients previously on immediate release levodopa should follow recommended conversions.	Extended-release capsule	
Duodopa (intestinal infusion of LD/CD)	Convert patients to Sinemet and calculate a total daily dose.	Dose consists of a morning dose, a continuous infusion, and additional doses. One extra dose per 2 hours is maximum. Maximum dose is 2000 mg of LD over 16 hours.	Intestinal suspension	
Dopamine Agonists				
Apomorphine (Apokyn)	Start trimethobenzamide 300 mg for 3 days; then give apomorphine 2 mg SC injection (1 mg if outpatient) while monitoring blood pressure.	Continue trimethobanzamide as necessary (generally no longer than 2 months). Increase apomorphine by 1–2 mg every ≥ 2 hours; usual MD is 2–6 mg three to five times daily for off periods.	Subcutaneous solution	Reduce initial dose to 1 mg in mild to moderate renal failure.
Bromocriptine (Parlodel)	1.25 mg twice daily	Increase by 2.5 mg daily every 14 to 28 days.	Capsule, tablet	Dosing adjustments may be necessary with hepatic impairment.
Pramipexole (Mirapex)	0.125 mg three times daily	Increase about weekly by 0.375– 0.75 mg/day to a MD of 0.5–1.5 mg three times daily.	Tablet	Dosage reduction needed in creatinine clearance < 50 mL/min (0.83 mL/s).
Mirapex ER	0.375 mg once daily	Increase up to 0.75 mg/day after a minimum of 5 days. Dose may then be increased in increments of 0.75 mg/day no more frequently than every 5–7 days.	Extended-release tablet	
Ropinirole (Requip)	0.25 mg three times daily	Increase about weekly by 0.75–1.5 mg daily to a MD dose of 3–9 mg three times daily. Then may increase by 3 mg/day on a weekly basis to a maximum of 24 mg/day.	Tablet	
Requip XL	2 mg once daily for 1–2 weeks	Increase by 2 mg/day in 1-week intervals; maximum dose is 24 mg/day.	Extended-release tablet	
Rotigotine (Neupro)	2 mg patch once daily for early-stage PD; 4 mg patch for advanced-stage PD	Increase by 2 mg/24 hours on a weekly basis.	Patch	
MAOIs				
Selegiline (Eldepryl)	5 mg in the morning	If symptoms continue, add 5 mg at noon; 5 mg daily may be as clinically effective as 10 mg daily with fewer side effects.	Tablet, capsule	Use is not recommended for creatinine clearance < 30 mL/min (0.50 mL/s) or severe hepatic impairment.

(*Continued*)

Table 33–2

Dosing of Medications Used to Treat PD[1,2,32,34] (*Continued*)

Generic Name (Trade Name)	Initial Dose	Titration and Maintenance Dose	Available Formulations	Hepatic or Renal Adjustments
Selegiline ODT (Zelapar)	1.25 mg once daily	If symptoms continue after 6 weeks, increase dose to 2.5 mg every morning. Avoid food or liquid for 5 minutes before or after the dose.	Dispersable tablet	
Rasagiline (Azilect)	If used with levodopa, 0.5 mg daily	If symptoms continue, increase to 1 mg daily.	Tablet Tablet	Use 0.5 mg/day in mild hepatic impairment. Do not use in moderate to severe impairment.
Safinamide (Xadago)	50 mg once daily	May increase after 2 weeks to 100 mg once daily.		Maximum dose is 50 mg once daily in moderate hepatic impairment and use is contraindicated in severe impairment.
COMT Inhibitors				
Tolcapone (Tasmar)	100 mg with first Sinemet dose once daily	If symptoms continue, increase to 2 and then 3 times daily, then to 200 mg each dose; usual MD is 100–200 mg three times daily.	Tablet	Do not use in patients with active liver disease or SGPT/ALT or SGOT/AST > the upper limit of normal.
Entacapone (Comtan)	200 mg tab with each Sinemet dose	Usual MD is 200 mg three to four times daily (up to eight tablets per day).	Tablet	Decrease dose by 50% with hepatic impairment.
Others				
Amantadine (Symmetrel) Gocovri (amantadine XR)	100 mg daily at breakfast 137 mg once daily at bedtime	After 1 week, add 100 mg daily; usual MD is 200–300 mg daily with last dose in afternoons. After 1 week, increase to 274 mg once daily.	Capsule, tablet, oral syrup Extended-release capsule	Decrease dose for creatinine clearance < 80 mL/min (1.33 mL/s). Start with 68.5 mg once daily in moderate renal impairment and use a maximum dose of 137 mg. In severe renal impairment, use 68.5 mg once daily. Do not use in end-stage renal disease.
Benztropine (Cogentin)	0.5 to 1 mg at bedtime	Assess if dose is adequate and titrate by 0.5 mg increments at 5- to 6-day intervals to a maximum of 6 mg if necessary.	Tablet, solution for injection	

Ach, acetylcholine; CD, carbidopa; COMT, catechol-*O*-methyltransferase; CR, controlled-release; DA, dopamine; LD, levodopa; MAO, monoamine oxidase; MD, maintenance dose; NMDA, *N*-methyl-D-aspartate; ODT, orally disintegrating tablet; PD, Parkinson disease; XR, extended-release.

Regardless of the drug initially chosen, the initial dose is low and increased gradually based on symptoms (see Table 33–2). Dose timing and frequency is then adjusted based on the patient's report of "on time" duration and wearing off symptoms. Dyskinesias may develop with the use of PD drugs and generally relate to dopamine concentrations. Decreasing the dose, frequency, or number of dopaminergic medications may be beneficial. If a PD medication is discontinued, gradual withdrawal is recommended with monitoring of worsening motor symptoms.

▶ *Anticholinergics*

Ach block acetylcholine, decreasing the acetylcholine to dopamine concentration ratio. They minimize resting tremor and drooling, but are not as effective as other agents for rigidity, bradykinesia, and gait problems. Because of their side effects including cognitive impairment, Ach are typically avoided in older patients.[1,2,9,27] Additionally, gastric motility may be compromised delaying gastric emptying and leading to erratic and decreased levodopa absorption. Lastly, they may worsen urinary retention or constipation.[31]

▶ *Amantadine*

Amantadine is an *N*-methyl-D-aspartate (NMDA)-receptor antagonist that blocks glutamate transmission, promotes dopamine release, and blocks acetylcholine. It is likely effective as monotherapy and adjunct therapy for off time and dyskinesia.[20,32,33] An extended release version was approved specifically for dyskinesias in PD making it the only FDA (Food and Drug Administration)-approved option for this complication.[34,35] Side effects include nausea, dizziness, livedo reticularis, peripheral

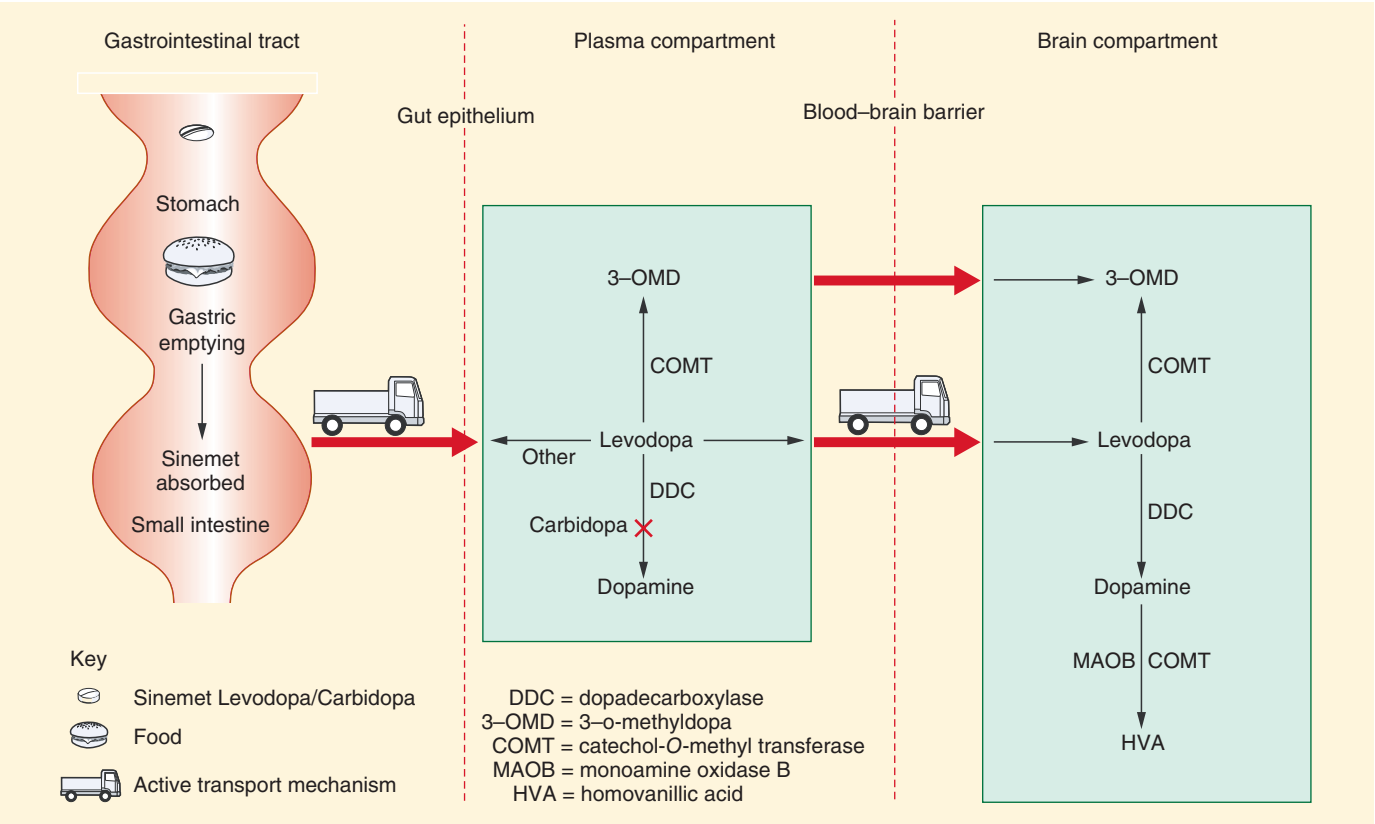

FIGURE 33–3. Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa decarboxylase, monoamine oxidase, and catechol-*O*-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport into the brain (plasma compartment to brain compartment). Food and anticholinergics delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

edema, orthostatic hypotension, hallucinations, restlessness, anticholinergic effects, and insomnia. Insomnia is minimized by taking the ER (extended-release) formulation at bedtime and the immediate release formulation earlier in the day. It should be avoided in the elderly who cannot tolerate its anticholinergic effects.[7,29,39]

▶ *MAO-B Inhibitors*

Safinamide, selegiline, and rasagiline work through selective blockade of dopamine metabolism through MAO-B. Selegiline and rasagiline provide a mild symptomatic benefit for patients who choose to delay dopaminergic medications and use MAO-B inhibitors as initial therapy. Combining selegiline or rasagiline with levodopa in early treatment may delay motor complications.[20,25,32] For patients with motor fluctuations, they reduce off time when added to levodopa therapy.[9–12,34]

Both rasagiline and selegiline may be neuroprotective and thus may be selected early in therapy, but there is no conclusive evidence to validate this.[36]

Selegiline is generally well tolerated. Adverse effects include nausea, confusion, hallucinations, jitteriness, insomnia, and orthostatic hypotension. Selegiline is available in an orally disintegrating tablet designed to avoid first-pass metabolism. This improves bioavailability and decreases serum concentrations of its amphetamine-like metabolite which may cause insomnia. Daily doses are limited to 10 mg because MAO-B selectivity may be lost at higher doses increasing the risk of drug and food interactions.[25]

Rasagiline has a similar adverse effect profile but is less likely to cause insomnia compared to selegiline. In contrast to nonselective MAOIs, restriction of tyramine-containing foods is not required at recommended dosages, but high tyramine-containing food or exceeding recommend dosing of rasagiline may increase the risk of hypertensive crisis.[32,34]

Safinamide, an MAO-B inhibitor, is the first unique compound approved in recent years for PD. It is indicated specifically in conjunction with levodopa/carbidopa after patients begin to experience off episodes; however, it will likely be used in similar situations as the other MAO-B antagonists.[3,32]

Risk of dyskinesias is minimized by decreasing the levodopa dose when adding any of these agents. Serotonin syndrome and hypertensive crisis may occur in patients using these medications with opioid analgesics, antidepressants, and other serotonergic agents, or sympathomimetic amines (cold and weight loss products) (see Chapter 38).[7,25]

▶ *Dopamine Agonists*

Dopamine agonists bind to postsynaptic dopamine receptors and are reasonable as initial therapy. Their advantages include

delay of levodopa therapy and smaller risk of developing motor fluctuations during the first 4 to 5 years of treatment. Eventually, they inadequately control the patient's symptoms, and levodopa is necessary. In advanced disease, they can be added to levodopa to minimize response fluctuations, decrease off time, improve wearing-off symptoms, allow a reduction in levodopa dose, and improve ADLs.[1,2,10,12,30,37]

Dopamine agonists include the ergot derivatives (bromocriptine) and the nonergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Generally, the nonergot agents are preferred due to a more favorable adverse effect profile and stronger efficacy evidence.[38] Rotigotine is available as a once-daily skin patch which minimizes pulsatile dopaminergic stimulation.[1,7,27,32]

Common side effects with all dopamine agonists include nausea (most common initial symptom), vomiting, sedation (greatest with apomorphine), pedal edema, orthostatic hypotension (greatest with pramipexole), and psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Uncommon ergot side effects include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.[1,7,27,32] Patients should be given instructions regarding the potential of the dopamine dysregulation syndrome (DDS). This includes drug seeking, complex stereotyped behavior (punding), and impulse control disorders (ICDs) such as gambling or compulsive shopping. Reducing or eliminating the agonist typically resolves DDS.[39] If symptoms continue, zonisamide, topiramate, valproic acid, amantadine, and quetiapine may be trialed to treat these effects.[32]

Dopamine agonists may cause excessive daytime sleepiness in 50% of PD patients. Sudden sleep attacks are potentially dangerous during driving. Modafinil and other agents to promote wakefulness may be used for daytime sleepiness, but use for sleep attacks remains controversial.[32,40]

All dopamine agonists are metabolized by the liver except pramipexole, which is eliminated unchanged in the urine. Ropinirole is metabolized by CYP1A2 and thus subject to drug–drug interactions including tobacco.[7,27]

Apomorphine is subcutaneously injected for acute off episodes in advanced PD when rapid rescue therapy is needed. It requires premedication with an antiemetic due to nausea and vomiting.[7,27,32]

► *Levodopa/Carbidopa*

Although levodopa, a dopamine precursor, is the most effective agent for PD, when to initiate therapy remains controversial. Patients experience a 40% to 50% improvement in motor function with levodopa versus 30% with dopamine agonists.[1,2,26] However, some argue delaying levodopa because approximately 70% of patients experience motor complications within 6 years. Others advocate earlier therapy because, historically, before levodopa availability, patients developed dyskinesias earlier than modern-era patients. Delaying levodopa therapy in early disease may not offer short- or long-term benefits.[1,7,19,22,27]

Levodopa usually peaks in the plasma in 30 to 120 minutes but the concentration is sensitive to GI variables. Excess stomach acid, food, or anticholinergic medications delay gastric emptying and decrease the amount of levodopa absorbed. Antacids improve levodopa absorption, while iron products bind levodopa and reduce bioavailability. Levodopa absorption requires active transport by a large neutral amino acid transporter protein (see Figure 33–3). Amino acids in food compete for this transport mechanism. Thus, in advanced disease, avoidance of protein-rich meals in relationship to levodopa doses may be helpful.[1,7,27]

Controlled-release (CR) formulations act longer than immediate-release tablets but are absorbed slower. This results in a delayed onset (45–60 minutes) compared with the standard formulation (15–30 minutes); thus patients may also require immediate-release (IR) tablets or even a liquid formulation when they want a quicker onset of effect. CR preparations are not directly interchangeable with IR but can be added to IR to extend the duration of action. Generally, the total daily dose of CR preparations should be increased by 30%. An ER formulation of levodopa (Rytary) is also approved, but its ideal place in therapy is yet to be determined.[1,26,27]

Converting patients from oral formulations to enteral or duodenal levodopa administration improves motor fluctuations and UPDRS scores. The levodopa/carbidopa combination can be administered directly to the duodenum via a small tube. This formulation (Duopa) is reserved for advanced PD with severe motor fluctuations.[41]

Levodopa is usually administered as a combination product with carbidopa, a dopa-decarboxylase inhibitor, which decreases the peripheral conversion of levodopa to dopamine. This allows for lower levodopa doses and minimizes levodopa peripheral side effects (nausea, vomiting, anorexia, and hypotension). Carbidopa does not cross the blood–brain barrier and does not interfere with levodopa conversion in the brain. Generally, 75 to 100 mg daily of carbidopa is required to adequately block peripheral dopa-decarboxylase. Higher doses of carbidopa may reduce nausea when initiating levodopa.[1,7]

Initial levodopa side effects include orthostatic hypotension, dizziness, anorexia, nausea, vomiting, and discoloration of urine/sweat. Most of these effects can be minimized by taking levodopa with food and by slowly titrating the dose. Side effects that develop later in therapy include dyskinesias, sleep attacks, ICDs, and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose.[1,7,26,27]

Because levodopa is short acting, it has a risk of end-of-dose wearing off that requires medication adjustments. Patients with severe dyskinesias and off periods may achieve more constant blood concentrations with a liquid formulation of levodopa/carbidopa compounded from tablets. This may allow for more precise dosing and improvements in motor symptoms and complications.[7,26,27,41]

► *Catechol–O–Methyltransferase (COMT) Inhibitors*

Inhibitors of COMT, an enzyme that catalyzes levodopa to 3–o-methyldopa, are added to levodopa/carbidopa to increase levodopa concentrations, extend its half-life, and decrease wearing off time. Using the COMT inhibitors, entacapone or tolcapone, may allow for a decrease in daily levodopa dose while increasing on time by 1 to 2 hours. Side effects include diarrhea (worse with tolcapone), nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations. Dyskinesias should improve with a decrease in the levodopa dose.[7,26,27]

Tolcapone should be used only in patients who do not tolerate or respond to entacapone due to its hepatic safety profile. Serum liver function tests should be monitored at baseline and throughout therapy.[7,26,30]

▶ *Herbs and Supplements*

There is very little support for using creatine, gingko, ginseng, green tea, ginger, yohimbine, or St John's wort in patients with PD. Patients should eat a balanced diet and consider a multivitamin with minerals, but specific vitamin supplementation is generally unceccesary.[8] Because of osteoporosis and fall risk, consider providing a vitamin D supplement in patients with low concentrations.[24]

Treatment of Nonmotor Symptoms

KEY CONCEPT Treatment of nonmotor symptoms should be based on whether they are exacerbated by an off state or might be related to other neurotransmitter dysfunction.

LO 4

The treatment of nonmotor symptoms, such as psychological conditions, sleep disorders, and autonomic dysfunction, should include both pharmacologic and nonpharmacologic approaches. Patients should be supported to maintain ADLs, a positive self-image, family communication, and a safe environment.

Psychological Symptoms

Psychological symptoms and psychosis are common complaints in PD. When these are present, infections, metabolic changes, electrolyte disturbances, or toxic exposures should first be examined.

▶ *Depression*

Depression is extremely common in patients with PD, affecting 40% or more of patients, and it often precedes the disease. Although evidence supports efficacy of tricyclic antidepressants, their adverse effects are limiting. Alternatively, selective serotonin reuptake inhibitors may be considered because of their increased tolerability. Pramipexole may also improve depression.[19] Antidepressants are also useful for the treatment of anxiety disorders. Because off periods can both precipitate anxiety and worsen depression, therapy should be adjusted to maximize on periods.[2,14,18]

▶ *Dementia*

Dementia occurs in approximately 80% of patients with PD 20 years after diagnosis. Cholinesterase inhibitors may be effective while the efficacy of memantine is unclear.[2,14,16,17,32]

Psychosis

Treating psychosis in PD can be difficult as most antipsychotics act as dopamine antagonists, machanistically opposing most PD drugs, and may worsen motor symptoms. Additionally, all antipsychotics carry a black box warning of increased risk of death when used in patients with dementia. Therefore, first treat any underlying medical causes for psychosis; then gradually decrease and stop low-efficacy PD medications. If these strategies fail, antipsychotics may be considered. Clozapine is more effective, but traditionally, low-dose quetiapine has been preferred because clozapine requires monitoring for neutropenia (see Chapter 37). Neither is approved in PD.[2,14-17,42] Although, pimavanserin, another antipsychotic, is specifically approved for PD psychosis and has the lowest risk of worsening motor symptoms, it is expensive, needs to be dispensed through a specialty pharmacy, interacts with CYP3A4 drugs and can prolong QT interval.[34,42]

Sleep Problems

Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled symptoms, or other causes such as nocturia, sleep attacks during the day, depression, SBD, or restless legs syndrome (RLS). Amantadine and selegiline may worsen insomnia, selegiline and tricyclic antidepressants may worsen REM sleep, and some antidepressants and antipsychotics may worsen RLS; therefore, careful evaluation of drug regimens is necessary in patients with sleep complaints.

Reducing RLS and nighttime leg movement may be achieved through PD medications. Levodopa reduces periodic leg movements while a nighttime dose of a COMT inhibitor may benefit RLS. Furthermore, the rotigotine patch may both improve overall sleep quality as well as morning motor symptoms.[43] Iron supplementation for RLS may decrease levodopa absorption in addition to worsening constipation.[2,14] Generally, improving nighttime motor symptoms, maximizing sleep hygiene, or implementing cognitive behavioral therapy may help.[14,18]

Autonomic and Other Problems

Drooling may accompany speech problems and dysphagia. Ach, botulinum toxin injections, and sublingual atropine can decrease drooling. Nausea improves if PD medications are taken with meals or antiemetic therapy (eg, domperidone or trimethobenzamide).

Sexual dysfunction may respond increased on time, removal of drugs that decrease sexual response, and pharmacologic therapy (eg, sildenafil). Studies of sexual dysfunction in women with PD are lacking.[6,14]

Patients with urinary frequency may find a bedside urinal and decreased evening fluid intake helpful. Improvement in PD symptoms can decrease urinary frequency, but symptoms may require catheterization or pharmacologic measures (eg, oxybutynin, tolterodine, propantheline, imipramine, hyoscyamine, or nocturnal intranasal desmopressin).

Constipation may improve with increased fluid intake, a fiber-rich diet, probiotics, and physical activity. Stool softeners, osmotic or bulk-forming laxatives, glycerin suppositories, or enemas may help; cathartic laxatives should be avoided.[6,14]

Dyskinesia-related sweating may respond to PD therapy adjustment or β-blockers.

Treating orthostasis includes the removal of offending drugs (eg, tricyclic antidepressants, PD medications, alcohol, and antihypertensives) increasing carbidopa doses, increased salt or fluids to the diet, and adding compression stockings, fludrocortisone, indomethacin, or midodrine. Droxidopa, a norepinephrine synthetic precursor is approved for treating orthostatic hypotension associated with PD. It can cause supine hypertension and requires monitoring of blood pressure with treatment. Elevating the head of the bed lessens the risk of supine hypertension and if the blood pressure cannot be managed, reduce or discontinue droxidopa.[32,34]

Seborrhea usually responds to over-the-counter dandruff shampoos or topical steroids.[2,9,15]

Treatment of Response Fluctuations

KEY CONCEPT As the disease progresses, most patients develop response fluctuations. Treatment is based on capitalizing on the pharmacokinetic and pharmacodynamic properties of PD medications.

LO 5

Treatment includes adjusting or adding medications to maximize the patient's on time, minimizing the time with dyskinesia, and minimizing off time (Table 33–3). Levodopa doses and intervals should be adjusted to minimize suboptimal or delayed peak levodopa concentrations. Longer acting formulations minimize wearing-off periods. Adding or adjusting

Table 33–3

Management of Motor Complications in Advanced PD[2,11,12,20,35]

I. Motor Fluctuations

Nonpharmacologic Approaches	Drugs to Alter Formulation or Dose	Drugs to Add
A. Suboptimal or delayed peak response		
Take Sinemet on an empty stomach Decrease dietary protein and fat around the delayed dose Minimize constipation Assess for *Helicobacter pylori* infection	Crush Sinemet, or make liquid Sinemet Substitute standard Sinemet for some of the Sinemet CR Withdraw drugs with anticholinergic properties	Intermittent subcutaneous apomorphine
B. Optimal peak but early wearing off		
	Decrease dose and increase frequency of standard Sinemet Substitute Sinemet CR for some of the standard Sinemet	Dopamine agonist MAO-B inhibitor Amantadine COMT inhibitor
C. Optimal peak but unpredictable offs		
Adjust time of medications with meals and avoid high-protein meals or redistribute the amount of protein in diet Deep brain stimulation procedure	Substitute or add liquid Sinemet Switch to a different dopamine agonist if already on an agent Consider continuous infusion of levodopa or apomorphine	COMT inhibitor Dopamine agonist if not using one
D. Freezing		
Gait modifications (use visual cues such as walkover lines, tapping, rhythmic commands, rocking; use rolling walker) Physical therapy	Difficult to treat—adjust current medications based on other PD symptoms. Guide changes based on: On freezing, reduce dopamine medications, inject botulinum toxin. Off freezing, increase Sinemet dose or add dopamine agonists.	If present, treat anxiety with pharmacologic agents

II. Dyskinesias

Nonpharmacologic Approaches	Drugs to Alter Formulation or Dose	Drugs to Add
A. Chorea		
Deep brain stimulation	Decrease risk of occurrence by lowering Sinemet dose when adding other PD medications Evaluate the value of adjunctive PD medications and discontinue if motor complications outweigh benefit Adjust levodopa formulation, dose, or frequency	Amantadine Propranolol Fluoxetine Buspirone Clozapine
B. Off period dystonia in the early morning (eg, foot cramping)		
No recommendations	Add or change short acting to long acting formulations at bedtime if having nighttime offs Change morning Sinemet CR dose to immediate-release with or without CR.	Lithium Baclofen Selective denervation with botulinum toxin
C. Diphasic dyskinesia		
Deep brain stimulation	Change CR preparations to immediate release; consider liquid Sinemet Increase Sinemet dose and frequency	Dopamine agonist Amantadine COMT inhibitor

III. Akathisia

Nonpharmacologic Approaches	Drugs to Alter Formulation or Dose	Drugs to Add
No recommendations	Evaluate if due to antidepressant or antipsychotic and decrease dose or change drug	Benzodiazepine Propranolol Dopamine agonist Gabapentin

LO 6

medications to combat unpredicted off periods and providing treatments that decrease freezing episodes may be necessary. Treatment plans also involve adjusting or adding medications to decrease chorea, dystonia, **diphasic dyskinesias**, or **akathisia**. When away from home, an extra dose of medication is advisable for wearing off.[2,11,13,18,20]

OUTCOME EVALUATION

LO 8

KEY CONCEPT Patient monitoring involves a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education. Evaluate the clinical outcomes of treatment over time by assessing the change in the UPDRS from baseline.

Patient Encounter Part 3: Follow-up Visit 3 Years Later

Three years have passed since the patient was started on a drug regimen for her PD symptoms. Levodopa/carbidopa 100/25 mg by mouth three times daily (8 AM, 3 PM, and 10 PM) was initiated for her motor symptoms. She was instructed in sleep hygiene and referred to physical and occupational therapy as well as an eye specialist for vision complaints. With her initial therapy, she reported a decrease in her tremor and an overall improvement in muscle stiffness for most of the day which continued unchanged until the past few weeks. Now, she says her symptoms tend to return in the evening and are also severe in the early morning upon wakening. This continues to cause problems when caring for her granddaughter. Her sleep has not improved despite sleep hygiene techniques. Additionally, she still complains of constipation frequently despite increasing fluids and using a stool softener. She was placed on sertraline 50 mg by mouth daily which has improved her mood.

Create a problem list and provide an assessment of each problem.

Considering the goals of therapy, treatment options, and your assessment of each of the problems, create a care plan for each problem.

Patient Care Process

Collect Information:

- Review the physical examination and note the specific type of symptoms including their frequency and exacerbating factors.
- Review diagnostic data such as the UPDRS and compare this data to previous encounters.
- Interview the patient to assess PD symptom impact on quality of life (QOL) and ADLs.
- Obtain a complete medication list.

Assess the Information:

- Identify any worsening of motor symptoms or disease progression.
- Determine if on time is maximized and or medications require adjustment.
- Identify drug-indiced dyskinesias and note specific times when these occur.
- Evaluate for appropriate use of each medication including noting drugs which may worsen PD symptoms as well as polypharmacy for PD.
- Assess if nonmotor symptoms are being adequately addressed and treated through pharmacologic or nonpharmcologic therapy.
- Assess the complete PD pharmacologic profile for drug or diet interactions, adverse drug reactions, adherence, and patient understanding of regimens.

Develop a Care Plan:

- Identify other specialists such as physical therapy, occupational therapy, speech, and a palliative care team and develop a plan in conjunction with their recommendations.
- Recommend a therapeutic regimen for motor symptoms that is effective in reducing UPDRS scores but also increases quality of life and daily functioning.
- Adjust dosages and timing of medications to maximize on time and reduce dyskinesia.
- Recommend drug therapy and other options for nonmotor symptoms which will not worsen motor symptoms.
- Develop a detailed medication administration schedule that is simple for the patient to follow, especially if medications with multiple daily dosing schedules are used.

Implement the Care Plan:

- Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.
- Provide instruction on how to use medications including timing of doses with food.
- Educate the patient on how to adjust medications for fluctuations in response.
- Provide information to the patient and family and document about risks with dopaminergic drugs such as impulse control disorders, sudden sleep attacks, and psychosis.
- Refer the patient and family members to further information such as books and websites (http://www.parkinson.org). Provide information concerning local PD support groups when available.

Follow-up: Monitor and Evaluate:

- Instruct the patient to follow up for assessment of symptoms and disease progression.
- Follow up at least every 6 to 12 months and determine when symptoms are controlled, if the patient is experiencing any drug interactions or adverse reactions.
- Provide patient education on changes to medication regimens and nonpharmacologic options.

Instruct patients to record the amount of on and off time daily to guide medication adjustment. Assess fall risk and implement appropriate safety measures to prevent falls. Scales assessing QOL, depression, anxiety, and sleep disorders are useful to track progression.

Abbreviations Introduced in This Chapter

Ach	Anticholinergics
ADL	Activities of daily living
COMT	Catechol-*O*-methyltransferase
CR	Controlled-release
DBS	Deep brain stimulation
DDS	Dopamine dysregulation syndrome
GI	Gastrointestinal
ICD	Impulse control disorder
MAO	Monoamine oxidase
NMDA	*N*-methyl-D-aspartate
PD	Parkinson disease
QOL	Quality of life
REM SBD	Rapid eye movement sleep behavior disorder
RLS	Restless legs syndrome
TRAP	Tremor, rigidity, akinesia/bradykinesia, postural/gait instability
UPDRS	Unified Parkinson Disease Rating Scale

34 Pain Management

Christine Karabin O'Neil

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and functional.
2. Explain the mechanisms involved in pain transmission.
3. Select an appropriate method of pain assessment.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

INTRODUCTION

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] KEY CONCEPT Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, and psychological processes. Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. There are no reliable objective markers for pain, thus the patient is the only person who can describe the intensity and quality of their pain.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. Thus identifying the exact prevalence of pain is a difficult task. Prevalence rates for a variety of different types of pain have been described (Table 34–1). Patients 65 years and older bear a significant burden of pain. The prevalence of pain in people older than 60 years is twice that in those younger than 60 years.[8] Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that 45% to 80% of nursing home patients and 25% of those with daily pain received neither analgesic medication nor nonpharmacologic treatment for their pain, contributing to functional impairment and a decreased quality of life.[8]

The financial impact of pain is considered to be significant. The total cost of pain in the United States has been estimated at $560–$635 billion annually, about half of this cost is due to direct costs of health care while the other half is due to lost productivity.[9]

Challenges in Pain Management

Despite the growing emphasis on pain management, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. In one series of reports, 50% of seriously ill hospitalized patients reported pain; however, 15% were dissatisfied with pain control, and some remained in pain after hospitalization.[10]

Barriers to adequate pain management may be due to fear of becoming addicted to opioids or cultural beliefs. Elderly patients might not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (eg, hospitalization, loss of independence), fear that the pain might be forecasting impending illness, inability to understand terminology used by health care providers, or a belief that showing pain is unacceptable behavior.

Concerns about adequate pain management must be balanced with concerns about opioid misuse, abuse, and diversion to achieve optimal pain management. Opioid use, abuse, and adverse effects have risen to epidemic proportions since the 1990s. While the United States has 4.6% of the global population, the country used 69% of the world's opioid supply.[11] Over the last 15 years, there has been an increase in deaths related to prescription opioids and increase in overdoses due to illicit opioids.[12] Several recent guidelines have been published by the Centers for Disease Control and Prevention (CDC) and American Society of Interventional Pain Physicians (ASIPP) to provide guidance for the use of opioids to ensure patients have access to safer, more effective chronic pain treatment while reducing the number of people who misuse, abuse, or overdose from these drugs.[13,14]

Table 34–1

Prevalence of Selected Pain Diagnoses[2–7]

Pain Diagnoses	Prevalence (%)
Back pain	74.7
Cancer	14–100
Chronic pain	10.4
Complex regional pain syndrome	1.2
Degenerative spine disease	63.6
Fibromyalgia	2
Limb pain	50
Migraine	12
Neuritis/radiculitis	52.8
Neuropathic pain	9.8

PATHOPHYSIOLOGY

Types of Pain

LO 1 Several distinct types of pain have been described, for example, nociceptive, inflammatory, neuropathic, and functional.[15] Nociceptive pain is a transient pain in response to a noxious stimulus at **nociceptors** that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors are classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brainstem, and the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body's autonomic withdrawal reflex. When tissue damage occurs despite the LO 2 nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.

LO 1 Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral or central nervous system (CNS). Functional pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or functioning of the CNS in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

Mechanisms of Pain

▶ *Pain Transmission*

LO 2 The mechanisms of nociceptive pain are well defined and provide a foundation for the understanding of other types of pain.[16] Following nociceptor stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that might further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated Aδ-fibers and unmyelinated C-fibers to the spinal cord. The Aδ-fibers are responsible for first, fast, sharp pain, and release excitatory amino acids that activate α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the dorsal horn. The C-fibers produce second pain, which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

▶ *Pain Modulation*

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate-control theory, pain modulation might occur at the level of the dorsal horn.[17] Because the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors might alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation can occur through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β-endorphins) that interact with μ-, δ-, and κ-receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ-aminobutyric acid (GABA), and neurotensin. The perception of pain involves not only nociceptive stimulation but also physiologic and emotional input. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

▶ *Peripheral Sensitization, Central Sensitization, and Windup*

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally, resulting in exaggerated responses and sensitization, such as that observed in inflammatory, neuropathic, or functional chronic pain. Pain in these settings might occur spontaneously without any stimulus or might be evoked by a stimulus. Evoked pain might arise from a stimulus that normally does not cause pain (**allodynia**) such as a light touch in neuropathic pain. **Hyperalgesia**, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the *N*-methyl-D-aspartate (NMDA) receptor is blocked by magnesium.[16] Repeated nerve depolarization causes release of the magnesium block, allowing the influx of calcium and sodium, and results in excessive excitability and amplification of signals. Continued input from C-fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as windup. Windup increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs, leading to allodynia, hyperalgesia, and spread to uninjured tissues.[18] The windup phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.

CLINICAL PRESENTATION AND DIAGNOSIS

Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have

demonstrated that unrelieved pain might lead to changes in the nervous system known as neural plasticity. Because these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, might be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic pain. Acute pain is also referred to as adaptive pain because it serves to protect the individual from further injury or promote healing.[17] However, chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

▶ *Acute Pain*

Acute pain is pain that occurs as a result of injury or surgery and is usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury. Visceral pain involves injury to nerves on internal organs (eg, intestines, liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain might assist in the differential diagnosis.

▶ *Chronic Pain*

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain might be nociceptive, inflammatory, neuropathic, or functional in origin; however, all forms share some common characteristics. Chronic pain can be intermittent or persistent, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms might predominate. The four main effects of chronic pain include (a) effects on the physical function, (b) psychological changes, (c) social consequences, and (d) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain might include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences might ensue, such as changes in relationships with friends and family, intimacy, and isolation. Management of chronic pain should be multimodal and might involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthesia.

Chronic Malignant Pain Chronic malignant pain is associated with a progressive disease that is usually life threatening such as cancer, AIDS, progressive neurologic diseases, end-stage organ failure, and dementia.[19] The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

Chronic Nonmalignant Pain Pain not associated with a life-threatening disease and lasting more than 6 months beyond the healing period is referred to as chronic nonmalignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered nonmalignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative but might involve the use of more potent analgesics including opiates in psychologically healthy patients.[20]

Neuropathic Pain Neuropathic pain is considered to be a type of chronic nonmalignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain might be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include postherpetic neuralgia (PHN), which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polyneuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of **central pain** include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). CRPS includes both reflex sympathetic dystrophy and **causalgia**, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock–like quality, or radiating pain. The patient might describe either a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Damage to the peripheral nerves might frequently be referred to the body region innervated by those nerves.

Clinical Presentation and Diagnosis of Pain

General

Patients may be in acute distress (acute pain) or have no signs or symptoms of suffering (chronic pain).

Symptoms

Pain is described based on the following characteristics: onset, duration, location, quality, severity, and intensity. Other symptoms may include anxiety, depression, fatigue, anger, fear, and insomnia.

Signs

Acute pain may cause hypertension, tachycardia, diaphoresis, mydriasis, and pallor.

Diagnosis

The patient is the only person who can describe the intensity and quality of their pain. There are no laboratory tests that can diagnose pain.

Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the mismanagement of pain.[21]

KEY CONCEPT Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.

▶ *Methods of Pain Assessment*

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and psychological) and physical are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain.[18] A thorough assessment of the characteristics of the pain should be completed, including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/precipitating, Quality, Radiation, Severity, and Time).[22] Some clinicians have suggested the addition of U ("you") to this mnemonic.[23] During the pain interview, the impact of pain on the patient's functional status, behavior, and psychological status should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain because depression and other affective disorders might be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who take opiates or other pain medications with a potential for abuse. Other conditions, such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function, can influence therapy choices and goals. A discussion of the patient's expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

▶ *Pain Assessment Tools*

LO 3

Pain, particularly acute pain, might be accompanied by physiologic signs and symptoms, but there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

Rating scales provide a simple way to classify the intensity of pain, and they should be selected based on the patient's ability to communicate (Figure 34–1).[24] Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 7 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale might be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong–Baker FACES of Pain Rating Scale.[25]

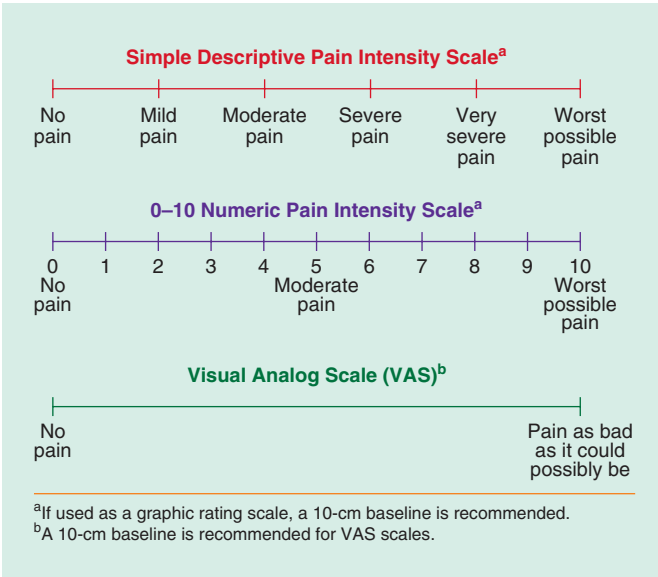

FIGURE 34–1. Pain rating scales. (From U.S. Department of Health and Human Services, Agency for Health Care Policy and Research. Clinical practice guideline, cancer pain management. Rockville, MD: AHCPR; 1994 [cited 2014 Nov 6]. http://www.ncbi.nlm.nih.gov/books/bookres.fcgi/hstat6/f37_capcf4.gif.)

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but they are often more time consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.[26–30] The pain intensity, enjoyment of life, general activity (PEG) assessment tool is an ultra-brief pain assessment tool derived from the Brief Pain Inventory and is recommended by the CDC.[31] The PEG score is the average of three individual scores.

▶ *Pain Assessment in Challenging Populations*

Children Pain interviews can be conducted with children as young as 3 or 4 years of age; however, communication might be limited by vocabulary.[32] Terms familiar to children such as *hurt, owie*, or *boo* boo might be used to describe pain. The VAS is best used with children older than 7 years. Other scales based on numbers of objects (eg, pokers chips), increasing color intensity, or faces of pain might be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years, behavioral or physiologic measures, such as pulse or respiratory rate, might be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions, body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits.[32] Preschool children experiencing pain might become clingy, lose motor and verbal skills, and start to deny pain because treatment might be linked to discomfort or punishment.

Patient Encounter Part 1

HPI: A 78-year-old man who is to undergo a left above the knee amputation due to a limb abscess

PMH: Peripheral artery disease for 18 years; cardiomyopathy, benign prostatic hypertrophy for 13 years

FH: Mother had osteoporosis; father had diabetes

SH: Lives with wife; has two grown children

Meds: aspirin 81mg daily; atorvastatin 80 mg at bedtime; multivitamin 1 daily; pantoprazole 40 mg daily; tamsulosin 0.4 mg daily

Pain Assessment: Patient rates pain as 8 on a scale of 0 to 10

Based on the type of injury, what type of pain is this patient likely to experience?

What type of pain management regimen would you recommend in the postoperative period?

Explain your answer.

School-age children might exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain; adolescents might respond to pain with oppositional behavior and depression.

Elderly Most of the previously discussed pain scales can be used in older persons who are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate to severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD) tool might be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability.[33] Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

TREATMENT

Desired Outcomes

Prevention, reduction, and/or elimination of pain are important goals for the treatment of acute pain. With chronic pain, elimination of pain might not be possible, and goals might focus on improvement or maintenance of functional capacity and quality of life.

General Approach to Treatment

KEY CONCEPT Effective treatment involves an evaluation of the cause, duration, and intensity of the pain, and selection of an appropriate treatment modality for the pain situation. Depending on the type of pain, treatment might involve pharmacologic and nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section "Patient Care Process." Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (Figure 34–2). Clinical practice guidelines for pain management are available from the American Pain Society (APS), the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

▶ *Selection of Agent Based on Severity of Pain*

KEY CONCEPT Whenever possible, the least potent oral analgesic should be selected. Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (Table 34–2).[34] Mild to moderate pain is generally treated with nonopioid analgesics. Combinations of medium-potency opioids and acetaminophen (APAP) or nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression, adjuvant medications are added, as needed, to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain), cost, pharmacokinetic profile of available drugs, and patient-specific factors (age, concomitant illnesses, previous response, and other medications) must also be considered. Pain medications might also be used in the absence of pain in anticipation of a painful event such as surgery to minimize peripheral and central sensitization.

LO 4

▶ *Mechanistic Approach to Therapy*

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to the various types of pain continue to be further elucidated.

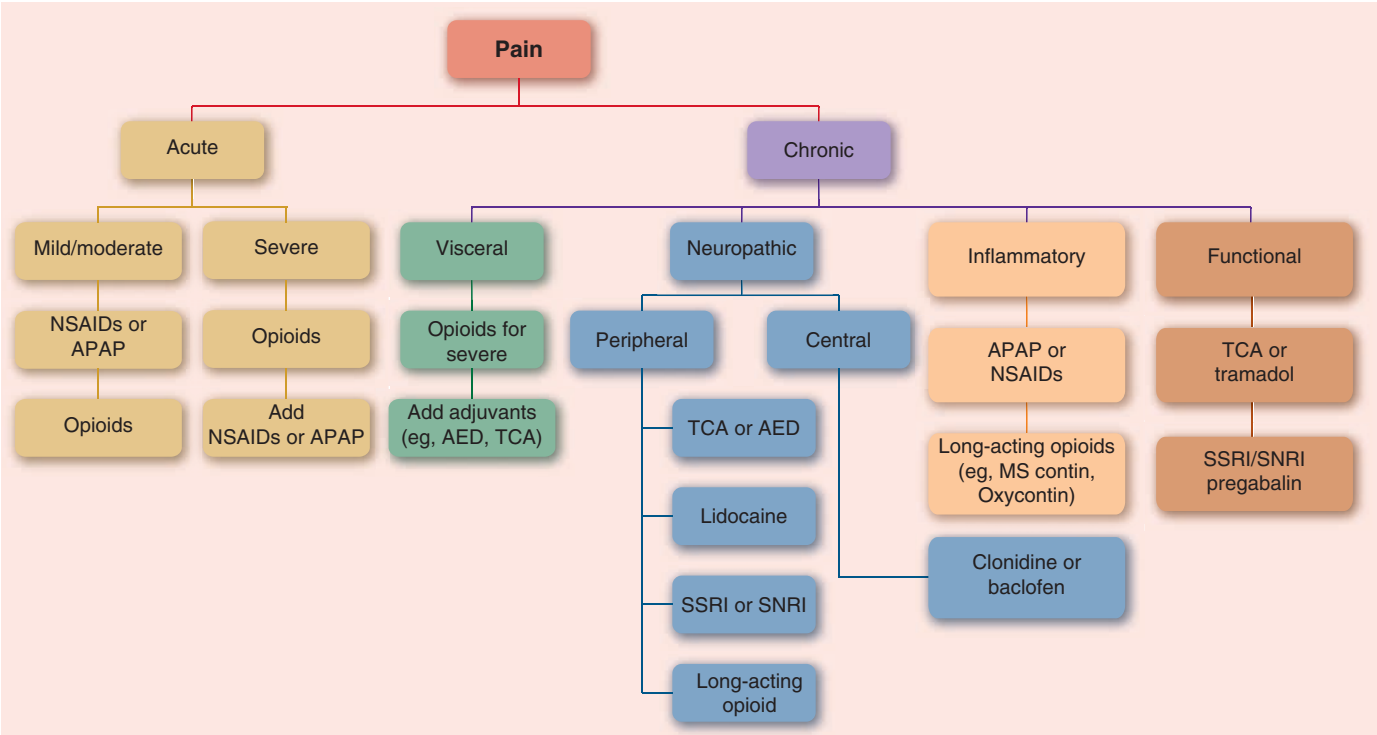

FIGURE 34–2. Pain algorithm. (AED, antiepileptic drugs; APAP, acetaminophen; MS, morphine sulfate; NSAIDs, nonsteroidal anti-inflammatory drugs; SNRI, serotonin norepinephrine reuptake inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.)

Table 34–2

Selection of Analgesics Based on Intensity of Pain[34,35,38]

Pain Intensity	Corresponding Numerical Rating	WHO Therapeutic Recommendations	Examples of Initial Therapy	Comments
Mild	1–3/10	Nonopioid analgesic; regular scheduled dosing	Acetaminophen 1000 mg every 6 hours; ibuprofen 600 mg every 6 hours	Consider adding an adjunct or using an alternate regimen if pain is not reduced in 1–2 days
Moderate	4–6/10	Add an opioid to the nonopioid for moderate pain; regular scheduled dosing	Acetaminophen 325 mg + codeine 60 mg every 4 hours; acetaminophen 325 mg + oxycodone 5 mg every 4 hours	Consider step-up therapy if pain is not relieved by two or more different drugs
Severe	7–10/10	Switch to a high-potency opioid; regular scheduled dosing	Morphine 10 mg every 4 hours; or hydromorphone 4 mg every 4 hours	

An understanding of these new mechanisms of pain transmission might lead to improvement in pain management as pharmacologic management of pain becomes more mechanism specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Because several mechanisms of pain often coexist, a multimodal approach seems rational to target each mechanism.

Nonpharmacologic Therapy

LO 6 Nonpharmacologic therapies (psychological interventions and physical therapy) might be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients might benefit from relaxation, biofeedback, cognitive behavioral therapy, psychotherapy, support groups, and spiritual counseling.

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains).

Pharmacologic Therapy

▶ *Nonopioid Analgesics*

LO 4 **Acetaminophen** APAP, an analgesic and antipyretic, is often selected as initial therapy for mild to moderate pain and is considered first line in several pain situations such as low back pain and osteoarthritis.[35] Mechanistically, APAP is believed to inhibit prostaglandin synthesis in the CNS and block pain impulses in the periphery. APAP is well tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving APAP doses of more than 2000 mg/day.[36] The maximum recommended dose for patients with normal renal and hepatic function is 4000 mg/day. Hepatotoxicity has been reported with excessive use and overdose, and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Due to concerns of unintentional overuse and hepatoxicity, the FDA requires warning labels on OTC APAP products and limited the APAP component of narcotic analgesic combination to 325 mg per dosing unit. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use.

Aspirin and Other Salicylates Aspirin, nonacetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold.

Aspirin is effective for mild to moderate pain; however, the risk of gastrointestinal (GI) irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the GI mucosa and irreversible platelet inhibition contribute to this risk, which can occur even at low doses. Hypersensitivity reactions are also possible and might occur in 25% of patients with coexisting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Nonacetylated salicylates (choline magnesium salicylate and sodium salicylate) have a reduced risk of GI effects and platelet inhibition and might be used in aspirin-sensitive patients.

LO 4 **Nonsteroidal Anti-inflammatory Drugs** NSAIDs are the preferred agents for mild to moderate pain in conditions that are mediated by prostaglandins (rheumatoid arthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bony metastasis, but they are of minimal use in neuropathic pain. NSAIDs provide analgesia equal to or better than that of aspirin or APAP combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis.[16] These agents are classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). Although only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects. All members of this class appear to be equally effective, but there is great intrapatient variability in response. After an adequate trial of 2 to 3 weeks with a particular oral agent, it is reasonable to switch to another member of the class. Ketorolac and ibuprofen are available in parenteral and oral

dosage forms; unlike other NSAIDs, ketorolac's duration of use is limited to 5 days due to risk of serious GI side effects. NSAIDs demonstrate a flat-dose response curve, with higher doses producing no greater efficacy than moderate doses but resulting in an increased incidence of adverse effects (GI irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced GI adverse effects (eg, dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/min (0.84 mL/s), and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as nonselective (they inhibit COX-1 and COX-2) or selective (inhibit only COX-2) based on degree of COX inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, whereas COX-1 inhibition contributes to increased GI and renal toxicity associated with nonselective agents. Because the antiplatelet effect of nonselective NSAIDs is reversible, concurrent use might reduce the cardioprotective effect of aspirin due to competitive inhibition of COX-1. A boxed warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription nonselective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on nonprescription NSAIDs. When an NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risks, and the lowest effective dose of the NSAID is recommended.[37]

▶ *Opioid Analgesics*

LO 4

Opioids are considered the agents of choice for the treatment of severe acute pain and moderate to severe pain associated with cancer.[38] Opioids are classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short acting versus long acting).

Selection and Dosing The opioids exert their analgesic efficacy by stimulating opioid receptors (μ, κ, and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ-receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenyl piperidine or meperidine-like, and diphenyl heptane or methadone-like. Partial agonists/antagonists (butorphanol, pentazocine, and nalbuphine) partially stimulate the μ-receptor and antagonize the κ-receptors. This activity results in reduced analgesic efficacy with a ceiling dose, reduced side effects at the μ-receptor, psychotomimetic side effects due to κ-receptor antagonism, and possible withdrawal symptoms in patients who are dependent on pure agonists.

LO 4

Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Because pure agonists are pharmacologically similar, choice of agent might be also guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, and pentazocine. Furthermore, the clearance of meperidine and morphine and their metabolites is reduced in renal dysfunction.

Table 34–3

Equianalgesic Doses of Selected Opioids[23,38,41,42]

Opioid (Brand Name)	Dose Equianalgesic to 10 mg of Parenteral Morphine (mg)	
	Parenteral (mg)	Oral (mg)
Mild to Moderate Pain		
Codeine (generic, various)	120	200
Hydrocodone (Vicodin, Lorcet)	N/A	30
Oxycodone (OxyContin, OxyFAST, Oxy IR)	N/A	20
Meperidine (Demerol)	100	400
Moderate to Severe Pain		
Morphine (Roxanol, MS Contin, Kadian, Avinza)	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Oxymorphone (Opana, Opana SR, Numorphan)	1	N/A
Levorphanol (Levo-Dromoran)	2	4
Fentanyl (Duragesic)	0.1–0.2	N/A[a]
Methadone (Dolophine)	10[b]	3–5[b]

[a]Transdermal: 100 mcg/hour = 2–4 mg/hour of IV morphine.

[b]Dosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 34–4).

IR, immediate release.

Table 34–3 provides a summary of opiate options, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia (PCA) devices, or for more than 1 to 2 days of intermittent dosing. Methadone is unique among the opiates because it has several mechanisms (μ-agonist, NMDA-receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine). The long half-life of methadone (30 hours) permits extended dosing intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversion and concerns for respiratory depression. Another safety concern with methadone involves risk of arrhythmia secondary to QT prolongation. Tramadol is a synthetic opioid with a dual mechanism of action (μ-agonist and inhibition of serotonin and norepinephrine reuptake) and efficacy and safety similar to that of codeine plus APAP. Tramadol has been evaluated in several types of neuropathic pain and might have a role in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and those taking medications that can lower the seizure threshold. The use of tramadol with other serotonergic drugs (eg, selective serotonin reuptake inhibitors [SSRIs]) might precipitate serotonin syndrome. Although originally thought not to be habit forming, dependence can occur with tramadol.

LO 5

About 70% of individuals will experience significant analgesia from 10 mg/70 kg of body weight of intravenous (IV) morphine or its equivalent.[16] For severe pain in opiate-naive patients, a usual starting dose is 5 to 10 mg of IV morphine every 4 hours.

In the initial stages of severe pain, medication should be given around the clock. Rescue doses should be made available for breakthrough pain in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively, one-sixth of the total daily dose or one-third of the 12-hourly dose might be used. Scheduled doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Alternatively, utilizing dose escalation, doses could be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days for cancer-related pain, conversion to a controlled-release or long-acting opioid may be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance might develop to analgesic effects, necessitating increasing doses to achieve the same level of pain relief. Physical dependence will occur with the long-term use of opioids. However, addiction or psychological dependence is unlikely in legitimate pain patients unless there are predisposing risk factors. Several opioid risk assessment screening tools have been proposed and may be helpful as part of a more comprehensive assessment to screen patients prior to opioid use.[39]

LO 4

Opioids are not first-line therapy for chronic pain. In response to the increase in opioid use and adverse events associated with such use, guidelines for the use of opioids in chronic pain have been recommended by the CDC.[14] The guidelines are not intended for patients receiving opioids for cancer treatment, palliative care, or in end-of-life. Table 34–4 provides a summary of these guidelines. In addition to these guidelines, the use of informed consent for chronic opioid therapy, medication management agreements, or pain contracts might be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids are administered by a variety of routes, including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, IV, subcutaneous, and intraspinal. Although the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so IV or subcutaneous administration might be preferred if more rapid relief is desired. Intramuscular (IM) injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively but might also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and a maximum hourly dose. Morphine, fentanyl, and

LO 4

Table 34–4

CDC Guidelines for Prescribing Opioids for Chronic Pain[14]

1. Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.
2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how opioid therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3. Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.
4. When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.
5. When opioids are started, clinicians should prescribe the lowest effective dosage. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when considering increasing dosage to ≥ 50 morphine milligram equivalents (MME)/day, and should avoid increasing dosage to ≥ 90 MME/day or carefully justify a decision to titrate dosage to ≥ 90 MME/day.
6. Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.
7. Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.
8. Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase risk for opioid overdose, such as history of overdose, history of substance use disorder, higher opioid dosages (≥ 50 MME/day), or concurrent benzodiazepine use, are present.
9. Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.
10. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications as well as other controlled prescription drugs and illicit drugs.
11. Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
12. Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioral therapies) for patients with opioid use disorder.

PDMP, prescription drug monitoring program.

hydromorphone are commonly administered via PCA pumps by the IV route but less frequently by the subcutaneous or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (eg, knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) might be used for epidural analgesia. Opiates given by this route might cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention might occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal because the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than IV doses, and intrathecal doses are 10 times less than epidural doses (ie, 10 mg of IV morphine is equivalent to 1 mg epidural morphine and 0.1 mg of intrathecally administered morphine).[37]

Combination Analgesics Combinations of opioids and nonopioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the nonopioid component reaches maximum dosage, and thus the usefulness of nonopioids in this situation is limited. Additionally, the combination products are short acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

Opioid Allergy True narcotic allergies are rare and should not be confused with pruritus associated with opiate use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed agonists/antagonists should be treated as morphine-like agents.

Tapering of Opioids Tapering of opioids should be considered in the following siutations: painful situation has resolved; in those with prolonged opioid use; upon requests for dosage reduction; lack of clinically meaningful improvement in pain and function (eg, at least 30% improvement on the 3-item PEG scale) dosages ≥ 50 morphine milligram equivalents (MME)/day without benefit or opioids are combined with benzodiazepines; signs of substance use disorder (eg, work or family, problems related to opioid use, difficulty controlling use); overdose or other serious adverse event; or shows early warning signs for overdose risk such as confusion, sedation, or slurred speech. In these situations, the dose should be reduced by 10% per week to avoid withdrawal symptoms.

Managing Opioid Side Effects and Drug Interactions Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. Table 34–5 shows management strategies for side effects. The most frequent side effects are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Tolerance to respiratory depression develops rapidly with repeated doses, and respiratory depression is rarely a clinically significant problem in pain patients even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does not develop, and prophylaxis with stimulant laxatives (eg, senna or bisacodyl) and stool softeners such as docusate is recommended.

Table 34–5

Managing Opioid Side Effects[24,38,41]

Adverse Effects	Drug Treatment/Management
Excessive sedation	Reduce dose by 25% or increase dosing interval
Constipation	Casanthranol-docusate one capsule at bedtime or twice daily; senna one to two tablets at bedtime or twice daily; bisacodyl 5–10 mg daily plus docusate 100 mg twice daily; polyethylene glycol 3350 17 grams daily; methylnaltrexone 0.15 mg/kg SQ every other day; naloxegol 12.5–25 mg daily
Nausea and vomiting	Prevention: Hydroxyzine 25–100 mg (po/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (po/IM) every 6 hours as needed; ondansetron 4 mg IV or 16 mg po Treatment: Prochlorperazine 5–10 mg (po/IM) every 3–4 hours as needed or 25 mg PR twice daily; ondansetron 4–8 mg IV every 8 hours as needed
Gastroparesis	Metoclopramide 10 mg (po/IV) every 6–8 hours (Caution: duration < 3 months)
Vertigo	Meclizine 12.5–25 mg po every 6 hours as needed
Urticaria/itching	Hydroxyzine 25–100 mg (po/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (po/IM) every 6 hours as needed
Respiratory depression	Mild: Reduce dose by 25% Moderate to severe: Naloxone 0.4–2 mg IV every 2–3 minutes (up to 10 mg) for complete reversal; 0.1–0.2 mg IV every 2–3 minutes until desired reversal for partial reversal; may need to repeat in 1–2 hours depending on narcotic half-life
CNS irritability	Discontinue opioid; treat with benzodiazepine

IM, intramuscular; IV, intravenous; po, orally; PR, per rectum; SQ, subcutaneous.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P450 (CYP) enzyme: CYP2D6.[40] Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (eg, morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is a substrate of CYP3A4 and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants might potentiate the sedative effects of opiates.

Patients with CYP450 pharmacogenetic variations may respond differently to opioids, ranging from drug unresponsiveness to toxicity with elevated serum levels.

Opioid Rotation Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (> 1 g morphine/day) become ineffective. In some settings, opioid rotation is used routinely to prevent the development of analgesic tolerance.[41]

Equianalgesic Dosing of Opioid Analgesics Conversion from one dosage form to another or from one opioid to another might be necessary in situations such as ineffective pain control, emergence of side effects, change in patient status, and in formulary restrictions. KEY CONCEPT Equianalgesic doses should be used when converting from one opioid to another. Clinicians should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Opioid potency is compared using a reference standard of 10 mg parenteral morphine. Switching from one dosage form to another of the same opioid (ie, IV to oral) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, the oral dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

LO 5

The first step in an opioid conversion is to calculate the patient's total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine-dosing equivalents using equianalgesic doses (see Table 34–3). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Because cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%.[38] If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.[42,43] Methadone appears to be much more potent than once believed, and morphine-to-methadone ratios vary according to the total dose of morphine taken at the time of making the conversion to methadone (Table 34–6).[44,45] Conversion to methadone is a complex process, and several different strategies have been proposed including a switch of the entire dose in 1 day or a gradual conversion over 3 days.

Patient Encounter Part 2

Following surgery, he was placed on morphine patient-controlled analgesia (PCA). He has been using 55 mg of morphine/24 hours with adequate pain control; however, he has developed redness and itching on his neck that is believed to be due to the morphine.

Current Meds: Morphine PCA; aspirin 81 mg daily; atorvastatin 80 mg at bedtime; multivitamin 1 daily; gabapentin 100 mg three times daily; pantoprazole 40 mg daily, tamsulosin 0.4 mg daily; heparin 5000 units twice daily until discharged home. He will be discharged to a skilled nursing facility for rehabilitation therapy.

The physician would like to convert him to a combination preparation of hydrocodone and APAP.

What dosing regimen would you suggest?

Recommend a monitoring plan for this patient.

How would you assess pain response?

The patient is concerned about the redness and itching she developed while on morphine. What other interventions or education may be necessary at this time?

Table 34–6

Methadone Dose Conversions

Total Daily Dose of Oral Morphine	Morphine:Methadone Factor
< 100 mg	3:1 3 mg morphine:1 mg methadone
101–300 mg	5:1
301–600 mg	10:1
601–800 mg	12:1
801–1000 mg	15:1
> 1000 mg	20:1

Data from Gazelle G, Fine PG. Fast fact and concepts #75. Methadone for the treatment of pain. End-of-life Physician Education Resource Center [Internet], [cited 2017 Aug 31]. http://www.eperc.mcw.edu/EPERC/FastFactsIndex/ff_075.htm, with permission.

▶ *Adjuvant Agents for Chronic Pain*

The role of NSAIDs and opioids in chronic nonmalignant pain has been discussed; however, a review of adjuvant agents for chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with nonopioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (eg, capsaicin), and a variety of other drugs (eg, NMDA antagonists, clonidine, and muscle relaxants).

LO 4

Published guidelines have been suggested for the general management of neuropathic pain.[46] Suggestions for first-line therapy include gabapentin or pregabalin, transdermal lidocaine, or tricyclic antidepressants (TCAs) (Table 34–7).[46–49] Newer antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs) (eg, duloxetine and venlafaxine) have been used successfully for painful diabetic peripheral neuropathy (DPN). A stepwise approach is suggested for managing the patient with neuropathic pain beginning with the least invasive, effective therapeutic choice and proceeding to the rational use of multiple drug regimens (see Figure 34–2). Choice of agent might also depend on dosing frequency and comorbidities. Data

Patient Encounter Part 3

He was discharged to a skilled nursing facility and is receiving physical therapy and occupational therapy 6 days each week.

Current Meds: Aspirin 81 mg daily, atorvastatin 80 mg at bedtime, multivitamin 1 daily, gabapentin 100 mg three times daily, pantoprazole 40 mg daily, tamsulosin 0.4 mg daily, heparin 5000 units twice daily until discharged home, hydrocodone/acetaminophen 5/325 mg every 6 hours as needed for pain.

Pain Assessment: Patient reports pain of 7 out of 10; worse with movement.

Physical therapy notes indicate patient is unable to complete therapy goals due to complaints of pain.

Based on this information, what would you recommend to optimize pain control?

Table 34–7

Selected Adjuvant Analgesics and Suggested Dosing[46–49]

Agent	Dosing Guidelines	FDA-Approved Indication
Amitriptyline (Elavil)	10–25 mg at bedtime with weekly increments to a target dose of 25–150 mg of amitriptyline or an equivalent dose of another TCA	
Duloxetine (Cymbalta)	DPN: 60 mg daily Fibromyalgia: 30 mg daily, may be increased to a target dose of 60 mg/day	DPN, fibromyalgia
Gabapentin (Neurontin)	Initially, 300 mg three times a day up to a maximum of 3600 mg daily, in divided doses[a]	PHN
Pregabalin (Lyrica)	DPN: Initially, 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability[a] PHN: Initially 75 mg twice a day or 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability[a] Fibromyalgia: Initially 75 mg twice a day, increase after 1 week to 300 mg to 450 mg/day (in divided doses every 12 hours)	DPN, PHN, and fibromyalgia
Lidocaine 5% (Lidoderm patch)	Up to three patches may be applied directly over the painful site once daily; patches are applied using a regimen of 12 hours on and 12 hours off	PHN

[a]Dosing for creatinine clearance of ≥ 60 mL/min (1.0 mL/s).

DPN, diabetic peripheral neuropathy; PHN, postherpetic neuralgia; TCA, tricyclic antidepressant.

on combination therapy are lacking, and the use of combined treatment is empirical based on the additive therapeutic benefit. Scheduled medication regimens instead of "as-needed" dosing should be used when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (eg, capsaicin) might be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

Patient Encounter Part 4

The patient has been at the skilled nursing facility for 4 weeks and is making progress toward rehabilitation goals; however, he complains that his leg is throbbing and feels like pins and needles. As a result, he requests to rest several times during his therapy sessions. During unit rounds, his therapist inquires whether his previous pain medication should be reordered.

Pain Assessment: 4 out of 10

Current Meds: Aspirin 81 mg daily, atorvastatin 80 mg at bedtime, multivitamin 1 daily, gabapentin 100 mg thrice daily, pantoprazole 40 mg daily, tamsulosin 0.4 mg daily, heparin 5000 units twice daily until discharged

What additional recommendations would you have at this time regarding pain management?

Are there any other therapeutic issues that should be addressed?

▶ *Complementary and Alternative Medicine*

Complementary and alternative medicine (CAM) is a term used to encompass a variety of therapies (eg, acupuncture, chiropractic, botanical and nonbotanical dietary supplements, and homeopathy). Painful conditions are among the most common reasons individuals seek relief from CAM. A variety of dietary supplements have been suggested for painful conditions such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew, γ-linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and chondroitin are the most popular and have the most evidence supporting their efficacy. Glucosamine in doses of 1500 mg/day has been shown to be effective in reducing the pain of osteoarthritis by fostering repair of cartilage, and it is recommended by the Osteoarthritis Research Society International (OARSI).[35]

Patient Care Process

Collect Information:

- Identify the source of pain.
- Assess the level of pain using a pain intensity scale.
- Review the medical and medication history.
- Determine if patient has insurance coverage for prescription medications.

Assess the Information:

- Determine if the patient is a candidate for pharmacotherapy.
- If patient is already receiving drug therapy, assess efficacy, side effects, adherence, and drug interactions.

Develop a Care Plan:

- Base the initial choice of analgesic on the severity and type of pain, as well as on the patient's medical condition and concurrent medications.
- Select the least potent oral analgesic that provides adequate pain relief and causes the fewest side effects.
- Avoid excessive sedation.

(*Continued*)

Patient Care Process (*Continued*)

- Adjust the route of administration if the patient is unable to take oral medications.
- Use equianalgesic doses as a guide when switching opioids.
- Use a dosing schedule versus as-needed dosing.

Implement the Care Plan:

- Communicate the recommendations to the prescriber and members of the team.
- Communicate expectations of the therapy to the patient.

Follow-up: Monitor and Evaluate:

- Assess the patient for analgesic effectiveness and for side effects at each visit or more frequently, depending on the acuity of the patient's condition.
- Titrate the dose to one that achieves an adequate level of pain control.

OUTCOME EVALUATION

Routine pain assessment is essential for evaluating outcomes of therapy. For example, pain goals for acute pain might include "pain scale less than 3" or 30% reduction in PEG scale. Functional goals such as "be able to play a game with grandchildren," or "be able to knit again" may be appropriate for chronic pain. Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

Abbreviations Introduced in This Chapter

AED	Antiepileptic drug
AGS	American Geriatrics Society
AHRQ	Agency for Healthcare Research and Quality
ASIPP	American Society of Interventional Pain Physicians
AIDS	Acquired immunodeficiency syndrome
AMPA	α-Amino-3-hydroxy-5-methylisoxazole-4-propionic acid
APAP	Acetaminophen
APS	American Pain Society
ASA	American Society of Anesthesiologists
CAM	Complementary and alternative medicine
CDC	Centers for Disease Control and Prevention
CNS	Central nervous system
COX	Cyclooxygenase
CRPS	Complex regional pain syndrome
CYP	Cytochrome P450 enzyme
DPN	diabetic peripheral neuropathy
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
HIV	Human immunodeficiency virus
IASP	International Association for the Study of Pain
IM	Intramuscular
IV	Intravenous
MME	Morphine milligram equivalents
NMDA	*N*-methyl-D-aspartate
NSAID	Nonsteroidal anti-inflammatory drug
OARSI	Osteoarthritis Research Society International
PAINAD	Pain Assessment in Advanced Dementia (tool)
PEG	Pain intensity, Enjoyment of life, General activity Assessment Tool
PCA	Patient-controlled analgesia
PHN	Postherpetic neuralgia
PQRST	Palliative/precipitating, Quality, Radiation, Severity, and Time
SAM-e	*S*-adenosylmethionine
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
TENS	Transcutaneous electrical nerve stimulation
VAS	Visual analog scale
WHO	World Health Organization

35 Headache

Joshua W. Fleming, Leigh Ann Ross, and Brendan S. Ross

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Differentiate types of headache syndromes based on clinical features.
2. Recommend nonpharmacologic measures for headache treatment and prevention.
3. Determine when the pharmacologic treatment of headache is indicated.
4. Construct individualized treatment regimens for the acute and chronic management of headache syndromes.
5. Monitor headache treatment to ensure its safety, tolerability, and efficacy.

INTRODUCTION

Headache is a common medical complaint with approximately 50% of the adult population experiencing at least one headache per year.[1] KEY CONCEPT Even when persistent or recurrent, headaches are usually a benign primary condition; secondary headaches are caused by an underlying medical disorder and may be medical emergencies. Primary headache syndromes are the focus of this chapter. Patients may seek headache care from multiple providers. All clinicians should be familiar with the various types of headache, clinical indicators suggesting the need for urgent medical attention or specialist referral, and nonpharmacologic and pharmacologic options for treatment. KEY CONCEPT The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.[2]

EPIDEMIOLOGY OF HEADACHE DISORDERS

Migraine Headache

Migraine is a primary headache disorder with an estimated 3-month prevalence rate in the United States of 14.2% in adults over 18. Prevalence is higher in females at 19.1% compared to 9%. Highest prevalence was in females 18 to 44 years of age at 23.5%.[3] In pediatric patients, there is also a higher incidence in females after the age of 10.[4] The difference in gender distribution is thought to be due to hormonal differences.

Tension-Type Headache

KEY CONCEPT Tension-Type Headache (TTH) is the most common primary headache disorder and can be further divided into episodic or chronic.[2] The term *TTH* is used to describe all headache syndromes in which sensitization to pericranial **nociception**, noxious stimuli, is the most significant factor in the pathogenesis of pain.[5] Overall reported prevalence of TTH is approximately 86%, and incidence is more common in women than men. Episodic TTH is the most common type followed by frequent episodic TTH, and chronic TTH. Incidence of TTH increases until approximately age 40, then incidence begins to slowly decline.[6] Environmental factors, as opposed to genetic predisposition, play a central role in the development of TTH. The mean frequency of attacks is 3 days per month in episodic disorders; chronic TTH is defined as 15 or more attacks in a 1-month period.[2]

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache disorders are uncommon and severe primary headache syndromes.[2] The lifetime prevalence is estimated to be 124 per 100,000.[7] Unlike migraine and TTH, cluster headaches are more frequently found in men. Onset most commonly occurs between 20 and 40 years.[2] A genetic predisposition is apparent, although affected individuals often provide the additional history of tobacco use, caffeine intake, and alcohol abuse.[7] Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time but may abate for extended periods, resulting in months or years between occurrences. In rare instances, cluster headache can be a chronic disorder without remission.[2]

ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

Migraine Headache

The exact mechanism by which migraines occur remains obscure, but the belief that only vascular changes are responsible for the pain is no longer accepted.[8] The vascular hypothesis suggested that intracerebral vasoconstriction led to neural ischemia, which was followed by reflex extracranial vasodilation and pain. Negative neuroimaging evidence for such vascular changes and the effectiveness of medications with no vascular properties make this contention untenable.[5] A neuronal etiology has emerged as the leading mechanism for the development of migraine pain.[9] It is believed that depressed neuronal electrical activity spreads across the brain, producing transitory neural dysfunction.[8] Headache pain is likely due to compensatory overactivity in the trigeminovascular system

of the brain. Activation of trigeminal sensory nerves leads to the release of vasoactive neuropeptides (eg, calcitonin gene-related peptide [CGRP], neurokinin A, substance P) that produce a sterile inflammatory response around vascular structures in the brain, provoking the sensation of pain.[9] Continued sensitization of central nervous system (CNS) sensory neurons can potentiate and intensify headache pain as an attack progresses.[8] Bioamine pathways projecting from the brainstem regulate activity within the trigeminovascular system. The pathogenesis of migraine is most likely due to an imbalance in the modulation of nociception and blood vessel tone by serotonergic and noradrenergic neurons.[9]

Tension-Type Headache

The pathophysiologic mechanisms producing TTHs are not clearly understood and are likely multifactorial. However, central sensitization to peripheral nociceptive input arising from the pericranial myofascia is the leading hypothesis. The belief that sustained muscle contraction is solely responsible for generating the pain cannot be supported. Muscle tenderness is prominent in this syndrome, but it only reflects a heightened sensitivity to pain. TTH pain is believed to arise by disturbances in the muscles and tissues of the head being misinterpreted due to disordered CNS pain processing.[10]

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache is one of a group of disorders referred to as trigeminal autonomic cephalalgias.[11] This autonomic nervous system dysfunction is characterized by sympathetic underactivity coupled with parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed to be the result of vasoactive neuropeptide release and neurogenic inflammation. The exact cause of trigeminal activation in this intermittently manifest syndrome is unclear.[11] One hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohumoral balance, is responsible for headache periodicity.[5] Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high-altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.[8]

CLINICAL PRESENTATION AND DIAGNOSIS OF HEADACHES

Migraine Headache

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. KEY CONCEPT Migraine headaches are classified as migraine with **aura** and migraine without aura.[2] Aura is defined as a transient focal neurologic symptom that can occur prior to or during an attack. These typically present as wavy lines or spots, but can also present as a **scotoma**.[2] The IHS outlines diagnostic criteria that differentiate migraine with and without aura. Migraines can be triggered by changes in behavior, environment, diet, and hormone levels. Migraines can additionally be triggered by intake of tyramine, aspartame, monosodium glutamate, and nitrites.[8] Migraines occurring 15 or more days per month for a 3-month period or longer, without the overuse of analgesic medications, are classified as chronic migraines.[2] Severe and debilitating migraine pain lasting more than 72 hours is termed status migrainosus.[2]

LO 1

Clinical Presentation and Diagnosis of Migraine Without Aura

Patients experiencing "migraine without aura" may display the following headache symptoms and characteristics:

Two or more of the following are present:

1. Pain interrupts or worsens with physical activity
2. Unilateral pain
3. Pulsating pain
4. Moderate to severe pain intensity

One or more of the following are present during headache:

1. Nausea/vomiting
2. Photophobia and phonophobia

Duration: 4 to 72 hours (treated or not treated)

Criteria for diagnosis: Five or more attacks fulfilling above criteria are necessary

Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood count (CBC), complete chemistry panel including liver function tests (LFTs), thyroid function tests (TFTs), erythrocyte sedimentation rate (ESR)

Tension-Type Headache

LO 1

TTH pain differs from migraine pain in that it is usually reported to be mild to moderate in severity, nonpulsating, and bilateral.[6] The pain is described by sufferers as a band-like tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare. TTHs

Clinical Presentation and Diagnosis of Migraine with Aura

Patients experiencing "migraine with aura" may display the following headache symptoms and characteristics:

One or more of the following present with no motor weakness:

1. Visual
2. Sensory
3. Speech and/or language
4. Motor
5. Brainstem
6. Retinal

Two or more of the following:

1. At least one aura symptom that spreads gradually over at least 5 minutes
2. Individual aura symptoms last 5 to 60 minutes
3. At least one aura symptom is unilateral
4. The aura is accompanied or followed by a headache within 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling above criteria are necessary

Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing TTH may display the following headache symptoms and characteristics:

Two or more of the following present and are not aggravated by routine physical activity:

1. Bilateral pain
2. Nonpulsating pain
3. Mild or moderate pain intensity

Both of the following:

1. No nausea or vomiting (anorexia possible)
2. Either photophobia or phonophobia (not both)

Duration: 30 minutes to 7 days

Criteria for diagnosis: 10 or more attacks fulfilling above criteria occurring on average less than 1 day per month are necessary

occurring more than 15 days per month for more than 3 months, without evidence medication overuse, would be classified as chronic TTH.[2]

Cluster Headache

LO 1

Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration.[5] Headaches typically occur at night, but attacks may occur multiple times per day.[11] The pain is usually unilateral, but, unlike migraine, it is not described as pulsatile.[5] Aura is not a feature, and pain intensity peaks early after onset, although it may persist for hours.[5] The headache is described as explosive, excruciating, and referred to as a "suicide headache." A constellation of features, ascribed to parasympathetic overactivity, can be seen, such as ipsilateral conjunctival injection as well as lacrimation, rhinorrhea, and

Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing "cluster headache" may display the following headache symptoms and characteristics:

At least one or more of the following symptoms:

1. Lacrimation
2. Nasal congestion and/or rhinorrhea
3. Eyelid edema
4. Forehead or facial sweating/flushing
5. Sensation of fullness in the ear
6. Miosis and/or ptosis

Or a sense of restlessness or agitation

Duration of pain: 15–180 minutes (untreated)

Frequency of attacks: One every other day and/or up to 8 per day for more than half the time the disorder is active (may have long periods when headaches are inactive)

Criteria for diagnosis: Five or more attacks fulfilling the above criteria

Patient Encounter Part 1

A 34-year-old woman who is 24 weeks pregnant and describes having headache pain that is so severe that she has to stay home from work and lie down in a darkened room. She describes her pain as sharp, unilateral, and pulsating. She reports that she can tell when it is about to begin because she can see "floaters" then her peripheral vision begins to fade. She reports using OTC pain relievers to help ease the pain, but she has not had any success thus far.

What type of headache is the patient most likely experiencing?

What characteristics of the headache support this diagnosis?

What are possible causes or triggers of headache in this patient?

What additional information is needed to formulate a treatment plan?

sweating. Cluster headache patients tend to become excited and restless during attacks, rather than seeking quiet and solitude as in migraine.[11]

TREATMENT OF HEADACHE DISORDERS

Desired Outcomes

KEY CONCEPT The short-term treatment goal of migraine is to achieve rapid pain relief to allow the patient to resume normal activities. The long-term goal of therapy is to prevent headache recurrences and to diminish headache severity.[12] Similarly, the goal of TTH care is to lessen headache pain, whereas the long-term goal is to avoid analgesic overuse and dependence.[8,13] The short-term therapeutic goal in cluster headache is to achieve rapid pain relief. Prophylactic therapy may be necessary to obtain the intermediate-term outcome of reducing the frequency and severity of headaches within a periodic cluster series as well as to achieve the long-term goal of delaying or eliminating recurrent periods.[14]

General Approach to Treatment

First-line pharmacologic agents include nonsteroidal and opiate analgesics, and serotonin-receptor agonists (triptans).[12]

LO 3

KEY CONCEPT Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and to improve response to therapy. The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options; if headaches are severe and frequent, then prophylactic pharmacologic therapy is needed.[12] KEY CONCEPT Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation (Table 35–1).[15]

Nonpharmacologic Therapy

LO 2

The successful management of headache disorders depends on comprehensive patient education. Recording headache frequency, duration, severity, possible triggers, and medication response in a "headache diary" provides beneficial information for the patient regarding headache precipitants and useful insights for the clinician selecting appropriate management strategies.[12] To prevent future occurrences, exposure to headache triggers (Table 35–2) should be limited.[14] In the acute setting, environmental control

Table 35–1

Headache "Red Flags" Indicating Need for Urgent Medical Evaluation

New-onset sudden and/or severe pain
Stereotyped pain pattern worsens
Systemic signs (eg, fever, weight loss, or accelerated hypertension)
Focal neurologic symptoms (ie, other than typical visual or sensory aura)
Papilledema
Cough-, exertion-, or Valsalva-triggered headache
Pregnancy or postpartum state
Patients with cancer, human immunodeficiency virus (HIV), and other infectious and immunodeficiency disorders
Seizures

Adapted from Refs. 8 and 15.

can lessen the severity of an attack, so patients may benefit from resting in a dark, quiet area. Behavioral interventions, such as biofeedback, relaxation therapy, and cognitive-behavioral training, are effective and can be recommended for headache prevention. Headache sufferers may also benefit from stress management training.[8] Acupuncture has yielded inconsistent benefits in clinical trials.[16] Although the response is variable, headache patients should be advised to moderate alcohol use and curtail tobacco abuse.[14] All such nonpharmacologic therapies may be useful in augmenting pharmacologic response.

Table 35–2

Migraine Triggers

Behavioral
Emotional let down
Fatigue
Menstruation or menopause
Sleep excess or deficit
Stress
Vigorous physical activity

Environmental
Flickering lights
High altitude
Loud noises
Strong smells such as perfumes
Tobacco smoke
Weather changes

Food
Alcohol
Caffeine intake or withdrawal
Chocolate
Citrus fruits, bananas, figs, raisins, avocados
Dairy products
Fermented or pickled products
Missing meals

Food Containing
Monosodium glutamate (MSG): Asian food, seasoned salt
Nitrites: processed meats
Saccharin/aspartame: diet soda or diet food
Sulfites: shrimp
Tyramine: cheese, wine, organ meats
Yeast: breads

Medications
Cimetidine
Estrogen or oral contraceptives
Indomethacin
Nifedipine
Nitrates
Reserpine
Theophylline
Withdrawal due to overuse of analgesics, benzodiazepines, decongestants, or ergotamines

Adapted from Refs. 8 and 44.

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Normal childhood illnesses

FH: Father living, age 67 years: HTN, diabetes mellitus; mother living, age 62 years: migraine headaches; two sisters in good health

SH: Medical lab technician; former smoker; 1–2 cups of coffee per day; eliminated alcohol intake since being pregnant

Meds: Acetaminophen 500 mg, one tablet orally every 4 to 6 hours as needed for headache

ROS: Headache, moderate-severe intensity, sensitivity to light; no dizziness; no chest pain or palpitations; no shortness of breath with exertion; no weakness or joint discomfort

PE:

VS: BP 122/81, P 91, RR 18, T 37.0˚C (98.6˚F) oral

HEENT: No papilledema, neck tender without stiffness

CV: RRR, normal S1, S2, S4 gallop, no MR

Chest: CTA

Abd: Benign, bowel sounds positive

Neuro: Nonfocal

Labs: CBC and complete chemistry panel within normal limits

What is your assessment of this patient's condition?

What medical comorbidities or drug therapies may be contributing to her distress?

Identify treatment goals for this patient.

What nonpharmacologic options are needed at present, and what options are appropriate in the long term?

What pharmacologic therapy would you recommend in the acute setting?

Does this patient require long-term pharmacologic prophylaxis against recurrent headaches?

Pharmacologic Therapy

► *Migraine*

LO 3

Analgesics, such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and combination products containing caffeine, with or without an opioid, are the initial pharmacologic option for the acute management of migraine headache especially when severity is mild to moderate. If these analgesics prove to be ineffective, and when headaches are severe, then migraine-specific medications, such as triptans, are administered. Early abortive treatment should be the rule. Larger doses of oral medications may be necessary for pain relief, due to the enteric stasis and poor drug absorption accompanying migraine attacks.

Intranasal, parenteral, and rectal administration can circumvent this complication.[12]

Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura. Acetaminophen alone or in proprietary combinations with aspirin, opioids, caffeine, or butalbital is also effective.[17]

Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1B/1D pathways in the brainstem, which modulate nociception. They also decrease the release of vasoactive neuropeptides leading to vascular reactivity and pain.[18] The triptans are available in intranasal, subcutaneous, and oral dosage forms including tablets or orally dissolving tablets. The available agents differ in their dosing and pharmacokinetic properties, but all are effective treatments to abort or diminish migraine headache (Table 35–3).[8,19–28] Patient responses can be variable; if a patient does not respond to one agent, then another is selected before a patient is prematurely labeled as triptan-unresponsive. The initial severity of headache correlates with symptomatic response; thus administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose-related, although adverse effects are less so. These medications are well tolerated; the most common side effects are dizziness, a sensation of warmth, chest fullness, nausea, and paresthesia. Rarely, ischemic vascular events may be precipitated by the potential vasoconstrictive nature of these drugs. An initial dose under direct practitioner supervision is indicated for patients at increased cardiovascular risk. Triptans are avoided in patients with migraine associated with neurologic focality, a history of previous stroke, poorly controlled hypertension (HTN), or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy.[29] Triptans should not be used with concurrent ergotamine administration with the wait time at least 24 hours between use depending on the half-life of the triptan.[8]

Ergotamine derivatives produce salutary effects on serotonin receptors similar to triptans. They also impact adrenergic and dopaminergic receptors. Ergotamine tartrate

Table 35–3

Comparison of Serotonin Receptor Agonists (Triptans)

Medication (Brand Name)	Dosage Forms	Strength (mg)	Usual Dosage (mg)	May Repeat (hours)	Hepatic and Renal Dosing Considerations (mg)	Potential Drug Interactions
Almotriptan (Axert)	Oral tablets	6.25 12.5	6.25–12.5	2	HI and severe RI: 6.25 starting dose and ≤ 12.5	Ergot derivatives Substrate: CYP 3A4, CYP 2D6
Eletriptan (Relpax)	Oral tablets	20 40	20–40	2	Severe HI: not recommended	Ergot derivatives Substrate: CYP 3A4, CYP 2D6
Frovatriptan (Frova)	Oral tablets	2.5	2.5	2	Severe HI: use caution	Ergot derivatives Substrate: CYP 1A2
Naratriptan (Amerge)	Oral tablets	1 2.5	2.5	4	Mild-mod RI or HI: do not exceed 2.5; severe RI (< 15 mL/min [0.25 mL/s]): do not administer	Ergot derivatives Substrate: CYP (various)
Rizatriptan (Maxalt and Maxalt MLT)	Oral tablets Disintegrating tablets	5 10	5–10	2	None identified	Ergot derivatives MAO-A inhibitors
Sumatriptan (Imitrex)	Oral tablets Subcutaneous injection Nasal spray	25, 50, 100 4,6 5, 20/spray	50 6 5–20	2 1 2	Mild-mod HI: oral dose not to exceed 50; severe HI: contraindicated	Ergot derivatives MAO-A inhibitors
Sumatriptan (Onzetra Xsail)	Nasal powder	11 mg/spray	22–44	2		
Sumatriptan/ Naproxen sodium (Treximet)	Oral tablets	85/500	85/500	2	RI (CrCl < 30 mL/min [0.50 mL/s]): not recommended; mild to severe HI: contraindicated	Ergot derivatives MAO-A inhibitors
Zolmitriptan (Zomig and Zomig-ZMT)	Oral tablets Disintegrating tablets Nasal spray	2.5, 5 2.5, 5 2.5, 5/spray	2.5 1.25–2.5 2.5	2 2 2	CrCl 5–25 mL/min (0.08–0.42 mL/s): clearance reduced by 25%, use caution; mod-severe HI: not recommended	Ergot derivatives MAO-A inhibitors Substrate: CYP 1A2

CrCl, creatinine clearance; CYP, cytochrome P450 enzyme; HI, hepatic impairment; MAO-A, monoamine oxidase type A; RI, renal impairment.

Adapted from Refs. 8 and 20–28.

and dihydroergotamine (DHE) are the most commonly used agents.[12] Analgesic onset is within 4 hours, although additional dosing is required if an acceptable response is not achieved. When dosed parenterally, these drugs are usually provided with an antiemetic due to their potential to worsen nausea associated with migraine. The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form with the exception of intranasal DHE which can be self-administered to abort an attack.[12] The same cautions associated with triptan use are also applicable to ergot use in patients at risk for vascular events.

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists. Some believe that nonspecific analgesics should be used first line, whereas others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability. A stepped-care approach within attacks from less to more specific drugs is usually recommended. Once a history of headache refractory to common analgesics is established, triptans should be used as initial therapy.[12] Selection of initial headache treatment is important in reducing the incidence of medication overuse headache (MOH). This occurs when patients use ergotamines, triptans, opioids, or other combinations for more than 10 days per month. This can also be considered in patients who are using nonspecific analgesics for more than 15 days per month.[13] In patients who present to the hospital with intractable pain, IV metoclopramide supplemented with DHE may be needed. Oral medications in this setting are not used because nausea and vomiting limit their bioavailability.[12] Migraine patients with frequent and severe attacks are candidates for prophylactic treatment.[30]

▶ *Tension-Type Headache*

LO 3 Most individuals who experience episodic TTHs will not seek medical attention.[2] Instead, they will find relief with the use of widely available OTC analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient LO 2 may benefit from topical analgesics (eg, ice packs) or physical manipulation (eg, massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent.[5] Relaxation techniques can often reduce headache frequency and severity. When pain is unrelieved, prescription-strength NSAID use is required, or the combination of acetaminophen with an opioid analgesic may be necessary. The frequent use of these more potent analgesics should be limited, so that the development of dependency is prevented. As described above, MOH can occur with frequent use of analgesics for TTH. For patients experiencing frequent TTH, prophylactic treatment should be considered.[13]

▶ *Cluster Headache*

Cluster headache responds to many of the treatment modalities used in acute migraine; however, initial prophylactic therapy is required to limit the frequency of recurrent headaches within LO 3 a periodic series. A therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 12 to 15 L/min by nonrebreather face mask for approximately 15 minutes.[31] If the pain is not aborted, retreatment is indicated. No long-term side effects are seen with short-term oxygen use. If oxygen therapy is not wholly effective, then drugs are useful adjunctive therapy. Drug therapy is also used when supplemental oxygen LO 3 is not readily available. The triptan class is safe and effective. Intranasal or subcutaneous sumatriptan as well as intranasal zolmitriptan has demonstrated efficacy in decreasing cluster headache pain.[32] Oral triptans are also effective, but their delayed onset of action may limit their applicability in acute cluster headache treatment.[18] Cluster headache is rapid in onset and achieves peak intensity quickly, but it can be of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or IV ergotamine agents are alternatives to triptan use.[5] Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain.[33] Octreotide is a somatostatin analogue that has a short half-life and may be administered subcutaneously. Unlike the other abortive agents, it has no vasoconstrictive effects; the most prominent treatment emergent adverse effect is gastrointestinal (GI) upset. Glucocorticoids, provided IV and later tapered orally, are effective when cluster headache attacks are not satisfactorily controlled.[12]

Pharmacologic Therapy for Headache Prophylaxis

KEY CONCEPT Prophylaxis for headache disorders is indicated if headaches are frequent or severe, if significant disability occurs, if pain-relieving medications are used frequently, or if adverse events occur with acute therapies.[12,30]

▶ *Migraine Prophylaxis*

LO 4 Migraine headaches that are severe, frequent, or lead to significant disability require long-term medication therapy. Prophylactic therapy is also recommended for migraines associated with neurologic focality because it may prevent permanent disability.[12] Although multiple medication classes have garnered US Food and Drug Administration (FDA) labeling for migraine prevention, there is no consensus on the best initial therapy (Table 35–4).[30]

Table 35–4

Medications for Prophylaxis of Migraines[12,17]

Medication (Brand Name)	Usual Dosage (mg/day)	Main Adverse Effects
Antiepileptics		
Topiramate (Topamax)[a]	25–200	Paresthesias, dizziness, fatigue, nausea
Valproic acid (Depakene)[a]	500–1500	
Divalproex sodium (Depakote)[a]	500–1500	
β-Blockers		
Atenolol (Tenormin)[b]	25–200	
Metoprolol (Lopressor)[a]	50–200	Fatigue, exercise intolerance
Nadolol (Corgard)[b]	20–160	
Propranolol (Inderal)[a]	80–240	
Timolol (Blocadren)[a]	10–30	
Antidepressants		
Amitriptyline (Elavil)[a]	10–150	Weight gain, dry mouth, sedation
Venlafaxine (Effexor)[a]	37.5–150	

[a]Level A: Established efficacy.

[b]Level B: Probably effective.

KEY CONCEPT The choice of pharmacologic agent is individually tailored to patient tolerability and medical comorbidities.

The β-blockers have long been a mainstay in migraine prevention, and many have been proven to be effective in improving patient symptoms. Cautious dosage titration is advised for those patients who do not have other indications for β-blocker use. Comorbid reactive airway disease is a relative contraindication to β-blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored.[17] Patients should also be advised to take only 5 mg of rizatriptan (max 15 mg/day) when they are prescribed propranolol.[24] Calcium channel antagonists are often used when patients cannot tolerate β-blockers. None of the calcium channel blockers carry an FDA indication, and their efficacy is considered to be variable. Angiotensin receptor blockers (ARBs) and angiotensin-converting enzyme inhibitors (ACEIs) have been evaluated for migraine prevention, but only two, lisinopril and candesartan, have shown possible efficacy.[17]

Low-dose amitriptyline or other tricyclic antidepressants (TCAs) have proven efficacy in migraine prevention.[17] Due to sedation, these medications are commonly administered at night. Later generation TCAs (eg, nortriptyline) or heterocyclic compounds (eg, trazodone) have fewer dose-limiting adverse effects than the TCAs, especially anticholinergic effects (eg, dry mouth, constipation, and urinary retention), but efficacy has been variable with these agents. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have been evaluated for migraine prevention, but thus far, only venlafaxine has demonstrated probable efficacy. The FDA has issued a controversial warning about using serotonergic antidepressants along with triptans due to the rare occurrence of serotonin syndrome.[34]

The antiepileptics valproic acid and topiramate are approved for migraine prophylaxis. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is used as prevention for both disorders.[17] Divalproex sodium doses are gradually titrated to 1000 mg/day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed.[17] Topiramate is especially useful in patients who have metabolic syndrome, diabetes, and dyslipidemia because it is unlikely to cause weight gain often seen with valproic acid. Topiramate does come with the potential for side effects such as paresthesia, fatigue, anorexia, nausea, and cognitive impairment which occurs at a lower frequency than the other mentioned side effects. These side effects can be mitigated by a slow dosage titration and maintaining adequate hydration.[35]

Methysergide is an ergotamine derivative that impacts central serotonin balance. Inflammatory fibrosis is a rare but serious, adverse reaction associated with the prolonged use of methysergide. Retroperitoneal fibrosis, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. These conditions may resolve upon drug withdrawal, but cardiac valvular damage can be irreversible. Some experts believe it is the best choice for refractory migraine with frequent attacks, but due to its significant adverse effect profile, it is not marketed in the United States.[36]

Given that migraines can be triggered by changes in hormonal balance, it is not surprising that some women have migraines around the time of menstruation. Often, these migraines can be prevented by starting NSAIDs prior to the beginning of menstruation. Triptans can be tried in patients unresponsive to NSAIDs. Three triptans have been shown to be effective in preventing menstrual migraines. Frovatriptan, naratriptan, and zolmitriptan can be considered and should be started 2 to 3 days prior to the beginning of menstruation.[30]

OnabotulinumtoxinA has received FDA approval for the treatment of chronic migraine, but the evidence supporting its use is conflicting. In 2008, the American Academy of Neurology conducted an evidence review and concluded that OnabotulinumtoxinA was probably ineffective for the prevention of migraines.[37] In the PREEMPT 1 and PREEMPT 2 trials, there was a statistically significant reduction in the number of headache days per month when compared to placebo, but the absolute difference between the two groups was only 1.8 days.[38,39]

While evidence is limited, some complementary alternative therapies can be considered for migraine prophylaxis. Petasites (butterbur) has been associated with a potential 60% reduction in the number of headaches experienced over a 1-month period when compared to placebo, but the risk of liver toxicity associated primarily with the plant's root and allergic reactions in asthmatics may limit it use. Studies for riboflavin have been mixed, with some older studies supporting its use for migraine prevention, but some newer studies have failed to show efficacy. Finally, MIG-99 (feverfew) has also shown possible efficacy with very limited trial evidence.[40]

► *Tension-Type Headache Prophylaxis*

LO 4 The prevention of chronic TTHs uses the same pharmacologic strategies as for migraine prophylaxis. TCAs are a mainstay of chronic therapy. The efficacy of serotonergic agonists remains in question. Although there is little need for muscle relaxants (eg, methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention. Combination prophylactic therapies may be needed to wean patients from daily analgesic abuse. Stress reduction techniques may be particularly effective in this setting.[5]

► *Cluster Headache Prophylaxis*

LO 4 The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.[5] Within an attack period, it is dosed at 240 to 360 mg/day. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed. Adverse effects include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease because verapamil is an inotropic and chronotropic cardiac suppressant.[5] Pharmacokinetic drug–drug interactions must be considered, as verapamil is a moderate inhibitor of oxidative metabolism through cytochrome P450 (CYP) enzyme 3A4. Eletriptan, a CYP 3A4 substrate, should be avoided concurrently with verapamil.[5,21] Lithium is another effective therapy to reduce headache frequency in a cluster series and to limit recurrences.[12] The dose administered should be individualized to achieve a low serum concentration (0.4–0.8 mEq/L [mmol/L]). Dose adjustments in the setting of renal disease or congestive heart failure are required.[5] Lithium is contraindicated in patients concurrently prescribed thiazide diuretics, NSAIDs, ACEIs, or ARBs. Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, GI distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible, bedtime dosing is recommended, given the nocturnal predilection of cluster headache attacks.[11]

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient's headache. Your plan should include:

A statement of the drug-related needs and/or problems.

The goals of therapy.

A detailed, patient-specific therapeutic plan.

A monitoring plan to determine whether the goals have been achieved and adverse effects avoided.

SPECIAL POPULATIONS

Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years.[4] The diagnosis and evaluation of headaches is especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients older than 6 years.[41] Aspirin use is avoided due to the risk of precipitating Reye syndrome. The use of triptans in children and adolescents has not been shown to be more effective than placebo. Only rizatriptan is FDA approved for children over 6 and almotription for children over 12. The rest are approved for greater than 18 years of age.[20,24,41] Medication prophylaxis for migraines in children and adolescents is understudied with conflicting data.[41,42] Nonpharmacologic interventions and trigger identification and avoidance are advised.

Pregnancy

Headaches are common in pregnancy likely related to hormonal shifts. TTHs predominate; migraine attacks may increase in frequency but more usually frequency decreases during pregnancy.[43] Recommendations for headache care during pregnancy are based on limited evidence and are largely anecdotal. Because headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices considered carefully. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus.[43] NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin alterations leading to premature ductus arteriosus closure. Opioids are second-line agents and should not to be used chronically because they can lead to dependence in the mother and to acute withdrawal in the infant after birth.[43] Centrally acting antiemetic agents are safe and may be useful as adjunctive agents. Corticosteroids

Patient Care Process

KEY CONCEPT Individualized treatment regimens for headache disorders are based on: headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.

Collect Information:

- Obtain a complete medical and social history to identify any potential drug–disease interactions or social factors that may influence treatment choices.
- Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
- Perform medication history including prescription and non-prescription medications along with dietary supplements. Identify medication allergies.
- Complete a review of systems and physical examination to identify causes or complications of headache.
- Review medical records including any laboratory assessments and radiographic findings.

Assess the Information:

- Based on information obtained for reviewing the patient's medical history, patient interview, review of systems, and physical examination, identify the type of headache.
- Determine if there are triggers for the patient's headaches.
- Assess laboratory assessments to determine renal function and liver function as these may affect medication choice.
- Based on patient history and family history, evaluate the patient's cardiovascular health especially if considering a triptan.
- If patient is already receiving pharmacotherapy, assess for appropriateness and efficacy.

Develop a Care Plan:

- Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
- When selecting new agents for acute management or for prophylaxis, ensure that the medication is financially accessible.
- Consider insurance coverage when selecting therapy.

Implement the Care Plan:

- Educate the patient on the administration, maximum dosage, and anticipated adverse effects of the prescribed medication, and advise the patient when to seek emergency medical attention.
- Instruct the patient to keep a headache diary to assess therapeutic response.
- Educate on the potential for medication overuse headache.

Follow up: Monitor and Evaluate:

- Follow-up should be scheduled within 4 weeks of starting any new medications for headache to assess efficacy.
- As patient becomes more aware of headache symptoms and appropriate agents are on board for prevention and treatment of headache, follow-up can become less frequent (ie, 3–6 months).

may be needed for intractable headache relief. Prednisone and methylprednisone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine, vasoconstrictive agents such as triptans are relatively contraindicated, even though maternal registry data reveal little teratogenicity. If triptans are considered for acute migraine treatment, sumatriptan, naratriptan, and rizatriptan have the greatest evidence of safe use during pregnancy.[43] Ergot compounds are strictly avoided because they may precipitate uterine contractions and placental ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously because β-blockers and calcium channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia.[43] Antiepileptic drug use in this setting has not been sufficiently studied to allow definitive recommendations.

Outcome Evaluation

LO 5

LO 5

Monitoring for therapeutic response is an important part of headache management. In acute management, monitor patients for the pain improvement within 2 to 4 hours and for normal functioning within 3 to 4 hours of treatment initiation. If pain control has not been achieved, additional therapy may be needed for a therapeutic effect. With chronic management for headache prevention, monitor overall headache status every several weeks to months for improvement. A slow decrease in headache frequency is anticipated over this time. Encourage patients to track progress in a headache diary to assist in monitoring improvements in frequency and severity of headaches and corresponding disability. Clinicians monitor attack frequency to determine therapeutic response, seeking a 50% or greater reduction over the course of treatment. Monitoring for adverse effects is central to successful treatment. For acute management, monitor for GI effects from analgesics such as NSAIDs or octreotide, vasoconstrictive symptoms from triptans, and nausea and vascular problems from ergotamine derivatives. Monitor those taking beta blockers for reactive airway disease and cardiac conduction disturbances. Monitor those taking TCAs for sedation and anticholinergic effects such as dry mouth, constipation, and urinary retention. Monitor patients taking calcium channel blockers for gastroesophageal reflux symptoms and constipation, and monitor those taking lithium for tremor, GI distress, and lethargy. To ensure optimal headache management, in acute treatment and prophylactic therapy, monitor regimens both for therapeutic outcomes and adverse events, which may impact quality of life and medication adherence.

Abbreviations Introduced in This Chapter

ACEI	Angiotensin-converting enzyme inhibitor
ARB	Angiotensin receptor blocker
BP	Blood pressure
CGRP	Calcitonin gene-related peptide
CNS	Central nervous system
CTA	Clear to auscultation
CYP	Cytochrome P450 isoenzyme system
DHE	Dihydroergotamine
FDA	Food and Drug Administration
GABA	γ-aminobutyric acid
GI	Gastrointestinal
HTN	Hypertension
IHS	International Headache Society
MAO-A	Monoamine oxidase type A
MOH	Medication overuse headache
MR	Murmur, rub
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over-the-counter
RR	Respiratory rate
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
TTH	Tension-type headache

36 Substance-Related Disorders

Chris Paxos and Christian J. Teter

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO
1. Identify the prevalence of use for alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids, and tobacco in the US population.
2. Explain the commonalities of action of substances of abuse on the reward system in the brain.
3. Determine when a patient meets criteria for substance use disorder.
4. Identify the typical signs and symptoms of intoxication and withdrawal associated with the use of alcohol, opioids, CNS stimulants, cannabinoids, and tobacco.
5. Determine the appropriate treatment measures to produce a desired outcome after episodes of intoxication and withdrawal.
6. Choose specific pharmacotherapeutic options based on patient-specific factors.
7. Recommend a comprehensive medication treatment and monitoring program to help maintain recovery and prevent relapse to substance use.

INTRODUCTION

Substance use disorders (SUDs) are highly prevalent worldwide. In the United States, patterns of substance use and abuse have been cyclical. For example, cocaine was first isolated from coca leaves in 1860. Its use was advocated by many in the medical establishment until the mid-1890s when it became evident chronic use might be addictive in some individuals and could have deleterious physiologic effects. Its use decreased after prescribing and dispensing restrictions in the early 20th century. In the 1980s, a smokeable formulation (ie, crack) became available, and cocaine use again became epidemic. This historically cyclic nature of substance abuse is common to many substances of abuse.

KEY CONCEPT Pharmacotherapy has a role in treatment of some substance-related disorders, including intoxication, withdrawal, and/or long-term relapse prevention. These substances include alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids, and tobacco. This chapter focuses on pharmacotherapy for these common substance-related disorders. Although other substances are misused (eg, prescription sedatives and tranquilizers), they are not the focus of this chapter.

EPIDEMIOLOGY AND ETIOLOGY

LO 1 The National Survey on Drug Use and Health (NSDUH) uses a representative sample of individuals 12 years or older to determine the annual prevalence of licit and illicit substance use.[1] In 2015, more than half (51.7%; 138.3 million) of Americans reported current (ie, past month) alcohol use. In the 30 days prior to the survey, nearly 1 in 4 Americans (24.9%; 66.7 million) reported binge drinking (ie, 5 or more drinks for men and 4 or more drinks for women), and 6.5% (17.3 million) reported heavy drinking (ie, binge drinking on 5 or more occasions). Approximately one-quarter (23.9%; 64.0 million) of Americans were current users of tobacco. Past month cigarette use declined in 2015; however, this may be due in part to electronic cigarettes. Regarding illicit drug use, 1 in 10 Americans (10.1%; 27.1 million) reported current use, with marijuana and prescription pain relievers being most common (Figure 36–1). Americans reporting current CNS stimulant use varied by substance (ie, 0.7% with cocaine, 0.6% with prescription stimulants, and 0.3% with methamphetamine). While uncommon by comparison, past month heroin use was 0.1% (0.3 million).[1] The NSDUH findings indicate that substance use is wide ranging and continues to be a major public health concern.

Reward Pathway

LO 2 KEY CONCEPT Virtually all substances of abuse appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the ventral tegmental area (VTA) and projecting to the nucleus accumbens (NA) and prefrontal cortex (PFC).

Figure 36–2 depicts the mesocorticolimbic dopamine (DA) pathway. Key components are DA projections from the VTA to the NA and PFC.[2,3] Many studies support mesolimbic DA system involvement in natural rewards and drug reinforcement; however, there is also evidence that reinforcement independent of DA exists.[4,5] The initial pleasurable experiences secondary to drug use appear to be primarily attributable to activation of primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce activities that promote survival, such as food and water consumption, social affiliation, or sexual activity. However, these systems appear to be disrupted, especially after repeated drug use in susceptible individuals.

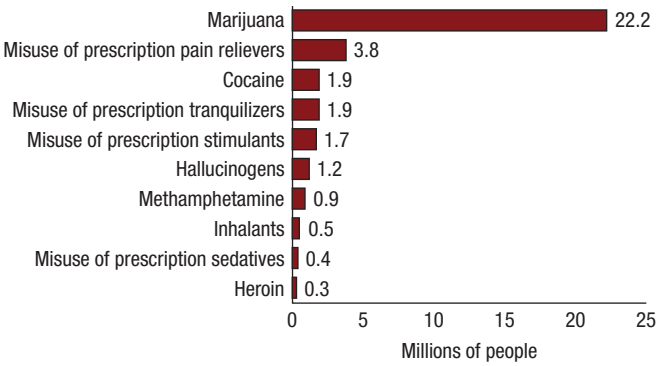

FIGURE 36–1. Past-month illicit drug use in the US among individuals 12 years and older in 2015. (Data and figure in the public domain from Substance Abuse and Mental Health Services Administration, Results from the 2015 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-51, HHS Publication No. (SMA) 16-4984. Rockville, MD: Substance Abuse and Mental Health Services Administration, 2016.)

Although most individuals experience pleasant effects, not everyone abuses these drugs or becomes dependent on them. Why some abuse drugs while most do not relates to complex genetic, environmental, and cultural factors.

PATHOPHYSIOLOGY

Neuronal Adaptation

KEY CONCEPT Although activation of reward pathways explains the pleasurable sensations associated with acute substance use, chronic use (which may result in substance-related disorders) may be related to neuroadaptive effects within the brain.

Addiction is often described as a repeating cycle with three phases: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation.[5] Binge/intoxication refers to the acute rewarding effects of drugs of abuse. In the withdrawal/negative affect phase, chronic use leads to neuroadaptations in the brain, including a generalized decrease in DA neurotransmission and increase in corticotropin-releasing factor (CRF). In phase 3, other neurotransmitters (ie, beyond DA) are postulated to be involved. For example, elevated CRF, norepinephrine (NE), and glutamate may exist in the "extended amygdala" during prolonged abstinence. Perhaps these changes lead to a long-term need to use substances to relieve unpleasant symptoms, such as stress.[5] Multiple factors are associated with an increased risk of relapse, including substance availability, psychological stressors, and triggers such as seeing a white powder or returning to a location where drugs were previously obtained. These factors may trigger residual adaptive changes (eg, elevated glutamatergic activity) that occurred during the period of drug addiction.

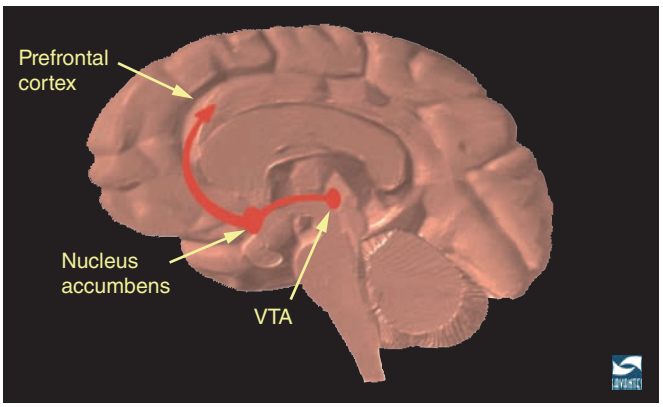

FIGURE 36–2. The mesocorticolimbic dopaminergic (ie, "reward") pathway. (VTA, ventral tegmental area.) (Data available in the public domain from The Neurobiology of Drug Addiction [Internet]. http://www.drugabuse.gov/publications/teaching-packets/neurobiology-drug-addiction/section-i-introduction-to-brain.)

Patient Encounter 1

A 66-year-old woman is admitted to the inpatient psychiatry unit secondary to depression. Past medical history includes major depressive disorder and alcohol use disorder. She reports home medications of sertraline and disulfiram but has not filled or taken either medication for nearly 3 months. On examination, the patient is diaphoretic and tremulous when arms are extended. Heart rate is 112 beats per minute. On further questioning, she reports relapsing to drinking approximately 2 months ago. She typically drinks 3 to 4 cases of beer per week and denies any tobacco or illicit substance use. The patient recently stopped drinking "cold turkey" and states she would like to "dump this drinking habit once and for all."

What is the most immediate action to be taken regarding this patient's treatment?

What pharmacotherapy can help her maintain abstinence from alcohol?

CLINICAL PRESENTATION AND DIAGNOSIS

LO 3

KEY CONCEPT Assess individuals with a pattern of chronic use of commonly abused substances to determine if they meet the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) criteria for substance-related disorders.[6] Most notably, in cases of addiction, there is a loss of control over substance use or use has become compulsive. Diagnostic criteria for SUDs from the *DSM-5* are listed in Table 36–1.[6] Consistent with the *DSM-5*, the remainder of this chapter is organized by pharmacologic class and discusses intoxication, withdrawal, and SUDs for each class (except tobacco use disorders, which do not have *DSM-5* intoxication criteria).

A variety of standardized instruments are available to screen for and assess the various stages of substance use and its consequences, such as withdrawal symptoms and functional impairment (Table 36–2).[7–9] The Addiction Severity Index (ASI) is the gold-standard instrument that assesses seven problem areas associated with substance use, such as medical and psychiatric status, in addition to measures of alcohol and drug use.[7] Many SUD instruments can be freely obtained from the Substance Abuse and Mental Health Services Administration (SAMHSA).

Intoxication Signs and Symptoms

Intoxication caused by most substances is described in the *DSM-5* as clinically significant, problematic behavioral or psychological changes to the individual which are caused by the physiological effects of the substance. These changes are observed during or shortly after use of the substance. Euphoria or experiencing a pleasurable sensation are effects of most drugs of abuse.[10] Other

Table 36–1

***DSM-5* Criteria for Diagnosis of Substance Use Disorders**

A problematic pattern of substance use leading to clinically significant impairment or distress; manifested by ≥ 2 of the following, occurring within a 12-month period:

1. Substance often taken in larger amounts or over longer period than intended.
2. Persistent desire or unsuccessful efforts to cut down or control substance use.
3. Great deal of time spent in activities necessary to obtain substance, use substance, or recover from its effects.
4. Craving, or a strong desire or urge to use the substance.
5. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home.
6. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance.
7. Important social, occupational, or recreational activities are given up or reduced because of substance use.
8. Recurrent substance use in situations in which it is physically hazardous.
9. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by substance.
10. Tolerance, as defined by either of the following:
    a. Need for markedly increased amounts of substance to achieve intoxication or desired effect.
    b. Markedly diminished effect with continued use of same amount of substance.
11. Withdrawal, as manifested by either of the following:
    a. Characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the *DSM-5* criteria set for substance withdrawal).
    b. Substance (or closely related substance) is taken to relieve or avoid withdrawal symptoms

Specify[a] current severity:
Mild: Presence of 2 to 3 symptoms.
Moderate: Presence of 4 to 5 symptoms.
Severe: Presence of ≥ 6 symptoms.

[a]Additional specifiers (eg, early vs. sustained remission) and substance-specific notes (eg, taking opioid under medical supervision) are included in the *DSM-5*.

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Arlington, VA: American Psychiatric Association; 2013; with permission.

LO 4 signs and symptoms are specific to the particular drug or drug class involved. Table 36–3 lists the psychological/behavioral and physiologic effects of intoxication from selected substances.[6,11–14]

Withdrawal Signs and Symptoms

Although most drugs of abuse can cause some degree of **physical dependence**, the severity of withdrawal varies considerably among these drugs. LO 4 Table 36–4 lists common withdrawal symptoms that emerge upon abstinence from drug use.[6,11–15] Typically, withdrawal symptoms are opposite of the acute effects of the substance. For example, although alcohol is a CNS depressant, signs and symptoms of withdrawal signify a hyperalert physiologic response.

TREATMENT OF SUBSTANCE USE DISORDER

SUDs cannot be cured with medications alone. However, medications can sometimes alleviate the effects of drug intoxication, attenuate withdrawal symptoms, or somewhat decrease craving and likelihood of relapse. For example, pleasurable and intoxicating effects of opioids appear to be caused by their action as agonists on μ-opioid receptors. Competitive μ-opioid receptor antagonists, such as naloxone, acutely reverse many opioid effects, including symptoms of intoxication. To date, specific antagonists for most other substances are unavailable. Similarly, reversal of withdrawal syndromes caused by substances of abuse is not always possible. Benzodiazepines are used for ethanol withdrawal because of cross tolerance with ethanol. For long-term medication management, patients addicted to opioids can be maintained on a regimen of medically managed, orally administered opioids (ie, substitution therapy) compared with more dangerous illicit opioid use. Regardless of the pharmacotherapy chosen, medications should always be used as adjuncts to a comprehensive psychosocial approach.[11]

Patient Encounter 2

A 26-year-old man is brought to the emergency department after he is found unconscious in a restaurant parking lot. The patient is somnolent and has slow and shallow breathing. His physical examination reveals miosis, bradycardia, and cyanosis. The patient slurs his speech when attempting to answer questions.

Which of the patient's signs and symptoms are suggestive of opioid intoxication?

How is the medication antidote for opioid intoxication used?

TREATMENT OF INTOXICATION SYNDROMES

LO 5 KEY CONCEPT Treatment goals for acute intoxication of ethanol, opioids, CNS stimulants, and cannabinoids include (a) management of psychological/psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, and stroke. In all cases of intoxication that require medical intervention, referral to and participation in substance abuse treatment programs is desirable.

Alcohol Intoxication

Desired outcomes are appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Most cases of mild-to-moderate alcohol intoxication, including cases with blood alcohol concentrations (BACs) at lower limits of legal intoxication, do not require formal treatment. Providing a safe environment and reassurance until alcohol effects have dissipated is sufficient in most cases. Initially, BACs may continue to rise if gastrointestinal (GI) absorption is still occurring. Otherwise, BACs generally decrease at a rate of 15 to 20 mg/dL (0.015%–0.02% or 3.3–4.3 mmol/L) per hour. Table 36–3 lists the physiologic effects of alcohol at various BACs; however, tolerant individuals may not show the same level of symptoms at a given BAC as nontolerant individuals.

At more severe levels of intoxication, confusion, stupor, coma, and death may occur. Clinicians must rule out other causes of these serious adverse events, because patients may combine alcohol with other substances, sustain head or other injuries, or have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, give thiamine by the intravenous (IV)

Table 36–2

Commonly Used Instruments for Assessing Patients with Substance Use Disorders[7-9]

Instrument	Purpose	Values and Interpretation
Addiction Severity Index (ASI)	Assessment tool Semi-structured interview that addresses seven problem areas: medical status, employment and support, alcohol use, drug use, legal status, family and social status, and psychiatric status Questions include frequency, duration, and severity of problems in the past 30 days or lifetime for various substances Clinician or technician-administered	200 items Patient and interviewer ratings included Interviewer severity ratings of "need for additional treatment" and composite scores to measure severity Composite score normative data from nationally representative sample of treatment programs is available for those seeking to compare a patient's ASI data with national data (www.tresearch.org); otherwise, comparisons with previous (eg, baseline) composite scores are useful
Alcohol Use Disorders Identification Test (AUDIT) Alcohol Use Disorders Identification Test—Consumption (AUDIT-C)	Screening tool Evaluates quantity and frequency of drinking, physiologic dependence on alcohol, and harmful use Clinician or self-administered	10 items; maximum score = 40 Score of ≥ 8 identifies heavy drinkers and those with possible alcohol use disorders AUDIT-C is an abbreviated 3-item version
CAGE Questionnaire	Screening tool Used to identify the presence of problematic drinking Clinician or self-administered	4 items; maximum score = 4 Score of ≥ 2 is positive and suggests problem drinking Positive screen prompts the need for further assessment
Clinical Institute Withdrawal Assessment-Alcohol, Revised (CIWA-Ar)	Assessment tool Gold-standard alcohol withdrawal assessment; used as part of a symptom-triggered approach Clinician-administered	10 items; maximum score = 67 < 10: mild withdrawal 10–18: moderate withdrawal > 18: severe withdrawal Monitor scores over time; ≥ 8–10 (depending on institutional protocols or co-occurring conditions) indicates need for medication
Clinical Opiate Withdrawal Scale (COWS)	Assessment tool Used to follow the course of opioid withdrawal symptoms and effectiveness of medication regimens Clinician-administered	11 items Score of 0 (asymptomatic) to 4 or 5 (severely symptomatic) for each item based on intensity of signs and symptoms 5–12: mild withdrawal 13–24: moderate withdrawal 25–36: moderately severe withdrawal > 36: severe withdrawal Monitor scores over time; higher scores may indicate need for medication; no standard cut-off exists
Fagerström Test for Nicotine Dependence	Assesses extent of nicotine tolerance, dependence, and craving	6 items Higher scores may predict greater difficulty quitting 0–2: very low 3–4: low 5: moderate 6–7: high 8–10: very high

or intramuscular (IM) route at 100 mg/day for at least 3 days. If hypoglycemia is suspected, administer thiamine before glucose-containing fluids to prevent precipitation of acute **Wernicke syndrome** (see Alcohol Withdrawal section). Interactions between alcohol and medications may also occur. **Table 36–5** details drug–drug interactions associated with substances of abuse.[16]

Behaviorally, patients may insist on driving, become aggressive and agitated, or otherwise become a danger to themselves or others. Indeed, most suicidal behaviors among those dependent on alcohol occur while they are intoxicated. Antipsychotics lower the seizure threshold and are best avoided. However, in some instances, agitation may require treatment with an oral or IM antipsychotic. Sedation with benzodiazepines has been used but, in the presence of alcohol, respiratory depression can be dangerous or even fatal.

Opioid Intoxication

The word *opioid* refers to the class of medications and substances that exert their action through the opioid system. Opioids encompass a wide range of substances, including naturally occurring (eg, morphine) and synthetic (eg, oxycodone).

Acutely intoxicated patients usually present with miosis, euphoria, slow breathing, slow heart rate, low blood pressure, and constipation. Seizures may occur with certain agents, such as meperidine. Monitor patients carefully to avoid cardiac and respiratory depression and death from opioid overdose. One strategy is to reverse intoxication using naloxone 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg; the IM, subcutaneous, or intranasal (IN) route may be used if IV access is not available. Naloxone is shorter acting than most abused opioids and may require readministration at periodic intervals; otherwise, patients could lapse into cardiopulmonary arrest after a symptom-free

Table 36–3

Signs and Symptoms of Drug Intoxication for Select Substances[6,11-14]

Drug	Behavioral Effects	Physiologic Effects
Ethanol	Changes in mood and behavior, inappropriate aggressive or sexual behavior, impaired judgment; possibly progressing to somnolence and coma as the blood level increases	Blood levels 0.02%–0.1% (20–100 mg/dL or 4.3–21.7 mmol/L): Euphoria, disinhibition, slight impairment (eg, reaction time) Blood levels 0.1%–0.2% (100–200 mg/dL or 21.7–43.4 mmol/L): Dysphoria, significant impairment (eg, balance, speech, vision) Blood levels 0.2%–0.3% (200–300 mg/dL or 43.4–65.1 mmol/L): Marked ataxia, mental confusion, nausea, vomiting Blood levels 0.3%–0.4% (300–400 mg/dL or 65.1–86.8 mmol/L): Severe dysarthria, amnesia, hypothermia Blood levels > 0.4% (400 mg/dL or 86.8 mmol/L): Coma, decreased respiration or respiratory arrest, aspiration of gastric contents, airway obstruction by flaccid tongue, drop in blood pressure and body temperature
Opioids	Drowsiness, sedation, slurred speech, impaired memory and attention, psychomotor retardation	Nausea, vomiting, respiratory depression (dose-related), stupor, coma, constipation common with chronic use, itching, miosis, hypothermia, bradycardia
CNS stimulants	Elated mood, anxiety, panic, impaired judgment, violent behavior, paranoia, delusions, hallucinations (tactile or auditory, rarely visual), increased motor activity, compulsive or stereotyped behavior (eg, skin picking)	Neurologic/Neuromuscular: mydriasis, headache, tremor, hyperreflexia, muscle twitching, flushing, hyperthermia or cold sweats, rhabdomyolysis (possibly resulting in renal failure), dyskinesias, seizures, coma Cardiovascular: tachycardia, hypertension, vasoconstriction, arrhythmias, myocardial infarction, cerebral hemorrhage GI: nausea, vomiting, weight loss
Cannabinoids	Anxiety, impaired judgment, social withdrawal	Euphoria, impairment motor coordination, tachycardia, xerostomia, conjunctival injection, increased appetite

CNS, central nervous system; GI, gastrointestinal.

interval of reversed intoxication. In addition, naloxone can induce withdrawal symptoms in opioid-dependent patients, so patients may awaken feeling distressed and agitated. Buprenorphine intoxication may be more difficult to reverse.[17]

Secure the airway and ensure breathing in cases of opioid overdose. In some cases, intubation and manual or mechanical ventilation may be required to avoid oxygen desaturation leading to brain hypoxia or anoxia and brain damage or death.

Recently, new opportunities for "take-home" naloxone have emerged in an effort to prevent overdose deaths. The US Food and Drug Administration (FDA) approved a naloxone auto-injector and IN naloxone for this purpose.[16,17] The IN naloxone

Table 36–4

Signs and Symptoms of Drug Withdrawal for Select Substances[6,12-15]

Drug	Timeline	Symptoms
Ethanol	As levels decrease:	
	Early symptoms	Tremor, nausea, vomiting, tachycardia (> 110 beats/minute), hypertension (> 140/90 mmHg), headache, insomnia
	Peak (24 hours)	Seizure-activity (usually 1 or 2 grand mal type, but can be numerous and possibly fatal)
	72–96 hours	Delirium tremens
	Onset at any time	Hallucinations (usually visual)
Opioids	For shorter-acting opioids (eg, heroin, morphine), withdrawal may begin 6–24 hours after last dose and last for about 1 week; with longer acting opioids (eg, methadone), may take up to 2–4 days for withdrawal to emerge and will last longer	EENT: lacrimation, mydriasis, rhinorrhea GI: nausea, vomiting, diarrhea Cardiovascular: increased heart rate and blood pressure CNS: irritability, restlessness, yawning Musculoskeletal: increased body temperature, piloerection
CNS stimulants	Stage 1: immediately following binge	Craving, intense dysphoria, depression, anxiety, agitation
	Stage 2: within 1–4 hours	Dysphoria, desire for sleep
	Stage 3: 3–4 days	Hypersomnia, increased appetite, craving may dissipate but return later
Cannabinoids	Withdrawal symptom onset typically within 24–72 hours; peaks within 1 week	Severity reflects degree and duration of cannabinoid use; symptoms include irritability, anxiety, sleep abnormalities, depressed mood, headache, tremors, sweating, chills
Tobacco	Begins within 24 hours of cessation; peaks within 1–2 weeks; may persist for months	Severity reflects degree and duration of nicotine use; symptoms include irritability, anxiety, frustration, craving, difficulty concentrating, decreased heart rate, increased appetite

CNS, central nervous system; EENT, ears, eyes, nose, and throat; GI, gastrointestinal.

Table 36–5

Clinically Relevant Drug Interactions with Substances or Medications Used to Treat Substance Use Disorders[16]

Drug	Interacting Drug	Type of Interaction
Amphetamines	MAOIs	Pharmacodynamic interaction resulting in increased blood pressure; possibly hypertensive emergency or stroke; AVOID combination
	Sodium bicarbonate	Sodium bicarbonate increases renal tubular reabsorption of amphetamine, resulting in prolonged amphetamine elimination half-life; closely monitor
Buprenorphine	Atazanavir	Combination of buprenorphine and atazanavir (without ritonavir) results in both lower atazanavir levels and higher buprenorphine levels; AVOID combination
	CYP3A4 inhibitors	May raise buprenorphine levels; monitor for greater than expected effects
Bupropion	MAOIs	Neurotoxicity; AVOID combination
	Substances that lower seizure threshold	Use caution when initiating other medications that lower the seizure threshold; AVOID bupropion in patients at risk for experiencing alcohol withdrawal
Cigarette smoking	CYP1A2 substrates	Cigarette smoking (but not NRT) induces CYP1A2, increasing metabolism of CYP1A2 substrates (eg, theophylline, olanzapine); may need to increase substrate dose when patient begins to smoke or decrease substrate dose if smoking is stopped
Disulfiram	Alcohol-containing solutions	Disulfiram reaction; AVOID combination
	Metronidazole	Combination has led to CNS effects (eg, psychosis); AVOID combination
	Benzodiazepines	Disulfiram (weakly) inhibits CYP1A2, 2C9, and 3A4; many benzodiazepines are metabolized via these pathways and doses may need to be lowered; lorazepam and oxazepam undergo conjugation and are alternatives
	Cocaine	Disulfiram decreases clearance of cocaine; may have increased or prolonged cocaine effects with combination
	Phenytoin	Disulfiram decreases metabolism of phenytoin, resulting in higher phenytoin levels; phenytoin dose may need to be reduced; because phenytoin undergoes nonlinear metabolism, it is difficult to predict magnitude of increase in blood levels; AVOID combination if possible
Ethanol (alcohol)	Acetaminophen	Chronic ethanol use increases hepatotoxicity risk when acetaminophen is used in high doses
	Bupropion	Abrupt discontinuation of alcohol with bupropion use may lower seizure threshold; AVOID bupropion in patients at risk for experiencing alcohol withdrawal
	Cefotetan or metronidazole	Disulfiram-type reaction may occur when these anti-infectives are combined with alcohol; AVOID combination
	Methotrexate	Risk of hepatotoxicity may be increased in those who chronically drink large amounts of alcohol; AVOID methotrexate in this population if possible; otherwise, monitor LFTs
	MAOIs	Ethanol DOES NOT interact with MAOIs; however, tyramine may be a component of aged alcoholic drinks, such as red wines or tap beers
	Tapentadol	Ethanol may result in higher maximum serum levels of extended-release tapentadol; AVOID combination
Methadone	Carbamazepine	Carbamazepine is a potent CYP3A4 inducer, and methadone is primarily metabolized via CYP3A4; if used together, may need to increase methadone dose to avoid withdrawal
	CYP3A4 inhibitors	May result in higher methadone levels; methadone dose adjustment should be based on clinical judgment, but a dose decrease may be necessary
	Didanosine	Methadone decreases oral absorption of didanosine; monitor the therapeutic effects of didanosine as a dose increase may be necessary
	Efavirenz	Efavirenz is a CYP3A4 inducer; efavirenz decreases methadone levels and has precipitated methadone withdrawal; may need to increase methadone dose
	MAOIs	Potential serotonin syndrome when MAOIs are combined with methadone; AVOID combination
	Nevirapine	Nevirapine is a CYP3A4 inducer and may decrease methadone levels, resulting in withdrawal complaints; may need to increase methadone dose
	QTc-prolonging medications	Medications that prolong the QT interval (eg, ziprasidone) should be AVOIDED with methadone when possible due to additive QT-prolonging effects
	St. John's wort	St. John's wort is a CYP3A4 inducer; caution dictates to AVOID combination; methadone withdrawal symptoms have been noted with this combination
	Zidovudine	Methadone increases zidovudine levels, likely via methadone inhibition of both metabolic and renal clearance of zidovudine; may need to decrease zidovudine dose to avoid toxicity
Naltrexone	Opioid analgesics	Blockade of pain relief; use nonopioid analgesics and treatment approaches

CNS, central nervous system; CYP, cytochrome P450; LFT, liver function test; MAOI, monoamine oxidase inhibitor; NRT, nicotine replacement therapy.

is commonly used in nonmedical settings due to ease of use. Most states allow for distribution of naloxone to third parties or first responders. Educate patients and caregivers on naloxone, including when to use, how to assemble, proper administration, and notifying emergency services.[18]

Stimulant (Cocaine and Amphetamines) Intoxication

Desired outcomes of stimulant intoxication treatment are appropriate management of medical and psychiatric complications. Medical problems include hyperthermia, hypertension, arrhythmias, chest pain, stroke, and seizures. Some problems are related to route of administration, such as nosebleeds or infections with IN or IV administration, respectively. Psychiatric effects include anxiety, aggression, and psychosis.[14]

Notably, stimulant intoxication is the only stimulant use disorder for which specific pharmacotherapy has demonstrated effectiveness. Recommended medications in acute settings include benzodiazepines, aspirin, nitroglycerin, nitroprusside, and phentolamine.[14] The American Heart Association guidelines indicate that acute use of β-blockers is not recommended and may lead to worsening cocaine-related chest pain and hypertension secondary to unopposed α-receptor mediated vasoconstriction.[19]

Cocaine is short-acting, and a single benzodiazepine may provide sufficient treatment for anxiety reactions. Depending on benzodiazepine half-life, multiple doses may be required for longer-acting amphetamine intoxication. Antipsychotics can manage psychosis, and psychotic symptoms usually respond rapidly in the absence of other co-occurring psychiatric disorders.[14]

Cannabinoid (Marijuana, etc) Intoxication

No established treatment recommendations exist for cannabinoid intoxication. Symptomatic treatment (eg, tachycardia, anxiety, and paranoia) is commonly used. Potent synthetic cannabinoids are the exception and may require aggressive benzodiazepine treatment for intense symptoms of anxiety or psychosis. These intense psychiatric symptoms are theorized to result either from the potent full-agonist cannabinoids that are used to prepare them or from the lack of cannabidiol in synthetic products.[14] Cannabidiol has been associated with antipsychotic effects.[20]

TREATMENT OF WITHDRAWAL SYNDROMES

LO 5

KEY CONCEPT Treatment goals for withdrawal from ethanol, opioids, CNS stimulants, and cannabinoids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term substance abuse treatment. Desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition to longer-term maintenance treatment. Referral to specialized SUD treatment is strongly recommended after treatment of withdrawal. Rapid referral can introduce patients to the concept of recovery while they still vividly recall the negative consequences from using substances. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence, or a reduction in substance use for some individuals, is the ideal outcome.

Alcohol Withdrawal

Alcohol withdrawal is characterized as either uncomplicated or complicated. Each differs in terms of pharmacologic treatment.

▶ *Uncomplicated Alcohol Withdrawal*

Uncomplicated alcohol withdrawal is the more commonly observed syndrome and, as the name implies, is not complicated by seizures, **delirium tremens** (DTs), or hallucinosis. Symptoms are typically rated using a validated scale, such as the Clinical Institute Withdrawal Assessment-Alcohol, revised (CIWA-Ar) (Table 36–2). The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications is 8 to 10. The risks of not treating high-scoring patients with medications are seizures and DTs, and those with a prior history of seizures or DTs have increased risk for subsequent episodes. There is some evidence for "kindling" during successive episodes of alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes.[12,21,22]

Benzodiazepines are the treatment of choice for uncomplicated alcohol withdrawal.[9,11] Anticonvulsants, such as carbamazepine, sodium valproate, and gabapentin, have been used; however, they are not as well-studied. The most commonly used benzodiazepines are lorazepam, diazepam, and chlordiazepoxide. They differ in three major ways: (a) pharmacokinetic properties, (b) routes for administration, and (c) rapidity of onset of action due to the rate of GI absorption and rate of crossing the blood–brain barrier. Benzodiazepines are given using either a symptom-triggered approach or loading dose strategy. Adjunctive "as needed" medications are typically used, as well.[12]

Benzodiazepines can be administered using a symptom-triggered approach when withdrawal signs and symptoms are present.[23] When the CIWA-Ar is greater than or equal to 8, this "triggers" the administration of a benzodiazepine. For example, lorazepam is given at the recommended 1 to 2 mg dose. The CIWA-Ar is then repeated hourly after each administration during the first 24 hours until the patient is comfortably sedated. Due to its short half-life, lorazepam dosing on subsequent days may be necessary, and the risk of seizures may potentially be higher.

Longer-acting agents, such as diazepam and chlordiazepoxide, are often used via the loading dose strategy in which larger doses are given initially followed by a 3–5 day taper. Their long half-lives and active metabolites usually provide a natural taper without further medication administration. Diazepam may be "preferred" to chlordiazepoxide secondary to its faster onset of action (ie, quicker GI absorption and rapid CNS entry due to high lipophilicity). However, a faster onset of action may be associated with euphoria and is a treatment disadvantage. This approach may be accompanied by "as needed" short-acting benzodiazepine doses for breakthrough alcohol withdrawal symptoms.

Special Dosing Considerations Unlike chlordiazepoxide and diazepam, lorazepam is not metabolized into active compounds. It is excreted by the kidneys after glucuronidation. This is important because many patients with alcohol use disorder have compromised liver function. Therefore, when treatment is initiated before results of liver function tests (LFTs) are known, lorazepam may be preferred. Patients with liver disease may still be treated with diazepam or chlordiazepoxide at lower doses.[12]

LO 6

American Psychiatric Association (APA) guidelines recommend thiamine for patients being treated for moderate to severe alcohol use disorders to prevent or treat adverse neurologic symptoms.[11] However, there are inadequate data with regard to the most efficacious thiamine dose, frequency, and route of administration to prevent or treat Wernicke syndrome associated with alcohol use disorders.[24] The APA guidelines recommend thiamine 50 to 100 mg per day given IV or IM, although other guidelines recommend higher doses

(eg, thiamine 300 mg/day).[11,25] Administration of thiamine, essential for proper energy utilization by the CNS, must precede glucose-containing IV fluid administration, which can help prevent an acute exacerbation of Wernicke syndrome.

▶ *Complicated Alcohol Withdrawal*

Alcohol Withdrawal Seizures Alcohol withdrawal seizures, a medical emergency, should be treated in an inpatient setting. Withdrawal seizures are usually generalized and few in number. Although binge drinking and alcohol withdrawal can lead to status epilepticus, the occurrence of focal seizures or status epilepticus may also suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. Give diazepam 5 to 10 mg IV to terminate a seizure if IV access is available. Repeat dose in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg IM may be given, followed by insertion of an IV line after convulsive movements subside. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient received IM lorazepam. Avoid IM diazepam or chlordiazepoxide because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. Intravenous benzodiazepines may depress respiration; therefore, they should only be administered if advanced cardiopulmonary support is available. When the patient can take oral medications, treatment may continue using either the symptom-triggered or loading dose strategy. Electrolyte imbalances can contribute to seizures and should be corrected.[22,26] Avoid phenytoin for preventing or treating alcohol-related seizures.[21] Phenytoin affects sodium channels rather than directly affecting γ-aminobutyric acid (GABA) and glutamate abnormalities indicative of alcohol withdrawal.

Alcohol Withdrawal Delirium (DTs) DTs is a medical emergency necessitating hospitalization. Signs and symptoms include hallucinations, delirium, severe agitation, fever, increased blood pressure and heart rate, and possible cardiac arrhythmias. Parenterally administered benzodiazepines are the treatment of choice.[23] The first-generation antipsychotic haloperidol is given for severe agitation unresponsive to benzodiazepines. Evidence does not support use of an antipsychotic as sole treatment.[26] Administer thiamine according to the previously described guidelines.

Opioid Withdrawal

It is rare to die from opioid withdrawal alone; however, underlying medical complications (eg, hypertension) and recent myocardial infarction increase risk of complications and death. Therefore, it is important to manage and stabilize any medical issues and then determine if hospitalization is appropriate. Evaluate patients with underlying medical problems for possible triage to an inpatient detoxification program to be followed up with either inpatient or outpatient substance abuse treatment. Withdrawal from opioids is commonly described by patients as resembling "a bad case of the flu." Symptoms include nausea; vomiting; diarrhea; anxiety; headaches; mydriasis; rhinorrhea; lacrimation; muscle, bone, and joint pain; piloerection; yawning; fever; increased heart rate; and hypertension.[13]

Use of clinical withdrawal scales (Table 36–2), such as the Clinical Opiate Withdrawal Scale (COWS), provides interrater reliability and clinical utility given their objective measurement of withdrawal severity. The baseline score assists in deciding whether to treat pharmacologically or to observe. As COWS scores increase (eg, 5 or greater), opioid substitution or a "symptoms-based approach" may be indicated. In severe withdrawal, either buprenorphine (ie, partial μ-opioid receptor agonist) or methadone (ie, full μ-opioid receptor agonist) are recommended for detoxification. Methadone is the gold-standard for treating opioid use disorders, but under current US law, methadone detoxification requires referral to a federally approved methadone detoxification program. The pharmacologic options for opioid withdrawal treatment in regular clinical settings are either opioid substitution with buprenorphine or a symptoms-based approach.[27]

▶ *Opioid Substitution*

LO 6

Treatment with μ-opioid receptor agonists is accomplished with either buprenorphine or methadone. Methadone can be used for opioid detoxification and long-term relapse prevention, particularly among patients with heavy opioid use. Methadone is also widely used to treat women during pregnancy. Given its extensive medical use restrictions (eg, used only in a federally approved opioid treatment program [OTP]) and wide availability of methadone detoxification regimens, this chapter focuses on buprenorphine. Refer to Chapter 34 for additional information on methadone.

Buprenorphine is a partial μ-opioid receptor agonist and is available in multiple formulations with varying pharmacokinetic profiles. For example, buprenorphine in combination with naloxone is available as a sublingual tablet, sublingual film, and buccal film.[16] Certain formulations (eg, sublingual film) may have greater buprenorphine bioavailability, and hence lower dosage requirements than other formulations (eg, sublingual tablets). Naloxone is poorly absorbed via the sublingual and buccal routes but is added to buprenorphine formulations to block opioid receptors if the medication is injected. Thus, naloxone has negligible effects when used appropriately while discouraging inappropriate IV use. Therefore, buprenorphine plus naloxone is the recommended formulation (versus buprenorphine alone) unless the patient is pregnant or hypersensitive to naloxone. Opioid antagonists, such as naloxone, have been associated with severe negative outcomes among pregnant women (eg, spontaneous abortion) and should be avoided in this population.[27]

LO 6

To initiate buprenorphine induction, a patient must be experiencing moderate to severe withdrawal, with the last opioid taken at least 12 to 24 hours earlier, depending on the half-life of the opioid used (ie, the longer an opioid's half-life, the longer a clinician should wait before initiating buprenorphine). Otherwise, buprenorphine will likely induce withdrawal because it has high affinity for μ-opioid receptors, displacing other full μ-opioid agonists, and is a partial rather than full agonist. Buprenorphine can be initiated following a protocol such as the example in Table 36–6.[8] There are generally two treatment approaches

Table 36–6

Sample Regimen[a] for Buprenorphine Induction Treatment of Opioid Withdrawal and Long-Term Relapse Prevention[8]

Day	Buprenorphine Sublingual/Buccal Dosage
1	2 mg every 2 hours (maximum, 8 mg on first day)
2	Start with total day 1 dose; additional 2–4 mg every 2 hours (maximum, 16 mg)
3	Start with total day 2 dose; additional 2–4 mg every 2 hours (maximum, 32 mg)
4–5	Maintain on dose required to alleviate withdrawal symptoms[b]

[a]For withdrawal from any opioid.

[b]Patient will likely be transitioned to long-term maintenance dose indefinitely.

Table 36–7

Symptoms-Based Treatment Approach for Opioid Withdrawal[8,11]

The following are examples of medications for withdrawal symptoms that cause distress:

1. Insomnia: trazodone 75–200 mg at bedtime
2. Headache, muscle aches, or pain: acetaminophen 500 mg–1000 mg every 6 hours
3. Noradrenergic hyperactivity: clonidine 0.1–0.2 mg every 6–8 hours; not to exceed 1.2 mg in 24 hours
4. Abdominal cramps: dicyclomine 10–20 mg every 6 hours
5. Constipation: milk of magnesia 30 mL daily
6. Diarrhea: loperamide 2 mg every 6 hours

once a final dose is established. Either the maintenance dose is prescribed or the dose is tapered and discontinued within 1 to 2 weeks (eg, 25% reduction per day as a general rule of thumb).

▶ *Symptoms-Based Treatment*

Symptomatic treatment focuses on minimizing withdrawal symptoms to increase patient comfort. Symptom-specific medications are often used as adjunct medication along with opioid substitution.[8,11] Examples of symptom-specific medications are listed in Table 36–7.

▶ *General Patient Guidelines for Outpatient Opioid Detoxification*

Patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms generally peak at 5 to 7 days and may last up to 2 weeks, depending on the half-life of the opioid used before detoxification. Educate patients on the side effects of medications used for detoxification. Balance the risk of adverse events with the potential benefits. Buprenorphine side effects include constipation, sedation, and headaches. Potential for serious overdose exists when buprenorphine is combined with benzodiazepines or other sedative–hypnotics.

Risk of developing physiologic tolerance to buprenorphine is high if used for prolonged periods. In this case, buprenorphine requires a slow taper to discontinuation. Withdrawal from buprenorphine is generally easier and less severe than withdrawal from a full agonist, such as methadone.[8] However, there is concern regarding a subset of patients who have difficulty discontinuing buprenorphine. The duration of buprenorphine treatment is specific to each patient's needs and resources, and difficulty in tapering the medication to discontinuation complicates this decision further.

Following detoxification, rehabilitation and acquiring recovery skills are tied to positive outcomes. This goal can be accomplished by either achieving detoxification on-site during rehabilitation or by quick and seamless transition from detoxification to a rehabilitation program. The more time that elapses between the two modalities, the greater the likelihood of treatment failure and relapse.

Stimulant (Cocaine, Amphetamines) Withdrawal

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in *DSM-5* are similar, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system.[6,14] Stimulants of this group also include methylphenidate, but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Major adverse complications of stimulant withdrawal are profound depression with suicidal thoughts, and the primary treatment goal is suicide prevention. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated in outpatient setting with psychological support and reassurance with an emphasis on patient safety. Medications have been studied to alleviate withdrawal symptoms and cravings, but inconsistent results preclude any recommendations for their routine use. Refer patients with stimulant use disorder for substance abuse treatment because of the high risk for continued use either during or immediately following stimulant withdrawal.

Cannabinoid (Marijuana, Hashish) Withdrawal

Symptoms of cannabinoid withdrawal are primarily behavioral. For example, significant anxiety may accompany cannabinoid withdrawal, which can lead many individuals to resume substance use. This is particularly problematic following heavy and prolonged use. Management of withdrawal focuses on these behavioral symptoms as there are no FDA-approved medications specifically targeted at cannabinoid withdrawal.

GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE USE DISORDERS

KEY CONCEPT A multimodal and comprehensive approach is preferred when treating patients with SUDs given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to psychosocial therapy. Steps to be taken in the management of SUDs are similar for all substances and are highlighted in the Patient Care Process.[11]

LO 7

Address comorbid psychiatric conditions such as anxiety, depression, insomnia, pain, and continued smoking. All of these conditions increase risk of relapse to substance use. Although complete abstinence may be desirable, decreasing substance use and negative consequences may be sufficient in certain cases (ie, the "harm reduction" concept).[28]

Nonpharmacologic Therapy

Although pharmacologic agents may help prevent relapse, psychotherapy is the core therapeutic intervention. Psychotherapy typically addresses 1 or more of the following:

- Motivation enhancement to stop or reduce substance use
- Coping skills education
- Providing alternative reinforcement
- Managing painful affect (eg, dysphoria)
- Enhancing social support and interpersonal functioning

A thorough review of psychosocial approaches is beyond the scope of this chapter and are available elsewhere.[11] However, a few of the commonly used techniques are cognitive-behavioral therapy, motivational-enhancement therapy, and other behavioral therapies (eg, community reinforcement).

Pharmacologic Therapy

▶ *Maintenance Treatment*

KEY CONCEPT Certain pharmacologic agents are helpful for long-term maintenance in patients with SUDs. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) drug substitution therapy with an agonist, (b) blocking drug effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action. Medications from each of these categories are discussed in greater detail in the following paragraphs for alcohol, opioid, cannabinoid, stimulant, and tobacco use disorders.

▶ *Alcohol Use Disorder*

The FDA-approved medications to treat alcohol use disorder are naltrexone (oral and depot), acamprosate, and disulfiram. Practice guidelines recommend naltrexone and acamprosate as first-line agents.[25,29] However, in motivated patients or with supervised administration to ensure adherence, disulfiram is another option.[30]

LO 6

Naltrexone Naltrexone is a competitive opioid receptor antagonist that decreases alcohol intake, craving for alcohol, and alcohol-induced euphoria (ie, reduces positive reinforcement of drinking).[3] Naltrexone is more efficacious than placebo for a variety of drinking measures.[29] According to a recent meta-analysis, it significantly improves abstinence rates, decreases relapse rates, and has a safety profile similar to placebo.[31] Predictors of naltrexone efficacy may include family history of alcohol use disorder and a specific μ-opioid receptor gene polymorphism.[32] In the landmark COMBINE study, which assessed the efficacy of behavioral intervention, medical management, medications, and their combinations for treatment of alcohol use disorder, naltrexone with medical management was associated with a higher percent of days abstinent than other interventions.[33] An oversimplified interpretation of this complex study suggests that naltrexone is effective (eg, higher percent of days abstinent), but acamprosate offers no discernable advantage.[33]

Naltrexone is available as an oral tablet and long-acting IM injection. Naltrexone is dosed 50 mg once daily, with a range from 25 to 100 mg. A 25 mg test-dose is commonly given, then increased to 50 mg/day as tolerated. While specific dosage adjustments are unavailable, caution is warranted in patients with severe hepatic or renal impairment.[16] Adherence to naltrexone strongly affects drinking outcomes; therefore, a long-acting IM formulation is available. Administered as 380 mg once monthly, the injection results in significantly greater reductions in heavy drinking days compared with placebo injection.[34]

Common side effects include nausea, headache, insomnia, and nervousness. Injectable naltrexone is associated with injection site reactions. Because naltrexone can precipitate withdrawal in patients who are opioid dependent, withhold the first dose for 7 to 10 days after last opioid use and give only when the urine drug screen for opioids is negative. Naltrexone can be hepatotoxic, albeit typically not at oral doses less than 250 mg/day or at recommended injectable dose of 380 mg once monthly. Baseline and periodic LFTs are recommended.[16]

Naltrexone can block effects of opioid receptor agonists, rendering them therapeutically ineffective (Table 36–5). Given that opioid agonists are a mainstay of pain management, alternative pain treatment (eg, conscious sedation) may be required in patients receiving naltrexone maintenance.

Educate patients taking naltrexone to carry a pocket warning card or wear a medical bracelet. In the event that emergency pain management is needed, the patient will be insensitive to opioid analgesia unless potentially toxic doses are administered. Warn patients of the potential for opioid overdose under two conditions. First, dosing with opioids to reverse opioid insensitivity (ie, naltrexone's competitive blockade of opioid receptors) requires high doses of opioids that can cause respiratory depression and death. Second, following chronic opioid receptor antagonist therapy, patients are likely to have reduced tolerance to opioids, thereby increasing risk of respiratory depression and death when previously tolerated doses of opioids are used.[16]

Acamprosate Acamprosate appears to be a glutamatergic N-methyl-D-aspartate receptor antagonist and may affect GABA.[3] Alcohol acutely inhibits glutamatergic function. During acute and postacute alcohol withdrawal, increased activity of the glutamate system is caused by upregulation of receptors combined with absence of alcohol-related inhibition. Thus, acamprosate may correct glutamate/GABA imbalances that occur following chronic alcohol use (eg, reduce negative reinforcement associated with craving and withdrawal).[3,16]

Generally, trials assessing efficacy of acamprosate have shown mixed results. This may be partly attributable to differences in research methodologies, such as varying levels of abstinence required in trials before acamprosate initiation.[29] Notably, in the aforementioned COMBINE study, acamprosate appeared to offer no treatment advantage,[33] but a recent meta-analysis suggests it is more efficacious than placebo.[35] Another meta-analysis suggests that acamprosate may be more effective at maintaining abstinence, whereas naltrexone may more effectively reduce heavy drinking and craving.[36] Despite variable methodologies and results, sufficient evidence demonstrates that acamprosate is more effective than placebo, although differences may be modest.

The dose of acamprosate is 666 mg orally three times daily. It is not metabolized by the liver and is excreted unchanged by the kidneys. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance less than or equal to 30 mL/min [0.50 mL/s]), and dose reduction is necessary when creatinine clearance is between 30 and 50 mL/min (0.50 and 0.83 mL/s). Closely monitor renal function in elderly patients to ensure proper dosing. Common side effects are nausea, diarrhea, and CNS effects, including insomnia, anxiety, and depressive symptoms.[16]

LO 6

Disulfiram Disulfiram irreversibly blocks the enzyme aldehyde dehydrogenase, a step in the metabolism of alcohol.[16] This results in increased blood levels of the toxic metabolite, acetaldehyde. As acetaldehyde levels increase, patients experience the disulfiram-ethanol reaction consisting of the following symptoms: decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea, vomiting, shortness of breath, blurred vision, and syncope. Symptom severity increases with amount of alcohol consumed, and emergency treatment may be warranted. Psychologically, disulfiram works to deter drinking due to the knowledge that the aversive disulfiram–ethanol reaction occurs if alcohol is consumed.[30] Efficacy of disulfiram directly depends on medication adherence and can be effective when procedures for enhancing adherence are used.[30,37]

The usual starting dose of disulfiram is 250 mg once daily. It can be started at 500 mg once daily for the first 1 to 2 weeks, and the range is 125 to 500 mg/day.[16] Compared with 250 mg, the larger dose is recommended if a patient does not experience a disulfiram–ethanol reaction after alcohol consumption. The smaller dose is given when intolerable side effects are experienced at higher doses or for elderly patients. Use disulfiram with caution in patients with renal and hepatic impairment. Dosing begins only after the BAC reaches zero (ie, 12–24 hours after the last drink) and after the patient is educated on the consequences of drinking with disulfiram.

Disulfiram is contraindicated in patients with cardiovascular or cerebrovascular disease, hypersensitivity to thiuram derivatives, and the anti-infective, metronidazole. Common side effects are rash, drowsiness, and metallic or garlic-like taste. Less common, but concerning, adverse effects include neuropathies, psychosis, and hepatotoxicity.[16] Given the serious

LO 6

nature of these adverse effects, baseline and periodic monitoring is recommended. If LFTs are greater than three times the upper limit of normal values, withhold disulfiram and repeat testing every 1 to 2 weeks. When LFTs return to normal, they may be repeated every 1 to 6 months.[38] Although elevated LFTs may signal disulfiram-induced hepatotoxicity, it may also indicate the patient was nonadherent to treatment and resumed alcohol consumption. Psychosis has been reported with doses exceeding 500 mg/day and may be related to disulfiram's inhibition of DA β-hydroxylase, resulting in increased DA activity. Nevertheless, patients with schizophrenia or other co-occurring psychiatric disorders have received disulfiram at usual doses without difficulties.[39]

The disulfiram–ethanol interaction serves as disulfiram's mechanism of action. Depending on the dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk for an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be educated accordingly. Table 36–5 lists relevant disulfiram interactions.

LO 6

Universally accepted treatment algorithms for alcohol use disorder treatment are lacking. Table 36–8 lists patient-specific factors that can guide medication selection.[38]

▶ *Opioid Use Disorder*

After conclusion of withdrawal, patients may not feel their usual selves for some time and could relapse to using opioids, just to "feel normal." Long-term use of opioids results in brain changes, and the brain might not readily return to its prior homeostasis. The goal of treatment is to encourage stability, both in the body and in the patient's life. If an individual is not successful in quitting opioids (eg, because of withdrawal symptoms or postacute craving), then maintenance treatment should be considered.

Opioid Agonists Methadone and buprenorphine are first-line medications for maintenance treatment, also called **medication-assisted treatment**, of opioid use disorder. Methadone is a full μ-opioid receptor agonist, and methadone maintenance treatment can only be provided in federally approved OTPs.[27] The other first-line agent for maintenance treatment, which will be the focus of this chapter, is buprenorphine. Alternatively, the long-acting naltrexone injection is FDA approved for prevention of opioid relapse, but its place in long-term treatment of opioid use disorder remains to be established.

The more widely available office-based opioid treatment (OBOT) exclusively uses buprenorphine, a partial μ-opioid receptor agonist, typically in formulations also containing naloxone.[8] Recently, the FDA approved a subcutaneous injection given every month and subdermal implants that deliver medication continuously for up to 6 months.[16] Under the Drug Addiction Treatment Act of 2000 and the Comprehensive Addiction and Recovery Act of 2016, clinicians may prescribe buprenorphine in the outpatient office-based setting once requirements (eg, training) are met. When these criteria are met, qualified providers obtain a separate "X" Drug Enforcement Administration number.[8]

Patients receiving buprenorphine maintenance should sign a treatment contract requiring full adherence, financial responsibility for treatment, adherence to office policies, and agreement to provide random urine samples for drug screens. Instruct patients to bring their prescribed medication for pill counts at every visit. In the event of OBOT failure, the alternative to buprenorphine maintenance is referral to an OTP for methadone administration. A recent meta-analysis indicates that methadone may offer an advantage over buprenorphine for select outcomes (eg, retention in treatment).[40] Therefore, there are circumstances under which referral to methadone maintenance remains the preferred treatment option.

Although there are no treatment algorithms to guide medication selection, there are protocols for some medications that assist with dosing and titration. For example, the extensive buprenorphine treatment protocol available from SAMHSA provides guidelines on how to dose buprenorphine from induction to maintenance treatment.[8] The effective maintenance dose of buprenorphine (with or without naloxone) is usually between 8 and 24 mg/day.[16] Initiate buprenorphine at the low end of the dosing range for elderly patients. Reduce initial and

Table 36–8

Alcohol Use Disorder Medication Decision Grid[38]

Pretreatment Indicator	Acamprosate	Disulfiram	Oral Naltrexone	Injectable Naltrexone
Renal failure	X	A	A	A
Significant liver disease	A	C	C	C
Coronary artery disease	A	C	A	A
Chronic pain	A	A	C	C
Current opioid use	A	A	X	X
Psychosis	A	C	A	A
Unwilling or unable to sustain total abstinence	A	X	A	A
Risk factors for poor medication adherence	C	C	C	A
Diabetes	A	C	A	A
Obesity that precludes intramuscular injection	A	A	A	X
Family history of alcohol use disorders	A	A	+	+
Bleeding or other coagulation disorders	A	A	A	C
High level of craving	A	A	+	+
Opioid use disorder in remission	A	A	+	+
History of postacute withdrawal syndrome	+	A	A	A
Cognitive impairment	A	X	A	A

+ = particularly appropriate; A = appropriate to use; C = use with caution; X = contraindicated.

Patient Encounter 3

A 35-year-old woman presents to the outpatient clinic for a medication therapy management appointment. She is diagnosed with schizophrenia and seasonal allergies and takes the following medications: olanzapine 15 mg once daily, loratadine 10 mg once daily, and a once daily multivitamin. The patient smokes approximately 1 pack of cigarettes per day and denies alcohol or illicit drug use. Laboratories are within normal limits.

What approach can assist the clinician in addressing the patient's tobacco use?

Is the patient a candidate for all first-line tobacco cessation pharmacotherapies?

How will smoking cessation affect the patient's current medications?

titration doses for patients with hepatic impairment and monitor for signs of toxicity or overdose.[16]

▶ *Cannabinoid Use Disorder*

There are no proven pharmacotherapies for treatment of cannabinoid use disorder. Pharmacotherapy trials have emerged in the literature, but universally accepted medication treatment strategies have yet to emerge.[41]

▶ *Stimulant Use Disorder*

There are no proven pharmacotherapies for treatment of stimulant use disorder. Combine medications with psychosocial approaches. The APA guidelines suggest three medications as possible treatment options: topiramate, disulfiram, and modafinil.[11,42] Disulfiram shows promise, possibly due to its inhibition of DA β-hydroxylase which converts DA to NE. The resulting increase in DA levels may counter DA deficiency states that are believed to underlie cocaine withdrawal and craving.[42]

▶ *Tobacco Cessation*

Nonpharmacologic Behavioral treatment, delivered by a variety of clinicians, increases abstinence rates. The 5 As model below can be used by all clinicians.[15]

- Ask about tobacco use.
- Advise to quit.
- Assess willingness to make a quit attempt.
- Assist in quit attempt.
- Arrange follow-up.

Provide tobacco cessation education to all patients who use tobacco, and assist those interested to achieve cessation. It is now standard practice for clinicians to screen for tobacco use, provide all patients who use tobacco with brief advice and assistance with appropriate medications to quit, or provide referral to specialized services when needed.[15]

Electronic cigarette use has grown considerably in recent years. Preliminary evidence suggests they may be useful for smoking cessation; however, long-term safety is unknown. They appear to contain toxins similar to those found in tobacco smoke, albeit at lower levels.[43,44] The FDA recently gained regulatory authority over electronic cigarettes, allowing them to restrict sales to minors and ensure products contain proper health warnings.[45]

Pharmacologic According to tobacco use practice guidelines, first-line medications for tobacco use disorder are nicotine replacement therapy (NRT), bupropion sustained-release (SR), and varenicline (Table 36–9).[15]

Symptomatic detoxification and maintenance for tobacco use disorders is achieved with any single or combination of the currently available NRTs.[15] Similar to opioid receptor agonists, NRTs act as substitution therapy as safer alternatives to tobacco use. While NRTs are generally considered safe, their pregnancy category D classification means the decision to use NRT for pregnant women must be made on a case-by-case basis. One meta-analysis of nearly 700 pregnant women concluded that there is inadequate evidence to determine whether NRT is safe or effective in pregnancy.[46] According to practice guidelines, pregnant women should be encouraged to quit without use of medication.[15] Given the various NRT products available, choice of NRT formulation depends on various factors, including patient preference.[11]

LO 6

Two nonnicotine medications are FDA approved for the treatment of tobacco use disorders: bupropion SR and varenicline. Bupropion is an antidepressant that blocks reuptake of DA and NE; in addition, it appears that one of its metabolites is a nicotinic antagonist. These mechanisms may help explain how bupropion reduces nicotine reinforcement, withdrawal, and craving.[3] Bupropion is contraindicated in patients with seizure disorders, eating disorders, and patients withdrawing from alcohol or sedative–hypnotics.[16] Varenicline is an $\alpha_4\beta_2$ nicotinic acetylcholine partial agonist. Varenicline decreases withdrawal and craving and prevents reinforcing effects of nicotine if the patient relapses.[3] Warnings include seizures and cardiovascular adverse events (eg, angina).[16] Both bupropion SR and varenicline have been associated with psychiatric disturbances when used for smoking cessation.[47]

LO 6

As shown in Table 36–10, various NRTs, bupropion SR, and varenicline increase abstinence rates at 6 months compared to placebo.[15] Combining NRTs (eg, nicotine patch and "as needed" gum) is common. A recent meta-analysis concluded that NRT, bupropion SR, and varenicline all improve smoking cessation rates. Varenicline was more effective than single NRT or bupropion SR, but varenicline and combination NRT were equally effective.[48]

OUTCOME EVALUATION

KEY CONCEPT A major component of successful SUD treatment is to monitor use of medications and identify a mechanism for long-term support of sobriety that might be appropriate for a specific patient such as Alcoholics Anonymous, Narcotics Anonymous, or recovery programs for health care professionals.

To determine immediate treatment outcomes for patients with intoxication and withdrawal syndromes, evaluate parameters such as blood pressure, heart rate, respirations, body temperature, and mental status. Select validated and standardized instruments to monitor the responsiveness of withdrawal syndromes to medical treatment. To determine the overall effectiveness of your health system for the treatment of substance-related disorders, monitor outcomes using sentinel events such as the rates of

Table 36–9

First-Line Medications for Treatment of Tobacco Use Disorder[15,16]

Medication	Dosing and Administration[a]	Adverse Effects, Warnings, and Precautions[b]
Nicotine patch (7, 14, and 21 mg)	Apply 1 patch/day to nonhairy area on the upper body; rotate application sites Use 21 mg for 4–6 weeks, 14 mg for 2 weeks, then 7 mg for 2 weeks if > 10 cigarettes/day Use 14 mg for 6 weeks, then 7 mg for 2 weeks if ≤ 10 cigarettes/day Duration: 8–12 weeks	Skin irritation, insomnia, vivid dreams Remove patch at bedtime if sleep disturbances occur and apply new patch in the morning
Nicotine gum (2 and 4 mg)	Chew slowly until gum tingles, then "park" in cheek until tingle is gone; repeat Avoid eating or drinking for 15 minutes before or during use Use 4 mg if first cigarette is smoked within 30 minutes of waking; otherwise, use 2 mg dose Use 1 piece every 1–2 hours for 1–6 weeks, then 1 piece every 2–4 hours for 7–9 weeks, then 1 piece every 4–8 hours for 10–12 weeks Maximum: 24 pieces of gum/day Duration: 12 weeks (or as needed)	Sore mouth, hiccups, dyspepsia, insomnia Limit swallowing excess saliva to avoid GI irritation
Nicotine lozenge (2 and 4 mg)	Avoid chewing; occasionally move lozenge around mouth until completely dissolved Avoid eating or drinking for 15 minutes before or during use Use 4 mg if first cigarette is smoked within 30 minutes of waking; otherwise, use 2 mg dose Use 1 piece every 1–2 hours for 1–6 weeks, then 1 piece every 2–4 hours for 7–9 weeks, and 1 piece every 4–8 hours for 10–12 weeks Maximum: 20 lozenges/day Duration: 3–6 months	Hiccups, cough, heartburn, nausea, insomnia Limit swallowing excess saliva to avoid GI irritation
Nicotine nasal spray (0.5 mg delivered to each nostril)	Do not inhale during administration 1 dose = 1 spray in each nostril Use 1–2 doses/hour Maximum: 5 doses/hour; 40 doses/day Duration: 3–6 months; taper	Nasal irritation or congestion, changes in smell Avoid in patients with reactive airway disease Dependence risk is higher than other formulations
Nicotine inhaler (4 mg in each cartridge)	Inhale ("puff") lightly 80 times/cartridge Cold temperature decreases nicotine delivery; store in warm area (eg, pocket) Avoid eating or drinking for 15 minutes before or during use Use 6–16 cartridges/day Maximum: 16 cartridges/day Duration: Up to 6 months; taper	Mouth and throat irritation (improves with use), cough, rhinitis, sneezing
Bupropion sustained-release	Dosing: 150 mg once daily for 3 days, then 150 mg twice daily Start 1–2 weeks before quit date	Neuropsychiatric events (eg, mood disturbances) when used for smoking cessation
Varenicline	Dosing: 0.5 mg once daily for 1–3 days, then 0.5 mg twice daily for 4–7 day, then 1 mg twice day on day 8 and after Renal dosing (CrCl < 30 mL/min [< 0.50 mL/s]): 0.5 mg once daily with a maximum of 0.5 mg twice daily Start 1 week before quit date	CNS: insomnia, abnormal dreams, neuropsychiatric events (eg, depression, suicidal thoughts) GI: dose-related nausea

[a]NRT dosage adjustments for renal or hepatic impairment are not established. Severe impairment may affect nicotine clearance.

[b]Avoid NRT in patients with recent myocardial infarction, arrhythmias, or unstable angina.

CNS, central nervous system; CrCl, creatinine clearance; GI, gastrointestinal; NRT, nicotine replacement therapy.

cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal is to enable the transition of patients to formal substance use treatment when indicated.

Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and improved psychosocial functioning. When complete abstinence has not been achieved, quantify the consumption of substances using quantity–frequency measures, rates of abstinence, and time to first relapse as determined by interviews, self-report, and biological markers such as urine and blood tests. The ASI (Table 36–2) assesses alcohol and drug-related problems in various domains, and provides a more comprehensive picture of the patient's life.

KEY CONCEPT Clinicians must be familiar with "essential" resources, many of which are in the public domain. Table 36–11 provides a list of these resources which provide useful information for clinical management, research, teaching, and policy development purposes.

Table 36–10

Six-Month Postquit Smoking Abstinence Rates and Associated Odds Ratios[a,15]

Medication	Abstinence Rate (%)	Odds Ratio (95% CI)
Placebo	13.8	1.0
NRTs		
Nicotine gum (6–14 weeks)	19.0	1.5 (1.2–1.7)
Nicotine patch (6–14 weeks)	23.4	1.9 (1.7–2.2)
Nicotine gum (> 14 weeks)	26.1	2.2 (1.5–3.2)
Nicotine patch (> 14 weeks)	23.7	1.9 (1.7–2.3)
Non-NRTs		
Bupropion SR	24.2	2.0 (1.8–2.2)
Varenicline (1 mg/day)	25.4	2.1 (1.5–3.0)
Varenicline (2 mg/day)	33.2	3.1 (2.5–3.8)
Combination Strategies		
Nicotine patch (> 14 weeks) + ad lib gum or spray	36.5	3.6 (2.5–5.2)
Nicotine patch + bupropion SR	28.9	2.5 (1.9–3.4)

[a]Meta-analysis; 83 studies included.

CI, confidence interval; NRT, nicotine replacement therapy; SR, sustained-release.

Patient Care Process

Collect Information:

- Conduct a medication history for prescription, nonprescription, herbal, and dietary supplement use. Identify medication allergies and associated reactions.
- Retrieve a state prescription drug-monitoring program report.
- Document medical history, family history (eg, SUDs, psychiatric disorders), social history (eg, alcohol, tobacco, and illicit substance use), physical assessment, and mental status examination findings.
- Document other factors (eg, transportation, employment) that may impact treatment.
- Determine the patient's preferences, beliefs, and functional goals.
- Consider the use of screening and assessment instruments (Table 36–2).
- Assess the patient's readiness to change.

Assess the Information:

- Assess medication appropriateness, efficacy, safety, and adherence.
- Review laboratory tests (eg, electrolytes, liver and renal function, drug screen, HIV test).
- Assess previous periods of abstinence and factors that worked to achieve this.

Develop a Care Plan:

- Substance *intoxication*: Management is typically supportive. The most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries to help identify causative substance and rule out other etiologies. Observe patient until intoxication has resolved.
- Substance *withdrawal*: Select instrument to monitor withdrawal symptoms and guide medication use (Table 36–2). Severe symptoms (eg, seizures) require inpatient treatment.
- Medication management is an adjunct to psychosocial approaches for achieving recovery.
- Align treatment (eg, detoxification versus longer-term treatment) with patient goals.

Implement the Care Plan:

- Educate the patient and the patient's support system about SUDs, medications, adverse effects, and adverse effect management. Ensure the patient has access to medications.
- Discuss the importance of medication adherence and psychosocial treatment approaches.
- Provide referrals for the treatment of co-occurring medical conditions or complications.
- Reduce stress and risk factors for relapse and improve attitude toward wellness.

Follow-up: Monitor and Evaluate:

- Assess treatment effectiveness, safety, and adherence regularly. Make changes as needed.
- Evaluate progress toward treatment goals (eg, improved coping skills, functioning, and relapse prevention).
- Continuously monitor for triggers, cravings, substance use, and relapse. Provide support.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Devon A. Sherwood, a co-author of this chapter in the fourth edition of this book.

37 Schizophrenia

Deanna L. Kelly, Mary Borovicka, and Heidi J. Wehring

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Recognize signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive impairments associated with the illness.
2. Explain potential pathophysiologic mechanisms that are thought to underlie schizophrenia.
3. Identify treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare side-effect profiles of individual antipsychotics.
6. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.
7. Describe components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.

INTRODUCTION

LO 1

Schizophrenia is a challenging disorder often requiring life-long treatment. The disorder may have many pathophysiological pathways that ultimately manifest with psychotic symptoms, including positive symptoms such as hallucinations and delusions, as well as disordered thinking. Commonly, these symptoms are accompanied by cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, and negative symptoms including loss of motivation (**avolition**), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and independent living compared with population norms. However, earlier diagnosis, treatment, advances in research, and newer treatment developments have led to better outcomes with the potential for remission and recovery.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 0.7% of the world population suffers from schizophrenia, with symptoms typically presenting in late adolescence or early adulthood.[1] Prevalence is equal in men and women, but symptoms appear earlier in men with first hospitalization typically occurring at 15 to 24 years compared to 25 to 34 years in women.

The etiology of schizophrenia remains unknown. A genetic basis is supported by the fact that first-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder, and when both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the concordance rate is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, there is probably no single "schizophrenia gene." Research continues to explore candidate genes, loci, and copy number variants, hoping to better understand the genetic contribution.[2] Possibly, when a genetic liability is present, environmental stimuli may trigger expression of the illness. Some data suggest intrauterine exposure to significant stress, viral or bacterial infections may be a risk factor; however, more research is needed.

PATHOPHYSIOLOGY

The dopamine hypothesis, the oldest pathophysiologic theory, proposes that psychosis is caused by excessive dopamine in the brain. This hypothesis followed the discovery that chlorpromazine, the first antipsychotic medication, was a postsynaptic dopamine antagonist. Drugs that cause an increase in dopamine (eg, cocaine and amphetamines) worsen or cause psychotic symptoms, and medications that decrease dopamine (eg, antipsychotics) improve psychotic symptoms. However, data reveal a more complicated picture with both hyperdopaminergic and hypodopaminergic brain regions in schizophrenia. Hyperdopaminergic activity in the mesolimbic pathway contributes to positive symptoms of psychosis, while hypoactivity of the **mesocortical pathway** in the prefrontal cortex may contribute to negative symptoms. Thus, a more modern reworking of the dopamine hypothesis is the "dysregulation hypothesis," which takes these findings into account and also focuses primarily on presynaptic dopamine.[3] It is possible, however, that the hypothesized dopamine abnormalities may represent changes occurring secondary to other pathophysiologic abnormalities. Other implicated neurotransmitter systems include a combined dysfunction of the dopamine and glutamate neurotransmitter systems. It is hypothesized that glutamate, possibly through malfunctioning *N*-methyl-D-aspartate (NMDA) receptors, impacts dopaminergic activity in the mesolimbic and mesocortical pathways. NMDA antagonists such as phencyclidine (PCP) and ketamine can elicit

LO 2

Patient Encounter Part 1

A 19-year-old man was admitted to the inpatient psychiatric unit after he barricaded himself in his bedroom at his parents' house and refused to eat. His parents report that they have been concerned about their son for several years. While in high school, he struggled academically, had difficulty making friends, and did not participate in any activities. At home, he spent most of his time in his bedroom. He graduated from high school 1 year ago and enrolled in the local community college. He dropped out after a few weeks because he could not concentrate and was skipping classes. Since that time, he has been at home and spends his days isolated in his bedroom watching Netflix. The patient was seen about 6 months ago by his primary care provider. He was diagnosed with major depressive disorder and was started on sertraline, but there was no improvement. His mother states that about 1 month ago, the patient began refusing meals stating that she was poisoning his food. He became more suspicious and fearful of others and barricaded himself in his room. When his parents tried to encourage him to come out of his room to go see a doctor, he started throwing furniture around his room and yelling that he did not want to leave. His parents had to call the police to bring their son to the emergency room.

In the emergency room, he was administered lorazepam 2 mg IM. He is now calm and cooperative. He answers questions with only a "yes" or "no" and frequently looks over his shoulder. The patient's mother and father state that they tried to be supportive of their son, but they just don't understand his odd behaviors and they express concern over his lack of friends and participation in activities. The patient states he "doesn't really miss" doing these things, and he doesn't want to be pressured to do them. His mother also worries that he has strange eating habits and that his sleep is "off"—up at night and sleeping too much during the day.

What diagnoses are suggested by this presentation?

What additional information would help to clarify the diagnosis and why?

Should the patient's parents be involved in his care?

a state resembling schizophrenia, including positive and negative symptoms and cognitive impairments.[3] There is evidence for the serotonergic system in schizophrenia as evidenced by serotonin-induced hallucinations and serotonin modulation of second-generation antipsychotics (SGAs).[4] It is notable that to date, antipsychotics without any primary or secondary dopamine-modulating properties have been ineffective for the treatment of positive symptoms of schizophrenia.

CLINICAL PRESENTATION AND DIAGNOSIS

In addition to the positive, negative, and cognitive symptoms of schizophrenia, people with schizophrenia may sometimes be uncooperative, suspicious, hostile, anxious, or aggressive. Psychotic and depressive symptoms may lead to poor hygiene and impaired self-care. Sleep and appetite disturbances may be present, and people with schizophrenia may have difficulty living independently, forming close relationships with others, and initiating or maintaining employment. Co-occurring medical and substance use disorders are common with cigarette smoking and illicit drug use about four to five times more prevalent than the general population.[5,6]

KEY CONCEPT A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.

The diagnosis is made by ruling out other causes of psychotic symptoms and meeting specified diagnostic criteria. When present, a family history of mental illness supports the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*)[7] (Table 37–1).

KEY CONCEPT Patients presenting with odd behaviors, illogical thought processes, fixed false beliefs, and hallucinations should be comprehensively assessed to rule out other diagnoses or contributing factors.[8]

At minimum, patients with psychotic symptoms should have a medical workup at the time of admission to rule out other diagnoses or contributing factors, such as medical illnesses, infections, or other psychiatric or substance use disorders. Often, people with

Table 37–1

Diagnostic Criteria for Schizophrenia

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3:
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (eg, frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (ie, diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before onset (or when onset is in childhood or adolescence, there is a failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meets Criterion A (ie, active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (eg, odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (a) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (b) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiological effects of a substance (eg, drug of abuse or medication) or another medical condition.

F. If there is a history of autism spectrum disorder or communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

psychosis are poor historians and the gathering of collateral information is necessary. Co-occurring substance abuse, medical illnesses, and psychosocial stressors often confound the diagnosis.

COURSE AND PROGNOSIS

Treatment of schizophrenia has been associated with poor long-term outcomes in the past; however, with earlier treatment and better care, many people can achieve remission and recovery is possible. Without early intervention, there are traditionally intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Though many of the more dramatic and acute symptoms may fade with time, severe residual symptoms may persist. Involvement with law enforcement is common for vagrancy, loitering, and disturbing the peace. Life expectancy is shortened primarily because of suicide, cardiovascular disease, accidents, and compromised self-care. Lifetime risk of suicide for people with schizophrenia is 5% to 10%, and it is estimated that suicide risk in this population exceeds that in the general population more than eightfold.[9] Persistent adherence with a tolerable medication regimen improves prognosis, while relapse without antipsychotic medication exceeds 50% in the year following discontinuation of antipsychotic treatment.

The onset of schizophrenia can be rapid with acute psychosis presenting as the first symptom, or can be insidious with negative symptoms and social impairments predating psychosis by many years. Whether insidious or acute, the period around the diagnosis is difficult for patients, families, and clinicians. Patients may hide symptoms from family and friends and isolate themselves from social support networks. Gradual development of psychosis and the misunderstanding of symptoms can delay diagnosis and treatment. Recent data suggest that people treated early in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to initiate treatment closer to the onset of psychosis.

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of treatment are to reduce symptomatology and psychotic relapses and to improve functional and social outcomes.[10] Patients should receive comprehensive treatment as early as possible and earlier treatment can lead to better outcomes.[11] In the past, the primary treatment goal was to decrease positive symptoms and associated hostile and aggressive behaviors. Newer approaches also focus on functional and social outcomes.

LO 3

Clinical Presentation of Schizophrenia

General

Schizophrenia is a chronic disorder of thought and affect, causing significantly impaired vocational and interpersonal function. Onset is usually preceded by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors. The clinical presentation of a person with schizophrenia is extremely varied.

Symptoms

Psychotic symptoms (positive symptoms):

- Hallucinations (distortions or exaggeration of perception)
  - Most frequently auditory, can also be visual, olfactory, gustatory, and tactile.
  - Can be voices or thoughts that feel distinct from the person's mind.
  - Voices may be threatening or commanding (eg, commanding the person to perform a particular action).
- Delusions (fixed false beliefs)
  - Beliefs despite invalidating evidence
  - May be bizarre in nature
  - Often paranoid in nature which may cause suspiciousness
- Thought disorder (illogical thought and speech)
  - Loosening of associations
  - Tangentiality
  - Thought blocking
  - Concreteness
  - Circumstantiality
  - Perseveration
  - Thinking and speech may be incomprehensible and illogical

Negative symptoms:

- Impoverished speech and thinking
- Lack of social drive (avolition)
- Flatness of emotional expression
- Apathy
- May be primary or occur secondarily to medication side effects, mood disorder, environmental understimulation, or demoralization
- The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time despite efforts at resolving the other causes

Cognitive impairments (diminished function in the following):

- Attention
- Processing speed
- Verbal, visual memory, and working memory
- Problem solving
- There is a loss of, on average, one standard deviation of preillness IQ, with the average IQ between 80 and 84.

Laboratory and Other Diagnostic Assessments

LO 1

An initial psychotic workup includes a thorough neurologic, medical, and laboratory evaluation to rule out other causes

- Electrolytes
- Blood urea nitrogen
- Serum creatinine
- Urinalysis
- Liver and thyroid function profile
- Syphilis serology
- Serum pregnancy test
- Urine toxicology

Though antipsychotic medications may improve combativeness, hostility, sleep, and appetite, other aspects of the illness are less responsive to treatment. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require adjunctive treatments and a longer period to improve.

General Approach to Treatment

LO3 LO7

The concept of recovery has become an increasingly prominent treatment goal. Treatment planning increasingly includes providing recovery-oriented services to people with schizophrenia. A range of nonpharmacologic interventions are now part of the long-term strategy to improve functioning. Implementation of evidence-based practice and prescribing behaviors has led to the use of interventions that promote a remission or recovery attitude, and new data suggest that 1 in 7 people with schizophrenia can achieve full recovery.[12,13] Moreover, recent attempts to improve and measure patient satisfaction and to include shared decision making have fostered patient empowerment and hope.

KEY CONCEPT The cornerstone of treatment is antipsychotic medications, and most patients with schizophrenia relapse when not medicated. Treatment with antipsychotic medications should begin as soon as psychotic symptoms are recognized. Many patients are on lifelong antipsychotic medication because nonadherence and discontinuation are associated with high relapse rates. Often, adjunctive medications may also be necessary for specific symptoms or comorbid diagnoses. If other symptoms are present, such as depression and anxiety, these symptoms should be aggressively treated. Nonpharmacologic and psychosocial treatments should also play an important role in treatment.

LO3 LO4

Antipsychotic Treatment

In the United States, we have two general classes of antipsychotic medications, the first-generation antipsychotics (FGAs; typical antipsychotics) and SGAs (atypical antipsychotics). The SGAs include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, iloperidone, asenapine, lurasidone, brexpiprazole, cariprazine, and clozapine. Clozapine, the prototype SGA, is currently reserved for treatment-resistant schizophrenia because of its unusual side-effect profile (see below). All antipsychotic medications share a common mechanism of dopamine antagonism, although there is significant variation among the agents. Dopaminergic antagonism is important in both treatment of symptoms and potential for medication-induced side effects. Of the four main dopaminergic pathways in the brain, positive symptoms are associated with hyperdopaminergic activity in the mesolimbic pathway, so blockade in this area is thought to reduce psychotic symptoms. However, blockade of dopamine activity in the other three main pathways may worsen some symptoms or lead to side effects. For example, hypodopaminergic activity in the mesocortical pathway may be associated with negative symptoms and cognitive symptoms, and further reducing dopamine activity could exacerbate these issues. Blockade of dopaminergic activity in the nigrostriatal pathway can lead to motor-related side effects, and blockade of dopaminergic activity in the tuberoinfundibular pathway may

Patient Encounter Part 2

PPH: The patient was seen 6 months ago by his primary care doctor and was diagnosed with major depressive disorder due to his lack of participation in activities, which was felt to be anhedonia. He was started on sertraline but had no improvement. This is his first psychiatric hospitalization.

PMH: He had a history of bedwetting until he was 14 years old but does not have any history of head trauma or seizure disorder.

SH: He grew up with his mother, father, and one sister, who is 2 years older than him. His sister is in her last year of college and upon interviewing her, she states "my brother was always a little odd and had a hard time making friends." His mother says he was always anxious—he often complained of stomach aches and headaches and did not want to go to school. He also refused to stay at other children's homes overnight. He drinks alcohol occasionally but does not use marijuana or other substances of abuse. He does smoke cigarettes and started smoking at age 14 years. He smokes 1 PPD. He has never held a job. He has no health insurance.

FH: His grandfather had an alcohol problem, and his great uncle has a history of psychiatric hospitalization, though the specific circumstances are unknown. His mother and aunt reportedly have depression.

Mental Status Examination

Appearance: Appears disheveled, dressed in dirty clothes, and hair looks like it has not been washed or brushed for several days. No abnormal movements. Poor eye contact. He is distracted and is looking around the room and over his shoulder.

Speech: Soft with one word answers

Mood: Nervous. Says he feels "normal." Denies feeling depressed.

Affect: Guarded and anxious with restricted range. He denies feeling sad, guilty, hopeless, or helpless.

Thought content: He is an adequate historian but has a tendency to leave out detail. He denies hearing voices but is very afraid that his mother is trying to poison his food. He thinks others may also be trying to poison him with arsenic or polonium and is refusing to eat. Sometimes, he feels that others know his thoughts. He has passing thoughts of suicide but no plan. He denies homicidal thoughts.

Thought processes: Vague, tangential, and illogical.

Cognition: Grossly intact.

Insight and judgment: Insight and judgment are poor. He does not believe he has a mental illness.

Given this additional information, how has your differential diagnosis changed?

What medications would you consider to be first-line options, and why?

What are the goals of initial treatment?

lead to prolactin elevation and related side effects.[3] Differences in dopaminergic and nondopaminergic receptor antagonism and receptor affinity across the antipsychotic agents and classes lead to differing potential for dopamine-related side effects.

KEY CONCEPT Compared with the FGAs, the SGAs are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia).

With the introduction of SGAs in the 1990s, the use of FGAs has progressively decreased, and FGAs have less than 10% market share of the antipsychotics used for schizophrenia. This decline occurred because of the touted better side-effect profile and other possible benefits of SGAs in nonpsychotic domains of the illness. However, a large landmark study (the Clinical Antipsychotics Trials of Intervention Effectiveness [CATIE trial]; $n > 1400$) examined the effectiveness of SGAs relative to a midpotency FGA, perphenazine. The study revealed that the FGA was equal to the SGAs for the primary endpoint of time to discontinuation of medication.[14] SGAs have historically been much more expensive than the FGAs; however, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and clozapine are now available in generic formulations. In conclusion, when selecting an antipsychotic, the risk-to-benefit profile becomes fundamental and the varying side-effect profiles must be considered.

LO 4 LO 5

Second-Generation (Atypical) Antipsychotics

FGAs exert most of their effects through dopamine-receptor blockade at the dopamine$_2$ (D_2) receptor. SGAs may have different receptor-binding profiles that contribute to their "atypicality." This possibly includes greater serotonin to dopamine antagonism, dopamine antagonism with rapid dissociation, partial dopamine antagonism and serotonin$_{1A}$ (5-HT$_{1A}$) partial agonism. Despite heterogeneous receptor binding, the efficacy among the SGAs is similar.[14] However, due to differences in specific receptor binding affinity, side-effect risks may vary between these agents. Additionally, recent data for SGAs and lower doses of FGAs document similar overall efficacy with an effect size for acute treatment of 0.30 to 0.60 for most antipsychotics.[15] These findings have led to a modest resurgence of FGA use. Only clozapine, however, has demonstrated superior efficacy and that is in treatment-resistant patients. An important distinction of the SGAs is their lower propensity to cause acute **extrapyramidal symptoms** (EPSs) and **tardive dyskinesia** (TD). TD risk with SGAs is 1.5% annually in adults (< 54 years of age) compared to approximately a 5% annual risk with FGA treatment.[16] However, side effects such as weight gain, the potential for glucose dysregulation, and lipid abnormalities may be caused by treatment with these agents. Weight gain may be caused by a combination of lifestyle and medication interaction with neurotransmitter systems that may increase appetite and food intake (serotonergic, histaminergic, and dopaminergic), and, although all antipsychotics may be associated with weight gain, certain SGAs such as clozapine, olanzapine, quetiapine, and risperidone may offer greater risk. Similarly, risk of lipid abnormalities mirrors the risk for weight gain. Risk for glucose dysregulation or new-onset diabetes generally follows the risk of agents with most weight gain potential, although it is important to note that clozapine and olanzapine have been associated with diabetic ketoacidosis in the absence of significant weight gain in isolated cases.

KEY CONCEPT The SGAs are heterogeneous with regard to side-effect profiles. Many SGAs carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential. Dosing and comparative side effects of SGA are shown in Tables 37–2 and 37–3.

▶ *Risperidone*

Risperidone, a benzisoxazole derivative, was the initial first-line oral SGA to become available generically. It has high binding affinity to both serotonin 2$_A$ (5-HT$_{2A}$) and D_2 receptors and binds to α_1 and α_2 receptors, with very little blockade of cholinergic receptors.[17] Risperidone is also approved for relapse prevention and is associated with significantly lower relapse rates than long-term haloperidol treatment.[18] At doses less than or equal to 6 mg/day, EPSs are low, although higher doses are associated with a greater incidence of EPS. Risperidone is often associated with elevated prolactin to a greater extent than most other SGAs and FGAs. Elevated prolactin levels can, but do not always, lead to amenorrhea, galactorrhea, gynecomastia, and sexual dysfunction. Mild to moderate weight gain and mild elevations in serum lipids and glucose may occur.

▶ *Olanzapine*

Olanzapine has greater affinity for 5-HT$_{2A}$ than for D_2 receptors. It also has affinity at the binding sites of D_4, D_3, 5-HT$_3$, 5-HT$_6$, α_1-adrenergic, muscarinic$_{1–5}$ ($M_{1–5}$), and histamine$_1$ (H_1) receptors.[19] In the CATIE trial, olanzapine was associated with the longest time to treatment discontinuation,[14] suggesting it may differ from the other SGAs in effectiveness. Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. Olanzapine causes significant weight gain across the dosage range, similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (ie, metabolic syndrome). Among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.[14]

▶ *Quetiapine*

Quetiapine, structurally related to clozapine and olanzapine, has high affinity for 5-HT$_{2A}$ receptors and lower affinity for D_2 and D_1 receptors. It has some affinity for α_1, α_2, and H_1 receptors but very little for muscarinic receptors. Quetiapine may be beneficial for anxiety and depression. Motor side effects and prolactin elevations are uncommon. Orthostasis occurred in 4% of subjects in clinical trials. Sedation is generally transient. Mild weight gain and minor elevations in triglycerides can occur. Use of quetiapine with agents that can prolong the QTc interval or in patients with prolonged QTc should be avoided. Quetiapine has been associated with some dose-related decreases in thyroid hormones.

▶ *Ziprasidone*

Ziprasidone was developed to block D_2 receptors but also to bind with greater affinity to central 5-HT$_{2A}$ receptors. It has a binding affinity ratio of 11:1 for 5-HT$_{2A}$:D_2 receptors. It has a relatively high affinity for 5-HT$_{2C}$, 5-HT$_{1D}$, α_1-adrenergic, and D_1 receptors.[20] It should be taken with food, as this results in absorption levels twice that of fasting administration. Liability for EPS, weight gain, and lipid elevations is low but does occur. Ziprasidone causes some prolongation of the QTc interval in adults. However, overdose data and pharmacokinetic interaction data show little evidence that significant QTc prolongation occurs. Use of ziprasidone with agents that can prolong the QTc interval or in patients with existing diseases associated with prolonged QTc should be avoided. Drug-reaction with eosinophilia and systemic symptoms (DRESS) has occurred rarely.

▶ *Aripiprazole*

Aripiprazole has both antagonist and agonist activity at the D_2 receptor. Aripiprazole is also a partial agonist at 5-HT$_{1A}$

Table 37–2

Second-Generation (Atypical) Antipsychotics

Second-Generation Antipsychotic	Usual Oral Starting and Target Dose (mg/day) (Schizophrenia)	Maximum Oral Dose Likely to Be Beneficial (mg/day)	Available Dosage Forms
Aripiprazole (Abilify; Aristada [aripiprazole lauroxil injection])	Initial: 10–15 Target: 15–30	30	• 2-, 5-, 10-, 15-, 20-, and 30-mg tablets • 1-mg/mL oral solution • 10- and 15-mg orally disintegrating tablets • IM 9.75 mg/1.3 mL • Abilify Maintena extended-release 300- and 400-mg vial powder for suspension or prefilled syringe long-acting injection • Aristada extended-release 441, 662, 882, and 1064-mg prefilled syringes
Asenapine (Saphris)	Initial: 5 twice daily Target: 10–20 total daily dose	10–20	• 2.5-, 5-, and 10-mg sublingual tablets
Brexpiprazole (Rexulti)	Initial: 1 Target: 2–4	4	• 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets
Cariprazine (Vraylar)	Initial: 1.5 Target: 1.5–6	6	• 1.5-, 3-, 4.5-, and 6-mg capsules
Clozapine (Clozaril, Fazaclo, Versacloz, also available generically)	Initial: 12.5–25 Target: 300–450	500–800	• 12.5-, 25-, 50-, 100-, and 200-mg tablets • FazaClo (orally disintegrating tablets) 12.5-, 25-, 100-, 150-, and 200-mg • Versacloz (oral suspension) 50 mg/mL
Iloperidone (Fanapt)	Initial: 1 twice daily Target: 12–24 total daily dose	24	• 1-, 2-, 4-, 6-, 8-, 10-, and 12-mg tablets
Lurasidone (Latuda)	Initial: 40 Target: 40–160	160	• 20-, 40-, 60-, 80-, and 120 mg tablets
Olanzapine (Zyprexa, also available generically)	Initial: 5–10 Target: 10 –20	30–40[a]	• 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets • Orally disintegrating tablets: 5, 10, 15, and 20 mg • IM 10 mg vial (after reconstitution, ~5 mg/mL) • Zyprexa Relprevv 210-, 300-, and 405-mg/vial powder for suspension long-acting injection
Paliperidone (Invega)	Initial: 6 Target: 3–12	12	• 1.5-, 3-, 6-, and 9-mg tablets • Invega Sustenna 39-, 78-, 117-, 156-, and 234-mg prefilled syringes • Invega Trinza 273-, 410, 546-, or 819 mg
Quetiapine (Seroquel, also available generically)	Regular release Initial: 25 twice daily Target: 300–750 Extended release Initial: 300 Target 400–800	800	• 25-, 50-, 100-, 200-, 300-, and 400-mg tablets • Seroquel XR (extended-release tablets) 50-, 150-, 200-, 300-, and 400-mg tablets
Risperidone (Risperdal, also available generically)	Initial: 1–2 Target: 4–6	6–8	• 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets • 1 mg/mL (30 mL) solution • orally disintegrating tablets: 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets • Risperdal Consta long-acting injectable 12.5-, 25-, 37.5-, and 50-mg vial/kit
Ziprasidone (Geodon, also available generically)	Initial: 20 twice daily Target: 120–160 total daily dose	160–240[a]	• 20-, 40-, 60-, and 80-mg capsules • IM 20 mg/mL

[a]Outside product labeling guidelines.

IM, intramuscular.

receptors, an antagonist at 5-HT_{2A} receptors, and has affinity for D_3 receptors. Additionally, it has moderate affinity for α_1 and H_1 receptors with no appreciable affinity for the M1 receptor.[21] In CYP2D6-poor metabolizers, start dosing with one-half the usual dose with adjustment to clinical efficacy. Sedation, nausea, and vomiting are the most often seen side effects. Elevations in weight, lipids, and glucose are generally negligible, and aripiprazole is not associated with elevations in serum prolactin. In fact, patients switched to aripiprazole from other antipsychotic agents may experience decreases in prolactin.

► *Paliperidone*

Paliperidone is the 9-hydroxy (9-OH) metabolite of risperidone. The efficacy of risperidone and paliperidone is similar. Receptor

[a]Side effects similar for paliperidone.

0, absent; ±, minimal; +, mild or low risk; ++, moderate; +++, severe; SGA, second-generation antipsychotic.

Cloz, clozapine; Risp, risperidone; Olan, olanzapine; Quet, quetiapine; Zip, ziprasidone; Ari, aripiprazole; Ilo, iloperidone; Asen, asenapine; Lur, lurasidone; Brex, brexpiprazole; Carip, cariprazine; Hal, haloperidol.

binding affinity is also similar between the two agents, with paliperidone having a greater affinity at 5-HT_{2A} compared with D_2 receptors. Unlike many other antipsychotic medications, paliperidone is mostly excreted unchanged, a potential advantage in patients with liver impairment, although adjustment may need to be made in renal impairment. Patients should be told to expect to see the shell of the tablet in the stool because it may not dissolve in the digestive tract.[22] Side effects of paliperidone are expected to be similar to those of risperidone, including the potential for dose-related EPS and prolactin elevation.[22]

▶ *Iloperidone*

Iloperidone is indicated for acute treatment of adults with schizophrenia. It exhibits high affinity for $5HT_{2A}$, dopamine D_2, and D_3 receptors and acts as an antagonist at these, as well as at the $5HT_{1A}$ and norepinephrine α_1/α_{2C} receptors. Doses must be titrated because of the risk of orthostatic hypotension, and dosing should be reduced by half in CYP2D6 poor metabolizers. Common adverse reactions include dizziness, dry mouth, fatigue, orthostatic hypotension, tachycardia, and weight gain. Dizziness, tachycardia, and weight gain were twice as common with higher dose (20–24 mg total daily dose) versus lower doses (10–16 mg total daily dose).[23] Use of iloperidone with agents that can prolong the QTc interval or in patients with diseases that are associated with prolonged QTc should be avoided.

▶ *Asenapine*

Asenapine is approved for the acute treatment of schizophrenia in adults. Its mechanism of action is thought to be its antagonistic activity at $5HT_{2A}$ and D_2 receptors. It also exhibits a high affinity for other serotonergic and dopaminergic receptors, as well as α_1- and α_2-adrenergic receptors and H_1 receptors. Asenapine tablets must be placed under the tongue and allowed to dissolve completely; tablets should not be chewed or swallowed. Patients should not drink or eat for 10 minutes after administration. No added benefit was seen with doses above 10 mg twice daily, but adverse effects increase. Common adverse effects include somnolence, dizziness, and akathisia. It has shown little effect on metabolic parameters and weight change. Labeling for asenapine was modified to address rare occurrence of hypersensitivity reactions, including anaphylaxis and angioedema.[24]

▶ *Lurasidone*

Lurasidone antagonizes D_2 and $5HT_{2A}$ receptors. It also has moderate affinity as an antagonist at α_{2C}, is a partial agonist at $5HT_{1A}$, and is an antagonist at α_{2A}-receptors. Lurasidone should be taken with caloric intake of at least 350 calories (~1.5 kJ) for maximal absorption. Adverse reactions reported in at least 5% of patients (and at least twice the placebo rate) include somnolence, akathisia, nausea, parkinsonism, and agitation. Lurasidone has shown only a small effect on body weight and causes minimal changes in other metabolic parameters.[24]

▶ *Brexpiprazole*

Brexpiprazole is a partial agonist at 5-HT_{1A}, D_2 and D_3 receptors. It is also an antagonist of 5-HT2A, 5-HT2B, 5-HT7, α_1A, α1B, α1D, α2C, and H1 receptors. It has negligible affinity for muscarinic receptors. In CYP2D6 poor metabolizers, usual dosage should be reduced by one-half. This medication is slightly less stimulating and has less akathisia than aripiprazole. The most commonly occurring side effects are weight gain and akathisia.[25]

▶ *Cariprazine*

Cariprazine is a dopamine D_3-preferring D_2/D_3 receptor partial agonist. It is given once daily and has a long half-life; thus, side effects should be monitored for several weeks after initiation or a dose change. Most common side effects are akathisia, EPS, nausea, vomiting, somnolence, and restlessness. Those having a known hypersensitivity reaction to cariprazine should not be treated with the medication.[26]

First-Generation (Typical) Antipsychotics

The FGAs are high-affinity D_2-receptor antagonists. During chronic treatment, they block 65% to 80% of D_2 receptors in the striatum and other dopamine tracts in the brain.[25] Clinical response is generally associated with 60% D_2-receptor blockade, while 70% and 80% are associated with hyperprolactinemia and EPS, respectively. During the 1990s, SGAs began to replace FGAs as first-line therapy.

Doses for FGAs are frequently given as **chlorpromazine equivalents**, which are defined as the FGA equipotent dose with 100 mg of chlorpromazine. The target dose recommendation for

Patient Encounter Part 3

The patient started treatment with risperidone in the hospital and was titrated to 6 mg/day. He was feeling less paranoid, began to eat again, and his sleep pattern normalized. He has now been out of the hospital for 3 months and came in for his regular appointment with his outpatient psychiatrist. While he was in the waiting room, he was noticed to be pacing around and seemed to be very restless. The patient told the doctor that he was unable to sit and he felt better when walking around. The patient's mother stated that her son seemed more agitated and his symptoms were getting worse again. She was concerned he might be readmitted to the hospital. It was also noted that the patient had gained 12 lbs (5.4 kg). After much discussion with the patient and his mother, the decision was made to switch him from risperidone to aripiprazole. The doctor informed the patient that he would call him in a few days to see how he was feeling. The doctor also encouraged him to exercise regularly and eat a healthy diet that is low in carbohydrates, and referred him to a dietician.

What symptom was the patient experiencing on risperidone? What other treatments could have been considered besides switching agents?

Discuss the differences in the side-effect profiles of risperidone and aripiprazole.

acute psychosis is 400 to 600 chlorpromazine equivalents unless the patient's history indicates that dose may not be tolerated. Generally, maintenance therapy is 300 to 600 chlorpromazine equivalents daily. Dosing and available dosage forms are shown in Table 37–4. All FGAs are equally efficacious when studied in equipotent doses in groups of patients. Relative potency of FGA agents is related to side-effect profile, with lower potency agents such as chlorpromazine demonstrating higher risk of anticholinergic and cardiovascular side effects and higher potency agents such as haloperidol displaying more potent EPS side effects. However, an individual patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic is based on patient variables, such as the need to avoid certain side effects or drug–drug interactions or previous patient or family history of response. Long-acting formulations of FGA medications are shown in Table 37–5.

Side Effects of the First-Generation Antipsychotics

As previously mentioned, the low-potency FGA agents are less likely to cause EPS than the high-potency agents (see Table 37–4). Of note, high-potency and mid-potency agents may cause less EPS than once believed and were similar to SGAs in the CATIE trial.[14]

The FGAs are commonly associated with early onset EPS (including akathisia [motor or subjective restlessness], dystonia [muscle spasm], and pseudoparkinsonism [akinesia, tremor, and rigidity]) caused by dopamine antagonism in the nigrostriatal pathways. SGAs also may have these side effects. Akathisia, or the feeling of restlessness, occurs in 20% to 40% of FGA patients. Roughly half of the cases of akathisia present within 1 month of FGA initiation, though it may present within 5 to 10 days after the first dose or after an increase in dosage. Younger people and those taking high doses of high-potency antipsychotics are at greater risk for development of akathisia.

Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. There is higher risk for dystonia in young male patients and those taking high-potency FGAs.

Pseudoparkinsonism may be present in 30% to 60% of people treated with FGAs. The onset of symptoms is usually within 1 to 2 weeks after dose initiation or dose increase. Clinical presentation may include cogwheel rigidity, pill-rolling hand movements, resting tremor, shuffling gait, stooped posture, and mask facies. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms. Anticholinergic medications are used for treatment of dystonic reactions and pseudoparkinsonism, while β-blocking agents are generally first line for akathisia.[27]

Table 37–4

First-Generation (Typical) Antipsychotics[a]

Class	Agent (Brand Name)	Dosage Range (mg/day)	Chlorpromazine Equivalents (mg)	Available Formulations
Butyrophenone	Haloperidol (Haldol)	5–30	2	T, LC, I
Dibenzoxazepine	Loxapine (Loxitane, Adasuve)	20–100	10	C, IP
Diphenylbutylpiperidine	Pimozide (Orap)	1–10	1–2	T
Phenothiazines	Chlorpromazine (Thorazine)	300–800	100	T, I
	Fluphenazine (Prolixin)	2–40	2	T, L, LC, I
	Perphenazine (Trilafon)	8–64	8–10	T

	Trifluoperazine (Stelazine)	15–30	5	T
Thioxanthenes	Thiothixene (Navane)	5–60	4	C

[a]Low-potency antipsychotics include thioridazine, mesoridazine, and chlorpromazine. High-potency antipsychotics include haloperidol, fluphenazine, thiothixene, and pimozide.

C, capsule; I, injection; IP, inhalation powder; LC, liquid concentrate; L, liquid solution, elixir, or suspension; T, tablet.

Table 37–5

Antipsychotic Dosing of Long-Acting Preparations

Drug	Starting Dose	Maintenance Dose	Comments
Aripiprazole long-acting injection (Abilify Maintena)	400 mg monthly Give 14 consecutive days of concurrent oral aripiprazole (10–20 mg) or current oral antipsychotic after first injection	300–400 mg monthly	Establish tolerability with oral agent first Dosage adjustments for CYP2D6 poor metabolizers, and in persons who take strong CYP2D6 or 3A4 inhibitors; recommend to avoid use if strong 3A4 inducer Available as 300, 400 mg kits
Aripiprazole lauroxil (Aristada)	441 if 10 mg/day oral 662 if 15 mg/day oral 882 if 20 mg/day or more oral Give 21 days of concurrent oral aripiprazole overlapping with first dose	Average 441–882 monthly or 882 every 6 weeks or 1064 every 2 months	Dose adjustments for CYP2D6 poor metabolizers, and persons who take strong CYP2D6 or 3A4 inhibitors; or CYP3A4 inducers > 2 weeks Available as 441, 662, 882, or 1064 mg prefilled syringes
Haloperidol decanoate	10–20 × oral haloperidol daily dose; in the elderly use 10–15 × oral haloperidol daily dose; Generally 100–450 mg/month Initial dose should not exceed 100 mg regardless of previous dose requirements (if > 100 mg, give 3–7 days apart) Oral supplementation may temporarily be necessary for first 2–3 injections unless loading dose given	10–15 × oral haloperidol daily dose, generally 50–300 mg/month	Deep IM injection generally with 21-gauge needle; maximum volume per injection site should not exceed 3 mL Available in 50 and 100 mg/mL (5-mL vials and 1-mL ampules)
Fluphenazine decanoate	Approximately 12.5 mg injection = 10 mg oral daily dose; usual starting dose 12.5–25 mg; generally 12.5–mg/2–3 weeks Give ½ oral dose after first injection, discontinue oral after second injection	Based on starting dose and clinical response but usually 2–4 weeks; doses above 50 mg increase cautiously in 12.5 mg increments; do not exceed 100 mg Generally 12.5–25 mg dosed at 2–4-week intervals (may be up to 6 weeks in some cases)	Can be administered IM or SC; 21-gauge needle, must be dry Should not exceed 100 mg; when dosing above 50 mg, should increase in increments of 12.5 mg Available in 25 mg/mL (5-mL vials)
Olanzapine (Zyprexa Relprevv)	To target oral 10 mg/day dose: Either 210 mg/2 weeks or 405 mg/4 weeks during first 8 weeks To target oral 15 mg/day dose: 300 mg/2 weeks for first 8 weeks To target 20 mg/day oral dose: 300 mg/2 weeks Establish tolerance with oral administration prior to initiation	To target oral 10 mg/day dose: after 8 weeks, give 150 mg/2 weeks or 300 mg/4 weeks To target oral 15 mg/day dose: after 8 weeks, 210 mg/2 weeks or 405 mg/4 weeks To target 20 mg/day oral dose: continue with 300 mg/2 weeks	Gluteal injection, 19-gauge needle Do not confuse with rapid-acting IM injection Must reconstitute with included diluent Measure amount to inject from vial (there will be remaining suspension in vial) Zyprexa Relprevv Patient Care Program: 3-hour observation period; patient must be accompanied to destination No refrigeration needed, use within 24 hours, or immediately once suspension is in syringe Available as 210, 300, 405 kits
Paliperidone monthly (Invega Sustenna)	Initiate with 234 mg on day 1 and 156 mg 1 week later, both in deltoid muscle Establish tolerance with oral administration prior to initiation	Recommended monthly maintenance dose is 117 mg (range, 39–234 mg)	First two doses must be given in the deltoid muscle; after that, monthly doses given in either the deltoid or gluteal muscle Adjust dose in mild renal impairment; avoid in moderate to severe impairment Available as 39-, 78-, 117-, 156-, and 234-mg prefilled syringes

(*Continued*)

Table 37–5

Antipsychotic Dosing of Long-Acting Preparations (*Continued*)

Drug	Starting Dose	Maintenance Dose	Comments
Paliperidone (every 3 months) (Invega Trinza)	If monthly 78 mg, 273 mg/3 months If monthly 117 mg, 410 mg/3 months If monthly 156 mg, 546 mg/3 months If monthly 234 mg, 819 mg/3 months Only initiate after at least 4 months of paliperidone monthly injections.	273–819 mg/3 months	Adjust dose in mild renal impairment; avoid in moderate to severe impairment Available as 273-, 410-, 546-, or 819-mg prefilled syringes
Risperidone long-acting injection (Risperdal Consta)	25 mg every 2 weeks Previous antipsychotics should be continued for 3 weeks after initial dose of risperidone long-acting injection	25–50 mg every 2 weeks	Recommended to establish tolerability with oral risperidone prior to initiation of long-acting injection Lower starting dose of 12.5 mg may be appropriate in some patients with renal/hepatic impairment Available in 12.5-, 25-, 37.5-, and 50-mg vial/kit; must use needle supplied with kit, administer IM

IM, intramuscular; SC, subcutaneous.

TD is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous) and athetoid (slow and irregular) movements beginning late in relation to initiation of antipsychotic therapy. It usually develops over several months or after at least 3 months of cumulative exposure to antipsychotics. When antipsychotics are tapered or discontinued, there is typically a transient worsening of abnormal movements, and movements may be irreversible in some cases. Risk factors for TD include older age; longer duration of antipsychotic treatment; and presence of EPS, substance abuse, and mood disorders. SGAs have a lower risk of approximately 2% to 4% risk of TD than FGAs (5%–6%).[16] A variety of approaches have been used for treating TD including switching to clozapine, using high dose vitamin E, and, most recently, the approval of new Food and Drug Administration (FDA)-approved medications for TD, valbenazine and deutetrabenazine, which inhibit vesicular monoamine transporter 2 (VMAT2).[27]

Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all FGAs and may also occur with SGAs. Rapid dose escalation, use of high-potency FGAs at higher doses, and younger patients have a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive, symptomatic treatment begun (eg, antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Benzodiazepines and dantrolene are recommended treatments along with intensive care management as needed.[27]

Dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine FGAs. Sedation is mediated by H_1 receptor antagonism; anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused by M_1-receptor antagonism; and α_1-receptor blockade is associated with orthostatic hypotension and tachycardia (Table 37–6). QTc prolongation may occur with the lower potency FGAs, and thioridazine has a black-box warning for QTc prolongation.

Pharmacologic Treatment Guidelines and Algorithms

There have been a variety of treatment recommendations published for schizophrenia. The American Psychiatric Association (APA) Practice Guidelines for Schizophrenia[8] were introduced in 2004 with a 2009 update, the Texas Implementation of Medication Algorithms (TIMA) were updated in 2008,[28] and the Schizophrenia Patient Outcomes Research Team (PORT) Treatment Recommendations[29] were published in 2009. More recent guidelines are available from the World Federation of Societies of Biological Psychiatry Guidelines (WFSBP),[30] British Association of Psychopharmacology (BAP),[31] and the National

Table 37–6

Side Effects of First-Generation Antipsychotics

Institute for Health and Care Excellence (NICE) guidelines.[10] While guidelines from the early 2000s generally recommend SGAs as first-line treatment, more recent guidelines generally suggest first-line treatment with either an FGA or SGA. Choice of the FGA/SGA is guided by side-effect profiles and patient clinical characteristics. Treatment with a given drug should be continued for 4 to 6 weeks to assess response and then a second antipsychotic should be started with the aim of crossing over to monotherapy with a different agent in conjunction with psychosocial support. Use of two antipsychotic medications concomitantly is discouraged due to increased side effect burden and paucity of data for increased efficacy.

Treatment Adherence

Antipsychotic nonadherence is estimated to occur in at least 40% to 50% of patients with schizophrenia. Patients who are nonadherent have about a fourfold greater risk of a relapse than those who are adherent.[32] Neurocognitive deficits, poor insight, and paranoid symptoms may hamper adherence, and identification of nonadherence by caretakers and providers can be challenging. Antipsychotic side effects such as EPS, weight gain, sexual dysfunction, substance use, and negative symptoms may all contribute to treatment nonadherence. For patients who have relapsed several times because of nonadherence, have a history of dangerous behavior, or risk a significant loss of social or vocational gains when relapsed, treatment with long-acting injection (LAI) should be encouraged. However, more recent data suggest that both FGA and SGA LAIs are more effective at reducing rehospitalization risk compared to oral treatment,[33] and thus may be considered for all patients as a routine treatment option. Risperidone, paliperidone, olanzapine, and aripiprazole are available as LAIs. In general, oral tolerability of these agents should be ensured prior to initiating LAI. Dosing and other information about these formulations is shown in Table 37–5.

Special Populations

▶ *Dosing in Renal and Hepatic Impairment*

Table 37–7 shows dosing guidance on specific antipsychotic medications.

▶ *Children and Adolescents*

Around 10% to 30% of patients with schizophrenia have psychotic symptoms before their 18th birthday. The diagnosis of schizophrenia in children and adolescents is often challenging, and the differential diagnosis includes autistic spectrum disorders, attention-deficit/hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions helps make the diagnosis because they are not prominent in other disorders. Children and adolescents developing schizophrenia before age 18 years have premorbid abnormalities such as withdrawal, odd traits, and isolation. Treatment for psychotic children and adolescents ideally is intensive, comprehensive, and structured. Early intervention in psychosis services such as NAVIGATE should be employed in first-episode schizophrenia.[34] Pharmacologic treatment is indicated if psychotic symptoms cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than are adults. Because of concerns about EPS and TD in children and adolescents, it is recommended that antipsychotic therapy be initiated with SGAs. Aripiprazole, risperidone, quetiapine, olanzapine, paliperidone, and lurasidone are approved by the FDA for the treatment of schizophrenia in adolescent patients. Initiation and target dosing is lower for adolescents than adults.

Agents with significant sedative and anticholinergic side effects are not preferred because they can interfere with school performance. Compared with adults, children and adolescents tend to gain more weight when taking these agents.

▶ *Elderly*

Psychotic symptoms in late life (after 65 years of age) generally result from an ongoing chronic illness; however, a small percentage of patients develop psychotic symptoms *de novo*, defined as late-life schizophrenia. Other illnesses with psychotic symptoms are common in this population; approximately one-third of patients with Alzheimer disease, Parkinson disease, and vascular dementia experience psychotic symptoms.

Antipsychotics can be safe and effective for the treatment of schizophrenia in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of the FGAs, and TD risk is over threefold risk in elderly patients.[16]

Orthostasis, estimated to occur in 5% to 30% of geriatric patients, is a major contributing factor to falls that often lead to injuries and loss of independence. Low-potency antipsychotics and clozapine are more likely to cause significant orthostasis. Antipsychotics may cause or worsen anticholinergic effects, including constipation, dry mouth, urinary retention, and cognitive impairment. Greater antipsychotic-associated impairment in cognitive functioning may occur in the elderly compared to younger adults. In the elderly, this can lead to decreased independence, a very problematic issue. As a result of data showing a statistically significant increase in mortality in elderly dementia patients taking SGAs, a black-box warning was added to the manufacturer's information for all antipsychotics. Patients and families should be informed of this risk before using these agents in patients with dementia. Dosing in the elderly is initiated lower, and titration is slower than in younger adults. Maximum doses are often half of adult doses (see Table 37–7).

▶ *Co-Occurring Substance Use Disorder*

Alcohol and illicit drug use is about threefold higher in schizophrenia than the general population.[5] The most common drugs of abuse are cannabis, cocaine, and alcohol. Substance use often worsens the clinical course and complicates treatment. People with schizophrenia having substance use disorder are more likely to be nonadherent with treatment. They may have a poorer response rate to the FGAs, more severe psychosis, and higher rates of relapse and rehospitalization than people without co-occurring disorders. EPS may occur more frequently in substance-using patients, and alcohol use is a risk factor for developing TD. It is important to incorporate a dual treatment approach for substance use disorders and schizophrenia with nonpharmacologic and pharmacologic treatments.[35]

▶ *Treatment-Resistant Schizophrenia*

For 20% to 30% of people with schizophrenia, first-line antipsychotic treatment is ineffective and another 30% of people have a partial treatment response.[30] A consensus guideline on the definition of Treatment Resistant Schizophrenia (TRS) was recently published. This guideline suggests a standard definition of TRS defined as (a) moderately severe illness as defined by rating instruments with a persistence of at least 5 years, (b) moderate

Table 37–7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic
Aripiprazole	Ages 13–17 years (schizophrenia): Initiate 2 mg every day, increasing to 5 mg daily after 2 days and target of 10 mg after several days, 30 mg/day maximum	No oral adjustment necessary	No adjustment necessary	No adjustment necessary
Asenapine	No pediatric FDA indication for schizophrenia (bipolar I indication only)	No adjustment necessary	No adjustments necessary	No adjustment necessary for mild to moderate impairment, but use not recommended in severe impairment
Brexpiprazole	No pediatric FDA indication	Experience is limited; low dose initiation, up to 3 mg/day kinetics similar to adults with MDD in safety/tolerability trial	CrCl < 60 mL/min (1.0 mL/s): maximum 3 mg	Moderate to severe: maximum 3 mg
Cariprazine	No pediatric FDA indication	Experience is limited; low dose initiation	CrCl < 30 mL/min (0.50 mL/s): not recommended	Mild to moderate: no adjustment required; severe: not recommended
Clozapine	No pediatric FDA indication	Experience is limited; low dose and slow titration	Adjustments may be necessary with significant impairment; no specific recommendations available	Adjustments may be necessary with significant impairment; no specific recommendations available
Iloperidone	No pediatric FDA indication	No adjustment necessary	No adjustment information provided, but unlikely necessary	No adjustment needed for mild impairment; exercise caution with moderate impairment; not recommended for severe impairment
Lurasidone	Ages 13–17 years (schizophrenia): Initial dose, 40 mg/day with target dose of 40–80 mg/day	No adjustment required	With moderate to severe renal impairment, recommended starting dose 20 mg daily; do not exceed 80 mg daily	With moderate impairment, initial dose 20 mg daily; max dose 80 mg daily With severe impairment, initial dose 20 mg daily, max dose 40 mg daily
Olanzapine	Oral: Ages 13–17 years (schizophrenia): Initial dose, 2.5–5 mg orally every day with target dose of 10 mg/day; maximum dose, 20 mg/day Long-acting injection: Not approved in children	Oral: 5 mg/day, if escalation needed use caution Long-acting injection: Consider starting dose of 150 mg every 4 weeks for elderly or debilitated patients	Oral: In renal impairment, no adjustment usually necessary; however, consider a lower initial dose of 5 mg/day Long-acting injection: No information given	Oral: No dosage adjustment noted in prescribing information except in combination with fluoxetine Long-acting injection: No information given
Paliperidone	Oral: Ages 12–17 years (schizophrenia) Dose by body weight: < 51 kg, initiate 3 mg/day oral, increase at increments of > 5 days; maximum, 6 mg/day At least 51 kg, initiate at 3 mg/day, increase at increments of > 5 days, maximum of 12 mg/day	Oral: For patients with normal renal function, no adjustment is required, but if renal impairment guidance is available	Long-acting injection: CrCl 50–79 mL/min (0.83–1.32 mL/s); initiate with 156 mg IM day 1, 117 mg IM 1 week later, with maintenance at 78 mg IM monthly CrCl < 50 mL/min (0.83 mL/s): Use not recommended Oral: CrCl 50–79 mL/min (0.83–1.32 mL/s): 3 mg once daily initiation, maximum 6 mg/day CrCl between 10 and 49 mL/min (0.17–0.82 mL/s): 1.5 mg once daily initiation; maximum, 3 mg/day CrCl < 10 mL/min (0.17 mL/s): Use not recommended	Long-acting injection: No dosage adjustment needed for mild or moderate impairment; no guidance given for severe impairment Oral: No dose adjustment is required for mild or moderate impairment

(*Continued*)

Table 37–7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations (*Continued*)

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic
Quetiapine	Regular-release tablets: Indicated for schizophrenia (ages 13–17 years): Initiate 25 mg twice daily; recommended target dose 400–800 mg/day; maximum, 800 mg/day Extended-release tablets: Initiate 50 mg/day; recommended target dose 400–800 mg	Regular-release tablets: Slower dose escalation and a lower target dose Extended-release tablets: Initiate at 50 mg/day and increase at 50-mg/day increments based on response or tolerance	No dosing recommendations for renal dysfunction	Regular-release tablets: Lower starting dose (25 mg) and slower titration may be needed Extended-release tablets: Should be initiated with 50 mg/day, increasing in 50-mg/day increments
Risperidone	Oral: Pediatric ages 13 years and older (schizophrenia): Initiate at 0.5 mg orally daily, adjusting at intervals of at least 24 hours and in increments of 0.5–1 mg/day as tolerated Recommended target dose, 3 mg/day	Long-acting IM: Initial dose, 25 mg IM every 2 weeks with a 3-week oral crossover; may consider 12.5 mg starting dose Oral: Initiate at 0.5 mg twice daily; may increase by 0.5 mg twice daily, increases above 1.5 mg twice daily done at intervals of at least 1 week	Long-acting IM: Patients with renal impairment should receive titrated doses of oral risperidone before initiation of IM (more detail in prescribing information) Oral: Recommended initial dose in CrCl < 30 mL/min (0.50 mL/s), 0.5 mg twice daily; dose may be increased by 0.5 mg twice daily, but increases above 1.5 mg twice daily should be done at intervals of at least 1 week. Clearance of risperidone is decreased by 60% in patients with moderate-to-severe renal disease (CrCl < 60 mL/min [1.0 mL/s])	Long-acting IM: Titrate with oral risperidone (see renal dosing) Oral: Recommended initiation in Child-Pugh Class C (see renal dosing)
Ziprasidone	No pediatric indication	No official adjustment recommended; consider starting at lower end of the dosage range	Oral doses: No adjustment necessary for mild to moderate renal impairment IM doses: Use with caution because of cyclodextrin sodium excipient	No adjustment necessary for mild to moderate hepatic impairment; however, caution is warranted

CrCl, creatinine clearance; FDA, Food and Drug Administration; IM, intramuscular.

or worse functional impairment, (c) treatment with at least two different antipsychotics given at adequate doses (a dose equivalent to at least 600 mg of chlorpromazine) for an adequate duration (6 weeks), (d) meeting minimum criteria of being adherent to current treatment, and (e) ideally having one prospective antipsychotic trial.[36]

Clozapine Clozapine remains the only drug with proven superior efficacy and approved by the FDA for TRS.[15] It is efficacious after nonresponse to other SGAs, in partially responsive patients and patients who have had a poor response to other medication for years. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials,[10,27,29,31] but may be considered sooner if the individual patient situation warrants.[8,30] Additionally, it has a beneficial effect for aggression and suicidality and is FDA approved for reducing the risk of recurrent suicidal behavior in schizophrenia or schizoaffective disorder.[37]

It remains unknown which pharmacologic properties account for clozapine's superior efficacy. Clozapine interacts with a multitude of receptors but notably has a low affinity for D_2 receptors, antagonism of D_1 receptors, and is a 5-HT_{2A} antagonist.

Clozapine's use is limited by the regulatory requirements resulting from the risk for severe neutropenia (ANC < 0.5×10^9/L [or $0.5 \times 10^3/mm^3$], was termed agranulocytosis previously). This is a rare but potentially life-threatening side effect occurring in < 1% of people treated. The required long-term hematologic monitoring (Table 37–8) can be a barrier for both patients and care providers. Other rare side effects include seizures and myocarditis. Other common unpleasant side effects include sedation, dizziness, constipation, enuresis, weight gain, and hypersalivation. Registration for clozapine must first occur prior to dispensing using a Clozapine REMS website.

The optimal plasma level of clozapine is a minimum trough level of 918 to 1071 nmol/L (300–350 ng/mL or mcg/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage must be individualized. Males and smokers tend to require higher doses to achieve the targeted blood level due to more rapid metabolism.

▶ *Acutely Psychotic and Agitated Patients*

Psychiatric emergencies occur in emergency departments, psychiatric units, medical facilities, and outpatient settings.

Table 37–8

Monitoring of Absolute Neutrophil Count During Clozapine Treatment

	General Population	BEN Population
Initiation to 6 months	Initiate if ANC ≥ 1.5 × 10^9/L; weekly monitoring for 6 months as long as ANC remain ≥ 1.5 × 10^9/L	Initiate if ANC ≥ 1.0 × 10^9/L (obtain at least 2 baseline levels); weekly monitoring for 6 months if ANC remain ≥ 1.0 × 10^9/L
6–12 months	Every 2 week monitoring for 6 months as long as ANC levels remain ≥ 1.5 × 10^9/L	Every 2 week monitoring for 6 months as long as ANC remain ≥ 1.0 × 10^9/L
After 12 months of therapy	Every 4 week monitoring as long as ANC levels remain ≥ 1.5 × 10^9/L	Every 4 week monitoring as long as ANC levels remain ≥ 1.0 × 10^9/L
ANC 1.0–1.49 × 10^9/L	**Mild neutropenia (general population)** 1.0 to 1.49 × 10^9/L (confirm with repeat ANC within 24 hours) Recommendation to continue treatment Monitor ANC three times weekly until ANC ≥ 1.5 × 10^9/L, then return to patient's last normal range monitoring interval if appropriate	These ANC levels considered normal for BEN population, continue monitoring as generally indicated above
ANC 0.5–0.99 × 10^9/L	**Moderate neutropenia (general population)** ANC 0.5–0.99 × 10^9/L (confirm with repeat ANC within 24 hours) Recommend hematology consult; interrupt treatment if clozapine-induced neutropenia is suspected. Resume treatment once ANC is ≥ 1.0 × 10^9/L Monitor ANC daily until ANC ≥ 1.0 × 10^9/L, then three times weekly until ANC ≥ 1.5 × 10^9/L, then check weekly × 4 weeks, then return to patient's last normal range ANC interval, if appropriate	**BEN neutropenia** 0.5–0.99 × 10^9/L (confirm with repeat ANC within 24 hours) Recommend hematology consult Continue treatment Monitor ANC thrice weekly until ANC ≥ 1.0 × 10^9/L or up to patient's known baseline Once at ANC ≥ 1.0 × 10^9/L or patient's known baseline, check ANC weekly for 4 weeks, then return to patient's last normal BEN range ANC monitoring interval, if appropriate
ANC < 0.5 × 10^9/L	**Severe neutropenia (general population)** Daily ANC until ANC ≥ 1.0 × 10^9/L, then three times weekly until ANC ≥ 1.5 × 10^9/L Recommend hematology consultation Interrupt treatment for suspected clozapine-induced neutropenia; no rechallenge unless benefits > risks If patient is rechallenged, resume treatment as a new patient under "normal range" monitoring once ANC ANC ≥ 1.5 × 10^9/L	**BEN severe neutropenia** Daily ANC until ≥ 0.5 × 10^9/L, then thrice weekly until ANC ≥ patient's baseline Recommend hematology consultation Interrupt treatment for suspected clozapine-induced neutropenia. Do not rechallenge unless benefit > risk. If patient is rechallenged, resume treatment as a patient under normal range monitoring once ANC ≥1.0 × 10^9/L or at patient's baseline
Whenever clozapine is discontinued	Weekly for at least 4 weeks from day of discontinuation	Weekly for at least 4 weeks from day of discontinuation

ANC, absolute neutrophil count (10^9/L is equivalent to 10^3/mm^3); BEN, benign ethnic neutropenia.

Although nonpharmacologic interventions such as relaxation techniques and decreasing sensory stimulation are most ideal for initial management, acutely psychotic and agitated patients also require pharmacologic interventions. Short-acting, intramuscular (IM) formulations are available for a number of FGAs (haloperidol most frequently) as well as the SGAs (aripiprazole, ziprasidone, and olanzapine). IM benzodiazepines are commonly used in addition to IM antipsychotics. IM lorazepam is generally suggested as it is the only benzodiazepine with rapid and complete IM absorption. Concomitant IM olanzapine and benzodiazepines may cause cardiorespiratory depression and should be avoided if possible. Loxapine oral inhalation is also available for acute agitation but is restricted to a REMS program and to enrolled health care facilities with onsite equipment and personnel to handle bronchospasm.

▶ *Pregnancy and Lactation*

Women with schizophrenia have higher rates of unwanted pregnancies and obstetric complications (eg, stillbirth, infant death, preterm delivery, low infant birth weight, and infants who are small for gestational age). Prolactin-related effects secondary to certain FGA and SGA treatments have led to infertility in the past. Irregular menstruation also complicated the ability to plan for pregnancies and potential false protection with sexual activity. When pregnancy occurs, the management of pregnancy and lactation in females with schizophrenia should include a multidisciplinary team and the patient's family should be involved if possible. The decision to continue antipsychotic must be weighed by the risks and benefits. The fetus is at risk for antipsychotic side effects but also the risk of relapse with schizophrenia during pregnancy is associated with a higher risk of birth complications. Guidelines suggest that antipsychotics are increasingly being used in pregnancy. Older data suggested teratogenic effects; however, larger and more recent epidemiologic studies find the majority of antipsychotics to be associated with no greater risk. Patients should still be cautioned that while the risk is low, congenital malformations have occurred rarely. There is now more published safety data with SGAs than FGAs. The safety data for FGAs is primarily for haloperidol. Low-potency phenothiazines may increase the risk of congenital abnormalities when used in the first trimester. There is some

Patient Encounter Part 4

The patient's aripiprazole dose was titrated to 30 mg once daily, which he was maintained on for 8 weeks. He returned again for follow-up with his outpatient psychiatrist who noted the patient was markedly worse. The patient looked disheveled and was answering questions with only a "yes" or "no." The patient admitted that he often skips his aripiprazole because he feels he does not need it. His mother reported that she does not observe him taking his medication but has suspected that he has not been taking it for at least a couple of weeks. The physician suggests that the patient consider getting "a shot" of aripiprazole once a month, then he would not need to take a pill every day. The patient's mother readily agrees that this is a reasonable solution. The patient is initially reluctant to get "a shot" but finally agrees, as he does not want to get into power struggles with his mother about whether or not he is taking his medication.

Over the next several months, he is more stable on the long-acting intramuscular form of aripiprazole, and he has not gained further weight. His eating habits are normal. He is less anxious, and his sleep is better.

How would a clinician discuss the advantages of taking a long-acting intramuscular medication?

What aripiprazole long-acting formulations are available?

What dose of aripiprazole LAI (Abilify Maintena) is appropriate for someone taking oral aripiprazole 30 mg once daily?

What if the patient was taking a strong CYP 3A4 inhibitor?

evidence to suggest a higher risk of congenital malformations with risperidone; however, this risk difference is only slightly higher at 5% versus 3% in the general population comparative group. If pregnancy occurs during antipsychotic treatment, continuation of previous antipsychotic is preferred to decrease relapse risk. Data do suggest that mothers who are pregnant have about a twofold risk of developing gestational diabetes; thus, monitoring and promoting healthy eating is very important. Babies born to mothers taking SGAs may also have increased birth weights compared to nonexposed mothers.[35,38] A labeling change for antipsychotic medications has been implemented by the FDA to address the potential risk for EPS and symptoms of withdrawal in newborns whose mothers were treated with antipsychotics in the third trimester. Withdrawal symptoms may include agitation, abnormal muscle tone (increased or decreased), tremor, sleepiness, and difficulty in breathing or feeding, which may last for hours to days after delivery. In some newborns, specific treatment for withdrawal is not needed, whereas in others, longer hospital stays may be required.

Although SGAs are excreted in breast milk, most case reports document a low frequency of deleterious effects on the infant. Breast feeding while on clozapine should be avoided.[35,38]

Pharmacokinetics

Most antipsychotics are, at least to some extent, metabolized by hepatic CYP450 metabolic enzymes to water-soluble compounds that are excreted by the kidneys (Table 37–9).[39] Unlike the other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system. Paliperidone, the 9-OH metabolite of risperidone, is mostly excreted unchanged in the urine, although up to one-third may be metabolized. The transmembrane energy-dependent efflux transporter P-glycoprotein may limit the ability of drugs to penetrate the blood–brain barrier and therefore impact pharmacologic activity in the brain. Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluphenazine, quetiapine, risperidone, paliperidone, aripiprazole, and olanzapine.[40]

Additive side effects may occur with combined drug therapies, and a few clinically significant drug interactions are notable (see Table 37–9). Cigarette smoking decreases serum concentrations of clozapine and olanzapine by induction of CYP1A2. Although antipsychotics are highly protein bound, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of lurasidone and ziprasidone. The mean maximum concentration of lurasidone increases threefold when administered with food, and ziprasidone's absorption is increased by 60% to 70% when given with meals.

Ziprasidone, iloperidone, and quetiapine have potential to prolong the QTc interval. Using them with other agents that prolong the QTc interval should be undertaken with caution. These other agents include, but are not limited to, quinidine, sotalol, chlorpromazine, droperidol, mesoridazine, pimozide, thioridazine, gatifloxacin, halofantrine, mefloquine, moxifloxacin, and pentamidine. Combining higher doses of ziprasidone, iloperidone, or quetiapine with ketoconazole or erythromycin should be undertaken cautiously.

Added pharmacodynamic effects are possible when combining antipsychotics with other drugs that can cause sedation, hypotension, anticholinergic symptoms, and weight gain or metabolic abnormalities.

Adjunct Treatments

The judicious use of pharmacologic therapies other than antipsychotics is often necessary for the treatment of motor side effects, anxiety, depression, mood elevation, and TRS that does not respond to clozapine. Anticholinergic medications (eg, benztropine, 1–2 mg twice daily; trihexyphenidyl, 1–3 mg thrice daily; and diphenhydramine, 25–50 mg twice daily) are used to treat EPS. They may be prescribed prophylactically with high-D_2-binding agents or in patients at risk for EPS or for treatment of EPS. β-Blockers (eg, propranolol 30–120 mg/day) are sometimes effective for patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (eg, lorazepam 1–3 mg/day) with the SGAs may be necessary for agitation.[27]

More recent guidelines suggest that regular assessment of depressive symptoms in schizophrenia is important and that waiting for the effect of antipsychotics to work instead of immediately adding an antidepressant is recommended. Evidence suggests that SGAs may be more effective than FGAs for depressive symptoms in people with schizophrenia; however, this evidence is limited.[35] Antidepressants may be useful for patients with schizophrenia who have depressive symptoms in the stable phase of schizophrenia; however, these agents may have the potential to worsen symptoms in the acute phase.[35] Because suicide risk may be increased, aggressive treatment may

Table 37–9

Metabolism and Drug Interactions with Antipsychotics

Antipsychotic	Major Metabolic Pathways	Other Metabolic Pathways	Increase Antipsychotic Concentrations	Decrease Antipsychotic Concentrations
Aripiprazole	CYP 3A4	CYP 2D6	Fluvoxamine, ketoconazole	Carbamazepine
Asenapine	Glucuronidation by UGT1A4 and CYP 1A2	CYP 3A4, CYP 2D6	Fluvoxamine	
Brexpiprazole	CYP 3A4, 2D6		Itraconazole, clarithromycin, ketoconazole, quinidine, paroxetine, fluoxetine	Rifampin, St. John's wort
Cariprazine	CYP 3A4	CYP 2D6	Itraconazole, ketoconazole	Rifampin, carbamazepine (use not recommended with strong CYP3A4 inducer)
Chlorpromazine	CYP 2D6	CYP 1A2, CYP 3A4		
Clozapine	CYP 1A2	CYP 3A4, CYP 2D6, CYP 2C19, CYP 2C9	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Fluphenazine	CYP 2D6		Paroxetine	
Haloperidol	CYP 2D6, CYP 3A4	CYP 1A2	Fluvoxamine, fluoxetine, ketoconazole	Carbamazepine
Iloperidone	CYP 2D6, CYP 3A4	CYP 1A2, CYP 2E1	Ketoconazole, fluoxetine, paroxetine	
Loxapine	CYP 1A2, CYP 2D6, CYP 3A4			
Lurasidone	CYP 3A4		Ketoconazole, diltiazem	Rifampin
Olanzapine	CYP 1A2, Glucuronidation by UGT1A4	CYP 2D6	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Paliperidone	CYP 2D6, CYP 3A4 (in vitro, but limited role in vivo)		Divalproex sodium, paroxetine	Carbamazepine (via increased renal elimination)
Perphenazine	CYP 2D6		Fluvoxamine, fluoxetine, paroxetine	
Pimozide	CYP 3A4	CYP 1A2	Strong CYP 2D6 inhibitors, CYP 3A4 inhibitors	CYP 3A4 inducers
Quetiapine	CYP 3A4	CYP 2D6	Fluvoxamine, ketoconazole	Carbamazepine
Risperidone	CYP 2D6	CYP 3A4	Fluoxetine, paroxetine	Carbamazepine
Thioridazine	CYP 2D6	CYP 2C19	Fluvoxamine	Cigarette smoking
Thiothixene	CYP 1A2		CYP 1A2 inhibitors	CYP 1A2 inducers
Trifluoperazine	CYP 1A2		CYP 1A2 inhibitors	CYP 1A2 inducers
Ziprasidone	Aldehyde oxidase	CYP 1A2, CYP 3A4	Fluvoxamine, ketoconazole	Carbamazepine

CYP450, cytochrome P450 isoenzyme.

be necessary when depression is present. The selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but they may inhibit the CYP450 enzymes, thus raising plasma concentrations of clozapine, olanzapine, and haloperidol. Mood stabilizers, such as lithium and the anticonvulsants, have been used adjunctively with the antipsychotics to treat the affective component of schizoaffective disorder.[35]

For patients with an inadequate response to clozapine, limited treatment options are available for these patients. A number of augmentation strategies have been tried, including FGAs, SGAs, mood stabilizers (eg, lithium, valproate, and topiramate), minocycline, antidepressants, transcranial magnetic stimulation (TMS), and **electroconvulsive therapy** (ECT). Though controlled trial results are mixed, some data support the adjunctive use of risperidone, lamotrigine, or aripiprazole in clozapine-treated patients.[30]

Psychosocial Treatment

KEY CONCEPT Psychosocial support helps improve functional outcomes. Residual symptoms often persist such as avolition, isolation, and impaired social functioning, limiting participation in social, vocational, and educational endeavors. Psychosocial interventions, as adjuncts to pharmacotherapy, are designed to improve psychosocial functioning, self-esteem, and life satisfaction. In the United States, psychosocial treatments are less frequently used than in Europe, but their use is on the rise and current guidelines suggest nonpharmacologic strategies in conjunction with antipsychotic treatment. There are much data to support family education in decreasing relapse rates and vocational support to improve vocational outcomes. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills training (SST), cognitive behavioral therapy (CBT), and cognitive remediation (CR). In addition, psychoeducation, supported employment, Assertive Community Treatment (ACT), and Medical Home care models have improved outcomes.[12,41]

Patient Education

KEY CONCEPT Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of treatment adherence must be ongoing and integrated into pharmacologic management. Medication management discussions offer an opportunity to provide illness and treatment education including the nature and course of schizophrenia, and can serve as a time to hear the patient's life goals. Key considerations include:

Patient Encounter Part 5

The patient has remained on aripiprazole long-acting injection for nearly a year, but the patient's paranoia returned and he felt agitated on the drug. Over the next 2 years, he was switched to various other agents including ziprasidone, perphenazine, and olanzapine, to which he only had a partial response. At his most recent outpatient appointment, the doctor suggested that he might benefit from a trial of clozapine, but the patient was not sure if clozapine was right for him. In a separate phone call to his parents, his doctor reviewed the pros and cons of the clozapine trial. The patient and his parents discussed everything they discussed with the doctor and agreed to a trial of clozapine.

Why is his clinician considering a clozapine trial?

What are the rare serious side effects of clozapine versus the common manageable side effects?

The patient still smokes cigarettes. How will cigarette smoking affect clozapine therapy?

LO 6

- Involve families in the education and treatment plans because family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.[40]
- Be clear that there is no cure for schizophrenia and that medication can be effective to decrease and improve many symptoms.
- Explain common and rare but dangerous side effects.
- Stress the importance of medication and treatment adherence for improving long-term outcomes.
- Decision making on the best course of treatment should be a shared process.

OUTCOME EVALUATION

Developing a good working alliance with the patient is essential. In the absence of a solid therapeutic relationship, patients are frequently reluctant to share their beliefs, personal experiences, and life goals.

Symptom Monitoring

Many assessments are available to objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales in clinical trials to measure symptoms include:

- Positive and Negative Symptom Scale (PANSS)
- Brief Psychiatric Rating Scale (BPRS)
- Clinical Global Impression (CGI) Scale
- Calgary Depression Scale for Schizophrenia (CDSS)

LO 7

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable means of monitoring symptoms. Symptom assessments cannot capture the full range of possible improvements, but they can be useful in deciding whether a medication is having substantial benefit.

Side-Effect Monitoring

LO 7

KEY CONCEPT Regularly monitor for side effects and overall health status.[27,31] Perform orthostatic blood pressure measurements and vital sign assessments before initiating antipsychotics and regularly throughout treatment. Ask about prolactin-related side effects such as impaired menstruation, libido, and sexual performance regularly. At baseline check body weight, fasting glucose, and lipid profile, and repeat these measurements 12 weeks after initiation of medication and then yearly.[42] For patients at higher risk of developing diabetes and those who gain weight, check body weight more often (Table 37–10). Every effort should be made to help with weight and metabolic side effects.[6,43–45] Metformin may be an option in addition to nonpharmacologic techniques for weight loss or attenuation of weight gain.[46]

Additionally, perform baseline electrocardiography for patients with preexisting cardiovascular disease or risk for arrhythmia. With clozapine therapy, there is a risk for the development of severe neutropenia, which is greatest in the first 6 months of treatment. Required monitoring of absolute neutrophil count (ANC) is described in Table 37–8. Separate monitoring guidelines now exist for general patients and those with Benign Ethnic Neutropenia. Overall, encourage patients to have annual physical, gynecologic, and ophthalmologic examinations and regularly ask about physical health and side effects at each visit.

LO 7

Table 37–10

Cardiometabolic Monitoring Protocol for Patients on Second-Generation Antipsychotics

	Baseline	4 Weeks	8 Weeks	12 Weeks	Annually
Personal or family history[a]	X				X
Weight (BMI)	X	X	X	X	X
Waist circumference	X	X		X	X
Blood pressure	X	X		X	X
Fasting plasma glucose	X			X	X
Fasting plasma lipids	X			X	X
ECG	X				X

[a]Of obesity, diabetes, dyslipidemia, hypertension, or cardiovascular disease.

Patient Care Process

Collect Information:

- Chief complaint and history of present illness
- Family history, psychiatric history (age when first diagnosed, time of first hospitalization for mental illness), medical history. Obtain collateral information from family, past medical records, and other providers to help clarify the psychiatric history.
- Social history (housing arrangements, social and vocational goals, support systems, employment, substance use history)
- Physical examination
- Key laboratory data and imaging studies
- Mental status examination
- Past and current medications (psychiatric and somatic, prescription, nonprescription, herbal or other dietary supplements)

Assess the Information:

- Review the patient's chief complaint, presenting symptoms, and history, including psychiatric history. Assess mental status examination for organization of thoughts and range of affect, presence of mood disturbance, likelihood of harm to self or others, and presence of hallucination, paranoia and/or delusions of control, evaluate judgment and insight.
- Assess medical records, including laboratory and imaging studies, to rule out medical causes of psychosis.
- Assess current treatments and outcomes of prior treatments for effectiveness and safety.
- Assess adherence to medications and willingness to take medications.

Develop a Care Plan:

- Identify medication-related problems.
- Determine the goals of therapy.
- Select or optimize the dose of an antipsychotic based on the side-effect profile that is most appropriate and acceptable to the patient.
- Collaborate with other health care professionals or caregivers in the development of the plan.
- Consider how income, insurance coverage, and access to care might influence pharmacotherapy choice.

Implement the Care Plan:

- Initiate, modify, discontinue, or administer the appropriate medication therapy.
- Educate patient and caregiver (with patient consent) about the illness, medication treatments, possible side effects, and goals of treatment.
- Discuss medication adherence and healthy lifestyle goals, including substance and cigarette use.
- Enlist adjunctive treatments, including psychosocial therapies to optimize outcomes.
- Coordinate referrals or transition of care to other health care professionals, such as social workers, home care nurses, or other medical specialists.
- Recommend placement of individuals in ACT, group homes, transitional housing, rehabilitation, or long-term care.
- Schedule follow-up appointments.

Follow-up: Monitor and Evaluate:

- Monitor medication therapy for effectiveness, using psychiatric rating scales when necessary.
- Monitor medication therapy for adverse events of antipsychotics using the AIMS, Simpson–Angus Scale, and Extrapyramidal Symptom Rating Scale.
- Monitor appropriate laboratory measures to prevent or minimize adverse effects, including metabolic abnormalities.
- Assess for emergence of new target symptoms.
- Monitor for adherence to the medication regimen.
- Optimize dosing and consider clozapine if criteria are met for treatment resistance.

Commonly used rating scales to monitor for EPS include the Simpson–Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias could represent the emergence of TD. Monitor patients on SGAs for TD at least annually, and patients taking FGAs at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

Abbreviations Introduced in This Chapter

5-HT	Serotonin
ACT	Assertive Community Treatment
AIMS	Abnormal Involuntary Movement Scale
ANC	Absolute neutrophil count
APA	American Psychiatric Association
BAS	Barnes Akathisia Scale
BPRS	Brief Psychiatric Rating Scale
CATIE	Clinical Antipsychotics Trials of Intervention Effectiveness
CBT	Cognitive behavioral therapy
CGI	Clinical Global Impression Scale
CR	Cognitive remediation
CYP450	Cytochrome P450 isoenzyme
D	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
ECT	Electroconvulsive therapy
EPS	Extrapyramidal symptoms
ESRS	Extrapyramidal Symptom Rating Scale
FDA	Food and Drug Administration
FGA	First-generation antipsychotic
H	Histamine
IM	Intramuscular
LAI	Long-acting injection
M	Muscarinic

NMDA	*N*-methyl-D-aspartate
NMS	Neuroleptic malignant syndrome
PANSS	Positive and Negative Symptom Scale
PCP	Phencyclidine
PORT	Schizophrenia Patient Outcomes Research Team
QTc	Corrected QT interval
SAS	Simpson–Angus Scale
SGA	Second-generation antipsychotic
SSRI	Selective serotonin reuptake inhibitor
SST	Social skills training
TD	Tardive dyskinesia
TIMA	Texas Implementation of Medication Algorithms
TMS	Transcranial magnetic stimulation
TRS	Treatment Resistant Schizophrenia
WBC	White blood cell

38 Major Depressive Disorder

J. Michael McGuire, Cherry W. Jackson, and Marshall E. Cates

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Explain the etiology and pathophysiology of major depressive disorder (MDD).
2. Identify the signs and symptoms of MDD.
3. Outline the treatment goals for a patient with MDD.
4. Recommend pharmacotherapy given a specific patient with MDD.
5. Develop a monitoring plan for a specific patient with MDD which includes the assessment of efficacy as well as adverse effects.
6. Predict, prevent, identify, and resolve potential drug-related problems.
7. Educate patients and caregivers on the proper use of antidepressant therapy.

INTRODUCTION

Major depression is a common, seriously disabling, disorder nonresponsive to volitional efforts to feel better. Individuals with major depressive disorder (MDD) experience pervasive symptoms affecting mood, thinking, physical health, work, and relationships. Suicide often results when MDD is inadequately diagnosed and treated.[1]

Over and under detection of MDD is an important consideration. Primary care providers have become increasingly involved in the management of MDD. Studies show that over detection of MDD can outnumber missed cases.[1] Antidepressants account for 15 of the top 200 prescription drugs dispensed in the United States.[2] Inadequate treatment remains a serious concern.[3]

EPIDEMIOLOGY AND ETIOLOGY

The lifetime and 12-month prevalence estimates for MDD are 16.2% and 6.6%, respectively.[4] Women are twice as likely as men to experience MDD.[5] In the United States, incidence peaks in the twenties. Many patients with MDD have comorbid psychiatric disorders, especially anxiety and substance use disorders.[5]

According to the World Health Organization (WHO), depression is the leading cause of disability worldwide and a major contributor to the overall global burden of disease.[6]

The etiology of depression is complex and is hypothetically due to a change in the brain neurotransmitters, primarily norepinephrine (NE), serotonin (5-HT), and dopamine (DA).[7]

Patient Encounter Part 1

A 43-year-old woman presents to the psychiatry clinic with complaints of depressed mood, poor sleep, and decreased appetite. She has lost 25 pounds (11.4 kg) in the last 2 months. She also has been isolating herself from other people, and has had crying spells. She says that she has been thinking about committing suicide, but she does not have a specific plan.

What symptoms of MDD does she have?

What medical or psychiatric issues could be contributing to her symptoms?

What additional information do you need to know before creating a treatment plan for this patient?

PATHOPHYSIOLOGY

LO 1

The cause of MDD is unknown but is probably multifactorial. Multiple theories abound, and practitioners suggest that development of depression likely involves a complex interaction of genetic predisposition, psychological stressors, and underlying pathophysiology. There are no currently accepted unifying theories to adequately explain the pathophysiology of depression.[7]

Genetics

First-degree relatives of MDD patients are about two to four times more likely to develop MDD compared with controls.[5] Adoption and twin studies also suggest that MDD is due to genetic influences.[8] Major depression has been associated with four different genes including polymorphisms in the glucocorticoid receptor gene NR3C1, the monoamine oxidase A gene, the gene for glycogen synthase kinase-3β, and a group-2 metabotropic glutamate receptor gene (GRM3).[9]

Stress

Major life stressors do not always cause depression. Nevertheless, there is an undeniable association between life stressors and depression, and there appears to be a significant causative interaction between life stressors and genetic predisposition. Although acute stressors may precipitate depression, chronic stressors cause longer episodes and are more likely to lead to **relapse** and **recurrence**.[10]

Biogenic Amine and Receptor Hypotheses

KEY CONCEPT The primary hypothesis is the biogenic amine hypothesis which states that a deficit of NE, DA, or 5-HT at the synapse is the cause of depression.[7] The fact that existing antidepressants increase synaptic monoamine concentrations supports this hypothesis (see Pharmacologic Therapy). One argument against this hypothesis is that patients with depression do not always have decreased monoamine levels. Additionally, monoamine levels are altered within hours of initiating antidepressant therapy, but **response** is delayed by 2 to 4 weeks or more.[7]

The receptor hypothesis suggests that depression is related to upregulation of **monoamine neurotransmitter** receptors in response to a depletion of monoamine neurotransmitters. In this hypothesis, chronic administration of antidepressants alters receptor sensitivity causing desensitization or downregulation of monoamine neurotransmitter receptors leading to therapeutic response.[7] Importantly, the time required for changes in receptor sensitivity correlates with antidepressant onset.[7] These hypotheses are clearly oversimplifications of the pathophysiology of depression. MDD probably involves a complex dysregulation of monoamine systems that modulate and are modulated by other neurobiological systems.

Other Neurobiological Hypotheses

At least three categories of peripheral hormones are associated with the pathophysiology of depression. They include (a) neurotrophic and other growth factors including brain-derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF), and insulin-like growth factor; (b) proinflammatory cytokines including interleukin-1β, interleukin-6, and tumor necrosis factor-α; and (c) the hypothalamic pituitary axis (HPA).[9]

Proinflammatory cytokines are increased in individuals with MDD, and antidepressants suppress the synthesis of these cytokines.[9] HPA axis regulation is impaired in depression, and antidepressants can attenuate the neuroendocrine response.[9] Similarly, BDNF is decreased in patients with MDD, and antidepressants reverse this response.[9]

CLINICAL PRESENTATION AND DIAGNOSIS

LO 2

The diagnosis of a major depressive episode (MDE) requires the presence of five depressive symptoms for a minimum of 2 weeks that cause clinically significant distress or impairment.[5] The diagnosis of MDD is based on the presence of one or more MDEs during a person's lifetime (Table 38–1).[5]

Differential Diagnosis

MDEs also occur in bipolar disorder. Individuals with bipolar disorder also experience hypomanic, manic, or mixed episodes (see Chapter 39) during the course of their illness, but individuals with MDD do not.[5]

Conditions that may mimic or coexist with MDD are anxiety, personality, and substance use disorders.[5] Several chronic medical conditions also have strong correlations with MDD. MDD is associated with a 65% increased risk of diabetes in elderly patients.[11] MDD is also strongly correlated with coronary artery disease.[11] Other medical disorders associated with depression include hypothyroidism, cancer, anemia, infections, electrolyte disturbances, folate deficiency, neurologic disorders, and cardiovascular and respiratory disease.[5,11] Identification and treatment of MDD in patients with chronic medical conditions is important. Inadequate recognition and undertreatment of depression may increase the mortality associated with these medical disorders.[11] Use of central nervous system (CNS) depressants, such as alcohol, benzodiazepines, or narcotics, is associated with an increased incidence of depression.[5,12] Some drugs that cause depressive symptoms include corticosteroids, contraceptives, phenobarbital, levetiracetam, topiramate, vigabatrin, gonadotropin-releasing hormone agonists, interferon-α, interleukin-2, varenicline, mefloquine, isotretinoin, propranolol, clonidine, methyldopa, and reserpine.[12]

Persistent depressive disorder (dysthymia) is a chronic form of depression that must be differentiated from MDD.[5] Many symptoms of dysthymia are similar to those of MDD, but they are chronic and milder.[5] Symptoms must be present for at least 2 years and may include sleep and appetite disturbances, lack of energy, poor self-image, and difficulty making decisions.[5] Individuals with dysthymia are more likely to develop MDD than the general population.[5]

Table 38–1

Clinical Presentation of Depression: Diagnostic Criteria for Major Depressive Episode[5]

At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning.

- Depressed mood[a]
- Markedly diminished interest or pleasure in usual activities[a]
- Increase or decrease in appetite or weight
- Increase or decrease in amount of sleep
- Increase or decrease in psychomotor activity (ie, agitation or retardation)
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Diminished ability to think, concentrate, or make decisions
- Recurrent thoughts of death, suicidal ideation, or suicide attempt

The symptoms cause clinically significant distress or impairment in functioning.

The symptoms are not due to the direct physiologic effects of a substance or medical condition.

[a]One of these two symptoms must be present.

Data from American Psychiatric Association. Major Depressive Disorders. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association, 2013:160–168.

COURSE AND PROGNOSIS

MDD may affect an individual at any age including children and elderly, although, as previously stated, the incidence peaks in the 20s in the United States.[5] Some individuals will experience only one episode of depression, others will experience distinct episodes with few or no symptoms between, while others will rarely experience **remission**. The course of MDD varies markedly between patients.[5] KEY CONCEPT It is not uncommon for a patient to experience only a single MDE, but most patients with MDD experience multiple episodes. The longer an individual is in remission, the lower their risk of recurrence. Individuals with longer symptom duration, psychotic features, prominent anxiety, and severe symptoms predict lower recovery rates.[5] The risk of recurrence increases in individuals with persistent mild depressive symptoms, severe episodes, younger age, and in those with a history of previous episodes.[5,13]

MDD is a risk factor for suicide.[14] The WHO estimates that nearly 800,000 people die from suicide every year and suicide is the second leading cause of death among 15- to 29-year olds.[6]

TREATMENT

Desired Outcomes

LO 3 The goal of therapy for patients with MDD is resolution of depressive symptoms, return to **euthymia,** and prevention of relapse and recurrence of symptoms.[14] KEY CONCEPT One extremely important goal is prevention of suicide attempts. LO 3 Other desired outcomes include improving quality of life including normalization of functioning in areas such as work and relationships, minimization of adverse effects, and reduction of health care costs.[14]

Nonpharmacologic Therapy

Evidence supports efficacy of interpersonal and cognitive-behavioral therapy in the treatment of MDD. Psychotherapy alone is an initial treatment option for mild to moderate depression, and it may be useful when combined with pharmacotherapy for the treatment of severe depression.[14] This combination can be more effective than either treatment alone in severe or recurrent MDD.[14] Combination treatment may be helpful for patients with psychosocial stressors, interpersonal difficulties, or comorbid personality disorders.[14]

Electroconvulsive therapy (ECT) is a highly efficacious and safe treatment alternative for MDD. The response rate is about 70% to 90%, and it exceeds 50% for patients who have failed pharmacotherapy.[14] ECT may be beneficial for MDD that is complicated with psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication or nonresponse to pharmacotherapy.[14] Typically, 6 to 12 treatments are necessary with response occurring in 10 to 14 days.[14] When ECT is discontinued, antidepressants are initiated to help maintain response. In addition, some patients will receive maintenance ECT with/without antidepressants. Side effects after ECT include temporary confusion and retrograde and anterograde amnesia.[14]

Light therapy may be an effective alternative treatment for depression associated with seasonal (eg, winter) exacerbations.[15] Side effects can include eye strain and mania.[14,15]

Vagus nerve stimulation (VNS) was approved by the Food and Drug Administration (FDA) in 2005 for treatment-resistant depression.[14] A pulse generator is surgically implanted around the vagus nerve which sends signals to the brain that may help relieve depressive symptoms.[16] Adverse effects of VNS include alterations in patients' voice, hoarseness, dyspnea, and neck pain.[14]

Transcranial magnetic stimulation is a noninvasive and well-tolerated procedure that is FDA approved for use after one failed trial of an antidepressant.[14,17] Physical exercise may reduce depressive symptoms, but well-controlled studies are needed to verify this.[18]

Pharmacologic Therapy

Individual antidepressants, even those within the same class, have important pharmacologic differences (**Tables 38–2** and **38–3**).[7,19] Clinicians and treatment guidelines categorize antidepressants by pharmacologic mechanism of action, chemical structure or whether the medication is a "newer antidepressant" which includes all of the nonmonoamine oxidase inhibitors (MAOIs) and nontricyclic antidepressants (TCAs) or "older antidepressants" which includes the MAOIs and TCAs.

▶ *Selective Serotonin Reuptake Inhibitors*

The primary action of the selective serotonin reuptake inhibitors (SSRIs) is serotonin reuptake inhibition (SRI), although each agent in the class has unique pharmacological profiles.[7] For example, paroxetine has mild anticholinergic effects, citalopram has mild antihistaminic effects, and fluoxetine antagonizes the 5-HT2C receptor which may contribute to its antibulimia effects.[7]

Patient Encounter Part 2

PMH: History of chronic migraine headaches, irritable bowel syndrome.

Past Psych History: She has had multiple psychiatric hospitalizations with the last being 2 years prior to this admission. She has a history of MDD.

FH: Mother had diabetes mellitus and MDD, died at age 60; father had a history of alcoholism and died at age 58; brother is a recovering alcoholic.

SH: Completed 4 years of college with bachelor's degree. Most recently, employed as a representative in the pharmaceutical industry but position was eliminated about 3 months ago. Drinks socially—admits to drinking several glasses of wine nightly recently after loss of her job. Married with two teenage children. Denies tobacco use.

Current Meds:

- Sertraline 200 mg by mouth daily
- Propranolol LA 80 mg by mouth once daily
- Dicyclomine 10 mg by mouth three times daily as needed
- Aspirin/acetaminophen/caffeine by mouth as needed for migraine headache

ROS: Decreased sleep; decreased appetite; weight loss; all others noncontributory

PE:

VS: Ht 5'7" (170 cm), Wt 120 lbs (54.5 kg), weight loss of 25 lbs (11.4 kg) over past 8 weeks

MSE: Depressed mood, decreased sleep, decreased appetite, isolation, positive suicidal ideation without plan

Labs: Within normal limits. Urine drug screen—negative

Given this additional information, what is your assessment of the patient's condition?

Does she have risk factors for depression?

Identify treatment goals for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient?

[a]See text for discussion of secondary pharmacologic actions.

Bup, bupropion; MAOI, monoamine oxidase inhibitor; Mirtaz, mirtazapine; Nefaz, nefazodone; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; Traz, trazodone; Vilaz, vilazodone; Vorti, vortioxetine.

▶ *Serotonin Norepinephrine Reuptake Inhibitors*

Venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran are 5-HT and NE reuptake inhibitors (SNRIs). Compared with venlafaxine and desvenlafaxine, which have primarily SRI activity and dose-related affinity for norepinephrine reuptake inhibition (NRI), duloxetine has more balanced SRI and NRI activities.[7] Levomilnacipran has higher activity at NRI than SRI.[7]

▶ *Norepinephrine Dopamine Reuptake Inhibitor*

Bupropion is an NE and DA reuptake inhibitor (NDRI). Bupropion's effects on NRI and DRI are weak but it is an efficacious antidepressant.[7] Bupropion is generally activating and may be especially useful at improving energy, alertness, as well as other symptoms of depression.[7]

▶ *Serotonin Antagonist and Reuptake Inhibitors*

Nefazodone and trazodone are 5-HT antagonists.[7] Their SRI activity is not as pronounced as that of the SSRIs, but they potently block 5-HT$_{2A}$ receptors, which allow more 5-HT to interact at postsynaptic 5-HT$_{1A}$ sites.[7] In addition, trazodone blocks histaminergic and α-adrenergic receptors, and nefazodone possesses weak NRI and α-adrenergic blocking properties.[7]

Table 38–3

Efficacy and Adverse Effect Profile Based on Pharmacology[7,9]

Pharmacologic Action	Result
SRI	Antidepressant and antianxiety efficacy (via interaction of 5-HT at 5-HT$_{1A}$ receptors) Anxiety, insomnia, sexual dysfunction (via interaction of 5-HT at 5-HT$_{2A}$ receptors) Anxiety, anorexia (via interaction of 5-HT$_{2C}$ receptors) Nausea, GI problems (via interaction of 5-HT at 5-HT$_3$ receptors)
NRI	Antidepressant efficacy Tremor, tachycardia, sweating, jitteriness, increased blood pressure
Dopamine reuptake inhibition	Antidepressant efficacy, euphoria, psychomotor activation, aggravation of psychosis
α_2-Adrenergic receptor blockade	Increase in serotonergic and noradrenergic activity—see actions of SRI and NRI above
Serotonin$_{1A}$ receptor agonist	Antianxiety, antidepressant augmentation, decreased blood pressure
Serotonin$_{1A}$ partial agonism	Antianxiety, antidepressant augmentation, decreased blood pressure, decreased heart rate
Serotonin$_{2A}$ receptor blockade	Antianxiety efficacy Increased REM sleep; decreased sexual dysfunction
Serotonin$_{2C}$ receptor blockade	Antianxiety efficacy Increased appetite or weight gain
Serotonin$_3$ receptor blockade	Antiemetic, decreased GI problems
Serotonin$_7$ receptor blockade	Antidepressant, modulates glutamate
α_1-Adrenergic receptor blockade	Orthostatic hypotension, dizziness, reflex tachycardia
Histamine-1 receptor blockade	Sedation, weight gain
Muscarinic cholinergic receptor blockade	Dry mouth, blurred vision, constipation, urinary hesitancy, sinus tachycardia, memory problems

GI, gastrointestinal; 5-HT, serotonin; NRI, norepinephrine reuptake inhibition; REM, rapid eye movement; SRI, serotonin reuptake inhibition.

▶ *Miscellaneous*

Vilazodone is best characterized pharmacologically as an SRI and a partial agonist at 5-HT_{1A} receptors. The 5-HT_{1A} effect is thought to reduce negative feedback on endogenous serotonin receptors which may improve the medication's antidepressant effect.[7] Vortioxetine is an agonist/antagonist/partial agonist at various 5-HT receptors.[20] Vortioxetine has affinity for β-adrenergic receptors which may be associated with side effects, and histaminic and acetylcholinergic receptors which may have a positive effect on memory.[20] Finally, mirtazapine is a **noradrenergic** and specific serotonergic antidepressant. It blocks presynaptic α_2 **autoreceptors** on noradrenergic neurons and **heteroreceptors** on serotonergic neurons, resulting in increases in NE and 5-HT synaptic concentrations.[7] Mirtazapine also blocks postsynaptic serotonergic receptors and histamine-1 receptors at lower doses inducing sleep and weight gain. At higher doses histaminic activity is offset by noradrenergic activity which reduces its effects on sleep and weight gain.[7,21]

▶ *Monoamine Oxidase Inhibitors*

MAOIs inhibit the enzyme responsible for the breakdown of 5-HT, NE, and DA.[7] There are two main forms of the MAO enzyme—MAO-A and MAO-B.[7] MAO-A and MAO-B are both located in the brain and MAO-A is also present in the gut. MAO-A is responsible for the breakdown of 5-HT, DA, NE, and tyramine.[7] MAO-B is responsible for the breakdown of dopamine, phenylethylamine, and tyramine.[7] Dietary restrictions limiting the consumption of tyramine are necessary for orally available MAOIs due to inhibition of MAO-A in the gut.[7] Dietary restrictions are not required for the transdermal formulation of selegiline at the starting dose of 6 mg/24 hours.[7]

▶ *Tricyclic Antidepressants*

The TCAs possess both SRI and NRI properties, but they also block other receptors, including α_1-adrenergic, histamine-1, and muscarinic cholinergic receptors, which contribute to side effects.[7]

Complementary and Alternative Treatments

St. John's wort (*hypericum perforatum*) is an herbal medication that has shown efficacy in mild to moderate depression, but minimal efficacy for moderate to severe depression.[14] It has mild MAO-inhibiting properties.[22] Many patients believe that herbal medications are devoid of adverse effects and drug interactions; however, St. John's wort can cause gastrointestinal (GI) irritation, headache, fatigue, and nervousness. It also triggers drug interactions through induction of CYP3A4 enzymes, as well as P-glycoprotein.[22] The safety and efficacy of St. John's wort combined with standard antidepressant medications remains unknown.[14,22]

Levels of s-adenosyl methionine (SAM-e), a naturally occurring compound in the body, tends to be lower in people with major depression.[23] It is sold as a nutritional supplement and lacks the standardization of medications that are FDA approved.

Low folate levels are associated with a greater risk of depression or a lack of response to antidepressants.[14] Because folic acid prevents neural tube defects in pregnancy and causes few to no adverse effects, it may be used in doses of 0.4 to 1 mg/day to improve the efficacy of the antidepressants.[14] L-methylfolate is the active metabolite of folate and is a prescription medical food approved for use in MDD along with an antidepressant.[18,24]

Low doses of omega-3 fatty acids (eicosapentaenoic, docosahexaenoic acid, or both) have been used adjunctively for major depression.[25] More studies are needed to establish their role in MDD.[14,25]

Adverse Effects

The adverse effects of the antidepressants are often a function of their underlying pharmacologic profiles (see Table 38–3).

The adverse effect profile of the SSRIs includes sexual dysfunction (eg, delayed or absent orgasms), CNS stimulation (eg, nervousness and insomnia), GI disturbances (eg, nausea and diarrhea), weight gain, anhedonia, and fatigue.[19] CNS stimulation, GI disturbances, headache, and fatigue are often transient and improve with time.[7] KEY CONCEPT Sexual dysfunction, common and challenging to manage, may lead to nonadherence.[26] Various strategies to manage antidepressant-induced sexual function include waiting for symptoms to subside, reducing the dosage, permitting periodic "drug holidays," prescribing adjunctive therapy, and switching antidepressants.[14,26] Some patients, however, report an improvement in sexual functioning as a result of improvement in depressive symptoms.[26] Reducing the dose and using drug holidays may weaken the antidepressant effects.[26] Clinicians often prescribe adjunctive therapy such as dopaminergic drugs (eg, bupropion), 5-HT_2 antagonists (eg, cyproheptadine), and phosphodiesterase inhibitors (eg, sildenafil) or simply switch to antidepressants with less likelihood of causing these effects, such as bupropion, mirtazapine, nefazodone, or vortioxetine.[26]

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect is **seizures**.[14,19] Because of the risk for seizures, patients with a CNS lesion, history of seizure disorder, head trauma, anorexia, or bulimia should not receive bupropion.[14,24] The total daily dose of bupropion should not exceed 450 mg/day (immediate release and extended release), and any single dose of the immediate-release formulation should not exceed 150 mg.[24] The maximum dose of sustained release is 200 mg twice daily.[24] Insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.

The adverse effects of the SNRIs are similar to those of the SSRIs.[14] Nausea can be troublesome with venlafaxine and desvenlafaxine, which sometimes necessitates using lower starting doses and giving the medication with food.[14] A dose-related elevation in blood pressure can occur at higher doses, and blood pressure monitoring should be conducted for patients receiving venlafaxine or desvenlafaxine.[14] Duloxetine should not be prescribed to patients with substantial alcohol use or evidence of chronic liver disease owing to the potential for hepatic injury.[24]

Trazodone causes sedation, and it is used more often as an adjunct with other antidepressants for sleep than as an antidepressant.[14] **Priapism** is a rare but serious adverse effect in men taking trazodone.[14] There have been no reported cases of priapism with nefazodone.[14] Unfortunately, nefazodone has been associated with development of fatal **hepatotoxicity**, which led to a black-box warning and significant reduction in its use.[14]

Mirtazapine can cause sedation and weight gain by blocking histamine-1 receptors.[7] Despite being partially a serotonergic drug, it rarely causes serotonergic-related adverse effects because it also blocks various postsynaptic 5-HT receptors.[7] Although it carries a bolded warning for neutropenia due to a handful of cases reported during clinical trials, it is questionable whether neutropenia is more problematic with mirtazapine than other antidepressants.[14,27]

The TCAs cause sedative, anticholinergic, and cardiovascular adverse effects.[7] Although adverse effects are common, they can be serious in some cases. The tertiary TCAs (eg, amitriptyline, imipramine) are more sedating and anticholinergic than the secondary TCAs (eg, desipramine, nortriptyline).[14] The TCAs

have a quinidine-like effect on the heart, which makes them toxic in overdose.[7] The average lethal dose of a TCA can occur with as little as 15 mg/kg in a young adult which is typically less than a 1-month supply.[19]

The relative incidence of adverse effects among the newer antidepressants is shown in Table 38–4.

Pharmacokinetic Parameters

Pharmacokinetic parameters related to the newer antidepressants are shown in Table 38–5. Several antidepressants are not highly protein bound; the most notable of these are venlafaxine, desvenlafaxine, and levomilnacipran.[24] The elimination half-lives of paroxetine, nefazodone, and venlafaxine are relatively short compared with the other agents.[24,28] Conversely, fluoxetine has a very long half-life (ie, 4–6 days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life.[14,24] Because of this, a 5-week washout of fluoxetine is required before starting an MAOI, whereas a 2-week washout is generally considered sufficient for other serotonergic agents.[14] Several antidepressants have notable active metabolites including

Table 38–5

Pharmacokinetic Parameters of Newer Antidepressants[14,24,33]

Drug	Protein Binding (%)	Elimination Half-Life (hours)	Active Metabolite	Cytochrome P450	
				Substrate	Inhibitor

amitriptyline (nortriptyline), imipramine (desipramine), and venlafaxine (desvenlafaxine), which have all been approved separately for the treatment of depression. Other antidepressants such as sertraline and citalopram also have active metabolites, but these metabolites (desmethylsertraline and desmethylcitalopram, respectively) are only about one-eighth as potent as the parent compounds for SRI activity.[29]

Drug Interactions

LO 6

Antidepressant drug interactions can be pharmacokinetic or pharmacodynamic resulting in a variety of drug-related problems. The usual pharmacodynamic drug interactions involve the "dirty receptors" blocked by some antidepressants (eg, H1, muscarinic).[7] TCAs can cause significant additive effects with other drugs that cause sedation, hypotension, or anticholinergic effects.[7,14] Similarly, trazodone can interact with other drugs that cause hypotensive and sedative effects.[14] By far, the most concerning pharmacodynamic interactions are hypertensive crisis and serotonin syndrome, which are both life-threatening. Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating.[14] It may result during MAOI therapy if the patient takes a **sympathomimetic** drug, such as ephedrine, pseudoephedrine, phenylephrine, or **stimulants** such as amphetamines or methylphenidate or if the patient consumes foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu.[14,30] There are extensive lists of foods and drinks that are not permitted during therapy with MAOIs, and these should always be provided to patients.[30] Because many over-the-counter (OTC) products contain sympathomimetics, patients should always be told to consult with their pharmacist or other clinician before using these drugs.[14]

Serotonin syndrome is characterized by confusion, restlessness, fever, abnormal muscle movements, hyperreflexia, sweating, diarrhea, and shivering.[31] It may result when a serotonergic agent is added to any other serotonergic agent, but the MAOIs are strongly associated with severe cases of serotonin syndrome.[31] Serotonin syndrome is complicated by (a) an unawareness by clinicians of the diagnosis and (b) the fact that many implicated drugs are not serotonergic in nature, such as dextromethorphan, meperidine, tramadol, linezolid, and methylene blue.[32]

Many antidepressants inhibit cytochrome P450 isoenzymes, elevating plasma levels of substrates for those isoenzymes and potentially leading to adverse effects or toxicity (see Table 38–5).[33]

Dosing

Antidepressant dosing is summarized in Table 38–6.[14,24,28] The extended release formulations of venlafaxine and bupropion allow for once daily dosing.[19] The delayed-release capsule of fluoxetine can be given weekly, which can be started 7 days after the last regular-release capsule or tablet.[24] Selegiline is available as a transdermal patch, and a dose of 6 mg/24 hours can be used without the usual dietary restrictions associated with MAOI use, although patients on the higher doses (9 and 12 mg/24 hours) should follow usual MAOI dietary restrictions.[14] Liquid dosage forms and disintegrating tablets of various antidepressants are ideal for patients who have difficulty swallowing tablets or capsules.

The starting dose is within usual therapeutic dosage range for most SSRIs, desvenlafaxine, duloxetine, and mirtazapine, but there is usually a need for at least some titration of venlafaxine, vilazodone, vortioxetine, bupropion, sertraline, levomilnacipran, nefazodone as well as TCAs.[14] A common first step in the management of partial response to an antidepressant is to optimize the dose even if the initial starting dose is within the therapeutic range.[14] An advantage of TCAs is that plasma levels may be used to help guide dosing, especially for those that have well-defined therapeutic plasma level ranges, including nortriptyline (50–150 ng/mL [190–570 nmol/L]).[28]

Efficacy of Pharmacotherapy

KEY CONCEPT Each antidepressant has a response rate of approximately 50% to 75%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.[14] There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective in patients with severe depression than the single action drugs such as the SSRIs, but the more general assertion that multiple mechanisms of action confer efficacy advantages is controversial.[14]

Selection of Medication

LO 4

Figure 38–1 depicts an algorithm based on the American Psychiatric Association Practice Guideline for the Treatment of Patients with Major Depressive Disorder and the Veterans Affairs/Department of Defense Clinical Practice Guideline for the Management of Major Depressive Disorder.[14,34] As depicted in the algorithm, the guidelines recommend the use of SSRI, SNRI, bupropion, or mirtazapine as a first-line treatment for patients with mild to severe depression.[14,34] Patients with mild depression may be managed with psychotherapy alone.[14,34]

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient's history of response (eg, efficacy, side effects, and overall satisfaction) to antidepressants.[14] To a lesser extent, the history of a first-degree relative's response to antidepressants may be used to predict a patient's response.[14] Adverse effect profiles should be considered, because adherence is influenced by tolerability.[19] The patient is the best source of information regarding acceptability of adverse effects. Patients should be educated about how to manage side effects (eg, using sugarless chewing gum, hard candy, or ice chips for dry mouth). The clinician must anticipate and be vigilant for potential drug–drug interactions and drug–disease interactions. For instance, a patient with a seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can suggest the best antidepressant to choose. For example, an SSRI can treat both MDD and panic disorder, obviating the need for two separate medications. Likewise, a patient with MDD and a chronic pain condition may be treated with an SNRI with efficacy for both conditions. The potential for accidental or intentional overdose must be considered. Patients with a risk of accidental or intentional overdose should not be prescribed TCAs. Additionally, affordability of the medication influences drug selection.

Time Course of Response

LO 5

Antidepressants do not produce an immediate clinical response. Improvement in physical symptoms, such as sleep, appetite, and energy, can occur within the first or second week of treatment. KEY CONCEPT Although a meta-analysis suggests earlier effects of antidepressant treatment, it is widely accepted that approximately

Table 38–6

Dosing of Antidepressants in Adults[14,24,28]

Generic Name	Brand Name	Generic	Form	Initial Dose (mg/day)	Usual Dosing Range (mg/day)	Usual Dosage Schedule	Renal Dosing Adjustment	Hepatic Dosing Adjustment
MAOIs								
Phenelzine	Nardil	Yes	T	15	45–90	Three times daily	None	None

ALT, alanine aminotransferase; AST, aspartate aminotransferase; C, capsule; CrCl, creatinine clearance; DR, delayed release; MAOI, monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine and dopamine reuptake inhibitor; ODT, orally disintegrating tablet; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; Sol, solution; SRI/5-HT$_{1A}$, partial agonist-serotonin reuptake inhibitor/serotonin$_{1A}$ partial agonist; SSRI, selective serotonin reuptake inhibitor; Sus, suspension; T, tablet; TCA, tricyclic antidepressant; TD, transdermal; XR, extended release.

2 to 4 weeks of treatment is required before improvement is seen in emotional symptoms such as sadness and anhedonia. As long as 6 to 8 weeks may be required to see full antidepressant effects.[14,35]

Managing Partial or No Response

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication.[36] In such cases, the clinician must evaluate the adequacy of antidepressant

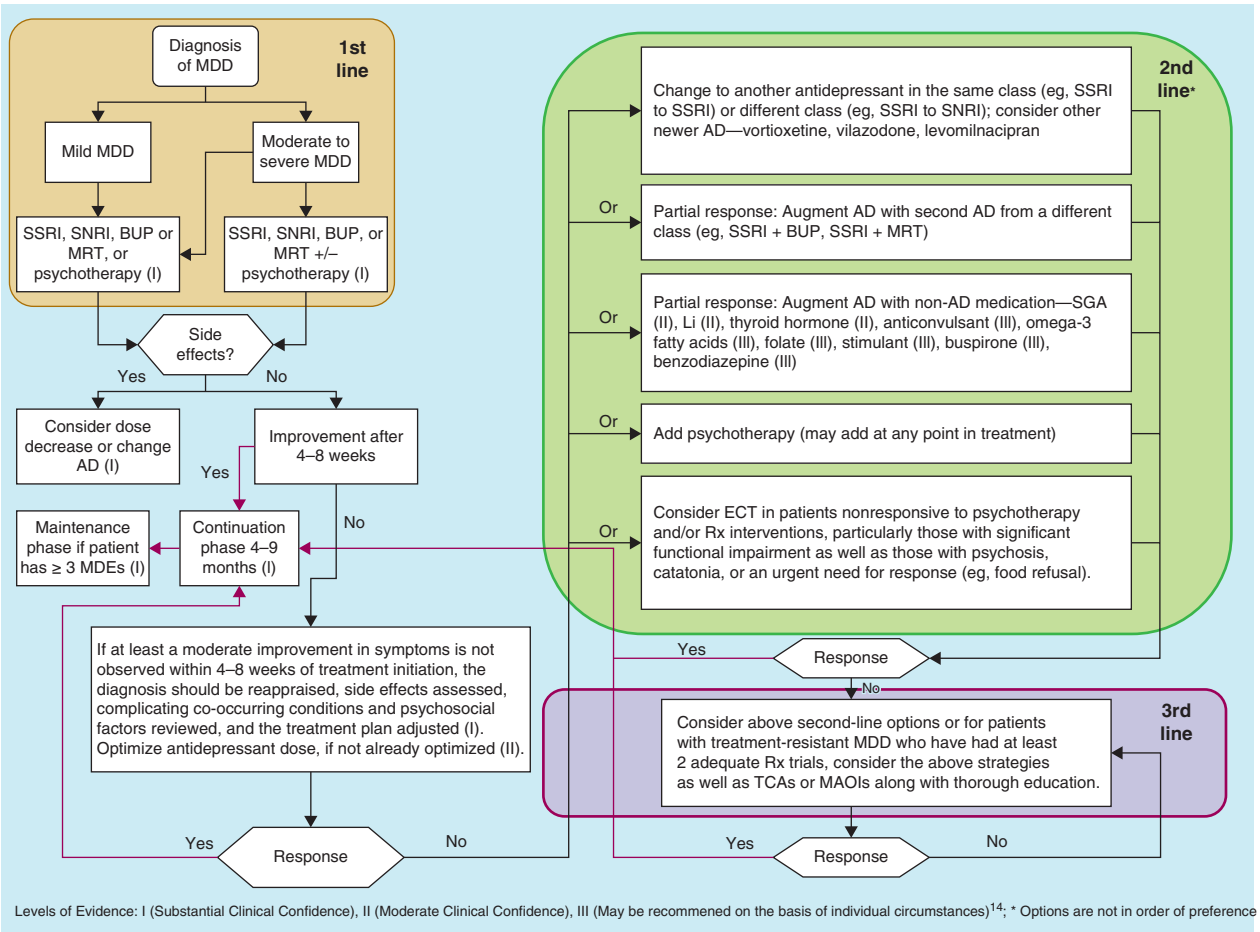

FIGURE 38–1. Algorithm based on the American Psychiatric Association Practice Guideline for the Treatment of Patients with Major Depressive Disorder[14] and VA/DoD Clinical Practice Guideline for the Management of Major Depressive Disorder.[34] (AD, antidepressant; BUP, bupropion; ECT, electroconvulsive therapy; Li, lithium; MAOI, monoamine oxidase inhibitor; MDE, major depressive episode; MRT, mirtazapine; Rx, prescription; SGA, second-generation antipsychotic; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant).

therapy, including dosage, duration, patient adherence, verification of the patient's diagnosis, and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (eg, thyroid disorder), comorbid psychiatric conditions or substance use disorders (eg, alcohol abuse), and psychosocial issues (eg, marital stress).[14]

A series of reports from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial revealed that remission is associated with a better overall prognosis than improvement alone.[3] STAR*D also established that in patients with a greater level of nonresponse to treatment, clinicians are less likely to push the patient to achieve remission, and in addition, those patients with the greatest levels of nonresponse had the highest rates of relapse.[3] STAR*D established some successful treatment recommendations. For patients experiencing a partial response, extending the medication trial and/or using higher doses within the recommended dosage range may be helpful.[3] Another option used in the STAR*D trials is augmentation therapy, that is adding a nonantidepressant such as lithium, buspirone, or triiodothyronine.[3]

Second-generation antipsychotics, aripiprazole, brexpiprazole, and the extended-release formulation of quetiapine are approved by the FDA for adjunctive treatment of MDD along with an antidepressant and are often added to an antidepressant in cases of partial or nonresponse.[18,37] Efficacy has been suggested for dopaminergic drugs (eg, pramipexole) psychostimulants (eg, methylphenidate), anticonvulsants (eg, lamotrigine), and modafinil although the evidence is less for these agents.[14,18] A third option is combination therapy, whereby another antidepressant, typically from a different pharmacologic class, is added to the first antidepressant.[18] Examples include combining bupropion or mirtazapine with SSRIs or SNRIs.[7] Switching to a different antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy, but also is acceptable in cases of partial response.[14] Relative to augmentation or combination therapy, advantages of switching include improved adherence, decreased costs, and less concern over drug–drug interactions. Disadvantages include loss of time, exacerbation of illness, and loss of any improvement seen with the initial drug. When switching from one antidepressant to another, clinicians may choose to stay within the same class (eg, sertraline to fluoxetine) or go outside of the class (eg, paroxetine to venlafaxine). The olanzapine-fluoxetine combination, Symbyax, is also approved for treatment-resistant depression.[18,37]

Nonpharmacologic interventions in cases of treatment nonresponse include adding or changing to psychotherapy or initiating ECT.

Duration of Therapy

Treatment of MDD encompasses three phases: acute, continuation, and maintenance (Figure 38–2).[38] The goal of antidepressant therapy is remission of MDE symptoms.[14] This acute phase of treatment typically lasts 6 to 12 weeks.[14] KEY CONCEPT Because the typical MDE lasts 6 months or longer, if antidepressant therapy is interrupted after the acute phase, the patient may relapse into a depressive episode.[14] When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase to prevent relapse.[14]

Maintenance treatment takes place after the normal course of an MDE to prevent recurrence, which is the development of future episodes.[14] This phase can last for years, or for a lifetime.[14] Although patients who have an MDE should receive acute and continuation treatment, not all of them require maintenance treatment, because not all patients experience multiple MDEs.[14] In some patients with multiple episodes, many years may separate the episodes.[14] Therefore, the clinician must consider various factors in determining whether an individual requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. The more prior episodes experienced, the higher the risk for future episodes. After three or more MDEs, patients are generally given lifelong maintenance treatment because of the high (ie, 90%) chance of experiencing additional episodes.[13,14] Other factors to consider are the severity of previous episodes, if suicide attempts were made, whether psychotic features were present, and patient preference.[14] The dose of the antidepressant required in the acute phase of treatment should be sustained during the continuation and maintenance phases.[14]

Discontinuing Therapy

When discontinuing therapy, it is best to gradually taper the antidepressant for two reasons. First, almost all antidepressants can produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (eg, venlafaxine, paroxetine, and fluvoxamine).[39] Withdrawal syndromes can cause sleep disturbances, anxiety, fatigue, mood changes, malaise, GI disturbances, and a host of other symptoms

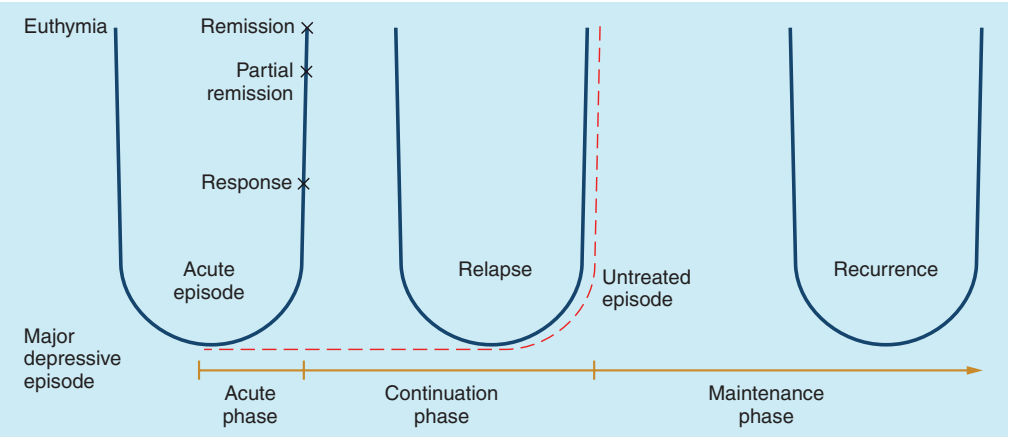

FIGURE 38–2. The course of depression and phases of treatment. Data from Refs. 7, 14.

which often are confused with depressive relapse or recurrence.[39] In general, the dose of the antidepressant should be tapered by no more than 25% per week to minimize the risk of withdrawal symptoms.[28] Tapering and discontinuation can be completed over 2 to 3 months.[28] Second, depressive symptoms may return upon taper or discontinuation of the antidepressant.[39] So, if the medication is gradually tapered, then early signs of depression can be countered with a return to the original dosage and a potentially quicker response.[39] Depending on the patient's illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence.

Special Considerations

▶ *Pregnant or Breastfeeding Patients*

Depression is quite common in pregnancy, especially for women with a history of recurrent depression.[14] Untreated depression carries risks for both the fetus and the mother. Likewise antidepressants have reported risks.[14] As such, both maternal and fetal well-being must be considered when weighing risks and benefits of antidepressant therapy during pregnancy.[14] Overall risk of teratogenicity with antidepressants after the first trimester appears to be low.[14] Paroxetine has been associated with an increased risk of cardiac malformations and should not be considered a first-line treatment in pregnant patients.[14] Fluoxetine has a long half-life and is more likely to be present at high levels in newborns after in utero exposure.[14] Antidepressant use late in pregnancy has been reported to occasionally cause perinatal sequelae, such as poor neonatal adaptation, feeding problems, and jitteriness.[14] Use of a single medication over multiple medications is favored in managing depression during pregnancy.[14] ECT may also be considered as a treatment option for pregnant patients.[14]

There is some drug exposure to the infant from nursing mothers who are taking antidepressants.[14] Although there have been rare anecdotal reports of adverse effects (ie, respiratory depression and seizure-like episodes) in infants exposed to antidepressants through breast milk, no rigorous study has confirmed this, and it is generally accepted that the benefits of breastfeeding outweigh the risks to the infant posed by antidepressant exposure.[14,40] However, the decision needs to be made on an individual basis.

▶ *Geriatric Patients*

Depression in older adults is underrecognized and undertreated.[14,41,42] Although not uncommon in community samples, MDD is prevalent among those living in long-term care facilities.[14] Barriers to recognition of geriatric depression include "masked" presentations, that is complaints of physical symptoms (eg, pain and GI problems) instead of mood symptoms, the frequent presence of medical illnesses, and the overlap of mood and cognitive symptoms with those of dementia.[41] Age-related pharmacokinetic and pharmacodynamic changes cause older patients to be more sensitive to antidepressant medications.[29] Thus, lower starting doses of antidepressants and slow upward titrations as tolerated are generally recommended for geriatric patients.[41] However, many older patients require the same dose as younger adult patients.[42] The SSRIs are chosen frequently for geriatric depression because of their overall favorable adverse effect profiles and low toxicity; most TCAs are avoided due to problematic anticholinergic, cardiovascular, and sedative properties.[42] The TCAs desipramine and nortriptyline are more tolerable in terms of these adverse effects and may be used in geriatric depression.[14] Other newer antidepressants, such as SNRIs, bupropion, vortioxetine, and mirtazapine, are alternatives for the treatment of geriatric patients.[42]

▶ *Pediatric Patients*

Antidepressant medications appear to be useful for certain children and adolescents, particularly those who have severe or psychotic depression, fail psychotherapy, or experience chronic or recurrent depression.[43] Fluoxetine and escitalopram are the only antidepressants FDA approved for depression in children younger than 18 years.[24] The SSRIs generally are considered the initial antidepressants of choice, but comorbid conditions may favor alternative agents.[43] "Behavioral activation" can occur with the SSRIs, including such symptoms as impulsivity, silliness, daring conduct, and agitation.[43]

All antidepressants have a black-box warning regarding the increase in the risk of suicidality (ie, suicidal thinking and behavior) in children and young adults.[44] A large analysis of clinical trials showed the risk of such events was 4% for antidepressants versus 2% for placebo, although no completed suicides occurred in the trials.[44] Following the addition of the black-box warning in 2003, prescriptions for antidepressants decreased among primary care providers by 58%.[45] The Centers for Disease Control and Prevention (CDC) estimated that suicide rates increased 8% in 2003 to 2004; however, a definite link between the black-box warning and increased suicide rates has not been conclusively determined.[45] Because antidepressants carry a black-box warning regarding suicidality, medication guides must be distributed with each prescription or refill of antidepressants.[44] KEY CONCEPT Patients 24 years and younger should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.[44]

▶ *Suicidal Patients*

As previously discussed, patients younger than 24 have an increased risk of suicidal thoughts or behaviors with antidepressant medications. However, all patients receiving antidepressant medications should be monitored for clinical worsening and emergence of suicidal thoughts and behaviors, especially during the first few months of drug therapy and at times of dosage changes.[44]

Whereas the TCAs and MAOIs have significant toxicity risk on overdose, most newer antidepressants are safer in overdose.[14]

Patient Counseling

LO 7

Major counseling points are outlined in Table 38–7. KEY CONCEPT Lack of patient understanding concerning optimal antidepressant

Patient Encounter Part 3

On the basis of information presented, create a care plan. Your plan should include: (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

Table 38–7

Patient Counseling[14,49]

Counseling Point	Clinical Rationale
Mechanism of action—The medication works by affecting certain chemicals in the brain	Patient may feel that depression is a character weakness or personality flaw instead of a biological disorder
Lack of addiction potential—Although the medication affects certain chemicals in the brain, it is not addicting	Patient may worry that because the antidepressant is psychoactive, it must be addicting
Need for routine use—The medication will only work if it is taken as prescribed every day	Patient may try taking the medication on an as-needed basis
Delayed onset of action—It may take several weeks to see significant improvement in symptoms	Patient may prematurely discontinue therapy before the onset of beneficial effects
Prolonged duration of therapy—The medication should be taken for at least 6–12 months; do not discontinue it without consulting with the prescriber	Patient may prematurely discontinue therapy after symptoms have remitted, which could lead to relapse or recurrence
Adverse effects—Mention common and expected adverse effects as well as what to do if they occur	Patient may be more likely to discontinue therapy and distrust the prescriber if adverse effects occur without forewarning
Avoidance of alcohol and CNS depressants—Use of alcohol or other CNS depressants could cause worsened depression and additive adverse effects with the medicine	Patient may be unaware of the possible consequences of drinking alcohol or taking other drugs with antidepressants
Risk of suicidality—Be alert to symptoms of worsening depression and suicidality	Patient may become suicidal or have suicidal thinking while taking the antidepressant

CNS, central nervous system.

therapy frequently leads to partial or nonadherence with therapy; thus the primary purpose of antidepressant counseling is to enhance adherence and improve outcomes.[46] Patients should be educated that while they may see some improvement in some symptoms like sleep and appetite as early as the first week, generally at least 4 to 8 weeks is required for optimal mood changes to occur. Patients should also recognize common side effects including how long those side effects might last, and if there are any simple remedies for treatment (eg, using ice chips or sugarless gum for dry mouth).

OUTCOME EVALUATION

Symptom Assessment

LO 5

The patient interview should assess response of target symptoms. Rating scales are useful in this regard. The Hamilton Depression Scale (HAM-D) and the Montgomery Asberg Depression Rating Scale are clinician-rated scales often used in depression research studies to assess treatment efficacy.[14] The Patient Health Questionnaire (PHQ-9) is a 9-item depression scale that is patient-rated (Table 38–8).[14,47] A score of 4 or less would be considered normal

Table 38–8

Patient Health Questionnaire-9[47]

Over the last 2 weeks, how often have you been bothered by any of the following problems?

	Not At All	Several Days	More Than Half the Days	Nearly Every Day
Little interest or pleasure in doing things	0	1	2	3
Feeling down, depressed, or hopeless	0	1	2	3
Trouble falling or staying asleep, or sleeping too much	0	1	2	3
Feeling tired or having little energy	0	1	2	3
Poor appetite or overeating	0	1	2	3
Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
Trouble concentrating on things, such as reading the newspaper or watching TV	0	1	2	3
Moving or speaking so slowly that other people could have noticed? Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3

Total Score = _____

Depression Severity, PHQ-9 Total Score: 1–4 minimal, 5–9 mild, 10–14 moderate, 15–19 moderately severe, 20–27 severe

If you checked any problems, how difficult have these problems made it for you to do your work, take care of things at home or get along with other people?

	Not Difficult At All	Somewhat Difficult	Very Difficult	Extremely Difficult

Patient Care Process

Collect Information:

- Perform a medication history for antidepressant and other psychotropic drug use as well as nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review the psychiatric history, medical history, physical assessment, laboratory findings, family history, and social history.
- Speak with the patient and review medical records to identify lifestyle habits, preferences, beliefs, health goals, and socioeconomic factors that may affect medication access and other aspects of care.

Assess the Information:

- Determine whether the patient is taking any substances that could induce or worsen the depressive episode.
- Based on the psychiatric and medical history, determine whether the patient has any factors that would suggest the selection of certain antidepressants or adjunctive agents.
- Identify comorbidities associated with MDD.
- Evaluate relevant laboratory tests (eg, complete blood count [CBC], thyroid stimulating hormone [TSH], urine drug screen).
- Assess the efficacy, safety, and patient adherence with current pharmacotherapy.
- Identify any significant adverse drug effects or interactions.
- Determine whether the patient may benefit from nonpharmacologic therapy (ie psychotherapy, lifestyle modifications).

Develop a Care Plan:

- Based on discussions with the patient, determine whether a change in antidepressant therapy is warranted or if the addition of another antidepressant or nonantidepressant adjunctive agent is more appropriate.
- Select lifestyle modifications and depression nonpharmacologic and pharmacologic therapy that are likely to be effective and safe for the patient.
- Choose medications and doses that are optimal for the patient.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential new adverse effects, and how to manage and report any adverse effects that occur.
- Review the patient's practices for self-monitoring symptoms of depression as well as her support system.
- Address any patient concerns about depression and its management.
- Discuss importance of medication adherence and lifestyle modifications to manage symptoms of depression.
- Determine whether recommended agents are included on the institution's formulary and whether the patient has insurance coverage to continue medication as an outpatient.

Follow-up: Monitor and Evaluate:

- Follow-up every 2 to 4 weeks after changes in pharmacotherapy until the patient reaches remission then every 3 to 6 months.
- Review medication adherence as well rating scale assessment of patient's symptoms of depression and adverse effects.

mood and greater than 20 as severe depression.[14,47] The use of rating scales can improve treatment outcomes in the treatment of depression.[48]

Monitoring Adverse Effects

LO5 LO6

Adverse effects associated with the treatments for depression can often be predicted based on knowledge of pharmacologic profiles (Table 38–3) as well as familiarity with the most common adverse effects (Table 38–4). Evaluation for suicidal ideation should be a part of every patient visit. Patients can be taught to manage side effects such as sedation, constipation, and dry mouth. Potential side effects such as weight gain and sexual dysfunction should be discussed with the patient and monitored at each visit. SNRIs may increase blood pressure, and patients should have their blood pressure monitored regularly during treatment.[14] Patients with cardiovascular risk factors or over the age of 40 should have an electrocardiogram (ECG) completed prior to initiating a TCA.[14] Patients taking TCAs such as amitriptyline, imipramine, nortriptyline, or desipramine should have antidepressant serum levels checked if overdose, side effects, or nonadherence is an issue.[14] Patients should be monitored for serotonin syndrome if they are taking two or more serotonergic medications.[14,31]

Abbreviations Introduced in This Chapter

5-HT	Serotonin
BDNF	Brain-derived neurotrophic factor
CBC	Complete blood count
CNS	Central nervous system
DA	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
ECG	Electrocardiogram
ECT	Electroconvulsive therapy
FDA	Food and Drug Administration
GI	Gastrointestinal
HAM-D	Hamilton Depression Rating Scale
HPA	Hypothalamic pituitary axis
MAOI	Monoamine oxidase inhibitor
MDD	Major depressive disorder
MDE	Major depressive episode
NaSSA	Noradrenergic and specific serotonergic antidepressant
NDRI	Norepinephrine and dopamine reuptake inhibitor
NE	Norepinephrine
NRI	Norepinephrine Reuptake Inhibitor
NR3C1	Nuclear Receptor Subfamily 3 Group C Member 1

PHQ-9	Patient Health Questionnaire-9
SAM-e	S-adenosyl methionine
SARI	Serotonin antagonist and reuptake inhibitor
SNRI	Serotonin and norepinephrine reuptake inhibitor
SRI	Serotonin reuptake inhibition
SSRI	Selective serotonin reuptake inhibitor
STAR*D	Sequenced Treatment Alternatives to Relieve Depression
TSH	Thyroid stimulating hormone
TCA	Tricyclic antidepressant
VEGF	Vascular endothelial growth factor
VNS	Vagus nerve stimulation
WHO	World Health Organization

39 Bipolar Disorder

Opal M. Bacon, Brian L. Crabtree, and Lydia E. Weisser

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode and in patients with bipolar disorder.
3. Identify common psychiatric comorbidities of bipolar disorder.
4. Recognize the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Identify the optimal use of medications as first-line therapy in bipolar disorder, including appropriate dosing.
7. Recommend drug therapy for acute treatment of mania and depressive episodes.
8. Recommend baseline and routine monitoring for assessment of adverse effects of medications used in the treatment of bipolar disorder.
9. Identify general treatment differences for agents used to treat bipolar disorder in the pediatric population.
10. Explain why medication education is important for patients with bipolar disorder.

INTRODUCTION

Bipolar disorder is characterized by one or more episodes of mania or hypomania, often with a history of one or more major depressive episodes.[1] It is chronic, with recurrent episodes and remissions. Mood episodes can be manic, hypomanic, or depressed. Mood episodes can be further classified with features, like **mixed mood features**. They can be separated by periods of long stability or cycle rapidly. They occur with or without psychosis. Disability and other consequences (eg, increased risk of suicide) can be devastating to patients and families. Correct and early diagnosis and treatment are essential to prevent complications and maximize response to treatment.

EPIDEMIOLOGY

Bipolar disorders are categorized into bipolar I disorder, bipolar II disorder, and other specified and unspecified bipolar and related disorders. Bipolar I disorder is characterized by one or more manic episodes, whereas bipolar II disorder is characterized by at least one hypomanic episode. Both disorders also typically have major depressive episodes.

The lifetime prevalence of bipolar I disorder is estimated at 0.6% of US adults. The lifetime prevalence of bipolar II disorder is about 0.4%. When including the entire spectrum of bipolar disorders, the prevalence is approximately 3%.[2]

Bipolar I disorder affects men and women equally. Bipolar II, **rapid cycling** and mixed mood features are more common in women. In all, 78% to 85% of individuals with bipolar disorder report having another *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), diagnosis during their lifetime. The most common comorbid conditions are anxiety, substance use disorder, and impulse control disorders. Medical comorbidities are also common.[2]

The mean age of onset is 20 years, although onset may occur in early childhood to the mid-40s.[1] If onset occurs after age 60, it is probably due to medical causes. An early onset is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts compared with later onset. Substance use and anxiety disorders are more common in patients with early onset. Patients with bipolar disorder have higher rates of suicidal thoughts, attempts, and completed suicides than the general population.

ETIOLOGY

The precise etiology is unknown. Thought to be genetically based, bipolar disorder is influenced by a variety of factors that may enhance gene expression. These include trauma, environmental factors, anatomical abnormalities, and exposure to chemicals or drugs.[3,4]

PATHOPHYSIOLOGY

Neurochemical

The pathophysiology of bipolar disorder remains incompletely understood. Imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance

Patient Encounter Part 1

Chief Complaint: "I went to my family physician after I wrecked my car. I told her I was fine but she insisted I see a psychiatrist."

HPI: Brad is a 34-year-old computer programmer who was evaluated by his primary care physician after running his car into a tree. Fortunately, he suffered no injuries and, since he had not had an annual physical for many years, examination and screening labs were obtained. Complete blood count, comprehensive metabolic profile, thyroid functions, chest X-ray, and electrocardiogram were normal with the exception of elevated creatinine at 2.3 mg/dL (203 µmol/L) and elevated blood urea nitrogen (BUN) at 40 mg/dL (14.3 mmol/L). Subsequent glomerular filtration rate (GFR) was decreased at 45 mL/min (0.75 mL/s). Brad does admit to increased nocturia, awakening him 3 to 4 times per night, as well as swelling of his hands and feet. Blood pressure on examination was elevated at 175/105 mm Hg.

Brad is a twice divorced, well-nourished, well-developed African American male appearing stated age. He is casually attired in jeans and shirt; however, his clothing is dirty and his shirt is untucked and wrinkled. His hair is long and uncombed and he is malodorous. He is unable to sit still and taps his foot and continually looks around the room during interview. Speech is pressured and loud, and patient frequently interrupts the examiner asking, "How much longer will this take? I'm going to Washington to meet the President and Buddha." He admits to increasing problems at work but states his boss does not appreciate his great talent. Although he has been an exemplary employee, over the past 2 weeks, he has made numerous mistakes on the job and has missed several days of work. He has spent his evenings going to various bars where he has been asked to leave due to getting into political arguments with patrons. He describes his mood as "spectacular" and states he is too busy to sleep. Brad recently attempted to buy an airplane "so I can get to Washington faster."

What diagnoses are suggested by this patient's presentation?

What additional information is needed to clarify the diagnosis (eg, differentiate between bipolar disorder and schizoaffective disorder)?

imaging (fMRI) are used to elucidate the cause. Historically, research focused on neurotransmitters such as norepinephrine (NE), dopamine (DA), and serotonin. One hypothesis is that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic activity. Serotonin is suggested to modulate catecholamines. Dysregulation of this relationship could cause mood disturbance. A variety of neurotransmitters are involved that interact with multiple neurochemical and neuroanatomic pathways.[3] The pathophysiology is also hypothesized based on the mechanisms of lithium and other drugs. Lithium, valproate, and carbamazepine all have similar effects on neuronal growth that are reversible by inositol, supporting a hypothesis that bipolar disorder may be related to inositol disturbance.[5] Brain-derived neurotrophic factor (BDNF) may play a role in bipolar disorder. Serum BDNF is low in mania and improves with treatment.[6]

LO 1

Genetic

Results of family studies suggest a genetic basis.[4] Lifetime risk of bipolar disorder in relatives of a bipolar patient is 40% to 70% for a monozygotic twin and 5% to 10% for other first-degree relatives.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Bipolar Disorder

KEY CONCEPT Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder. Bipolar disorder is categorized into five subtypes: bipolar I (periods of major depressive, at least 1 manic episode, and/or hypomanic episodes); bipolar II (periods of major depressive and hypomanic episodes); cyclothymic disorder (periods of hypomanic episodes and depressive episodes that do not meet all criteria for diagnosis of a major depressive episode); other specified bipolar and related disorders; and unspecified bipolar and related disorders. The defining feature of bipolar disorder is one or more manic or hypomanic episodes in addition to depressive episodes that are not caused by a medical condition, substance use, or other psychiatric disorders.[1]

Initial and subsequent episodes are mostly depressive.[7] Studies show patients with bipolar I spend about 32% of weeks with depressive symptoms compared with 9% of weeks with manic or hypomanic symptoms.[8] Patients with bipolar II disorder spend 50% of weeks symptomatic for depression and only 1% with hypomania.[9] Because patients may present with depression and spend more time depressed than with mood elevation, bipolar disorder is often misdiagnosed or underdiagnosed. It is helpful to use a screening tool such as the mood disorder questionnaire.[10] *DSM-5* criteria for the diagnosis of major depressive, manic, and hypomanic episodes are summarized in Table 39–1.

LO 4

► *Bipolar I Disorder*

The diagnosis of bipolar I disorder requires at least one episode of mania for at least 1 week (or any duration if hospitalization due to symptoms is required). Mania is characterized by a persistently elevated, expansive, or irritable mood with related symptoms of increased goal-directed activity or energy including **grandiosity**, decreased need for sleep, excessive talkativeness, racing thoughts, **flight of ideas (FOI)**, distractibility, and a propensity to be involved in high-risk activities.[1] Bipolar I depression can be misdiagnosed as major depressive disorder (MDD); therefore, it is essential to rule out past episodes of hypomania or mania. If bipolar depression is mistaken for MDD and the patient is treated with antidepressants, it can precipitate a manic episode or induce rapid cycling.

LO 2

► *Bipolar II Disorder*

The distinguishing feature of bipolar II disorder is a current or past hypomanic episode and a current or past major depressive episode. Hypomanic symptoms last for at least 4 days, but fewer than 7 and include the same symptoms as mania without causing severe impairment or requiring hospitalization. Psychotic features are not present,[1] while irritability and anger are common. There cannot have been a prior full-manic episode.[1]

Table 39–1

Evaluation and Diagnosis of Mood Episodes

Diagnosis Episode	Impairment of Functioning or Need for Hospitalization[a]	*DSM-5* Criteria[b]
Major depressive	Yes	At least 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased or increased appetite, weight loss or weight gain • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of excessive guilt or worthlessness • Impaired concentration or indecisiveness • Recurrent thoughts of death, suicidal thoughts or attempts
Manic	Yes	At least 1-week period of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	At least 4 days of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)

[a]Impairment in social or occupational functioning; may include need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

[b]The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, medications, drugs of abuse). Numerous specifiers are available to further characterize episodes (eg, with mixed features, with anxious distress, with rapid cycling, with melancholic features).

DSM, Diagnostic and Statistical Manual of Mental Disorders.

Reproduced, with permission, from Drayton SJ, Fields CS. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:1063–1078.

▶ *Cyclothymic Disorder*

Cyclothymic disorder is a chronic mood disturbance lasting at least 2 years (1 year in children and adolescents) and is characterized by mood swings that include periods of hypomanic symptoms that do not meet the criteria for a hypomanic episode and depressive symptoms that do not meet the criteria for a major depressive episode.

Suicide

Patients with bipolar disorder have high risk of suicide. Factors that increase risk are early age at onset, high number and severity of depressive episodes, comorbid alcohol use disorder, comorbid personality disorder, history of antidepressant-induced mania, history of previous suicide attempt, and family history of suicidal behavior. About one-third of individuals with bipolar disorder report a previous suicide attempt.[11] Twenty percent of attempts are fatal, in contrast to 5 to 10 percent in the general population. Patients should be assessed for potential for violence and harm to themselves or others. Friends or family can be asked to remove from the home guns, caustic chemicals, medications, and objects that patients might use to harm themselves or others.[11]

Differential Diagnosis

Schizophrenia, schizoaffective disorder, and bipolar disorder share certain symptoms, including psychosis in some patients. Psychosis of schizophrenia occurs in the absence of mood symptoms in contrast to psychosis only occurring with mood symptoms in bipolar disorder. Schizoaffective disorder is characterized by major depressive episodes or manic episodes, concurrent with symptoms that meet criteria for schizophrenia and delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.[1]

Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society

Patient Encounter Part 2: Medical History, Physical Examination, and Laboratory Examination

Your interview reveals the following information:

PMH: No previous medical problems except recent finding of abnormal renal function and hypertension. Patient was recently started on furosemide (Lasix) 20 mg daily with improved blood pressure control and resolution of pedal edema.

PPH: Noncontributory

FH: Father deceased secondary to coronary artery disease and chronic renal failure. Patient's father previously on dialysis. Mother alive and well. The patient's paternal aunt was hospitalized multiple times at the state psychiatric hospital for "mood swings" prior to her death. No family history of suicide or substance use disorder. Patient denies prior suicide attempts. The patient has two brothers and one sister in good health.

SH: Brad has been married twice and states he is currently "playing the field." He admits to frequently "hooking up" with women at bars but is not currently in a relationship. He states his marriages were brief because his wives did not appreciate his intellect and complained about his mood swings. He has a master's degree in Computer Science but states his college grades were erratic. He admits to daily use of alcohol.

SUH: Brad smokes one-half pack of cigarettes per day × 10 years. He denies use of stimulants, opioids, benzodiazepines, hallucinogens, marijuana, or intravenous drugs. He does admit to drinking 4 to 6 beers each night and occasional shots of liquor. He drinks 3 to 4 cups of coffee each day.

Medications: Lasix 20 mg by mouth daily. Denies use of vitamins or herbal supplements.

ROS: Decreased need for sleep obtaining 2 to 3 hours per night. Increased energy, rapid speech, decreased appetite with 10 lb (4.5 kg) weight loss, hypersexuality, and distractibility with difficulty focusing on work tasks.

PE:

VS: BP 140/85 mm Hg, P 90 beats/min, RR 16 breaths/min, T 98.8°F (37.1°C)

HEENT: PERRLA. Extraocular movements intact. Nares patent. Ear canals patent and eardrums visualized. Neck supple without JVD, bruits, or lymphadenopathy. Thyroid midline, symmetric, and nontender.

CV: Heart reveals regular rate and rhythm without murmurs, gallops, or rubs.

ABDOMEN: Soft, nontender, without organomegaly or masses. Positive bowel sounds in all four quadrants.

EXTREMITIES: Without clubbing or cyanosis. Trace pedal edema. Peripheral pulses full and equal bilaterally.

CN: Cranial nerves II–XII intact.

LABS: Urine drug screen negative. HIV negative. Basic metabolic profile reveals Na^+ 138 mEq/L (mmol/L), K^+ 3.7 mEq/L (mmol/L), Cl^- 102 mEq/L (mmol/L), CO_2 29 mEq/L (mmol/L), BUN 42 mg/dL (15.0 mmol/L), creatinine 2.4 mg/dL (212 µmol/L), glucose 102 mg/dL (5.7 mmol/L). Urinalysis yellow, clear, negative for glucose, ketones, or protein.

Considering this additional information, what is the most likely diagnosis?

Identify your treatment goals for this patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient?

beginning in adolescence or early adulthood.[1] Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

Comorbid Psychiatric and Medical Conditions

Lifetime prevalence rates of comorbidity with bipolar disorder are as high as 58%.[2] Comorbidities, especially substance use disorders, make establishing a diagnosis more difficult and treatment complicated. Comorbidities also place the patient at risk for a poorer outcome, higher rates of suicidality, increased episodes of depression, and higher costs of treatment.[1]

Patient Encounter Part 3: Creating a Care Plan

Based on all information presented, create a care plan for this patient's bipolar disorder. Your plan should include (a) a statement of the drug-related needs or problems, (b) the goals of therapy, (c) a patient-specific therapeutic plan, and (d) a plan for follow-up to assess therapeutic response and adverse effects.

LO 3 Psychiatric comorbidities include personality disorders, alcohol and substance use or dependence, anxiety disorders, obsessive-compulsive disorder, eating disorders, and attention-deficit/hyperactivity disorder. Medical comorbidities include migraine, multiple sclerosis, type 2 diabetes mellitus, and obesity.

TREATMENT

Desired Outcomes

LO 5 KEY CONCEPT Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.

General Approach to Treatment

LO 7 General treatment guidelines for manic and depressive episodes of bipolar disorder are included in Table 39–2.

Although it is a goal of treatment, not all patients achieve remission. The mainstay of drug therapy has been mood-stabilizing drugs but research based on multiple treatments indicates antipsychotic drugs, both first-generation (FGAs) and second-generation (SGAs), may be more effective for acute mania.[12] Antipsychotic drugs may be used as monotherapy or adjunctively with mood-stabilizing drugs. A person entering treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out nonpsychiatric causes. A variety of conditions can cause similar

Table 39–2

Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode		Acute Depressive Episode	
General guidelines Assess for secondary causes of mania or mixed states (eg, alcohol or drug use) Taper off antidepressants, stimulants, and caffeine if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy		General guidelines Assess for secondary causes of depression (eg, alcohol or drug use) Taper off antipsychotics, benzodiazepines, or sedative-hypnotic agents if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy	
Hypomania	**Mania**	**Mild to Moderate Depressive Episode**	**Severe Depressive Episode**
First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium,[a] valproate,[a] carbamazepine[a], or SGAs Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed Alternatives: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine Second, if response is inadequate, consider a two-drug combination: • Lithium[a] plus an anticonvulsant or an SGA • Anticonvulsant plus an anticonvulsant or SGA	First, two- or three-drug combinations: lithium or valproate plus a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia. If psychosis is present, initiate SGA in combination with above Alternatives: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine Second, if response is inadequate, consider a three-drug combination: • Lithium plus antipsychotic plus an antidepressant • Anticonvulsant plus an SGA Third, if response is inadequate, consider ECT for mania with psychosis or catatonia[a]; or add clozapine for treatment-refractory illness	First, initiate and/or optimize mood-stabilizing medication: lithium[a], lurasidone, quetiapine Alternatives: olanzapine/fluoxetine, valproate[a] or lamotrigine[b]	First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium,[a] lurasidone, or quetiapine If psychosis is present, initiate an antipsychotic in combination with above, do not combine antipsychotics Alternatives: olanzapine/fluoxetine, lamotrigine[b], valproate[a] Second if inadequate response carbamazepine[a] or add an antidepressant[c] Third, if response is inadequate, consider a three-drug combination: • Lithium plus lamotrigine[b] plus an antidepressant • Lithium[a] plus an anticonvulsant plus an SGA Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[d]

[a]Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b]Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

[c]Antidepressant monotherapy is not recommended for bipolar depression.

[d]ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

ECT, electroconvulsive therapy; SGA, second-generation antipsychotic.

Data from Refs. 15 and 38.

symptoms (Table 39–3). Because early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Treatment is often lifelong. Comorbid conditions should also be addressed.

Nonpharmacologic Therapy

KEY CONCEPT Interpersonal, family, or group psychotherapy with a qualified therapist or clinician adjunctive to medication assists individuals with bipolar disorder to improve functional outcomes; they may also help treat or prevent mood episodes, establish a daily routine and sleep schedule, and improve interpersonal relationships.[13]

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that stresses the importance of recognizing patterns of cognition (thought) and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors.

Table 39–3

Secondary Causes of Mania

Medical Conditions That Induce Mania
- CNS disorders (brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington disease)
- Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyperglycemia or hypoglycemia)
- Endocrine or hormonal dysregulation (Addison disease, Cushing disease, hyperthyroidism or hypothyroidism, menstrual-related or pregnancy-related or perimenopausal mood disorders)

Medications or Drugs That Induce Mania
- Alcohol intoxication
- Drug withdrawal states (alcohol, α_2-adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (LSD, PCP)
- Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (α_2-adrenergic antagonists, β-agonists, NE reuptake inhibitors)
- Steroids (anabolic, adrenocorticotropic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (caffeine, theophylline)
- Nonprescription weight loss agents and decongestants (ephedra, pseudoephedrine)
- Herbal products (St. John wort)

Somatic Therapies That Induce Mania
- Bright light therapy
- Deep brain stimulation
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.

Reproduced, with permission, from Drayton SJ, Fields CS. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:1063–1078.

With CBT, patients are taught self-management skills to change negative thoughts even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of electrical impulses to the brain for the treatment of severe or treatment refractory depression, psychotic depression, and treatment refractory mania. It also may be used in pregnant women who cannot take carbamazepine, lithium, or divalproex.

Education for patients, families, and groups about chronicity of bipolar disorder and self-management through sleep hygiene, nutrition, exercise, stress reduction, and abstinence from alcohol or drugs is critical to success. The development of a crisis intervention plan is essential.

Pharmacologic Therapy

KEY CONCEPT The primary treatment modality for manic episodes is mood-stabilizing agents or antipsychotic drugs, often in combination.[14,15]

Mood-stabilizing drugs like lithium and divalproex are generally first-line treatments for acute mania. Many of the SGAs also have approvals for acute mania and are often used in combination with mood stabilizers especially if psychosis is present. Carbamazepine can be considered as second line therapy. Drugs used with less research support and without Food and Drug Administration (FDA) approvals include topiramate and oxcarbazepine. Benzodiazepines are used adjunctively for agitation and insomnia in acute manic episodes. Often the medications used for acute episodes are continued for maintenance therapy.

KEY CONCEPT The primary treatment for depressive episodes in bipolar disorder is mood-stabilizing agents or certain antipsychotics.

For treatment of bipolar depression episodes, quetiapine as monotherapy, lurasidone as monotherapy or adjunctive to lithium or divalproex, and olanzapine in combination with fluoxetine are approved. Antidepressants can be used but along with a mood stabilizer to reduce risk of a mood switch to mania and after the patient has failed to respond adequately to mood-stabilizing therapy. Evidence of efficacy of antidepressant drugs in bipolar depression is considered controversial.[12,14] Among antidepressants, serotonin-norepinephrine reuptake inhibitors (SNRIs) and tricyclic antidepressants (TCAs) are possibly more likely than other antidepressants to cause a pharmacologic mood switch to mania or a mood episode with mixed mood features.[16] Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an antipsychotic or antidepressant drug are common, especially in acute mood episodes.

KEY CONCEPT The primary treatment for relapse prevention is mood-stabilizing agents, often combined with antipsychotic drugs. Lamotrigine, lithium, aripiprazole (oral and long-acting injectable [LAI]), risperidone LAI, and quetiapine are approved for maintenance therapy.

LO 6 Table 39–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 39–2.

▶ *Mood-Stabilizing Drugs*

The optimal mood-stabilizing drug is effective in treatment of acute mania, hypomania, acute bipolar depression, and in prevention of mania relapse and bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these types of episodes, but there are differences among them with regard to specific patient populations. The choice of treatment is dictated by patient characteristics and history. Few studies systematically compare mood stabilizers with each other. Efficacy of individual agents in placebo-controlled trials is similar. Lithium and divalproex are first-choice drugs for the most typical presentation of bipolar disorder.

Lithium Lithium, the first approved mood-stabilizing drug, remains a first-line agent and sets the standard for efficacy against which other drugs are measured. It is antimanic, prevents relapse, and has modest efficacy for acute bipolar depression. As one of the oldest drugs used for psychiatric illness, research continues to support its use.[12] In most studies, lithium's efficacy is equivalent to that of anticonvulsant mood stabilizers and SGAs. It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium. Evidence suggests genetic phenotypes that are more responsive to lithium.[17] However, patients with rapid cycling are less responsive to

Table 39–4

Product Formulation, Dose, and Clinical Use of Agents Used in Treatment of Bipolar Disorder

Generic Name	Brand Names	Formulations	Dosages	Clinical Use	Dosage Adjustment in Renal or Hepatic Impairment
Lithium Salts					
FDA approved in bipolar disorder					
Lithium carbonate	Lithobid Generic Generic Generic	ER tablets: 300 mg ER tablets: 450 mg ER tablets: 300 mg Tablet: 300 mg Capsules: 150, 300, 600 mg	900–2400 mg/day once daily or in two to four divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and 12-hour serum lithium concentration (ie, 0.6–1.2 mEq/L [mmol/L] for maintenance therapy and 1.0–1.5 mEq/L [mmol/L] for acute mood episodes taken 12 hours after last dose). Single daily dosing is effective and causes fewer renal effects	Monotherapy or in combination with other drugs for the acute treatment of mania and for maintenance treatment	Reduce starting dosage by at least 50% in renal impairment
Lithium citrate	Generic	300 mg (8 mmol)/5 mL			
Anticonvulsants					
FDA approved for use in bipolar disorder					
Carbamazepine	Equetro (only the Equetro brand is FDA approved for bipolar disorder) Tegretol, generic Tegretol XR Carbatrol	Capsules: 100 mg, 200 mg, 300 mg SR; may open capsule but do not crush or chew beads; take with food Tablets: 200 mg Chewable tablet: 100 mg Suspension: 100 mg/5 mL ER tablets: 100, 200, 400 mg ER capsules: 100, 200, 300 mg	Start at 100–200 mg bid; increase by 200 mg every 3–4 days to 200–1800 mg/day in two to four divided doses Target serum concentration is 4–12 mcg/mL (mg/L; 17–51 µmol/L)	Monotherapy or in combination with other drugs for the acute treatment of mania or mixed episodes for bipolar I disorder	Reduce starting dosage by at least half or avoid in hepatic impairment
Divalproex sodium	Depakote, generic	Enteric-coated, delayed-release tablets: 125, 250, 500 mg	750–3000 mg/day (20–60 mg/kg/day) in two to three divided doses for delayed-release divalproex or valproic acid	Monotherapy or in combination with other drugs for the acute treatment of mania. Although commonly used for relapse prevention, maintenance treatment is not FDA approved	Reduce starting dosage by half or avoid in hepatic impairment
	Depakote ER	Sprinkles: 125 mg ER tablets: 250, 500 mg	ER divalproex may be given once daily A loading dose of 20–30 mg/kg/day can be given, then 20 mg/kg/day and titrated to a serum concentration of 50–125 mcg/mL (mg/L; 347–866 µmol/L)		

(*Continued*)

Table 39–4

Product Formulation, Dose, and Clinical Use of Agents Used in Treatment of Bipolar Disorder (*Continued*)

Generic Name	Brand Names	Formulations	Dosages	Clinical Use	Dosage Adjustment in Renal or Hepatic Impairment
Valproic acid	Depakene, generic	Capsules: 250 mg			
Valproic acid syrup	Depakene, generic	250 mg/5 mL			
Lamotrigine	Lamictal, generic	Tablets: 25, 100, 150, 200 mg Chewable tablets: 2, 5, 25 mg ODT: 25, 50, 100, 200 mg	50–400 mg/day in divided doses. Dosage should be slowly increased by following prescribing information. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by half	Monotherapy or in combination with other drugs for maintenance treatment	
	Lamictal XR (not FDA approved for bipolar disorder)	ER tablets: 25, 50, 100, 200 mg			
Anticonvulsants and Other Drugs Not FDA Approved for Use in Bipolar Disorder					
Clonazepam	Klonopin, generic	Tablets: 0.5, 1, 2 mg Wafers: 0.125, 0.25, 0.5, 1, 2 mg	0.5–20 mg/day in divided doses or one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects	Use in combination with other drugs for the acute treatment of mania or mixed episodes	
Lorazepam	Ativan, generic	Tablets: 0.5, 1, 2 mg Oral solution: 2 mg/mL Injection: 2, 4 mg/mL	2–10 mg/day in divided doses or one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects		
Oxcarbazepine	Trileptal, generic	Tablets: 150, 300, 600 mg Suspension: 300 mg/5 mL	300–1200 mg/day in two divided doses Doses should be slowly adjusted up and down according to response and adverse effects (eg, 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals)	May cause fewer adverse drug–drug interactions than carbamazepine, but causes more gastrointestinal side effects and hyponatremia. Evidence is limited regarding efficacy	
Second Generation Antipsychotics					
FDA approved for bipolar disorder					
Aripiprazole	Abilify MyCite Abilify Abilify Discmelt Abilify Maintena	Tablets: 2, 5, 10, 15, 20, 30 mg Tablets: 2, 5, 10, 15, 20, 30 mg Oral solution: 5 mg/5 mL ODT: 10, 15 mg Long-acting injectable: 400 mg	10–30 mg once daily 10–30 mg/day once daily 400 mg IM once monthly	Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse Use as monotherapy for maintenance treatment of bipolar I disorder	
Asenapine	Saphris	Sublingual tablets: 5, 10 mg	5–20 mg/day in two divided doses. Must be held under the tongue until dissolved completely, not chewed or swallowed, with no food or liquid for 10 minutes after administering	Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states of bipolar I disorder	

Lurasidone	Latuda	Tablets: 20, 40, 60, 80, 120 mg	20–120 mg once daily	Use as monotherapy or in combination with lithium or valproate for depression of bipolar I disorder
Olanzapine	Zyprexa, generic Zyprexa Zydis	Tablets: 2.5, 5, 7.5, 10, 15, 20 mg ODT: 5, 10, 15, 20 mg	5–20 mg/day in one or two doses	Used as monotherapy or in combination with lithium or valproate for acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse. Used in combination with fluoxetine for treatment of bipolar depression
Olanzapine/Fluoxetine combination	Symbyax	Capsules: 3/25, 6/25, 6/50, 12/25, 12/50 mg		Approved for bipolar depression
Quetiapine	Seroquel Seroquel XR	Tablets: 25, 50, 100, 200, 300, 400 mg ER tablets: 50, 150, 200, 300, 400 mg	50–800 mg/day in divided doses or once daily when stabilized	Used as monotherapy or in combination with lithium or divalproex for acute treatment of mania, mixed states for bipolar I disorder, and depression of bipolar I and bipolar II disorder. Used adjunctively with lithium or divalproex for relapse prevention of bipolar mania and depression
Risperidone	Risperdal, generic	Tablets: 0.25, 0.5, 1, 2, 3, 4 mg	0.5–6 mg/day in one or two doses	Used as monotherapy or adjunctively with lithium or divalproex for acute mania or mixed episodes of bipolar I disorder
		Oral solution: 1 mg/mL		Used as monotherapy or adjunctively with lithium or divalproex for maintenance treatment of bipolar I disorder
	Risperdal M-Tabs	ODT: 0.5, 1, 2, 3, 4 mg	25–50 mg every 2 weeks	Used as monotherapy or adjunctively with lithium or divalproex for acute mania or mixed episodes of bipolar I disorder
	Risperdal Consta	Long-acting injectable: 12.5, 25, 37.5, 50 mg		Used as monotherapy or adjunctively with lithium or divalproex for maintenance treatment of bipolar I disorder
Ziprasidone	Geodon	Capsules: 20, 40, 60, 80 mg	40–160 mg/day in divided doses	Used as monotherapy or manic or mixed episodes of bipolar I disorder Used adjunctively with lithium or divalproex for maintenance treatment of bipolar I disorder

DIVALPROEX, divalproex; ER, extended release; FDA, Food and Drug Administration; ODT, oral disintegrating tablet; SR, sustained release; XR, extended release.

Data from Refs. 12, 14, 20, 21, 23, 24, 27–29, and 38.

lithium than to other mood-stabilizing drugs such as divalproex. Additionally, its efficacy for bipolar depression is less robust than for mania.[12] It may also be less effective in mood episodes with mixed mood features (symptoms of mania and depression occurring simultaneously).

Evidence shows lithium's effect on suicidal behavior is superior to that of other mood-stabilizing drugs.[18] Lithium reduces the risk of deliberate self-harm or suicide by 70%.

Lithium's mechanism of action is not well understood and is multimodal. Possibilities include altered ion transport, effects on neurotransmitter signaling, blocking adenyl cyclase, effects on inositol, neuroprotection or increased BDNF, and inhibition of second messenger systems.[19]

Lithium is usually initiated at a dosage of 600 to 900 mg/day. Although it is commonly given in a divided dosage, once-daily dosing is recommended, especially with sustained-release formulations. Once-daily dosing can improve adherence and reduce renal side effects. Lithium has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage. Lithium requires regular serum concentration monitoring as a guide to titration and to minimize adverse effects. At least weekly monitoring is recommended until stabilized; then the frequency can be decreased. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. The dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.2 mEq/L (mmol/L). Higher serum concentrations are required to treat an acute episode than to prevent relapse. Serum lithium above 0.8 mEq/L (mmol/L) may be more effective at preventing relapse than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour postdose sample collection, usually a morning trough in patients taking more than one dose per day. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial. Table 39–5 shows pharmacokinetic parameters and desired serum concentrations of mood-stabilizing drugs. It is common for lithium to be combined with other mood stabilizers or antipsychotics to achieve more complete remission.

The most common adverse effects are gastrointestinal (GI) upset, tremor, and polyuria, which are dose-related.[20] Nausea, dyspepsia, and diarrhea are minimized by coadministration with food, use of the sustained-release formulation, and giving smaller doses more frequently to reduce the amount of drug in the GI tract. Tremor is present in up to 50% of patients. In addition to these approaches, low-dose β-blockers, such as propranolol 20 to 60 mg/day, reduce tremor.

Lithium impairs the kidney's ability to concentrate urine because of its inhibitory effect on vasopressin. This causes an increase in urine volume and frequency of urination and an increase in thirst. Polyuria and polydipsia occur in up to 70% of patients. A severe form of polyuria, when urine volume exceeds 3 L/day, is termed lithium-induced nephrogenic **diabetes insipidus**. It can be treated with hydrochlorothiazide or amiloride. If the former is used, the lithium dosage should be reduced by 33% to 50% to account for the drug–drug interaction that increases serum lithium and causes toxicity. Long-term lithium has been associated with structural kidney changes, such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.

Lithium is concentrated in the thyroid gland and can impair thyroid hormone synthesis. Although goiter is uncommon, as many as 30% of patients develop at least transiently elevated thyroid-stimulating hormone. Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with levothyroxine.

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, impaired glucose regulation, and benign leukocytosis. Lithium causes a flattening of the T wave of the electrocardiogram (ECG), considered benign and not clinically significant. Less commonly, it can cause or worsen arrhythmias.[20]

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of adverse effects. Guidelines for such monitoring are outlined in Table 39–6.

LO 8

Acute lithium toxicity, which usually occurs at serum concentrations over 2 mEq/L (mmol/L), can be severe and life threatening, necessitating emergency treatment. Milder toxicity can occur at concentration between 1.5 and 2 mEq/L (mmol/L). Symptoms include severe vomiting and diarrhea, deterioration in motor coordination, including coarse tremor, ataxia, and dysarthria, and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage are reported. Treatment includes discontinuation of lithium, IV fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated. Clinical symptoms continue after the serum concentration is lowered because clearance from the central nervous system (CNS) is slower than from serum. Factors predisposing to lithium toxicity include fluid and sodium loss from hot weather or exercise or drug interactions that increase serum lithium.[20]

Drug interactions involving lithium are common. Because lithium is not metabolized or protein bound, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme (ACE) inhibitor drugs. If a diuretic must be used with lithium and a thiazide is not required, loop diuretics such as furosemide are less likely to increase lithium retention. The ACE inhibitors and angiotensin receptor blockers (ARBs) can abruptly increase serum lithium with the potential for acute toxicity, including fatal toxicity, even after months of no change in serum lithium. This combination is strongly discouraged.[20] Any drug or condition that can cause hyponatremia may increase lithium toxicity.

Divalproex Sodium and Valproic Acid Divalproex sodium is composed of sodium valproate and valproic acid. The delayed-release and extended-release formulations are converted in the intestine into valproic acid (VPA), which is systemically absorbed. It is FDA approved for treatment of the manic phase of bipolar disorder. It is equal in efficacy to lithium and some other drugs for bipolar mania. It has utility in bipolar disorder with rapid cycling, mood episodes with mixed mood features, and substance use comorbidity. Although not FDA approved for relapse prevention, studies support its use, and it is widely prescribed for maintenance therapy. Divalproex can be used as monotherapy or in combination with lithium or an antipsychotic.[14]

The mechanism for bipolar disorder is not well understood. It is known to affect ion transport and enhance activity of γ-aminobutyric acid (GABA). Similar to lithium, it has possible neuroprotective effects through enhancement of BDNF.[19]

Divalproex is initiated at 500 to 1000 mg/day, but studies indicate a therapeutic serum VPA concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg/day. Using this approach, patients may respond with a significant

Table 39–5

Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder

	Lithium	Carbamazepine	Oxcarbazepine	Divalproex (DIVALPROEX) Sodium/ Valproic Acid (VPA)	Lamotrigine
Gastrointestinal Absorption					
Regular release	Rapid: 95%–100% within 1–6 hours	Slow and erratic: 85%–90%	Slow and complete: 100%	Rapid and complete (VPA)	Rapid: 98%
Syrup, suspension, solution	Faster rate of absorption: 100%	Faster rate of absorption	Unknown	Faster rate of absorption than tablets	NA
ER/enteric-coated tablets	Delayed absorption: 60%–90%	Delayed absorption: 89% of the suspension; and less than regular-release tablets	NA	Delayed absorption with delayed-release tablets; valproate is rapidly converted to VPA in the intestine and then is rapidly and almost completely absorbed from the GI tract ER bioavailability is approximately 15% less than delayed release	Delayed absorption but not significantly different from regular release
Delay in absorption by food	Yes	No; reports of increased rate of absorption with fatty meals (ER capsule)	No	Yes; food slows the rate of absorption but not the extent for DIVALPROEX	Bioavailability not affected by food
Time to reach peak serum concentrations	0.5–3 hours (regular-release) 4–12 hours (ER) 0.25–1 hour (oral solution)	4–5 hours (regular-release); 1.5 hours (suspension); 3–12 hours (ER tablets); 4.1–7.7 hours (ER capsules); higher peak concentrations with chewable tablets	4.5 hours (range of 3–13 hours)	1–4 hours (VPA) 3–5 hours (DIVALPROEX single dose) 7–14 hours (DIVALPROEX ER multiple dosing)	1–4 hours (regular release), 4–6 hours (ER)
Distribution					
Volume of distribution	Initial: 0.3–0.4 L/kg Steady state: 0.7–1 L/kg	0.6–2 L/kg (adults)	10-monohydroxy metabolite: 49 L/kg	11 L/1.73 m^2 (total valproate); 92 L/ 1.73 m^2 (free valproate)	0.9–1.3 L/kg
Crosses the placenta	Yes; pregnancy risk category: D Risk of cardiac defects: 0.1%–0.5%	Yes; pregnancy risk category: D	Yes; pregnancy risk category: C	Yes; pregnancy risk category: D Risk of neural tube defects: 1%–5%	Yes; pregnancy risk category: C
Crosses into breast milk	Yes; 35%–50% of mother's serum concentration; breastfeeding not recommended	Yes; ratio of concentration in breast milk to plasma is 0.4 for drug and 0.5 for epoxide metabolite; considered compatible with breastfeeding	Yes; both drug and active metabolite; breastfeeding not recommended	Yes; considered compatible with breastfeeding	Yes; breastfeeding not recommended
Protein binding	No	75%–90%	40% of active metabolite	80%–90% (dose dependent)	55%
Renal clearance	Yes; 10–40 mL/min with 90%–98% of dose excreted in urine; 80% of lithium that is filtered by the renal glomeruli is reabsorbed	Yes; 1%–3% excreted unchanged in urine	Yes; 95% excreted in the urine; < 1% excreted unchanged	Yes; 30%–50% excreted as glucuronide conjugate; < 3% excreted unchanged	Yes; 94% excreted as glucuronide conjugate

Table 39–5

Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder (*Continued*)

	Lithium	Carbamazepine	Oxcarbazepine	Divalproex (DIVALPROEX) Sodium/ Valproic Acid (VPA)	Lamotrigine
Metabolism					
Hepatic metabolism	No	Yes; oxidation and hydroxylation; induces liver enzymes to increase its own metabolism and metabolism of other drugs	Yes; oxidation and conjugation	Yes; oxidation and glucuronide conjugation	Yes; glucuronic acid conjugation induces its own metabolism in normal volunteers
Metabolites	No	Yes; 10, 11–epoxide (active)	Yes; 10-monohydroxy metabolite (active)	Yes (not active)	No
Kinetics	First-order	First-order after initial enzyme induction phase	First-order	First-order	First-order
Half-life ($t_{½}$)	18–27 hours (adult); > 36 hours (elderly or patients with renal impairment)	Half-life decreases over time due to autoinduction: 25–65 hours (initial) 12–17 hours (adult multiple dosing) 8–14 hours (children multiple dosing)	2 hours (parent) 9 hours (metabolite)	5–20 hours (adults)	25 hours; increases to 59 hours with concomitant VPA therapy
Cytochrome P450 (CYP450) Isoenzyme					
CYP450 substrate	No	2C8 and 3A3/4	Unknown	2C19	Unknown
CYP450 inhibitor	No	No	2C19	2C9, 2D6, and 3A3/4	Unknown
CYP450 inducer	No	1A2, 2C9/10, and 3A3/4	3A3/4	No	Unknown
Therapeutic Serum/Plasma Concentrations					
	1–1.5 mEq/L (mmol/L): for adult, acute mania 0.4–0.6 mEq/L (mmol/L): for elderly or medically ill patients 0.6–1.2 mEq/L (mmol/L): for adult, maintenance; ranges based on 12-hour postdose sample collection	4–12 mcg/mL (mg/L; 17–51 µmol/L): for adult, acute mania and maintenance 4–8 mcg/mL (mg/L; 17–34 µmol/L): for elderly or medically ill	No established therapeutic range; 12–30 mcg/mL (mg/L; 47–118 µmol/L) for 10-hydroxy metabolite based on epilepsy trials	50–125 mcg/mL (mg/L; 347–866 µmol/L): adult, acute mania and maintenance 40–75 mcg/mL (mg/L; 277–520 µmol/L): elderly or medically ill	No established therapeutic range: 4–20 mcg/mL (mg/L; 16–78 µmol/L) based on epilepsy trials

ER, extended release; GI, gastrointestinal; NA, not applicable.

Data from Refs. 19–21, 23, and 24.

reduction in symptoms of acute mania within the first few days of treatment. The dosage is then titrated according to response, tolerability, and serum concentration. The most often referenced desired VPA serum concentration is 50 to 125 mcg/mL (mg/L; 347–866 µmoles/L), but it is not unusual for patients to require more than 100 mcg/mL (mg/L; 693 µmoles/L) for optimal efficacy. Some patients require high milligram dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on trough values. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently. The extended-release formulation can be taken once daily (see Table 39–4). If the extended-release formulation is administered at night, a morning blood sampling is a peak, not a trough. The drug should be given in the morning so that blood sampling the following morning would be a trough value and more easily interpreted if the typical blood sampling time is in the morning. The systemic bioavailability of extended-release divalproex is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation. The immediate-release formulation, either capsules or syrup, is given three or four times per day.[21]

Table 39–6

Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Examination and General Chemistry[a]	Hematologic Tests[b]		Metabolic Tests[c]		Liver Function Tests[d]		Renal Function Tests[e]		Thyroid Function Tests[f]		Serum Electrolytes[g]		Dermatologic[h]	
	Baseline	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	3–6 Months
SGAs[i]	X			X	X										
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X
Lamotrigine[k]	X													X	X
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X
Oxcarbazepine[m]	X											X	X		
Valproate[n]	X	X	X	X	X	X	X							X	X

[a]Screen for drug abuse and serum pregnancy.

[b]Complete blood count (CBC) with differential and platelets.

[c]Fasting glucose, serum lipids, weight.

[d]Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.

[e]Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.

[f]Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

[g]Serum sodium.

[h]Rashes, hair thinning, alopecia.

[i]SGA, second generation antipsychotic: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

[j]Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are less than 100,000/mm^3 (100×10^9/L), if WBC is less than 3000/mm^3 (3×10^9/L) or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

[k]Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dose escalation, or using doses exceeding the recommended titration schedule.

[l]Lithium: Obtain baseline ECG for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume more than 3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, then monitor every 3 to 6 months.

[m]Oxcarbazepine: Hyponatremia (serum sodium concentrations less than 125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.

[n]Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are less than 100,000/mm^3/L (100×10^9/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Data from Refs. 15 and 38.

The most common adverse effects are GI (loss of appetite, nausea, dyspepsia, diarrhea), tremor, and drowsiness. GI distress can be reduced by coadministration with food. The delayed-release and extended-release formulations are less likely to cause gastric distress than immediate-release VPA. Dosage reduction can reduce all of the common side effects. As with lithium, a low-dose β-blocker may alleviate tremor. Weight gain is common, occurring in up to 50% of patients.[21]

Other less common adverse effects include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Polycystic ovarian syndrome associated with increased androgen production is reported. Thrombocytopenia is common, and the platelet count should be monitored periodically. It is a dose-related, reversible adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count is less than $100 \times 10^3/mm^3$ ($100 \times 10^9/L$). Rarer are hepatic toxicity and pancreatitis, which are not always dose-related. Hyperammonemia has been reported. If patients develop unexplained lethargy and vomiting or changes in mental status, an ammonia level should be measured. Severe GI symptoms of hepatic or pancreatic toxicity include vomiting, pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. Divalproex has a wide therapeutic index. Acute toxicity for high dosages or over dosage is not life threatening.

Drug interactions involving divalproex are common. It is a weak inhibitor of some drug metabolizing liver enzymes and can affect metabolism of other drugs. These include other anticonvulsants and antidepressants. The interaction between divalproex and lamotrigine is significant. The risk of a dangerous rash caused by lamotrigine is increased when given concurrently with divalproex. Conversely, the metabolism of divalproex can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin, but divalproex may simultaneously slow metabolism of the other agents.[21]

Carbamazepine Although used frequently as a mood-stabilizer, only the extended-release formulation is FDA approved for treatment of bipolar disorder. Carbamazepine has efficacy for mood stabilization; however, it is less desirable as a first-line agent because of safety and drug interactions. It is reserved for patients who fail to respond to lithium or for patients with rapid cycling or bipolar disorder with episodes of mixed mood features. Carbamazepine can be used as monotherapy or in combination with lithium or an antipsychotic drug.[22]

The mechanism of action of carbamazepine is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its efficacy as a mood stabilizer is not known.[22]

Carbamazepine is initiated at 400 to 600 mg/day. The sustained-release formulation can be given in two divided doses. An additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.[22] The suggested therapeutic serum concentration is 4 to 12 mcg/mL (mg/L; 17–51 μmol/L). As with divalproex, some patients require high dosages to achieve a desired serum concentration and therapeutic effect. The dosage can be increased by 200 to 400 mg/day as often as every 2 to 4 days. Serum concentration monitoring is suggested at least every 2 weeks until stabilized.[22]

The most common adverse effects are drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic levels, it causes diplopia and dysarthria. These can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. GI upset is common. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur, but hepatitis is less common. Mild, dose-related leukopenia is not unusual and not an indication for discontinuation. More serious blood count abnormalities such as aplastic anemia and agranulocytosis are rare but life threatening.[22] Additionally, toxic epidermal necrolysis (TEN) and SJS have been reported. Higher risk of these serious dermatologic reactions is associated with the HLA-B*1502 allele found almost exclusively in Asian ancestry. Patients with ancestry from the at-risk population should have genetic testing done prior to initiation of carbamazepine.[23] See the epilepsy chapter for a full discussion. Suggested baseline and routine laboratory monitoring are reviewed in Table 39–6.

Carbamazepine induces hepatic metabolism of many drugs, including other anticonvulsants, antipsychotics, some antidepressants, oral contraceptives, and antiretroviral agents. Carbamazepine is an autoinducer (ie, it induces its own metabolism). The dosage may require an increase after 1 month or so of therapy because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme inhibiting drugs such as some antidepressants; macrolide antibiotics, including erythromycin and clarithromycin; azole antifungal drugs, including ketoconazole and itraconazole; and grapefruit juice.

Lamotrigine Lamotrigine is effective for maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse prevention. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, it is sometimes used in combination with lithium or divalproex, although combination with divalproex increases the risk of rash, and lamotrigine dosage adjustment is required.[24]

The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism is not clear.[24]

Lamotrigine is initiated at 25 mg/day for 1 to 2 weeks, then increased in a dose-doubling manner every 1 to 2 weeks to a target of 200 to 400 mg/day. If lamotrigine therapy is interrupted for more than 5 half-lives, it should be restarted at the initial dosage and retitrated. Serum concentration monitoring is not recommended.[24]

The adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.[24] Although usually benign and temporary, some rashes can progress to life-threatening Stevens-Johnson syndrome. The risk of rash is greater with a rapid dosage titration, when given concurrently with divalproex or other metabolic enzyme inhibitors, and in pediatric patients.[24] The risk is minimal in adults when the dosage titration schedule is slow. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and divalproex, lamotrigine does not significantly influence body weight.

The mechanisms of drug–drug interactions involving lamotrigine are unclear. Lamotrigine's primary route of metabolism is conjugative glucuronidation, although it is known to exhibit metabolic autoinduction. It is not significantly metabolized by CYP P450 enzymes. It does not affect drug metabolizing hepatic enzymes. Divalproex slows the rate of elimination of lamotrigine by about half. If lamotrigine is added to divalproex, the starting dosage is 25 mg every other day with a slower titration to reduce risk of rash. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50% for the same reason. Conversely,

carbamazepine and estrogen-containing oral contraceptives increase the rate of lamotrigine metabolism. Upward adjustment in lamotrigine dosage may be needed.[24]

Oxcarbazepine Oxcarbazepine is an analogue of carbamazepine, developed as an anticonvulsant. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations is not indicated because it is less likely to cause hematologic abnormalities.[25] Additionally, drug interactions are less significant, although it is a mild inducer of certain metabolic pathways. Vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,[14] but clinical trial data are limited.[26]

Adverse effects include drowsiness, dizziness, GI upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine.[25]

Others High-potency benzodiazepine agents such as clonazepam and lorazepam are used as adjunctive therapy, especially during acute mania, to reduce anxiety and improve sleep.[27] As complementary or alternative medicines gain wider usage, omega-3 fatty acids have been used in mood disorders, but do not appear in treatment guidelines.

▶ *Antipsychotic Drugs*

First-generation antipsychotics (FGAs) such as chlorpromazine and haloperidol have long been used in the treatment of acute mania. SGA drugs, including aripiprazole, asenapine, cariprazine, olanzapine, quetiapine, risperidone, and ziprasidone, are approved for the treatment of bipolar mania or mixed mood features as monotherapy or in combination with mood stabilizers.[14] Among the LAI antipsychotic drugs, risperidone microspheres and aripiprazole monohydrate are approved for maintenance therapy in bipolar disorder. Aripiprazole LAI is approved as monotherapy and risperidone LAI is approved both as monotherapy and combined with lithium or valoprate.[14] Oral aripiprazole tablets with a sensor for tracking adherence is approved for maintenance as monotherapy or adjunctively to lithium or valproate. The combination of olanzapine and fluoxetine is approved for treatment of acute bipolar depression. Quetiapine is approved as monotherapy for acute bipolar depression and as adjunctive therapy with lithium or divalproex for prevention of bipolar depression relapse. Lurasidone is approved as monotherapy and as adjunctive therapy with lithium or divalproex for acute bipolar depression. Asenapine and olanzapine are approved as monotherapy for maintenance therapy. Approval of antipsychotic drugs in patients with bipolar disorder applies without regard to presence of psychosis. In comparative studies, SGAs are equivalent or superior in efficacy to lithium and divalproex for treatment of acute mania. Treatment guidelines include antipsychotic drugs as first-line therapy.[14] The combination of mood stabilizers and antipsychotics is more likely to achieve remission than monotherapy. Quetiapine data in relapse prevention of both manic and bipolar depression episodes favored combination therapy over mood-stabilizer monotherapy.[28]

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in the chapter on schizophrenia. Dosages in bipolar disorder are similar to those used in schizophrenia. Higher dosages are often required to treat an acute episode. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg/day, somewhat higher than the average dosage used in schizophrenia.[29] The recommended dosage for quetiapine in treatment of acute bipolar depression is 300 mg/day, less than the 600 mg/day recommended in acute mania.[30]

SGAs are less likely than FGAs to cause neurologic side effects, especially movement abnormalities. SGAs are more likely to cause metabolic side effects, such as weight gain, glucose dysregulation, and dyslipidemia.[31] Among SGAs approved for treatment of bipolar disorder, olanzapine is most likely to cause metabolic side effects.

▶ *Antidepressants*

Treatment of depressive episodes in patients with bipolar disorder presents a particular challenge because of the risk of a drug-induced mood switch to mania. The FDA requires the product label of all antidepressants to contain language about the potential risk of inducing a mood switch to mania. Most research shows no advantage for adjunctive antidepressant use compared with mood-stabilizer therapy alone.[12,14] Treatment guidelines and current FDA approvals indicate lithium and quetiapine as first-line therapy.[14] Although lurasidone is FDA indicated for acute bipolar depression, its place in therapy relative to lithium and quetiapine is not established. When usual treatment fails, evidence supports use of antidepressants.[12,14]

Guidelines agree that when antidepressants are used, they should be combined with a mood stabilizer to reduce risk of mood switch. The question of which antidepressant drugs are less likely to cause a mood switch is not resolved, but TCAs and SNRI are thought to carry greater risk. A comparison of venlafaxine, sertraline, and bupropion as adjunctive therapy to a mood stabilizer showed venlafaxine with highest risk of a mood switch to mania or hypomania and bupropion with the least.[32]

Special Populations

Assessment and management by appropriate psychiatric specialists is important for special populations, such as pediatric, geriatric, and pregnant patients.

▶ *Pediatrics*

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults. Children and adolescents are sensitive to medication side effects, including metabolic side effects of SGAs. With these caveats, evidence supports use of mood stabilizers and SGAs in children and adolescents with bipolar disorder. Lithium is FDA approved for treatment of bipolar disorder in children and adolescents as young as age 12. Aripiprazole, olanzapine/fluoxetine combination, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10.[14,33]

LO 9

Initial dosages in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, so they may actually require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability.

Children and adolescents are especially likely to experience weight gain from SGAs.[34] Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired learning, is difficult to detect and is a consideration in the pediatric population so that intellectual and educational development is not hindered.

For comorbid bipolar disorder and attention-deficit/hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant to avoid exacerbation of mood symptoms.

▶ *Geriatrics*

Treatment of older adults with bipolar disorder requires care because of increased risks associated with medical conditions and drug–drug interactions.[35] General medical conditions, including endocrine, metabolic, or infectious diseases, can mimic mood disorders. Patients should be evaluated for such medical illnesses that cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of VPA. As a result, dosages required for therapeutic effect are lower in geriatric patients. Also, changes in membrane permeability increase risk of CNS side effects. Increased frequency of patient monitoring is required, including serum drug concentration monitoring. As a result, older patients may respond at lower serum levels and may experience toxicity when serum levels are within the normal therapeutic range for younger adults.

Vigilance for drug–drug interactions is required because more medications tend to be prescribed to older adults and their enhanced sensitivity to adverse effects. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (eg, divalproex and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increases risk of falls and other impairments.

▶ *Pregnancy and Postpartum*

Treatment of bipolar disorder during pregnancy is fraught with controversy and conflicting recommendations. The key issue is the relative risk of teratogenicity with drug use during pregnancy versus risk of bipolar relapse without treatment with consequent harm to both patient and fetus. Therapeutic judgments depend on the history of the patient and whether the pregnancy is planned or unplanned. Treatment is best managed when pregnancy is planned. Clinicians should discuss the issue with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained before initiating therapy. For a patient with severe illness or a history of multiple mood episodes, rapid cycling, or suicide attempts, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long-term stability and contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about risks versus benefits of stopping or continuing therapy so they can make an informed decision. Patients who decide to discontinue medication before pregnancy should taper medication slowly.[14,36]

Lithium administration during the first trimester is associated with Ebstein's anomaly, a downward displacement of the tricuspid valve. Although cardiac defects are more likely to occur in children of patients who took lithium during pregnancy, the absolute risk appears to be small.[37] Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It is advisable to decrease or discontinue lithium at term or onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.[38]

Lithium can cause hypotonicity and cyanosis in the neonate, termed the "floppy baby" syndrome. Most data indicate normal neurobehavioral development when these symptoms resolve. Lithium is readily transferred via breast milk. Breastfeeding is not advised for patients taking lithium.[20]

VPA and carbamazepine are human teratogens. Neural tube defects such as spina bifida occur in up to 9% of infants exposed during the first trimester. The risk of neural tube defects is related to exposure during the third and fourth weeks of gestation. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Extreme caution is recommended when patients are taking VPA.[38]

Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors. The risk of facial abnormalities is increased with carbamazepine and VPA, and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.[39,40]

Fewer data are available on other anticonvulsant mood-stabilizing drugs. Lamotrigine may be associated with an increased risk of oral clefts but, overall, may be relatively safer in pregnancy than other anticonvulsants.[39,40]

The FGAs have been available for many years, and more data are available on their use in pregnancy compared with SGAs, but guidelines for bipolar disorder do not otherwise support FGAs as an initial choice.

Use of antidepressant drugs during pregnancy is discussed in the chapter on depression.

OUTCOME EVALUATION

Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing response. Understand the particular symptom profile and needs of individual patients. These are the primary therapeutic monitoring parameters. In

Patient Encounter Part 4: Outcome Evaluation

After an initial assessment, including evaluation of suicide risk, presence of support systems, and need for inpatient versus outpatient treatment, Brad was hospitalized for 5 days and subsequently followed in the community on a mood stabilizer. He was also enrolled in cognitive behavioral therapy to focus on maintaining healthy relationships and decreasing his use of alcohol. Brad has cut back his alcohol intake to one beer each night and his job performance has returned to normal although he is still on probation. He has stopped frequenting bars, preferring to stay home and watch TV. Due to Brad's abnormal renal function and family history of kidney disease, he was started on divalproex DR 500 mg by mouth three times daily. Current serum valproic acid level is 105 mcg/mL (mg/L; 728 µmol/L). He returns to the clinic for routine follow-up.

Brad initially complained of mild nausea and somnolence which have resolved, but he reports difficulty remembering to take his medication three times each day and asks if his medication can be changed. He also asks how much longer he will need to take the medication. He is switched to extended release divalproex 1750 mg by mouth daily and tolerates this well.

How would you assess therapeutic and adverse effects of treatment for this patient?

How would you educate the patient regarding the need for continued maintenance treatment?

Patient Care Process

Collect information:

- Assess the patient's symptoms.
- Review the family history, including the history of response to treatment by family members.
- Obtain an initial medical evaluation to rule out other causes of mood episodes.
- Evaluate physiologic parameters that may influence pharmacokinetics.
- Obtain a thorough medication use history, including present and past prescription and nonprescription drugs, the patient's self-assessment of response and side-effects, alcohol, tobacco, caffeine, illicit substances, herbal products, dietary supplements, allergies, and adherence.

Assess the Information:

- Assess potential drug–disease, drug–drug, and drug–food interactions.

Develop a Care Plan:

- Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of the patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring as appropriate.
- Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
- Determine the role of nonpharmacological therapy and how it is to be integrated with drug therapy.

Implement the Care Plan:

- Educate the patient on the nature of bipolar disorder, its treatment, and what to expect with regard to response and side effects, and stress the need for adherence to treatment even when feeling well.
- Encourage a healthy lifestyle, including eliminating or stopping substance abuse, smoking cessation, and encouraging proper nutrition and exercise.

Follow-up: Monitor and Evaluate:

- See the patient daily if hospitalized or weekly if an outpatient to assess efficacy and safety until stabilized. Utilize the clinical interview, physical examination, and lab tests.
- Once stabilized, follow-up at decreased frequency, every 3 to 6 months. Use the same parameters and check for new drugs or drug–drug interactions.

addition to clinical interview, some clinicians use symptom rating scales such as the Young Mania Rating Scale (YMRS) for mania and the Hamilton Depression Rating Scale (Ham-D, discussed in the chapter on depression). The YMRS is composed of 11 items based on a patient's perception over the preceding 48 hours. Adjunctive information is obtained from clinical observations. The scale takes about 15 to 30 minutes to administer.[41] Check serum concentrations of mood-stabilizing drugs as a guide to dosage adjustment for optimal efficacy. The frequency of follow-up visits depends on response, tolerability, and adherence.

Assessment of Adverse Effects

Adverse effects cause more nonadherence than any other factor. Monitor patients regularly for adverse effects and health status, especially because mood stabilizers and antipsychotics commonly cause metabolic side effects such as weight gain. Repeat laboratory tests for renal and thyroid function for patients taking lithium and hematology and liver function for patients taking carbamazepine or divalproex. More specific discussion of metabolic side effect monitoring of patients taking SGAs is provided in the chapter on schizophrenia.

Patient Education

LO 10

KEY CONCEPT Education of the patient regarding benefits and risks of drug therapy and the importance of adherence to treatment must be integrated into pharmacologic management. This is important because responsiveness to treatment declines as the number of mood episodes increases. Discuss the nature and chronic course of bipolar disorder and risks of repeated relapses. Help patients understand treatment is not a cure but that many patients enjoy symptom-free or nearly symptom-free function. Make it clear that long-term recovery is dependent on adherence to pharmacologic and nonpharmacological treatment. Explain the purpose of medication, common side effects to expect, and how to respond to side effects. Provide the patient and family with written information about indications, benefits, and side effects. Discuss less frequent but more dangerous side effects of drugs, and give written instructions on seeking medical attention immediately should they occur.

Abbreviations Introduced in This Chapter

5-HT	5-hydroxytryptamine
Abd	Abdomen
ACE	Angiotensin-converting enzyme
ARB	Angiotensin receptor blocker
BDNF	Brain-derived neurotrophic factor
BP	Blood pressure
CBC	Complete blood count
CBT	Cognitive-behavioral therapy
CN	Cranial nerve
CNS	Central nervous system
DA	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
ECG	Electrocardiogram
ECT	Electroconvulsive therapy
Exts	Extremities
FDA	Food and Drug Administration
FGA	First-generation antipsychotic
fMRI	Functional magnetic resonance imaging
FOI	Flight of ideas
GABA	γ-Aminobutyric acid

GI	Gastrointestinal
HAM-D	Hamilton Depression Rating Scale
β-HCG	Beta-human chorionic gonadotropin
HIV	Human immunodeficiency virus
JVD	Jugular venous distention
LMP	Last menstrual period
MDD	Major depressive disorder
MRI	Magnetic resonance imaging
NE	Norepinephrine
P	Pulse
PERRLA	Pupils equal round and reactive to light and accommodation
PET	Positron emission tomography
RR	Respiration rate
SGA	Second-generation antipsychotic
T	Temperature
THC	Tetrahydrocannabinol, psychoactive substance in marijuana
VPA	Valproic acid
YMRS	Young Mania Rating Scale

40 Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Sheila R. Botts, Sallie H. Charles, and Douglas A. Newton

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying anxiety disorders.
2. Recognize common presenting symptoms of generalized anxiety, panic, and social anxiety disorder (SAD).
3. List treatment goals for patients with generalized anxiety, panic, and SAD.
4. Identify appropriate lifestyle modifications and over-the-counter medication use in these patients.
5. Compare the efficacy and tolerability profiles of psychotherapy and pharmacotherapy interventions for anxiety disorders.
6. Design a patient-specific pharmacotherapy treatment plan for patients with generalized anxiety, panic, and SAD.
7. Develop a monitoring plan for patients with anxiety placed on specific medications.
8. Formulate appropriate educational information to be provided to a patient receiving pharmacotherapy for generalized anxiety, panic, and SAD.

INTRODUCTION

Anxiety disorders are among the most frequent mental disorders encountered by clinicians.[1-3] All anxiety disorders are highly comorbid and share features of fear and anxiety that differ from developmentally normative fear or anxiety by being excessive, persistent, and resulting in behavioral disturbances.[1] Anxiety disorders are associated with significant patient and family burden, functional impairment, and increased risk of developing comorbid major depressive disorder (MDD).[1-4]

Initial detection and diagnosis generally falls to primary care clinicians, to whom most patients present in the context of other complaints.[4] Anxiety disorders are often missed or attributed incorrectly to other medical illnesses, and most patients are treated inadequately.[4] Untreated anxiety disorders are associated with increased health care utilization, morbidity and mortality, and a poorer quality of life.[1-4]

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

▶ *Prevalence*

The lifetime prevalence of anxiety disorders collectively is 28.8% with specific phobia (12.5%) and social anxiety disorder (SAD; 12.1%) being the most common.[2,3] Data from the National Comorbidity Survey, Revised (NCS-R) estimate the lifetime prevalence of generalized anxiety disorder (GAD) for those 18 years of age and older to be 5.7%, closely followed by panic disorder (PD) at 4.7%.[2,3]

Anxiety disorders are more prevalent among women than men (2:1).[2] Prevalence rates across the anxiety spectrum increase from the younger age group (18–29 years) to older age groups (30–44 and 45–59 years); however, rates are substantially lower for those older than age 59 years.[2]

▶ *Course of Illness*

PD and GAD have median ages of onset of 24 and 31 years, respectively, whereas SAD develops earlier (median age 13 years).[3] Although GAD and PD may not fully manifest until adulthood, as many as half of adult patients with anxiety report subthreshold symptoms during childhood.[5]

Anxiety disorders are chronic, and symptoms tend to wax and wane, with fewer than one-third of patients experiencing spontaneous symptom **remission**.[6] As such, the risk for relapse and recurrence of symptoms is high. In a 12-year follow-up study of anxiety disorder patients, recurrence rates ranged from 58% of PD and GAD patients to 39% of SAD patients.[7]

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode.[6] Similarly, the highest rates of relapse are within the same time frame. This suggests that many patients need ongoing maintenance treatment. Rates of remission and relapse do not appear to vary by sex.[6] Patients with anxiety disorders spend a significant portion of time "being ill" during a particular episode, ranging from 41% to 80% of the time.[7] Anxiety disorders are associated with impaired psychosocial functioning and a compromised quality of life.[8] Appropriate treatment improves overall quality of life and psychosocial functioning.[8]

▶ *Comorbidity*

More than 90% of individuals with an anxiety disorder have a lifetime history of one or more other psychiatric disorders.[9] Depression is the most common comorbidity, followed by alcohol and substance use disorders, as well as other co-occurring anxiety disorders, especially GAD and PD.[9] Generally, the onset of SAD and GAD symptoms precedes MDD, but there is an equal chance of PD onset before, during, or after MDD.

Etiology

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders.[10,11] Moderate genetic risk has been identified for all anxiety disorders. Family and twin epidemiologic studies support familial aggregation of anxiety disorders (odds ratio [OR] 4–6) with heritability of 30% to 50%.[11] Twin studies further suggest that anxiety disorders share genetic risk factors which may help to explain the pattern of comorbidity. Candidate gene studies as well as genome wide association sequence (GWAS) studies seeking to identify genes contributing to risk have been inconclusive to date.[11]

Genetic factors may create a vulnerable phenotype for anxiety disorders, but environmental factors (eg, stressful life events, illness, parental relationships) contribute to the development and persistence of the disorder.[11] Marital status (single or divorced vs married), poor social support, low socioeconomic status, and education are associated with increased risk of developing an anxiety disorder.[1] Some researchers believe that stressful life events may have a strong role in the onset of anxiety disorders, especially in GAD and PD.[10] It has been reported that those experiencing one or more negative life events have a threefold increased chance of developing GAD.[1] Similar findings have been reported with PD.[12]

PATHOPHYSIOLOGY

LO 1

The thalamus, amygdala, nucleus accumbens, hippocampus, hypothalamus, and prefrontal cortex are key components of the neurocircuitry of fear response[13] and may play a central role in most anxiety disorders (Figure 40–1). Sensory data from environmental threats are first processed by the thalamus.

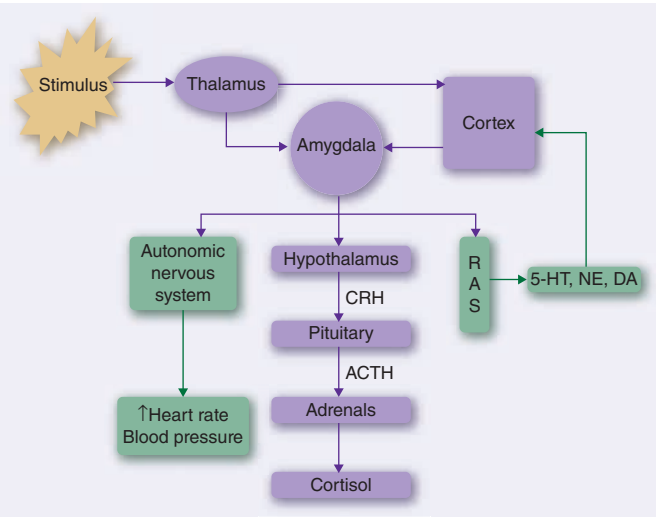

FIGURE 40–1. Neurocircuitry and key neurotransmitters involved in mediating anxiety disorders. (ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; DA, dopamine; 5-HT, serotonin; NE, norepinephrine; RAS, reticular activating system.)

Information is simultaneously passed on to cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala provides emotional valence or importance of the information and enables quick action or response to an ambiguous but vital threat. The cortex performs a more detailed analysis and sends updates to the amygdala for comparison and any needed course corrections.

Anxiety disorders develop when the fear-response system leads to maladaptive behavior or distress. Anxiety occurs independent of stimuli (PD), is associated with benign stimuli (eg, phobias), or continues beyond the stimulus duration (eg, GAD). Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. These connections are modulated by serotonin (5-HT) and norepinephrine (NE), which have their primary origins in the RAS.[14] The amygdala sends projections to the hypothalamus, thus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. It also influences the hypothalamic–pituitary–adrenal (HPA) axis, leading to a cascade of stress hormones.[14] Elevation of stress hormones, such as cortisol, for prolonged periods can damage the brain and other organs.[14]

Noradrenergic System

Norepinephrine-producing cells reside primarily in a region of the brain called the locus ceruleus (LC). Increased activity in this region is associated with an increase in arousal, anxiety, and panic. Drugs such as yohimbine that increase activity in the LC can be anxiogenic; drugs that decrease activity in the LC appear to improve anxiety. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.[15]

Serotonergic System

The raphe nuclei and the resident cell bodies of 5-HT-producing neurons have a complicated role related to anxiety symptoms. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences include their ability to regulate cells in the prefrontal cortex and amygdala. Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in treatment of anxiety disorders.[14]

γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) plays a complex role as an inhibitory neurotransmitter with nonspecific effects. GABAergic drugs reduce anxiety, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.[14]

Hypothalamic–Pituitary–Adrenal Axis

The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain.[13] A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides may provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

Patient Encounter 1, Part 1

A 32-year-old woman presents to her primary care team with complaints of fatigue, headaches, abdominal pain, and insomnia. She is tearful and reports "not feeling well" and is concerned she might have a serious illness. She has a family history of breast cancer and worries that she too will have cancer. She reports worrying about her health, her relationship with a significant other, her job, and finances. She is an elementary school teacher and likes her job, but worries she is not performing to expectations. She drinks wine daily, and smokes cannabis 1 to 2 times a month. She presented to the emergency department 2 weeks ago with a panic attack and was discharged with a prescription for diazepam. Her medical history is positive for depression.

Meds: Diazepam 5 mg po BID prn anxiety

What manifestations described above are suggestive of an anxiety disorder?

What additional information do you need to establish a diagnosis and develop a treatment plan?

What other diagnoses should be considered in your differential diagnosis?

Could her medication be contributing to her symptoms?

Neuropeptides

Several neuropeptides (eg, neuropeptide Y [NPY], substance P, and cholecystokinin) are under investigation for their role in anxiety disorders. NPY appears to reduce the effect of stress hormones and inhibit activity of the LC. Both mechanisms may contribute to the anxiolytic properties seen experimentally. Substance P may have anxiolytic and antidepressant properties partly because of its effects on corticotropin-releasing hormone.[16]

CLINICAL PRESENATION AND DIAGNOSIS

Anxiety disorders share common etiology and risk factors yet have distinct clinical presentation, diagnostic criteria, and treatment recommendations and thus will be discussed separately. Treatment guidelines recommend screening for the presence of anxiety symptoms using general questions such as "During the past 2 weeks how much have you been bothered by the following: (1) feeling nervous, anxious, frightened, worried, or on edge, (2) feeling panic or being frightened, (3) avoiding situations that make you anxious."[1,17] Positive **responses** should result in further assessment. Suicide risk assessment is recommended for all anxiety disorders as the risk of suicide attempts is increased irrespective of the presence of a comorbid mood disorder.[17,18]

TREATMENT: GENERALIZED ANXIETY DISORDER

Desired Outcomes

LO 3

The goals of therapy for GAD are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal is to achieve and maintain remission. With a positive response to treatment, comorbid depressive symptoms should be minimized.

Clinical Presentation and Diagnosis of GAD

General

Onset is typically in early adulthood. Anxiety emerges and dissipates more gradually than in PD. The intensity and duration of anxiety is out of proportion to the likelihood or impact of the anticipated event. Laboratory evaluation usually is reserved for later onset, atypical presentation, or poor response to treatment.

Symptoms[1]

LO 2

- Essential feature is excessive anxiety or worry involving multiple events or activities occurring more days than not for at least 6 months
- Difficulty controlling worry
- Anxiety and worry associated with at least three of the following:
  - Restlessness
  - Easily fatigued
  - Poor concentration or mind going blank
  - Irritability
  - Muscle tension
  - Insomnia or unsatisfying sleep
- The anxiety or worry causes significant distress or functional impairment and is NOT attributable to another substance, medical, or psychiatric condition

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 40–1 and 40–2)

Table 40–1

Medical Conditions That Can Cause Anxiety

Psychiatric Disorders
Mood disorders, hypochondriasis, personality disorders, alcohol or substance abuse, alcohol or substance withdrawal, other anxiety disorders

Neurologic Disorders
CVA, seizure disorders, dementia, stroke, migraine, encephalitis, vestibular dysfunction

Cardiovascular Disorders
Angina, arrhythmias, congestive heart failure, mitral valve prolapse, myocardial infarction

Endocrine and Metabolic Disorders
Hypothyroidism or hyperthyroidism, hypoglycemia, Cushing disease, Addison disease, pheochromocytoma, hyperadrenocorticism, hyponatremia, hyperkalemia, vitamin B_{12} deficiency

Respiratory Disorders
Asthma, COPD, pulmonary embolism, pneumonia, hyperventilation

Other
Carcinoid syndrome, anemias, SLE

COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; SLE, systemic lupus erythematosus.

Data from Refs. 1 and 17.

Table 40–2

Medications Associated with Anxiety Symptoms

Category	Examples
Anticonvulsants	Carbamazepine, ethosuximide
Antidepressants	Bupropion, SSRIs, SNRIs, TCAs
Antihypertensives	Felodipine
Antimicrobials	Cephalosporins, ofloxacin, isoniazid
Antiparkinson drugs	Levodopa
Bronchodilators	Albuterol, isoproterenol, theophylline
Corticosteroids	Prednisone, methylprednisolone
Decongestants	Pseudoephedrine, phenylephrine
Herbals	Ma huang, St. John's wort, ginseng, guarana, belladonna
NSAIDs	Ibuprofen, indomethacin
Stimulants	Amphetamines, caffeine, cocaine, methylphenidate
Thyroid hormones	Levothyroxine
Toxicity	Anticholinergics, antihistamines, digoxin
Withdrawal of CNS depressants (abrupt)	Alcohol, barbiturates, benzodiazepines

CNS, central nervous system; NSAID, nonsteroidal anti-inflammatory drug; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 1, 19, and 20.

General Approach to Treatment

KEY CONCEPT Patients with GAD may be managed with psychotherapy, pharmacotherapy, or both. Treatment should be individualized based on symptom severity, comorbid illnesses, medical status, age, access to care, cost, and patient preference. Patients with severe symptoms resulting in functional impairment should receive antianxiety medication.

Nonpharmacologic Therapy

LO 4 Nonpharmacologic therapy includes psychoeducation, exercise, stress management, and psychotherapy. Psychoeducation should provide information on GAD and its management. Patients should be instructed to avoid stimulating agents, for example, caffeine, decongestants, diet pills, and excessive alcohol use. Regular exercise is also recommended. Cognitive-behavioral therapy (CBT) is the most effective psychological therapy for GAD patients. It helps patients to recognize and alter patterns of distorted thinking and dysfunctional behavior. Treatment gains with CBT may be maintained for up to 1 year.[20] CBT may be delivered in individual or group settings.[17,21] Computerized CBT offered over the Internet is effective and may offer an alternative to face-to-face therapy for patients with access barriers.[22] LO 5 The effect sizes of trials with CBT are comparable to those of pharmacologic therapies.[17,20] CBT is effective for children with GAD and combined with medication may be superior to either treatment alone.[23]

Pharmacologic Therapy

Antidepressants, benzodiazepines, pregabalin, buspirone, hydroxyzine, and the second-generation antipsychotics (SGAs) have controlled clinical trial data supporting their use in GAD. KEY CONCEPT Antidepressants are the drugs of choice for chronic GAD because of a tolerable side-effect profile; no risk for dependency; and efficacy in common comorbid conditions, including depression, panic, obsessive-compulsive disorder (OCD), and SAD. Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety when immediate relief of symptoms is desired. They are also recommended for intermittent or adjunctive use during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment.[17,20] Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine is usually adjunctive and is less desirable for long-term treatment because of side effects, for example, sedation and anticholinergic effects.

Patient Encounter 1, Part 2

After a medical workup, she was diagnosed with GAD, unspecified depressive disorder and alcohol use disorder.

PMH: Depression

FH: Mother treated for depression; father, alcohol dependence

SH: Two to three drinks per night; lives alone in apartment

Meds: Diazepam 5 mg po BID prn anxiety

What are first-line treatment options for this patient?

What factors should be considered in selecting the patient's treatment?

What is the role of benzodiazepines for this patient?

How should the patient be monitored when receiving an antidepressant?

LO 3 Patients with GAD should be treated to symptom remission. Continuation of antidepressant therapy after acute response significantly decreases the risk of relapse (OR 0.2 [0.15–0.26]).[24] Guidelines recommend continuing treatment for 6 months to 1 year.[17,20,21,25] An algorithm for the pharmacologic management of GAD is shown in Figure 40–2.

▶ *Antidepressants*

Antidepressants (Table 40–3) reduce the psychic symptoms (eg, worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (eg, tremor, rapid heart rate, and/or sweating). All antidepressants evaluated provide a similar degree of anxiety reduction. The onset of antianxiety effect is delayed 2 to 4 weeks. Selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) are preferred over tricyclic antidepressants (TCAs) because of improved safety and tolerability. Selection of a specific antidepressant generally is based on history of prior response, side effect and drug interaction profile (see Chapter 38), cost, or formulary availability.

Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes modify the expression of genes and proteins important in stress response (eg, glucocorticoid receptors, brain-derived neurotrophic factor, corticotropin-releasing hormone).[26] Activation of these "stress-adapting" pathways may improve both somatic and psychic symptoms of anxiety.[26]

Selective Serotonin Reuptake Inhibitors The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms in adults with GAD. Response rates range from 56% to 68% during acute treatment, with remission achieved in

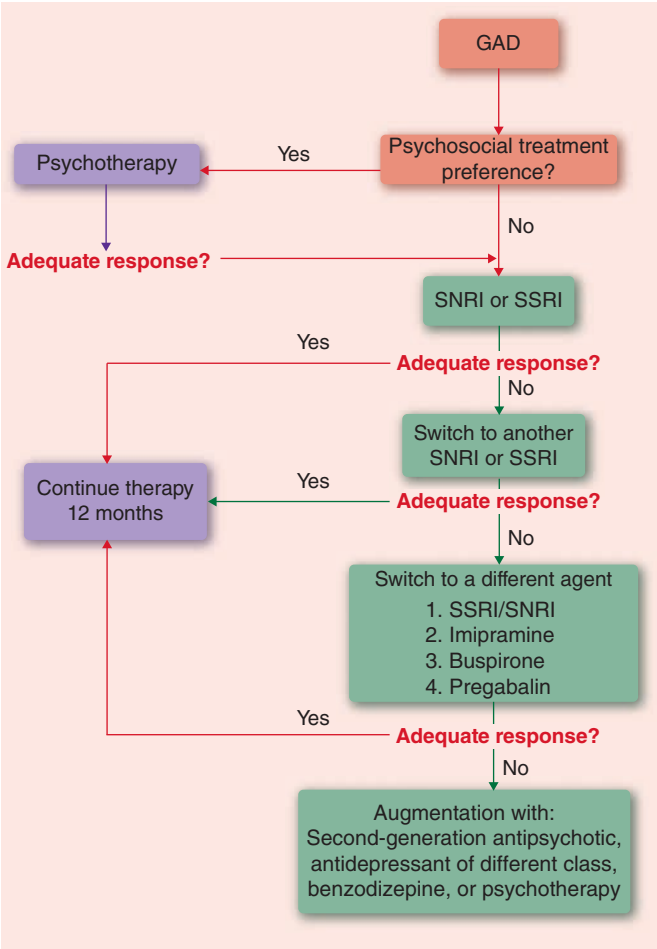

FIGURE 40–2. Treatment algorithm for generalized anxiety disorder. (SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.) (Data from Refs. 17, 19, 20, 25.)

approximately one-third of patients.[17,20,25,27] Common side effects include somnolence, headache, nausea, dry mouth (paroxetine), diarrhea (sertraline), sweating (sertraline), decreased libido, ejaculation disorder, anorgasmia, and asthenia.

SSRI therapy is better tolerated than TCAs, and tolerability is similar to that of SNRIs. The SSRIs, sertraline, fluoxetine, and fluvoxamine, have demonstrated benefits in children and adolescents with GAD and are the preferred pharmacologic treatment in this population.[21]

Serotonin Norepinephrine Reuptake Inhibitors Venlafaxine and duloxetine alleviate anxiety with or without comorbid depression, and maintain response with extended treatment.[17,20,25,27] Venlafaxine and duloxetine are effective for GAD in children and adolescents.[22] Common side effects reported in patients with GAD are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.

Vortioxetine has been evaluated in the treatment of GAD with conflicting results; however, a recent meta-analysis of four randomized controlled acute trials found vortioxetine more effective than placebo in reducing anxiety symptoms.[28]

Tricyclic Antidepressants Imipramine treatment of GAD results in a higher rate of remission of anxiety symptoms than treatment with trazodone or diazepam.[20] Both antidepressants were more effective than diazepam or placebo in reducing psychic symptoms of anxiety. TCA use is limited by bothersome adverse effects (eg, sedation, orthostatic hypotension, anticholinergic effects, and weight gain). TCAs have a narrow therapeutic index and are lethal in overdose because of atrioventricular block.

Novel Antidepressants Mirtazapine, an α-2 adrenergic antagonist and postsynaptic 5-HT_2 and 5-HT_3 receptor antagonist, is an effective antidepressant but has not been extensively evaluated in anxiety disorders. It is not associated with sexual dysfunction, but does have a propensity to cause sedation and weight gain. Bupropion, a DA and NE reuptake inhibitor, lacks the common antidepressant side effects of weight gain and sexual dysfunction. Bupropion has not been studied or used extensively in anxiety disorders. However, a small controlled trial comparing bupropion XL with escitalopram found bupropion to have comparable anxiolytic efficacy and tolerability.[17,20] Vilazodone, a SSRI and 5-HT1A receptor partial agonist, has shown benefit compared to placebo in several short-term randomized controlled trials in GAD, but does not appear to have advantages over generically available SSRIs/SNRIs.[29]

▶ *Benzodiazepines*

KEY CONCEPT Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.[17,20,27] Benzodiazepine treatment results in a significant improvement in 65% to 75% of GAD patients, and most of the improvement occurs in the initial 2 weeks.[20] They are more effective for somatic symptoms than psychic symptoms. Major benzodiazepine disadvantages are lack of effectiveness for depression; risk for withdrawal and potential need for taper; risk for dependency and abuse; and potential interdose rebound anxiety, especially with short-acting benzodiazepines. They should be avoided in older adults and patients with current or past chemical dependency.

Benzodiazepines enhance transmission of the inhibitory neurotransmitter GABA through interaction with the $GABA_A$-receptor complex.[19,20] All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. They differ substantially in their pharmacokinetic properties and potency for the $GABA_A$-receptor (Table 40–4).

Benzodiazepines are metabolized by hepatic oxidation (cytochrome P450 3A4) and glucuronide conjugation. Because lorazepam and oxazepam bypass hepatic oxidation and are conjugated only, they are preferred agents for patients with reduced hepatic function secondary to aging or disease (eg, cirrhosis; hepatitis B or C from intravenous drug use). Many benzodiazepines are metabolized to long-acting metabolites (Table 40–4) that provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or glucuronidation can cause drug interactions (Table 40–5).

The most common side effects of benzodiazepine therapy include central nervous system (CNS) depressive effects (eg, drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (eg, poor recall and anterograde amnesia). Anterograde amnesia is more likely with high-potency benzodiazepines such as alprazolam.[33] Some patients also may be disinhibited and experience confusion, irritability, aggression, and excitement.[19,20] Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and a high rate of relapse. Higher doses of benzodiazepines and a longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered rather than discontinued abruptly from benzodiazepine therapy

Table 40–3

Pharmacotherapy for the Treatment of Generalized Anxiety Disorder

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Hepatic Insufficiency	Renal Insufficiency
Antidepressants				
SSRIs				
Citalopram[a] (Celexa)	20	20–40	Maximum, 20 mg/day	
Escitalopram[b] (Lexapro)	10	10–20	Maximum, 10 mg/day	
Fluoxetine (Prozac)	20	20–80	Titrate with caution	
Fluvoxamine (Luvox)	50	100–300	Titrate with caution	
Paroxetine (Paxil)[b]	20	20–50	Titrate with caution	
Paroxetine CR (Paxil CR)	25	25–62.5	Maximum, 50 mg/day	Maximum, 50 mg/day
Sertraline (Zoloft)	50–100	50–200	Reduce dose	
SNRIs				
Venlafaxine XR[b] (Effexor XR)	75	75–225	Reduce dose by 50%	Reduce dose 25%–50%
Desvenlafaxine (Pristiq)	50	50–100	Maximum, 100 mg/day	Maximun, 50 mg/day; CrCl < 30 mL/min (0.50 mL/s), dose once every other day
Duloxetine[b,c] (Cymbalta)	30	60–120	Use not recommended	CrCl < 30 mL/min (0.50 mL/s) Use not recommended[b]
TCAs				
Imipramine (Tofranil)	50–75	75–200	Titrate with caution	
Other Agents				
Hydroxyzine (Atarax)	25–50	50–100		Reduce dose by 50% GFR < 50 mL/min (0.83 mL/s)
Azapirones				
Buspirone (Buspar)	5–15	20–30	Not recommended in severe hepatic impairment	Not recommended in severe renal impairment
Anticonvulsants				
Pregabalin (Lyrica)	150	150–600		Reduce dose[d]
Second-Generation Antipsychotic				
Quetiapine XR (Seroquel XR)	50	50–300		

[a]Maximum daily dose of citalopram is 20 mg/day when used in the elderly or when given concomitantly with CYP2C19 inhibitors.

[b]Food and Drug Administration approved for use in generalized anxiety disorder.

[c]Duloxetine use is not recommended in severe renal impairment (creatinine clearance < 30 mL/min [0.50 mL/s]).

[d]Dose reduction recommended for CrCl < 60 mL/min (1.0 mL/s) and again for CrCl, 30 mL/min (0.50 mL/s) and 15 mL/min (0.25 mL/s).

CR, controlled-release; CrCl, creatinine clearance; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; XR, extended release.

Data from Refs. 19 and 30.

to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy.[19,20] A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (eg, return of original symptoms at increased intensity) are transient. The patient should be educated that rebound anxiety is not a relapse. Relapse or recurrence of anxiety may occur in as many as 50% of patients discontinuing benzodiazepine treatment.[19,20] It is unclear if this relapse rate represents an inferiority of benzodiazepines or supports the chronic nature of GAD.

► *Pregabalin*

Pregabalin is a calcium channel modulator, and its anxiolytic properties are attributed to its selective binding to the α-2-delta subunit of voltage-gated calcium channels. Pregabalin reduces anxiety with a similar onset to alprazolam.[17,27,29] Compared with venlafaxine and placebo, pregabalin was safe, well tolerated, and efficacious in GAD, and results were seen one week sooner than with venlafaxine.[17] Pregabalin reduces the risk of relapse during maintenance treatment.[17,27,29] It has a short elimination half-life and must be dosed two to three times daily. It is excreted renally with a low risk of drug–drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria, and may cause withdrawal symptoms if discontinued abruptly. It should be used cautiously in patients with a current or past history of substance abuse. It is not beneficial for depression or other anxiety disorders.

► *Alternative Agents*

Hydroxyzine, buspirone, and SGAs are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety[20] but not for psychic features of anxiety, depression, or other common comorbid anxiety disorders. Buspirone, a 5-HT_{1A} partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing.[34]

Table 40–4

Comparison of Benzodiazepines

Drug Name (Brand Name)	Metabolite	Time to Peak Concentration (hours)	Half-Life Range (hours)	Approved Dosage Range (mg/day)	Dose Equivalent (mg)
Alprazolam[a,b] (Xanax)		1–2	12–15	1–4 (GAD) 1–10 (PD)	0.5
Lorazepam[a] (Ativan)		2–4	10–20	0.5–10	0.75–1
Oxazepam[a] (Serax)		2–4	5–15	30–120	15
Clonazepam[b] (Klonopin)		1–4	18–50	1–4	0.25
Chlordiazepoxide[a] (Librium)		1–4	5–30	25–100	10
	Desmethyldiazepam		40–120		
	Desmethlychlordiazepoxide		18		
	Demoxepam		14–95		
	Oxazepam		5–15		
Clorazepate[a] (Tranxene)		1–2		7.5–60	7.5
	Desmethyldiazepam		40–120		
	Oxazepam		5–15		
Diazepam[a] (Valium)		0.5–2	20–80	2–40	5
	Desmethyldiazepam		40–120		
	Oxazepam		5–15		
	Temazepam		8–15		

[a]Food and Drug Administration (FDA) approved for use in generalized anxiety disorder.

[b]FDA approved for use in panic disorder.

[c]CYP2C19 genetic polymorphisms resulting in little or no enzyme activity are present in 15% to 20% of Asians and 3% to 5% of blacks and whites, resulting in reduced clearance of desmethyldiazepam.[34]

GAD, generalized anxiety disorder; PD, panic disorder.

Data from Refs. 30 and 31.

Table 40–5

Pharmacokinetic Drug Interactions with Benzodiazepines

Drug	Effect
Alcohol (chronic)	Increased CL of BZs
Carbamazepine	Increased CL of alprazolam
Cimetidine	Decreased CL of alprazolam, diazepam, chlordiazepoxide, and clorazepate and increased $t_{1/2}$
Disulfiram	Decreased CL of alprazolam and diazepam
Erythromycin	Decreased CL of alprazolam
Fluoxetine	Decreased CL of alprazolam and diazepam
Fluvoxamine	Decreased CL of alprazolam and prolonged $t_{1/2}$
Itraconazole	Potentially decreased CL of alprazolam and diazepam
Ketoconazole	Potentially decreased CL of alprazolam
Nefazodone	Decreased CL of alprazolam, AUC doubled, and $t_{1/2}$ prolonged
Omeprazole	Decreased CL of diazepam
Oral contraceptives	Increased free concentration of chlordiazepoxide and slightly decreased CL; decreased CL and increased $t_{1/2}$ of diazepam and alprazolam
Paroxetine	Decreased CL of alprazolam
Phenobarbital	Increased CL of clonazepam and reduced $t_{1/2}$
Phenytoin	Increased CL of clonazepam and reduced $t_{1/2}$
Probenecid	Decreased CL of lorazepam and prolonged $t_{1/2}$
Propranolol	Decreased CL of diazepam and prolonged $t_{1/2}$
Ranitidine	Decreased absorption of diazepam
Rifampin	Increased metabolism of diazepam
Theophylline	Decreased alprazolam concentrations
Valproate	Decreased CL of lorazepam

AUC, area under the plasma concentration time curve; BZ, benzodiazepine; CL, clearance; $t_{1/2}$, elimination half-life.

Adapted from Melton ST, Kirkwood CK. Anxiety disorders: I. Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:1079, with permission.

Unlike benzodiazepines, it does not have abuse potential, cause withdrawal reactions, or potentiate alcohol and sedative-hypnotic effects. It has a gradual onset of action (ie, 2 weeks) and does not provide immediate anxiety relief. Data are inconsistent regarding its efficacy in chronic GAD or GAD with comorbid depression.[17,20,27,29] It may be less effective in patients who have been treated previously (4 weeks–5 years) with benzodiazepines.[20]

Buspirone is well tolerated and most common side effects include dizziness, nausea, and headaches. Buspirone elimination is affected significantly by drugs that inhibit (eg, verapamil, diltiazem, itraconazole, fluvoxamine) or induce (eg, rifampin) CYP3A4.[32] Buspirone may increase blood pressure when coadministered with a monoamine oxidase inhibitor (MAOI).

The SGAs, quetiapine, olanzapine, and risperidone have demonstrated benefit in GAD. In three large placebo-controlled trials, quetiapine in daily doses of 50 to 300 mg resulted in 26% greater likelihood of treatment response (effect size, ~0.3).[35] Quetiapine had similar outcomes to paroxetine 20 mg/day and escitalopram 10 mg/day.[35] Low dose risperidone (0.5–1.5 mg/day) and olanzapine (2.5–15 mg/day) may improve treatment outcomes in patients with inadequate response to initial pharmacotherapy.[17,20,27] SGAs are associated with a risk of weight gain, glucose intolerance, sedation, fatigue, and extrapyramidal symptoms which limit their use.

Outcome Evaluation

Assess patients for improvement of anxiety symptoms and return to baseline of occupational, social, and interpersonal functioning. Brief questionnaires like the Generalized Anxiety Disorder 7-Item (GAD-7) may be used to monitor changes in symptoms and measure response to treatment.[36] With effective treatment, patients should have no or minimal symptoms of anxiety or depression. With initiation of drug therapy, evaluate patients frequently for tolerability and response. Monitor for suicidal ideation and behaviors for children, adolescents, and young adults (24 years of age or less) initiated on antidepressants.[21,37,38] Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment as some patients require up to 1 year of treatment.[17,20,27]

LO 7

TREATMENT: PANIC DISORDER

Desired Outcomes

LO 3

The main objectives of treatment are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and avoidant behavior, and minimize symptoms of depression or other comorbid disorders.[39] The long-term goal is to achieve and sustain remission and restore overall functioning.

General Approach to Treatment

LO 5

Treatment options include medication, psychotherapy, or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without comorbid agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms. KEY CONCEPT The acute phase of PD treatment lasts about 12 weeks and should markedly reduce or eliminate panic attacks and minimize anticipatory anxiety and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.[17,20,39] For patients who relapse after discontinuation, therapy should be resumed.[39]

Clinical Presentation and Diagnosis of PD

General

Typically presents in late adolescence or early adulthood. Onset in older adults raises suspicion of a relationship to medical disorders or substance use. Laboratory evaluation must be driven by history and physical examination.

Symptoms[1]

LO 2

Recurrent, unexpected panic attacks. A panic attack is an abrupt surge of intense fear or discomfort peaking within minutes, and with four or more of the following symptoms:

- Palpitations or rapid heart rate
- Sweating
- Trembling or shaking
- Sensation of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy or lightheaded
- Chills or hot flushes
- Paresthesias
- Derealization or depersonalization
- Fear of dying
- Fear of losing control or "going crazy"

At least one of the attacks has been followed by 1 month or more of one or both:

- Persistent concern or worry about additional attacks
- Significant maladaptive change in behavior related to the attacks (eg, avoidance)

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 40–1 and 40–2).

Laboratory Evaluation

- Urine drug screen
- Basic metabolic panel (HbA_{1C})
- Thyroid-stimulating hormone
- Electrocardiogram

Patient Encounter 2

A 15-year-old male presents to the pediatric clinic for his annual examination. He reports having difficulty with his grades and feels very anxious when taking an examination at school or presenting to his class. He did not try out for the high school soccer team as he was afraid he would embarrass himself and would not make the team. He avoids study groups after school as it makes him "nervous". He has one close friend and avoids going to parties or hanging out with large groups of his peers. He denies substance use.

His medical history is positive for ADHD.

Meds: None

His medical workup is noncontributory, and he is diagnosed with SAD.

What treatment options should be considered?

What are the benefits of using pharmacotherapy versus psychotherapy versus both?

Nonpharmacologic Therapy

LO 4 Patients with PD should avoid stimulant agents (eg, decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT generally includes psychoeducation, self-monitoring, countering anxious beliefs, exposure to fear cues, and modification of anxiety-maintaining behaviors.[20,39] Exposure therapy is useful for patients with phobic avoidance.[20,39]

LO 5 CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. Some studies suggest lower risk of relapse after CBT versus drug therapy.[39] CBT in combination with antidepressant treatment is more effective than either treatment alone.[40]

Pharmacologic Therapy

LO 6 Patients with PD may be treated with TCAs, SSRIs, SNRIs, or MAOIs, as well as benzodiazepines[17,20,39] (Table 40–6) with similar effectiveness, but SSRIs are the treatment of choice. Benzodiazepines often are used concomitantly with antidepressants, especially early in treatment, or as monotherapy to acutely reduce panic symptoms. Benzodiazepines are not preferred for long-term treatment but may be used when patients fail several antidepressant trials.[17,20,39] PD patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in Figure 40–3.

▶ *Antidepressants*

Antidepressants typically require 4 weeks for onset of antipanic effect, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. KEY CONCEPT PD patients are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses (see Table 40–6) in PD patients than in depressed patients. Target doses are similar to those used for depression. KEY CONCEPT Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.

Table 40–6

Antidepressants Used in the Treatment of Panic and Social Anxiety Disorder[18,23,42]

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Advantages	Disadvantages
SSRIs/SNRIs			**SSRIs (in General)** Antidepressant activity; antianxiety activity; single daily dosing (all but fluvoxamine); low toxicity; available in generic	**SSRIs (in General)** Activation; delayed onset of action; may precipitate mania; sexual side effects; GI side effects
Citalopram	10	20–40		
Escitalopram[b]	5–10	10–20		
Fluoxetine[a]	5–10	20–60		
Fluvoxamine	25	100–300		
Paroxetine[a,b]	10	20–60		
Sertraline[a,b]	25	50–200		
Venlafaxine XR[a,b]	37.5	75–225		
TCAs			**TCAs (in General)** Established efficacy; available in generic	**TCAs (in General)** Activation; sedation; anticholinergic effects; cardiovascular effects; delayed onset of action; may precipitate mania; sexual side effects; toxic in overdose; weight gain
Clomipramine	25 mg (twice a day)	75–250		
Imipramine[a]	10–25	75–250		
MAOI				
Phenelzine	15	45–90	Antidepressant effects; available in generic	Dietary restrictions; drug interactions; weight gain; orthostasis; may precipitate mania

[a]Food and Drug Administration approved for use in panic disorder.

[b]Food and Drug Administration approved for use in social anxiety disorder.

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 20, 25, and 39.

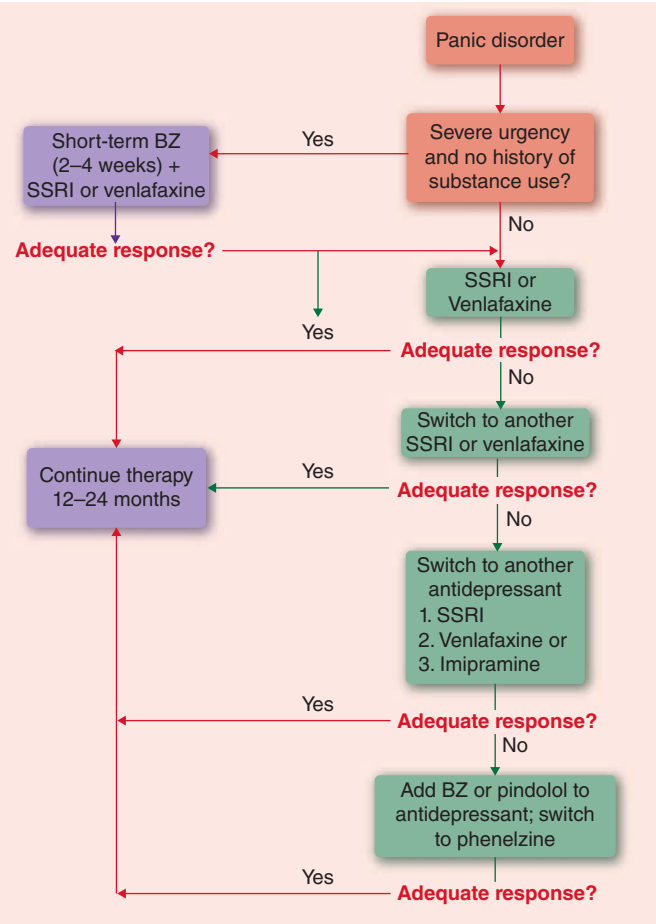

FIGURE 40–3. Algorithm for the pharmacotherapy of panic disorder. (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) (Adapted from Young AS, Klap R, Sherbourne CD, Wells KB. The quality of care for depressive and anxiety disorders in the United States. Arch Gen Psychiatry. 2001;58:55–61 and Bruce SE, Yonkers SE, Otto MW, et al. Influence of psychiatric comorbidity on recovery and recurrence in generalized anxiety disorder, social phobia, and panic disorder: a 12-year prospective study. Am J Psychiatry. 2005;162:1179–1187, with permission.)

Selective Serotonin and Serotonin-Norepinephrine Reuptake Inhibitors SSRI and SNRIs are the medications of choice for patients with PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients achieving a panic-free state.[17,20,39] Similarly, venlafaxine, in dosages of 75 to 225 mg/day, reduced panic and anticipatory anxiety in short-term controlled trials and prevented relapse with extended treatment over 6 months.[17,39] Given lack of head-to-head trials and similar efficacy between agents, drug selection is generally based on pharmacokinetics, drug interactions, side effects, and cost differences (see Chapter 38).

Tricyclic Antidepressants Treatment with imipramine has resulted in 45% to 70% of patients achieving a panic free state. Desipramine and clomipramine have also demonstrated effectiveness in PD. TCAs are considered second- or third-line therapeutic options because of poorer tolerability and toxicity upon overdose which may be fatal.[20,39] Owing to their side-effect profile, TCAs are associated with a higher rate of treatment discontinuation than SSRIs.[39] PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain. In addition, stimulant-like side effects occur in up to 40% of patients.[39]

Monoamine Oxidase Inhibitors MAOIs have not been evaluated systematically for treatment of PD under the current diagnostic classification. In general, they are reserved for patients who are refractory to other treatments.[39] They have significant side effects that limit adherence coupled with restrictions to avoid tyramine-containing foods and sympathomimetic drugs to prevent hypertensive crisis (see Chapter 38). The reversible inhibitors of monoamine oxidase (RIMAs) (brofaromine and meclobemide [unavailable in the United States]) have been studied with mixed results.[17,20,39]

Other Antidepressants There is insufficient evidence to support the use of bupropion, trazodone, nefazodone, or mirtazapine for treatment of PD.[17,20,39]

► *Benzodiazepines*

Benzodiazepines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the benzodiazepine most studied, is associated with significant panic reduction after 1 week of therapy (eg, 55%–75% panic free).[39,41] Benzodiazepines achieve outcomes similar to antidepressants over extended treatment, but benzodiazepine-treated patients are more likely to relapse when the drugs are discontinued.[39] The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of patients with PD. There is no evidence that tolerance to therapeutic effect occurs. Patients with PD experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do patients with GAD.[20,39] Tapering should be done at a slower rate and over a more extended period of time than with other anxiety disorders.[20,39]

KEY CONCEPT The dose of benzodiazepine required for improvement generally is higher than that used in other anxiety disorders, and this may explain why high-potency agents such as alprazolam and clonazepam generally are preferred. Lorazepam and diazepam, when given in equivalent doses, produce similar treatment benefits.[20,39] Doses should be titrated to response (see Table 40–4). The use of extended-release alprazolam or clonazepam may minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.[41]

► *Adjunctive Treatment*

LO 6 Pindolol, a mixed beta-adrenergic/serotonergic medication, at a dose of 25 mg three times a day is effective as adjunctive treatment with an SSRI for treatment resistant PD.[39] Propranolol, a nonselective β-blocker, is not effective for PD and is not recommended.[39]

Outcome Evaluation

LO 8 Assess patients for symptom improvement frequently (eg, weekly) during the first 4 weeks of therapy. With effective therapy, patients should experience significant reductions in the frequency and intensity of panic attacks, anticipatory anxiety, and phobic avoidance with resumption of normal activities.

Clinical Presentation and Diagnosis of SAD

General

Individuals have marked fear or anxiety about one or more social situations where they are exposed to possible scrutiny or negative evaluation (eg, common social interactions, conversation, eating, drinking, or performing). SAD differs from specific phobia, in which the fear and anxiety are limited to a particular object or situation (eg, insects, heights, public transportation). In children, the anxiety must be present in peer settings, not just in interactions with adults.

Symptoms[1]

LO 2

- The individual fears acting in a way or showing anxiety that will be negatively evaluated (ie, humiliating or embarrassing or lead to rejection or offend others)
- Social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety. Children may express fear or anxiety by crying, tantrums, freezing, clinging, or failing to speak in social situations.
- The fear or anxiety is
  - out of proportion to the actual threat posed by the social situation;
  - persistent, typically lasting for 6 months or more;
  - causes clinically significant distress or impairment in social, occupational, or other areas of functioning;
  - not attributable to physiological effects of a substance or another medical condition; and
  - not better explained by the symptoms of another mental disorder (eg, panic disorder, body dysmorphic disorder, or autism spectrum disorder)

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 40–1 and 40–2).

Laboratory Evaluation

Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

LO 7 Rating scales, such as the Panic Disorder Symptom Scale (PDSS), can be useful in measuring symptom change over time. Assess patients for comorbidities (eg, depression) as well as suicidal ideation. Alter the therapy of patients who do not achieve a significant reduction in panic symptoms after 6 to 8 weeks on an adequate dose of antidepressant or 3 weeks on a benzodiazepine.

LO 8 Regularly evaluate patients for adverse effects and medication adherence, and educate them about appropriate expectations of drug therapy.

When significant response to drug therapy is achieved, continue treatment for at least 1 year. Evaluate for symptom relapse and adverse effects that may emerge with continued treatment (eg, weight gain and sexual dysfunction). During drug discontinuation, monitor frequently for withdrawal, rebound anxiety, and relapse.

TREATMENT: SOCIAL ANXIETY DISORDER

Desired Outcomes

LO 3 SAD is a chronic disorder that begins in adolescence and occurs with significant functional impairment and high rates of comorbidity. The goal of acute treatment is to reduce physiologic symptoms of anxiety, fear of social situations, and phobic behaviors. Patients with comorbid depression should have a significant reduction in depressive symptoms. The long-term goal is to restore social functioning and improve the patient's quality of life.

General Approach to Treatment

LO 5 Patients with SAD may be managed with pharmacotherapy or psychotherapy. There is insufficient evidence to recommend one treatment over the other, and data are lacking on the benefits of combining treatment modalities. Children with SAD should be offered psychotherapy first.[17,42,43] Pharmacotherapy often is the first choice of treatment owing to relative greater access and reduced cost compared with psychotherapy.[42,43] Many patients will not achieve a full response.

Nonpharmacologic Therapy

LO 8 Patient education on disease course, treatment options, and expectations is essential. Support groups may be beneficial for some patients. CBT targets avoidance-learning and negative-thinking patterns associated with social anxiety. CBT is effective for reducing anxiety and phobic avoidance with response in 50% to 65% of patients, and leads to a greater likelihood of maintaining response after treatment discontinuation than does pharmacotherapy.[17,42] Web-based CBT is an alternative when access to face-to-face CBT is a barrier.[17,43]

Pharmacologic Therapy

Several pharmacologic agents have demonstrated effectiveness in SAD, including the SSRIs, venlafaxine, phenelzine, RIMAs, benzodiazepines, gabapentin, and pregabalin (Table 40–6). KEY CONCEPT SSRIs are considered the drugs of choice based on their tolerability and efficacy for SAD and comorbid depression if present. The onset of response for antidepressants may be as long as 8 to 12 weeks.[20,44] Patients responding to medication should be continued on treatment for at least 1 year.[17,20,43] Many patients relapse when medication is discontinued, and there are no clear predictive factors for who will maintain response.[44] Some patients may elect more long-term treatment owing to fear of relapse. A suggested treatment algorithm is shown in Figure 40–4.

▶ *Selective Serotonin Reuptake Inhibitors and Venlafaxine*

The efficacy of paroxetine, sertraline, escitalopram, fluvoxamine, and venlafaxine was established in large controlled trials.[20,44,45] SSRIs and SNRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. SSRIs reduce the risk of relapse with extended treatment.[46] Limited data support the effectiveness of citalopram and fluoxetine in SAD.[46,47]

The initial dose of SSRI and venlafaxine is similar to that used in depression. Patients should be titrated as tolerated to response. Patients with comorbid PD should be started on lower doses (see Table 40–6). When discontinuing SSRI/SNRIs, the dose should be tapered slowly to avoid withdrawal symptoms. Relapse rates

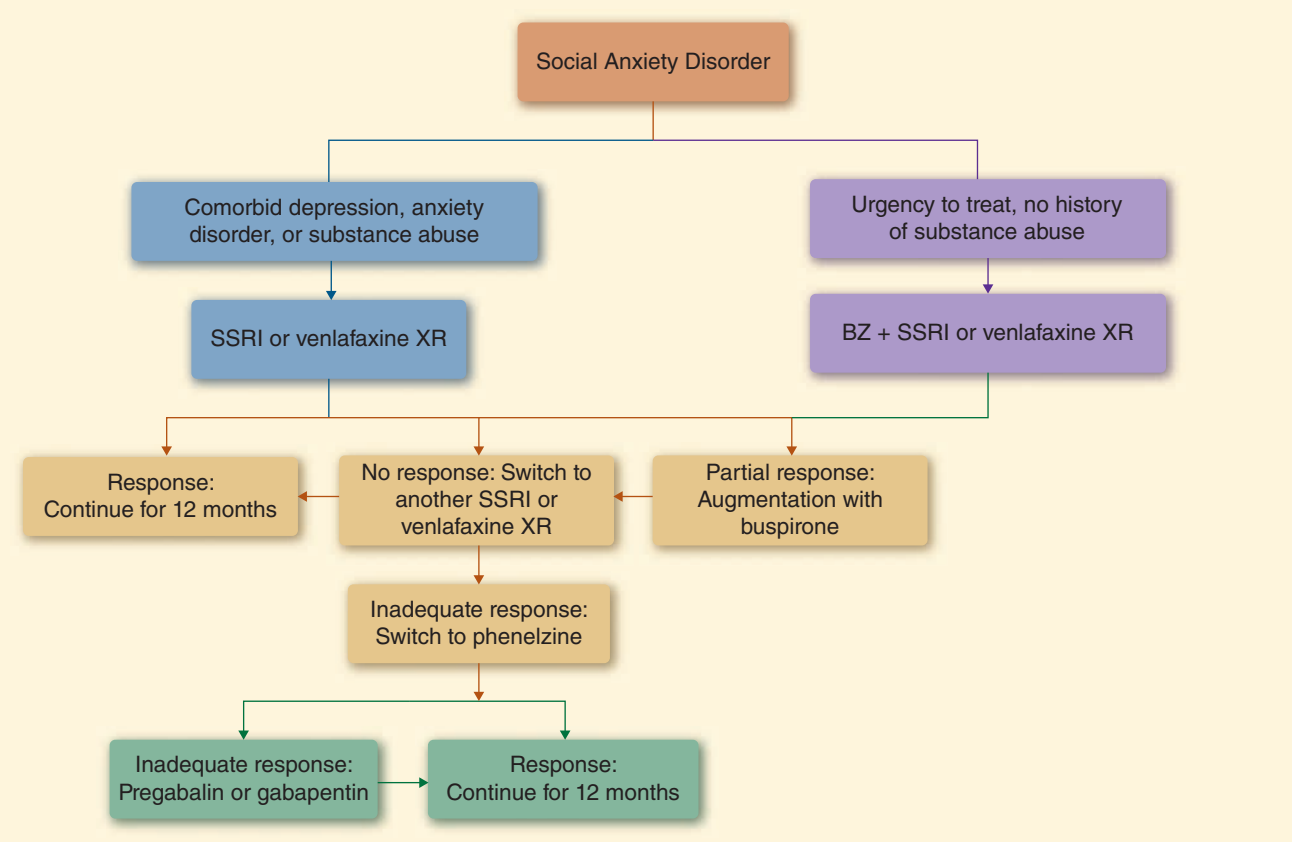

FIGURE 40–4. Algorithm for the pharmacotherapy of social anxiety disorder. (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor; XR, extended release.) (Adapted from Melton ST, Kirkwood CK. Anxiety disorders I: generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill; 2011:1209–1227, with permission.)

may be as high as 50%, and patients should be monitored closely for several weeks.[43,44] Side effects of SSRI/SNRIs in SAD are similar to those seen in depression.

▶ *Monoamine Oxidase Inhibitors and Reversible Inhibitors of Monoamine Oxidase*

Phenelzine, effective in 64% to 69% of SAD patients,[44] is generally reserved for treatment-refractory patients owing to dietary restrictions,[47] drug interactions, and side effects. The RIMAs brofaromine and meclobemide are also effective.

▶ *Alternative Agents*

Benzodiazepines Benzodiazepines are used commonly in SAD; however, limited data support their use. Clonazepam was shown effective for social anxiety, fear, and phobic avoidance, and it reduced social and work disability during acute treatment.[44] Long-term treatment is not desirable for many SAD patients because of the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms. Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy.

Anticonvulsants Gabapentin and pregabalin, structurally similar anticonvulsants, have each demonstrated modest benefit in a randomized, placebo-controlled trial.[17,20,46] Gabapentin was titrated to a maximum dose of 3600 mg/day and pregabalin to 600 mg/day. While both medications have good tolerability, they should be considered for patients with inadequate response to SSRI/SNRIs.

β-Blockers β-Blockers decrease the physiologic symptoms of anxiety and are useful for reducing performance anxiety (eg, speech, interview). Propranolol or atenolol should be administered 1 hour before a performance situation. β-Blockers are not useful for management of SAD.[44,46]

Outcome Evaluation

KEY CONCEPT Pharmacotherapy for patients with SAD should lead to improvement in anxiety and fear, functionality, and overall well-being.[20,43] Many patients will experience significant improvement in symptoms but may not achieve full remission. Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. Inquire about adverse effects, SAD symptoms, suicidal ideation, and symptoms of comorbid psychiatric conditions at each visit. Ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations.[20] Administer the Liebowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a "self-assessment" tool.[43,48] Counsel patients on appropriate expectations of pharmacotherapy in SAD, including gradual onset of effect and the need for extended treatment of at least 6 months following response.

LO 7

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications.
- Review medical history and physical examination findings.
- Review mental status examination and screen for depression, anxiety, and substance use.
- Interview the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect treatment access or preference.

Assess the Information:

- Determine whether the patient is taking any medication or substance that could cause or worsen anxiety (Table 40–2).
- Review relevant laboratory tests (eg, urine toxicology, thyroid stimulating hormone).
- Document pertinent family medical and mental health history (eg, depression, anxiety, substance use, suicide).
- Based on clinical presentation, mental status examination, and screening tools (eg, GAD-7), determine whether the patient is experiencing symptoms of sufficient intensity and duration to warrant treatment.
- Document current symptom severity using a valid measurement-based tool (eg, GAD-7, LSAS).
- Identify comorbidities that will affect treatment choice (eg, depression, substance use).
- Assess the efficacy, safety, and adherence of current pharmacotherapy, if applicable.
- Identify any significant adverse drug effects or interactions.

Develop a Care Plan:

- Select lifestyle modifications and antianxiety therapy that are likely to be effective and safe.
- Use shared decision making for selection of behavioral and pharmacotherapy treatment intervention(s).
- Choose medications and doses that are optimal for the patient based on age, anxiety disorder, and comorbid conditions (see Tables 40–3, 40–4, and 40–6).

Implement the Care Plan:

- Educate the patient about antianxiety medication effectiveness, onset and expected time to benefit, administration, and common adverse effects.
- Address any patient concerns about anxiety and its management.
- Discuss the importance of lifestyle modifications to reduce anxiety (eg, social support, substance use, exercise).
- Determine whether the patient has access to recommended medication or behavioral treatment (eg, insurance, medication on formulary, CBT provider nearby).

Follow-up: Monitor and Evaluate:

- Follow-up at monthly intervals or more frequently during acute treatment to assess effectiveness and tolerability until treatment goal achieved.
- Review medication adherence and anxiety symptom control.
- Use appropriate rating scales to assess symptom change over time.
- Once anxiety is controlled and baseline function restored, determine the appropriateness of treatment beyond 1 year based on the patient's previous treatment and comorbid conditions.

Abbreviations Introduced in This Chapter

CBT	Cognitive-behavioral therapy
CNS	Central nervous system
DA	Dopamine
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
GAD	Generalized anxiety disorder
HPA	Hypothalamic–pituitary–adrenal
5-HT	Serotonin
LC	Locus ceruleus
LSAS	Liebowitz Social Anxiety Scale
MAOI	Monoamine oxidase inhibitor
MDD	Major depressive disorder
NCS-R	National Comorbidity Survey, Revised
NE	Norepinephrine
NPY	Neuropeptide Y
OCD	Obsessive-compulsive disorder
OTC	Over-the-counter
PD	Panic disorder
PDSS	Panic Disorder Symptom Scale
RAS	Reticular activating system
RIMA	Reversible inhibitors of monoamine oxidase A
SAD	Social anxiety disorder
SGA	Second-generation antipsychotic
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant

41 Sleep Disorders

John M. Dopp and Bradley G. Phillips

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. List the sequelae of undiagnosed or untreated sleep disorders and appreciate the importance of successful treatment of sleep disorders.
2. State the incidence and prevalence of sleep disorders.
3. Describe the pathophysiology and characteristic features of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless legs syndrome (RLS), obstructive sleep apnea (OSA), and parasomnias.
4. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize daytime and nighttime symptoms and characteristics of common sleep disorders.
5. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.
6. Recommend and optimize appropriate pharmacotherapy for sleep disorders.
7. Describe the components of the patient care process to implement and assess safety and efficacy of pharmacotherapy for common sleep disorders.
8. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

INTRODUCTION

Individuals with normal sleep patterns sleep up to one-third of their lives and spend more time sleeping than in any other single activity. Despite this, our understanding of the full purpose of sleep and the mechanisms regulating sleep homeostasis remains incomplete. Sleep is necessary to enable one to maintain wakefulness and good health. Disruption of normal sleep is a major cause of societal morbidity, lost productivity, and reduced quality of life.[1] Sleep disturbances may contribute to the development and progression of comorbid medical conditions.[1]

LO 1

Sleep is governed and paced by the suprachiasmic nucleus in the brain that regulates circadian rhythm. Environmental cues and amount of previous sleep also influence sleep on a daily basis. There are two main types of sleep: **rapid eye movement (REM) sleep**, during which eye movements and dreaming occur but the body is mostly paralyzed, and **non–rapid eye movement (NREM) sleep**, which consists of four substages (stages 1–4). Stage 1 serves as a transition between wake and sleep. Most of the time being asleep is spent in stage 2 NREM sleep. Stage 3 sleep is referred to as *deep sleep*, or *delta sleep*, because prominent delta waves are seen on the electroencephalogram (EEG) during this stage of sleep.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 50% of adults will report a sleep complaint over the course of their lives.[2] In general, sleep disturbances increase with age, and each disorder may have gender differences. The full extent and impact of disordered sleep on our society are not known because many patients' sleep disorders remain undiagnosed. Normal sleep, by definition, is "a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment."[3] Individuals with sleep disorders exhibit or complain about consequent symptoms (eg, daytime sleepiness) or a bed partner often observes hallmark characteristics of the sleep disorder. Insomnia, restless legs syndrome (RLS), and sleep-related breathing disorders are the most common sleep disorders.

Insomnia

LO 2

The prevalence of insomnia increases with age and is nearly 1.5 times greater in women than in men. Approximately one-third of patients older than age 65 years have persistent insomnia.[4,5] About 10% of adults experience chronic insomnia, and slightly more experience short-term insomnia. KEY CONCEPT Diagnostic criteria for insomnia specify difficulty initiating sleep, maintaining sleep or early morning awakenings occur at least three times per week for a minimum duration of at least 3 months. Forty percent of patients with psychiatric conditions have accompanying insomnia.[6] Insomnia is frequently triggered by acute stress and resolves when the stress resolves. Numerous coexisting medical conditions, such as pain, thyroid abnormalities, asthma, and gastroesophageal reflux, and medications, including selective serotonin reuptake inhibitors (SSRIs), steroids, stimulants, and β-agonists, can cause insomnia.

Narcolepsy

LO 2

Although difficult to estimate, the prevalence of narcolepsy is between 0.03% and 0.06%.[7] Significant differences have been reported for various ethnic groups. Narcolepsy has a higher prevalence in Japanese and a lower prevalence in Israeli

populations.[8,9] The new classification system reclassifies the disorder into narcolepsy type 1 (narcolepsy with cataplexy), and narcolepsy type 2 (narcolepsy without cataplexy). Between 50% and 80% of patients with narcolepsy have accompanying **cataplexy**.[10]

Restless Legs Syndrome (Willis-Ekbom Disease) and Periodic Limb Movement Disorder

LO 2

RLS occurs in 6% to 12% of the population.[11,12] Prevalence increases with age and in various medical conditions, such as end-stage renal disease, pregnancy, and iron deficiency.[13] RLS appears to be more common in women than in men and has a genetic link in a majority of patients.[14]

Obstructive Sleep Apnea

LO 2

Obstructive sleep apnea (OSA) affects 4% of middle-aged white men and 2% of middle-aged white women.[15] In women, the frequency increases after menopause. Prevalence is the same or higher in African Americans and lower in Asian populations. The risk for OSA increases with age and obesity. Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. Severity is determined by **nocturnal polysomnography** (NPSG) or home sleep study and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) experienced during sleep. Severity is expressed as the **respiratory disturbance index** (RDI), quantified in events per hour.

Parasomnias

NREM **parasomnias** have variable prevalence rates depending on patient age and comorbid diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. Nightmares appear to occur with similar frequency in adults and children. REM-sleep behavior disorder (RBD), an REM-sleep parasomnia, has a reported prevalence of 0.5%, is more common in elderly men, and frequently is associated with concomitant neurologic conditions.[16]

PATHOPHYSIOLOGY

Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Whereas serotonin is thought to control NREM sleep, cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, **hypocretin**, substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatments are beneficial.

Insomnia

LO 3

There is no single pathophysiologic explanation for the manifestations of insomnia. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

Narcolepsy

LO 3

The onset of narcolepsy–cataplexy is typically in adolescence, suggesting that the disease may require environmental influence to develop. Currently, it is believed that narcolepsy results from autoimmune insult to the CNS because it is associated with human leukocyte antigen (major histocompatibility complex) DQB10602 and DQ1A1*0102.[17,18] Concentrations of hypocretin (a wake-promoting neuropeptide) in the cerebrospinal fluid of patients with narcolepsy and cataplexy are reduced significantly (< 110 pg/mL [ng/L; 31 pmol/L]), suggesting that the autoimmune attack is against hypocretin-producing cells in the hypothalamus.[19]

RESTLESS LEGS SYNDROME (WILLIS-EKBOM DISEASE) AND PERIODIC LIMB MOVEMENTS DISORDER (PLMD)

LO 3

RLS is a neurologic medical condition characterized by an irresistible desire to move the limbs. It is thought that these abnormal sensations are a result of iron deficiency in the brain and iron-handling abnormalities in the CNS. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, are reduced in the substantia nigra of patients with RLS.[20] These iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra. Recently, it has been suggested that local hypoxia in the legs may contribute to pathophysiology of RLS.[21]

OBSTRUCTIVE SLEEP APNEA

LO 3

At least 20 muscles and soft tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse, including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller lower jawbone, also may play a role in the pathogenesis of OSA. Patients with sleep apnea often are obese and may be predisposed to weight gain.

Poor sleep architecture and fragmented sleep secondary to OSA can cause excessive daytime sleepiness (EDS) and neurocognitive deficits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, heart failure, and stroke.[22,23] OSA is likely an independent risk factor for the development of hypertension.[24] Furthermore, when hypertension is present, it is often resistant to antihypertensive therapy. Breathing against a closed upper airway during sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses.[25]

PARASOMNIAS

LO 3

The pathogenesis of parasomnias (eg, sleepwalking, enuresis, sleep talking) is variable, poorly described, and involves state dissociation, whereby two states of being overlap simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active inhibition of motor activity in the perilocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

Clinical Presentation and Diagnosis

KEY CONCEPT Patients with sleep complaints should have a careful sleep history performed to assess their possible sleep disorder in order to guide diagnostic and therapeutic decisions.

Daytime Symptoms and Associated Characteristics

EDS is the primary symptom described by patients with sleep disorders. It is usually described as not waking up refreshed in the morning or falling asleep or fighting the urge to sleep during the day despite a night of sleep. Other daytime characteristics of sleep disorders include:

- Irritability, fatigue, or depression
- Confusion or impaired performance at work or school
- Cataplexy
- Hypertension

Nighttime Sleep Complaints

Depending on the sleep disorder, patients may exhibit or experience various nocturnal complaints during sleep. Some complaints can be uncovered by clinical history alone (eg, hallucinations, RLS, snoring), but others can be diagnosed during sleep studies (eg, OSA, nighttime awakenings, somnambulism, PLMS [Periodic limb movements of sleep], etc). Frequent complaints include:

- Inability to fall asleep, nighttime awakenings
- Sleep walking (somnambulism), sleep talking (somniloquy)
- Cessation of breathing (apnea), snoring
- Sleep paralysis or hallucinations when waking or falling asleep
- Restlessness (PLMS or RLS)

CLINICAL PRESENTATION AND DIAGNOSIS

LO 4

KEY CONCEPT Although the clinical history guides diagnosis and therapy, only NPSG, home sleep studies, and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA, narcolepsy, and periodic limb movement disorder. All patients presenting with sleep complaints should have a thorough interview and history to inventory their sleep habits and sleep hygiene.

Insomnia

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, and early morning awakenings, which may result in daytime impairments in concentration and school or work performance. In some situations, social factors (eg, family difficulties, bereavement), medications (eg, antidepressants, β-agonists, corticosteroids, decongestants), and coexisting medical or psychiatric conditions (eg, depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep.

Narcolepsy

The hallmark of narcolepsy is EDS, and may also include disrupted nighttime sleep. Patients with narcolepsy experience the tetrad of EDS, cataplexy, sleep paralysis, and hypnagogic/hypnopompic hallucinations (dream-like images that appear at sleep-wake transitions). Cataplexy is a weakness or loss of skeletal muscle tone in the jaw, legs, or arms that is elicited by emotion (eg, anger, surprise, laughter, or sadness).

Restless Legs Syndrome and Periodic Limb Movement Disorder

Although RLS symptoms can vary, patients commonly report creepy-crawly, burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor restlessness. Symptoms are worse in the evening and are worse or exclusively present at rest, with temporary relief with movement. Symptoms also can occur during sleep and often lead to semi-rhythmic PLMS. PLMS are objective findings during NPSG recorded by leg electrodes. PLMS are present in most patients with RLS but can occur independently.

Obstructive Sleep Apnea

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches. A bed partner or roommate may observe these symptoms and witness apneic episodes where the patient stops breathing. Patients with large neck sizes (> 45 cm [~18 in] neck circumference) and a body mass index (BMI) of 30 kg/m^2 or greater are at higher risk for OSA.

Parasomnias

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep (eg, sleepwalking, sleep eating, sleep talking, bruxism [grinding of teeth], enuresis, night terrors, and RBD). People with RBD act out their dreams during sleep, often in a violent manner.

Circadian Rhythm Disorders

The most common circadian rhythm disorders (CRDs) include jet lag, shift-work sleep disruption, delayed sleep-phase disorder, and advanced sleep-phase disorder. Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Delayed and advanced sleep-phase disorders occur when bed and wake times are delayed or advanced (by 3 or more hours) compared with socially prescribed bed and wake times.

Sleep Diagnostics

Complete NPSG is the "gold standard" for diagnosing and identifying sleep-disordered breathing, PLMS, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting using an EEG, electrooculography, electromyography, electrocardiography, air thermistors, abdominal and thoracic strain belts, and an oxygen saturation monitor. This setup records sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, airflow, respiratory effort, and oxygen desaturations. Home sleep studies are increasingly used to diagnose sleep apnea due to their reduced cost and increased patient convenience. These devices typically measure nasal airflow, respiratory effort, oxygen saturation, and heart rate to determine if a patient experiences apnea/hypopnea episodes.

The MSLT is a commonly performed test to assess daytime sleepiness. During the MSLT, the patient attempts to take a 20-minute nap every 2 hours during the day beginning 2 hours

after morning awakening (after a normal night's sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. Sleep latency of less than 5 to 6 minutes is considered pathologically sleepy. The occurrence of a REM onset period during two naps with short sleep latency is indicative of a diagnosis of narcolepsy.

TREATMENT

Desired Outcomes

KEY CONCEPT Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.

General Approach to Treatment

LO 5 LO 6 LO 8

Nonpharmacologic interventions for insomnia are outlined in Table 41–1. Sleep hygiene should be reinforced in all patients, and behavioral, cognitive, and stimulus-control interventions are used mainly for patients with insomnia-type complaints. Both pharmacologic and nonpharmacologic therapies are effective at improving sleep and reducing insomnia complaints. An algorithm for the initial assessment and first treatment step of EDS is provided in Figure 41–1.

Insomnia

KEY CONCEPT Early treatment of insomnia may prevent the development of persistent psychophysiologic insomnia. The ideal hypnotic drug would be effective at reducing sleep latency, increasing total sleep time, and would be free of unwanted side effects. KEY CONCEPT Benzodiazepine receptor agonists (BZDRAs) (including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone) and ramelteon are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.[2,26,27] Pharmacologic treatment of insomnia is recommended for transient and acute insomnia. Long-term use of hypnotics is not contraindicated unless the patient has another contraindication to their use. Eszopiclone is the only sedative hypnotic approved by the FDA for chronic use up to 6 months.[28] Although not first-line agents for insomnia, sedating antidepressants are also commonly prescribed.

Table 41–1

Nonpharmacologic Therapies for Insomnia

Sleep Hygiene
- Keep a regular sleep schedule.
- Exercise frequently but not immediately before bedtime.
- Avoid alcohol and stimulants (caffeine, nicotine) in the late afternoon and evening.
- Maintain a comfortable sleeping environment that is dark, quiet, and free of intrusions.
- Avoid consuming large quantities of food or liquids immediately before bedtime.

Stimulus Control
- Go to bed only when sleepy.
- Avoid daytime naps.
- If you cannot sleep, get out of bed and go to another room—only return to your bed when you feel the need to sleep.
- Bed is for sleep and intimacy only (no eating or watching TV in bed).
- Always wake up at the same time each day.

Relaxation Training
- Reduce somatic arousal (muscle relaxation).
- Reduce mental arousal (eg, attention-focusing procedures, imagery training, meditation).
- Use biofeedback (visual or auditory feedback to reduce tension).

Cognitive Therapy
- Alter beliefs, attitudes, and expectations about sleep.

▶ *Benzodiazepine Receptor Agonists*

Pharmacokinetic differences between the eight BZDRAs help to guide selection, depending on patient considerations and specific sleep complaints (Table 41–2). These agents occupy the benzodiazepine site on the γ-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.[33] BZDRAs are the first-line agents for treating insomnia and sleep-maintenance problems. They are all efficacious, have wide therapeutic indices, and have a low incidence of abuse.[26,28,29]

Patients should be instructed to take BZDRAs at bedtime and avoid activities requiring alertness after ingestion. Although BZDRAs generally are well-tolerated and have good safety profiles, mild to moderate side effects can occur, and precautions are warranted.

Precautions and Safety The most common side effects associated with BZDRAs include residual sedation into the waking hours after sleep, grogginess, and psychomotor impairment.[30] Selection of a hypnotic with a duration of action matching the patient's budgeted sleep time can help minimize the risk of residual sedation. BZDRAs should be initiated at low doses, and agents with active metabolites (see Table 41–2) should be avoided in elderly patients. BZDRAs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug. All sedatives can cause anterograde amnesia, and higher doses increase the extent of amnesia.[31,32]

On discontinuation of hypnotic BZDRAs, patients may experience rebound insomnia that may last for a few nights. Rebound insomnia occurs more frequently after discontinuation of shorter duration BZDRAs compared with longer duration BZDRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside. In general, eszopiclone, zaleplon, and zolpidem appear to be associated with lower risk of tolerance, rebound insomnia, and withdrawal than traditional benzodiazepines. Zolpidem, however, is associated with increased reports of complex sleep behaviors (sleep eating, sleep driving, etc). Female patients have reduced zolpidem clearance compared to males, and the maximum dose of zolpidem is 5 mg for female patients.

▶ *Sedating Antidepressants*

Sedating antidepressants (eg, trazodone, amitriptyline, mirtazapine, doxepin) are commonly used for insomnia and may be an appealing option in patients with concomitant depression. However, at the doses frequently used for sleep, only mirtazapine exhibits significant antidepressant activity. Furthermore, quality clinical studies demonstrating efficacy for insomnia are lacking. Side effects from antidepressants can be frequent, including carryover sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs; eg, amitriptyline) should be used with caution in the elderly and patients with cardiovascular and hepatic impairment. The TCA doxepin

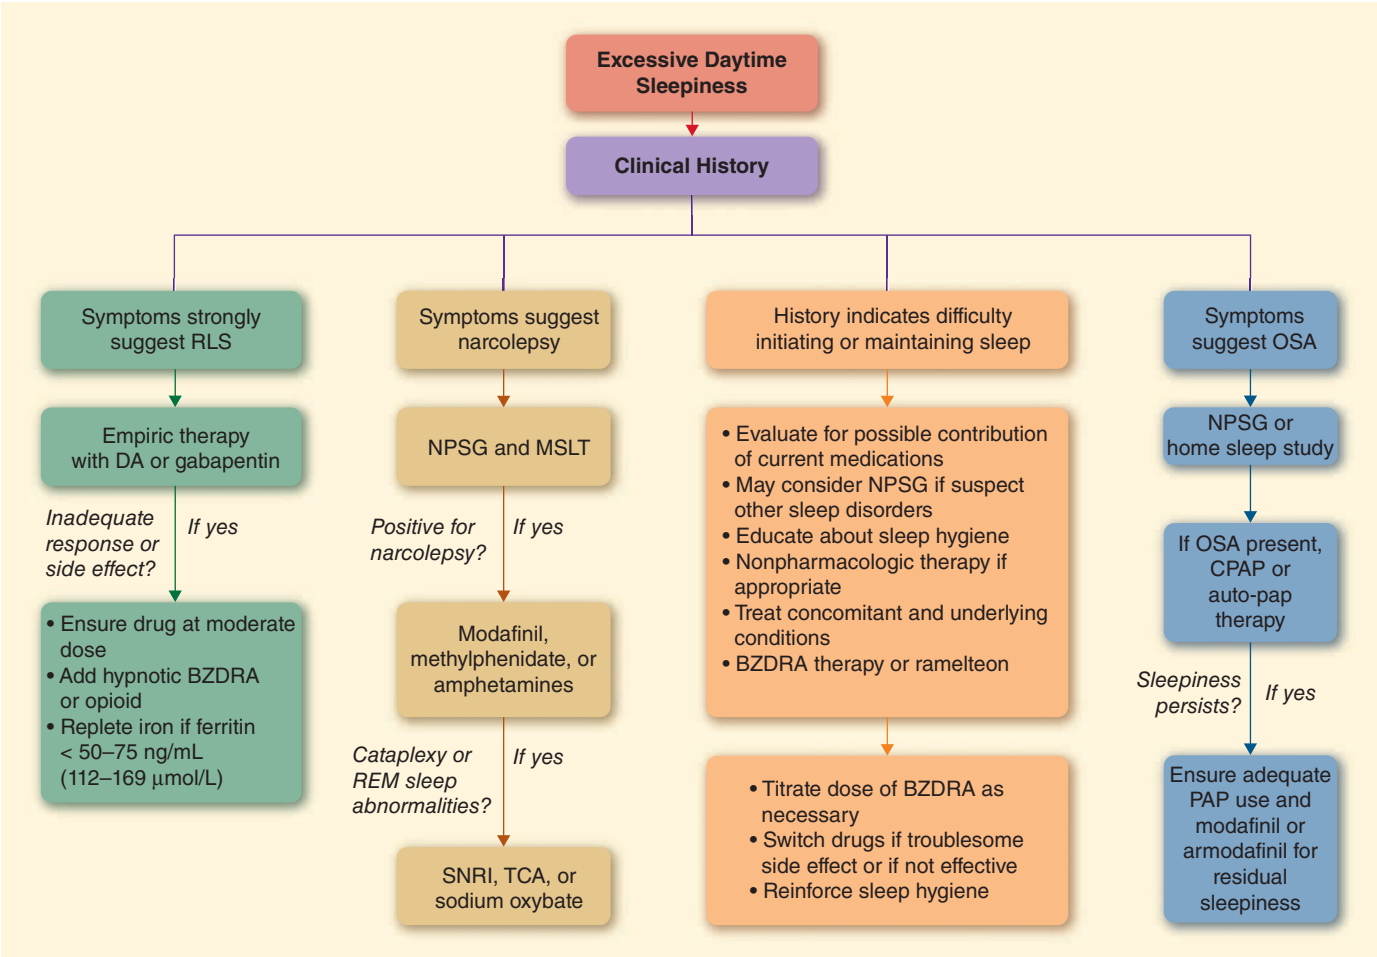

FIGURE 41–1. Primary assessment and initial treatment for complaint of excessive daytime sleepiness. (BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure; DA, dopamine agonist; MSLT, multiple sleep latency test; NPSG, nocturnal polysomnography; OSA, obstructive sleep apnea; PAP, positive airway pressure; REM, rapid eye movement; RLS, restless legs syndrome; SNRI, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant.)

is approved for treatment of sleep maintenance insomnia at low doses (3–6 mg). Mirtazapine can cause daytime sedation, dizziness, and weight gain; trazodone can cause orthostatic hypotension and dizziness and should be used with caution in patients with heart disease or hypertension and those taking cardiovascular agents.[33,34]

▶ *Over-the-Counter Agents*

Over-the-counter antihistamines such as diphenhydramine are frequently used (usual doses, 25–50 mg) for difficulty sleeping. Diphenhydramine is FDA-approved for the treatment of insomnia and can be effective at reducing sleep latency and increasing sleep time.[35] However, diphenhydramine produces undesirable anticholinergic effects and carryover sedation that limit its use, especially in the elderly. Valerian root is an herb that has inconsistent effects on sleep but may reduce sleep latency and increase efficiency at commonly used doses of 400 to 900 mg valerian extract.

▶ *Miscellaneous Agents*

Ramelteon, a melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse. Suvorexant, an orexin receptor antagonist, is the first medication that turns off wakefulness mechanisms instead of stimulating pathways that induce sleepiness. Suvorexant is indicated for both difficulty initiating and maintaining sleep, and like BZDRAs, it is classified as a Schedule IV controlled substance.[36] Both suvorexant and ramelteon have documented safety in those with chronic obstructive pulmonary disease and OSA.[36-39]

Narcolepsy

Therapy for narcolepsy involves two key principles: (a) treatment of EDS with scheduled naps and CNS stimulants and (b) suppression of cataplexy and REM-sleep abnormalities with aminergic signaling drugs. Modafinil, armodafinil, methylphenidate, and amphetamines are effective FDA-approved drugs for the treatment of EDS with narcolepsy.[40] Modafinil and armodafinil (the active R-isomer of modafinil) are Schedule IV medications, and these drugs may have fewer peripheral and cardiovascular effects than traditional stimulants. Selegiline, a selective monoamine oxidase B enzyme inhibitor, is metabolized to amphetamines and can reduce daytime sleepiness. In an individual patient, one wake-promoting agent may work better than another, and if the first drug selected is not successful at

Table 41–2

Pharmacokinetics and Dosing of Prescription Medications[a] Approved to Treat Insomnia

Generic Name	Parent $t_{½}$ (hours)	Duration of Action (hours)	Daily Dose Range (mg)	Recommended Daily Dose in Elderly (mg)[b]	Dose or Action in Hepatic Impairment	Comments
Doxepin (Silenor)	15.3	Unpublished[c]	3–6	3	3 mg	Effective for sleep maintenance difficulties only
Estazolam (Prosom)	2	12–15	1–2	0.5	Dose ↓ may be needed	Moderate duration
Eszopiclone (Lunesta)	6	8	2–3	1–2	1 mg in severe impairment	Can be used up to 6 months for chronic insomnia
Flurazepam (Dalmane)	8	10–30	15–30	15	No change necessary	High risk of hangover and residual effects
Quazepam (Doral)	2	25–41	7.5–15	7.5–15	Dose ↓ may be needed	High risk of hangover and residual effects
Ramelteon (Rozerem)	1–2.6	Unpublished[c]	8	No specific recommendations	Do not use in severe hepatic impairment	Noncontrolled substance; may be useful in patients with a history of substance abuse
Suvorexant (Belsomra)	12	Unpublished	10–20	No specific recommendations	No change necessary	Novel mechanism of action—little documented rebound upon discontinuation
Temazepam (Restoril)	10–15	7	7.5–30	7.5	No change necessary	Moderate duration, well tolerated, inexpensive
Triazolam (Halcion)	2	6–7	0.125–0.25	0.125	0.125 mg	Short acting; little residual hangover
Zaleplon (Sonata)	1	6	5–10	5	5 mg	Short acting; only for difficulty falling asleep
Zolpidem (Ambien)	2–2.6	6–8	5–10[d]	5	5 mg	Short to moderate duration; no effects on sleep architecture
Zolpidem CR (Ambien CR)	2.8	7–8	6.25–12.5[d]	6.25	6.25 mg	Longer duration of action than regular release zolpidem
Zolpidem sublingual (Intermezzo)	2.5	Less than 4	1.75–3.5[d]	1.75	1.75 mg	Approved for middle-of-the-night insomnia taken more than 4 hours before awakening

[a]In 2007, the Food and Drug Administration required additional information added to the safety labeling of sedative–hypnotic drugs concerning potential risks, including severe allergic reactions and complex sleep-related behaviors, which may include sleep driving. Sleep driving is defined as driving while not fully awake after ingestion of a sedative–hypnotic product with no memory of the event.

[b]If a dosing range is displayed, the first dose listed should be the starting dose.

[c]Data not available.

[d]For zolpidem, recommended dose for women is 5 mg, 6.25 mg for zolpidem CR, and 1.75 mg for sublingual zolpidem.

CR, controlled release.

adequate doses, a trial with another agent should be attempted. KEY CONCEPT Treatment of EDS in narcolepsy and other sleep disorders may require sustained- and immediate-release stimulants to promote wakefulness throughout the day and at key times that require alertness. One potential treatment regimen includes a sustained-release stimulant preparation first thing in the morning and again at noon followed by an immediate-release stimulant preparation as needed in the late afternoon or before driving to maintain wakefulness. One advantage of traditional CNS stimulants over modafinil is their ability to help control cataplexy and REM-sleep abnormalities.

Traditional CNS stimulants have the potential to increase blood pressure and heart rate when used long term. In addition, excessive CNS stimulation can cause tremors and tics and can carry over into evening hours, disrupting normal nighttime sleep. Caution should be used in patients with underlying cardiovascular or cerebrovascular disease and in patients with a history of seizures because stimulants may lower the seizure threshold.

► *Cataplexy*

Traditionally, aminergic signaling antidepressants have been used effectively to control symptoms of cataplexy, sleep paralysis, and other REM-sleep manifestations of narcolepsy.[40] These include TCAs and certain selective serotonin and serotonin/norepinephrine reuptake inhibitors (SSRIs and SNRIs). Clomipramine, protriptyline, imipramine, venlafaxine, and fluoxetine are the agents used most frequently. In addition,

Patient Encounter Part 1

A 48-year-old woman with a history of RLS complains of worsened RLS symptoms, excessive daytime sleepiness, disrupted nighttime sleep, and change of her RLS symptoms. She states her symptoms now appear in her arms and legs and start to appear in the late afternoon. Additionally, her husband tells you that now she has begun snoring quite loudly over the past year. She takes pramipexole 0.75 mg two hours before bedtime and sertraline 100 mg daily.

What sleep problems do her symptoms suggest?

What additional information do you need to know in your assessment of this patient?

low-dose selegiline may be effective at reducing cataplexy. Although not approved by the FDA for treatment of cataplexy, these drugs suppress REM sleep and have been the mainstay of anticataplectic therapy for years. Sodium oxybate, a potent sedative with a very short duration of action, is FDA approved for the treatment of narcolepsy with cataplexy. Its mechanism of action is not entirely known. Two doses per night are taken, one at bedtime and one follow-up dose taken 2½ to 4 hours later. Sodium oxybate is tightly regulated and is available from only one central pharmacy because of its high abuse potential.

Restless Legs Syndrome and Periodic Limb Movement Disorder

KEY CONCEPT RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative–hypnotic medications are prescribed commonly. Dopamine agonists (DAs) successfully treat RLS symptoms and offer many advantages over levodopa–carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa–carbidopa eventually will experience symptom augmentation: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, duration of relief gets shorter, and higher doses of medication are required to control symptoms.[41] Augmentation should be managed by tapering and discontinuing dopaminergic medications, repleting body iron stores (if low) and switching to alternative medications such as gabapentin. Additionally, use of longer-duration DAs may reduce symptom augmentation.[42] Ropinirole, pramipexole, and rotigotine are FDA approved for the treatment of RLS and are available in sustained-release products.[43]

Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms.[44] The gabapentin prodrug (gabapentin enacarbil) is FDA approved for RLS at a recommended dose of 600 mg taken with food at about 5 pm.[45] Although not FDA approved for RLS, pregabalin has demonstrated similar or greater efficacy compared to DAs for RLS treatment.[46] BZDs (eg, temazepam, clonazepam) and GABA-agonists (eg, zolpidem, zaleplon) reduce arousals in patients with RLS.[47] Their main benefit is derived from improving sleep continuity in patients with RLS, particularly as adjunct treatment with other pharmacologic therapies. Opioids are effective in some patients with RLS symptoms, with oxycodone, hydrocodone, and methadone being used most frequently. For both BZDRAs and opioids, caution should be used in the elderly, in patients who are at risk for sleep apnea, and in patients with a history of substance abuse. Low iron levels frequently exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 to 75 mcg/L (ng/mL; 112–169 pmol/L) improves RLS symptoms. Medications frequently used for RLS are shown in Table 41–3.

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Test

The patient undergoes further workup for her sleep complaint, which includes an overnight sleep study (in-lab).

PMH: Restless legs syndrome × 4 years, depression × 10 years

FH: Noncontributory

SH: Married, no children. No tobacco or alcohol intake.

Meds: Pramipexole 0.75 mg taken at 8:00 PM

Sertraline 100 mg daily

ROS: (+) daytime sleepiness (Epworth sleepiness score: 16 out of 24); (+) symptoms of RLS

PE:

VS: BP 122/68 mm Hg, P 72 beats/min, RR 16 breaths/min, T 37°C (98.6°F); BMI 21 kg/m^2

Labs: TSH 1.6 μIU/mL (mIU/L), Ferritin 31 ng/mL (mcg/L; 70 pmol/L)

Overnight Polysomnogram: Bedtime at 10 PM; awake at 7 AM. Significant snoring but no significant apneas observed, with accompanying frequent awakenings.

- RDI 4.6 events/hour
- 230 limb movements, 124 caused arousal

Given this additional information, summarize what is occurring with this patient.

Identify your treatment goals and therapy recommendations for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient if the prescribed therapy is not successful or not tolerated?

Patient Encounter Part 3: Modifying the Treatment Plan

The patient returns to the clinic 3 months later. The physician previously tapered pramipexole due to RLS symptom augmentation and initiated gabapentin and oral iron therapy. The patient was instructed to gradually reduce her pramipexole dose by 0.25 mg per week and then discontinue it. She reports today that the gabapentin has helped improve her RLS symptoms but she still feels like she awakens frequently during the night and her sleep is still disrupted. She still is somewhat sleepy during the day. Her Epworth sleepiness scale (ESS) score today is 13 out of 24.

Based on the information presented, recommend therapy and a plan for the patient.

Table 41–3

Frequently Used Medications for Restless Legs Syndrome

Generic Name (Brand Name)	Half-Life (hours)	Dose Range (mg/day)[a]	Potential Side Effect or Disadvantage
Dopaminergic Agents[b]			
Levodopa–carbidopa (Sinemet)	1.5–2	100–200 of levodopa	Nausea or vomiting; high incidence of symptom augmentation
Pramipexole (Mirapex)	8–12[c]	0.125–0.5	Nausea or vomiting; risk of compulsive behaviors[d]
Ropinirole (Requip)	6[e]	0.25–3	Nausea or vomiting; risk of compulsive behaviors[d]
Rotigotine (Neupro)	5–7	1–3	Application site reactions with patch
Anticonvulsants			
Gabapentin (Neurontin, Horizant)	5–7[c]	300–3600	Dizziness, ataxia
Pregabalin (Lyrica)	5–6.5	50–300	Weight gain, daytime sedation
Hypnotic Agents			
Clonazepam (Klonopin)	30–40	0.5–2	Tolerance, carryover sedation
Temazepam (Restoril)	10–15	7.5–30	Tolerance, carryover sedation
Zolpidem (Ambien)	2–2.6[e]	5–10	Tolerance
Zaleplon (Sonata)	1[e]	5–10	Tolerance; may not last entire night
Opioids			
Hydrocodone	3.8–4.5[e]	5–10	Constipation, nausea, sedation
Codeine	2.5–3.5[e]	30–60	Constipation, nausea, sedation
Methadone	22[e]	5–20	Constipation, nausea, sedation
Oxycodone	3.2–12[c,e]	5–30	Constipation, nausea, sedation

[a]Usual range; all medications (other than dopaminergic agents) are dosed at bedtime.

[b]Dopaminergic agents are frequently given at bedtime or 2 hours before bedtime or the anticipated onset of RLS symptoms.

[c]May be longer in patients with renal dysfunction.

[d]Compulsive behaviors such as gambling, shopping, sexual behaviors, and eating have been reported in patients taking dopamine agonists.

[e]May be longer in patients with hepatic dysfunction.

Data from Earley CJ. Restless legs syndrome. N Engl J Med. 2003;348:2103–2109.

Obstructive Sleep Apnea

KEY CONCEPT The main therapy for OSA is nasal **continuous positive airway pressure (CPAP)** therapy, which alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. A flexible tube connects the CPAP machine to a mask that covers the nose. CPAP therapy has a favorable impact on blood pressure and attenuates some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

Not all individuals tolerate CPAP therapy, in part because it requires wearing a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be reduced by properly fitting the mask, adding humidity to therapy, or using bilevel positive airway pressure (BiPAP) or auto-titrating continuous positive airway pressure (AutoPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase. AutoPAP machines are set for a pressure range and individualize the pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open.

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, and studies have reported reduced severity of OSA following bariatric surgery. For patients who cannot tolerate CPAP, oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who have OSA only when on their backs during sleep, positional therapies may be effective. Surgical therapy (uvulopalatopharyngoplasty) is not a first-line option because of its invasiveness and relatively low long-term effectiveness.

There is no drug therapy for OSA. Drug therapy for symptoms of OSA may be considered in selected patients. Modafinil and armodafinil are wake-promoting medications that are approved by the FDA to treat residual daytime sleepiness despite CPAP therapy. Initiation of these medications should be attempted only after patients are using optimal CPAP therapy to alleviate sleep-disordered breathing. The need for treating residual sleepiness in this population is not clear because it may not be related to the OSA and is similar to sleepiness in the general population.[48] OSA should always be considered and evaluated in hypertensive patients who are resistant to therapy.

Parasomnias

NREM parasomnias usually do not require treatment. If needed, low-dose BZDRAs such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stages 3 and 4 of NREM sleep, when most NREM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective. Patients with RBD also should have dangerous objects removed from the bedroom and environmental accommodations made to reduce the chance of injury from breakthrough episodes.

Circadian Rhythm Disorders

Melatonin, 0.5 to 5 mg taken at appropriate target bedtimes for east or west travel, is the drug of choice for jet lag. Melatonin significantly reduces jet lag and shortens sleep latency in travelers.[49] Hypnotic agents with relatively short durations of action (3–5 hours) may also be used to sustain sleep during the initial adaptation to the new time zone.

Drug–Disease and Drug–Drug Interactions

KEY CONCEPT It is important to review medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug–drug interactions and assessed for treatment adherence. Pharmacotherapy for sleep disorders should be individualized. Often medications can treat several concomitant sleep disorders. Conversely, drug therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate symptoms of RLS. Medications that block dopaminergic transmission may worsen RLS symptoms. Alcohol and CNS depressants, including opiates, sedatives, and muscle relaxants, can worsen OSA, even in small doses, by reducing respiratory drive and relaxing the upper airway muscles responsible for maintaining patency. CNS depressants should be avoided, and if they are necessary, they should not be administered before sleep. Drug therapy for sleep disorders should be patient specific, and careful consideration should be given to coexisting diseases, concomitant medications, and potential drug–drug and drug–disease interactions to optimize patient care and treatment.

OUTCOME EVALUATION

Evaluate whether the treatment plan restored normal sleep patterns, reduced daytime sequelae, and improved quality of life without causing adverse effects. Schedule patients for follow-up within 3 weeks for insomnia and within 3 months for other sleep disorders. Perform a detailed clinical history to determine the patient's perception of treatment progress and symptoms along with medication effectiveness and side effects.

Instruct patients to keep sleep diaries (number of hours, number of awakenings, and worsening or improved sleep) and daytime symptoms, along with documentation of episodes such as cataplexy or RBD. Increase medication to effective doses, and if necessary, start additional therapy to control symptoms. Patients with sleep disorders should experience relief of symptoms the first night of drug therapy but may not receive maximal benefit (effect on daytime symptoms) for a few weeks. Perform a detailed history of prescription, nonprescription, and complementary or alternative medications and review the patient's sleep diary, daytime symptoms, and nonpharmacologic therapies on a regular basis.

LO 7

Patient Care Process

Collect Information:

- Perform a detailed history of prescription, nonprescription, and complementary or alternative medication use.
- Based on patient nighttime and daytime complaints and bed partner report, determine the suspected sleep problem and its consequences.
- Review objective and subjective data regarding sleepiness, nighttime sleep quality, and limb movements, sleep disordered breathing, and parasomnias.
- Evaluate concomitant sleep and medical conditions that influence therapy decisions.

Assess the Information:

- Evaluate effectiveness, safety, adherence, and side effects of therapy.
- Assess whether patient is taking any medications that may contribute to sleep complaint and/or daytime complaints.
- Determine whether the patient has insurance coverage for prescribed medications.
- Review relevant laboratory parameters for sleep (eg, serum TSH, ferritin).

Develop a Care Plan:

- If patient requires sedative-hypnotic therapy, determine best agent based on timing of sleep complaint (difficulty initiating and/or maintaining sleep).
- For treatment of insomnia, try to ensure the lowest possible doses are prescribed and used for the shortest possible time period.
- If patient complaints are not entirely improved, consider increasing dose or adding a complementary agent.
- Ensure sleep hygiene (see **Table 41–1**) and drug therapy are appropriate for each sleep complaint.
- Determine if medication doses are optimal for treatment of various sleep disorders (see **Tables 41–2** and **41–3**).
- For insomnia, select medications whose duration of action matches the timing of the difficulty sleeping (eg, difficulty initiating or maintaining sleep).

Implement the Care Plan:

- Educate patient about medication changes, sleep hygiene, and importance of proper medication use and adherence.
- Address patient concerns about the sleep medication and possible adverse effects.

Follow-up: Monitor and Evaluate:

- Evaluate improvement in the specific sleep complaint (eg, how has therapy affected sleep latency or sleep maintenance?).
- Monitor daytime sleepiness, sleep diaries, and diaries of sleep events (PLMS, hallucinations, snoring, apneas, etc) and monitor cataplexy and other daytime symptoms to determine if therapy is effective.
- Make appropriate changes to therapy to address inadequately controlled symptoms and reported adverse effects.

Abbreviations Introduced in This Chapter

AutoPAP	Auto-titrating continuous positive airway pressure
BiPAP	Bilevel positive airway pressure
BMI	Body mass index
BZDRA	Benzodiazepine receptor agonist
CNS	Central nervous system
CPAP	Continuous positive airway pressure
CRD	Circadian rhythm disorder
DA	Dopamine agonist
EDS	Excessive daytime sleepiness
EEG	Electroencephalogram
ESS	Epworth sleepiness scale
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
MSLT	Multiple sleep latency test
NPSG	Nocturnal polysomnography
NREM	Non–rapid eye movement
OSA	Obstructive sleep apnea
PLMS	Periodic limb movements of sleep
RBD	REM-sleep behavior disorder
RDI	Respiratory disturbance index
REM	Rapid eye movement
RLS	Restless legs syndrome
SNRI	Serotonin/norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant

42 Attention-Deficit/ Hyperactivity Disorder

Julia Boyle, Kevin W. Cleveland, and John Erramouspe

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Explain accepted criteria necessary for the diagnosis of attention-deficit/hyperactivity disorder (ADHD).
2. Recommend a therapeutic plan, including drug selection, initial doses, dosage forms, and monitoring parameters, for a patient with ADHD.
3. Differentiate among the available pharmacologic agents used for ADHD with respect to pharmacology and pharmaceutical formulation.
4. Recommend second-line and/or adjunctive agents that can be effective alternatives in the treatment of ADHD when stimulant therapy is less than adequate.
5. Address potential cost–benefit issues associated with pharmacotherapy of ADHD.
6. Recommend strategies for minimizing adverse effects of ADHD medications.

Attention-deficit/hyperactivity disorder (ADHD) is characterized by a persistent pattern of inattention and/or hyperactivity-impulsivity. It can have a severe impact on a patient's ability to function in both academic and social environments. Early diagnosis and appropriate treatment are essential to compensate for areas of deficit.

EPIDEMIOLOGY AND ETIOLOGY

KEY CONCEPT This disorder usually begins in young children and must occur before 12 years of age to meet current diagnostic criteria. In the United States, ADHD is the most common neurobehavioral disorder that affects children.[1] ADHD has been diagnosed in approximately 11% of school-aged children.[2] ADHD occurs more than twice as often in school-aged boys than girls.[3]

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adult ADHD is estimated to be 2.5%; majority of adults with ADHD have symptoms that manifested in childhood.[3,4] Furthermore, problems associated with ADHD (eg, social, marital, academic, career, anxiety, depression, smoking, and substance abuse problems) increase with the transition of patients into adulthood. Untreated adults with ADHD have high rates of psychopathology, substance abuse, and social and occupational dysfunction.

PATHOPHYSIOLOGY

KEY CONCEPT The exact pathologic cause of ADHD has not been identified. ADHD is generally thought of as a disorder of self-regulation or **response inhibition** and **cognitive deficits**.[5] Patients who meet the criteria for ADHD have difficulty maintaining self-control, resisting distractions, concentrating on ideas, and often alternate between inattentiveness to overexcitement.[3,6]

KEY CONCEPT Dysfunction of the **neurotransmitters** is thought to be key in the pathology of ADHD. Norepinephrine is responsible for maintaining alertness and attention; dopamine is responsible for regulating learning, motivation, goal setting, and memory. Both of these neurotransmitters predominate in the frontal subcortical system, an area of the brain responsible for maintaining attention and memory. Genetics appears to play a role because a child who has a parent with ADHD has a 50% chance of developing ADHD. An association has been made between the development of ADHD and fetal alcohol syndrome, lead poisoning, maternal smoking, and hypoxia.[3,6]

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT ADHD is rarely encountered without comorbid conditions such as oppositional defiant and conduct disorder and often is misdiagnosed.[1] It is important to identify and appropriately treat coexisting conditions in patients with ADHD.

According to most recent diagnostic guidelines, all patients 4 to 18 years of age presenting with inattention, hyperactivity, impulsivity, academic, and/or behavioral problems should be evaluated for ADHD. Additional behavior information from various settings should be gathered from the patient, family, and teachers. The age of onset, frequency, severity, and duration of symptoms should be documented.[3,6]

LO 1

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*).[3] The *DSM-5* defines three presentations of ADHD: (a) predominately inattentive; (b) predominantly hyperactive-impulsive; and (c) combined, in which both inattentive and hyperactive or impulsive symptoms are evident.[3,6] It is recommended that parents and teachers complete a standardized rating scale based on the *DSM-5* criteria.[3] Rating scales are not by themselves diagnostic but are diagnostic aids when added to a careful history and interview.[7]

TREATMENT

Desired Outcomes

KEY CONCEPT The primary therapeutic objectives in ADHD are to improve behavior and increase attention or response inhibition; secondary goals of treatment are to:

- Improve interpersonal relationships and academic performance
- Decrease disruptive behavior
- Increase independence
- Minimize adverse effects of therapy

Nonpharmacologic (Behavioral) Therapy

LO 2 Behavioral therapy can be useful; however, it is generally not recommended as first-line monotherapy except in preschool-aged children (4–5 years of age).[3,6] KEY CONCEPT Studies have demonstrated pharmacotherapy alone is superior to behavioral intervention alone in improving attention. However, combined behavioral and stimulant therapy is better at improving opposition and aggression.[8] Behavioral modification involves training caregivers and teachers to change environmental factors and establish a reward/consequence system.[6] Success of behavioral modifications depends on the cooperation of the caregivers and teachers.

Pharmacologic Therapy

LO 3 The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitter function in order to improve academic and social functioning. Pharmacotherapy can be divided into two categories—stimulants and nonstimulants.

▶ *Stimulants*

KEY CONCEPT Psychostimulants (eg, methylphenidate and amphetamines) are the most effective agents in treating ADHD. Following diagnosis of ADHD, a stimulant medication should be considered first-line therapy in patients 6 years of age or older. Stimulants theoretically exert their primary effect by blocking the reuptake of dopamine and norepinephrine. In preschool-aged children, methylphenidate can be added to the patient's treatment if behavioral modification monotherapy is not sufficient.[6] Generally, LO 2 a trial of at least 3 months on a stimulant is appropriate, and this includes dose titration to response as tolerated.[6] KEY CONCEPT If treatment with the first stimulant formulation fails, it is recommended to switch to a different stimulant formulation.[3,6] For example, if the patient was started on methylphenidate but could not tolerate the side effects, switching to dextroamphetamine with or without amphetamine is appropriate. Most patients LO 4 who fail one stimulant will respond to an alternative stimulant.[6] KEY CONCEPT If the patient fails two adequate trials of different stimulant medications, a third stimulant formulation or second-line nonstimulant such as bupropion, atomoxetine, guanfacine, or clonidine can be considered. The diagnosis of ADHD should be revalidated as well.

Stimulants theoretically exert their primary effect by blocking the reuptake of dopamine and norepinephrine. They have been shown to decrease fidgeting and finger tapping, increase on-task classroom behavior and positive interactions at home and in social environments, and ameliorate conduct and anxiety disorders.[9]

LO 2 Stimulants should be initiated at recommended starting doses and titrated up with a consistent dosing schedule to the appropriate response while minimizing side effects (Table 42–1). Generally, stimulants should not be used in patients who have glaucoma, severe hypertension or cardiovascular disease, hyperthyroidism, severe anxiety, or previous illicit or stimulant drug abuse.

LO 3 Stimulant drug formulations can be divided into short-, intermediate-, and long-acting preparations (see Table 42–1). Initial response to short-acting stimulant formulations (eg, methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours.[6] Thus short-acting stimulant formulations must frequently be dosed at least twice daily, increasing the chance of missed doses and noncompliance. Patients using any stimulant formulation, but especially short-acting formulations, can experience a rebound effect of ADHD symptoms as the stimulant wears off.[9]

Most intermediate-acting stimulants release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules). The onset of action for this category of stimulants (typically 60–90 minutes) may be inadequate for some patients. Some practitioners prescribe a short-acting stimulant concurrently with an intermediate-acting stimulant to curtail the delay in onset of action of the intermediate-acting stimulant. However, this practice can increase patient copay costs.

To minimize rebound symptoms associated with short-acting formulations and still achieve early stimulant release, long-acting formulations with rapid onsets have been developed. These formulations have an early release of medication and deliver a delayed release of stimulant in either a pulsed (Adderall XR, Focalin XR, Metadate CD, Quillivant XR, and Ritalin LA) or continuous manner (Concerta). Formulations available as capsules contain coated beads that can be opened and sprinkled on semisolid food. Concerta tablets have an immediate-release overcoat and an oral osmotic controlled-release that delivers methylphenidate in an extended manner. Patients should be counseled that the empty tablet shell of Concerta can be seen in the stool.

Clinical Presentation and Diagnosis of ADHD

General

Patients with ADHD can present with inattention, hyperactivity–impulsivity, or both. ADHD is typically encountered with comorbid conditions.

Symptoms

- Inattentive type: difficulty paying attention to details in all activities; difficulty completing tasks that require a lot of mental effort; easily distracted; forgetful
- Hyperactive–impulsive type: difficulty sitting still, fidgets; has trouble playing quietly and waiting turns; frequently interrupts
- Combined: exhibits both inattention and hyperactivity–impulsivity

Diagnostic Criteria

- Must exhibit at least 6 diagnostic symptoms before 12 years of age that persist for at least 6 months
- Symptoms must be present in two or more settings and adversely affect functioning in social situations, school, or work
- Must meet the diagnostic criteria in *DSM-5* for ADHD
- Symptoms cannot be better explained by another mental disorder (eg, autism)

Table 42–1

Selected Medications for ADHD[a]

Drug, Generic (Brand Name)	Initial Dose	Titration Schedule Increments	Typical Dosing Range (Maximum Dose)
Stimulants			
Short Acting			
Methylphenidate[b] (Methylin, Ritalin)	5 mg twice daily	5–10 mg/day in weekly intervals	5–20 mg two to three times daily (60 mg/day)
Dexmethylphenidate[b] (Focalin)	2.5 mg twice daily	2.5–5 mg/day in weekly intervals	5–10 mg twice daily (20 mg/day)
Dextroamphetamine[b] (Dexedrine)	2.5–5 mg every morning	2.5–5 mg/day in weekly intervals	5–20 mg twice daily (40 mg/day)
Intermediate Acting			
Methylphenidate[b] (Ritalin SR, Metadate ER, Methylin ER)	10 mg once daily	10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
Dextroamphetamine–amphetamine[b] (Adderall)	2.5–5 mg once to twice daily	2.5–5 mg/day in weekly intervals	10–30 mg every morning or 5–20 mg twice daily (40 mg/day)
Dextroamphetamine[b] (Dexedrine Spansule)	5 mg every morning	5 mg/day in weekly intervals	5–30 mg daily or 5–15 mg twice daily (40 mg/day)
Long-Acting			
Methylphenidate[b] (Concerta)	18 mg every morning	9–18 mg/day in weekly intervals	18–54 mg every morning (54 mg/day in children)
(Metadate CD)	20 mg every morning	10–20 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
(Ritalin LA)	20 mg every morning	10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
(Quillivant XR)[c]	20 mg every morning	10–20 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
(Aptensio XR)	10 mg every morning	10 mg/day in weekly intervals	10–60 mg daily in the morning (60 mg/day)
(Cotempla XR-ODT)	17.3 mg every morning	8.6–17.3 mg/day in weekly intervals	17.3–51.8 mg daily in the morning (51.8 mg/day)
Dextroamphetamine/amphetamine[b] (Adderall XR)	5–10 mg every morning (children); 20 mg once daily (adults)	5–10 mg/day in weekly intervals	10–30 mg every morning or 5–15 mg twice daily (30 mg/day, children) (60 mg/day, adult)
Dexmethylphenidate[b] (Focalin XR)	5 mg every morning (children); 10 mg every morning (adults)	5 mg/day in weekly intervals	10–20 mg daily in the morning (20 mg/day)
Lisdexamfetamine[b] (Vyvanse)	30 mg every morning (children and adults)	10–20 mg/day in weekly intervals	30–70 mg daily in the morning (70 mg/day)
Amphetamine[b] (Dyanavel XR)	2.5–5 mg every morning	2.5–10 mg/day every 4–7 days	2.5–20 mg daily in the morning (20 mg/day)
(Evekeo)	2.5 mg every morning (3–5 years) or 5 mg every morning or twice daily (6 years or older)	2.5 mg/day (3–5 years) or 5 mg/day (6 years or older) in weekly intervals	2.5–40 mg daily in a single morning or twice daily divided dose (40 mg/day)
Nonstimulants			
Atomoxetine[b,d] (Strattera)	≤ 70 kg: 0.5 mg/kg/day divided once to twice daily > 70 kg: 40 mg once daily	To target dose of 1.2 mg/kg/day after 3 days 40 mg/day after 3 days (may ↑ to total of 100 mg/day after 2–3 weeks)	40–60 mg/day (1.4 mg/kg or 100 mg/day, whichever is less) 40–80 mg/day divided once to twice daily (100 mg/day)
Clonidine (Catapres)	0.05 mg once daily	0.05 mg/day every 3–7 days	0.1 mg 1 to 4 times daily (0.4 mg/day)
(Kapvay)[b]	0.1 mg at bedtime	0.1 mg/day in weekly intervals	0.1–0.2 mg twice daily (0.4 mg/day)
Guanfacine (Tenex)	0.5 mg at bedtime	0.5 mg every 3–14 days	1.5–3 mg/day divided into 2–3 doses (4 mg/day)
(Intuniv)[b]	1 mg once daily	No more than 1 mg/week	1–4 mg daily (4 mg/day)
Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL)	3 mg/kg/day for 7 days (children); 150 mg once daily of SR or XL (adults)	3 mg/kg/day in weekly intervals (children); increase 150–300 mg/day in weekly intervals (adults)	6 mg/kg/day or 400 mg/day—whichever is smaller (children); 150–450 mg/day (400 mg/day SR; 450 mg/day XL—adults)

[a]Pediatric dosing except when adult dosing specified.

[b]Approved by the US FDA for the treatment of ADHD.

[c]Oral extended-release suspension.

[d]Dose adjustment required in patients with hepatic insufficiency.

CD, extended release (biphasic immediate release with extended release); ER, extended release; LA, long acting; ODT, orally disintegrating tablet; SR, sustained release; XL, extended release; XR, extended-release.

Two long-acting stimulants, Daytrana and Vyvanse, have slower onsets of action than the other long-acting stimulants with a rapid release. Daytrana transdermal patches are to be applied for only 9 hours per day and have a delayed onset of 2 hours, and their effects persist for 3 hours after being removed. Some patients report skin sensitization and irritation. Vyvanse is a prodrug that is hydrolyzed to its active form, dextroamphetamine, after oral ingestion. Inhalation or injection abuse potential is minimized because of impeded hydrolysis by these routes. Onset of action for Vyvanse has been reported to be 2 hours.[10]

LO 6

Adverse effects of stimulants can be generalized to the whole class (Table 42–2). Most side effects can be managed by changing the dosing routine (ie, giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects (eg, hallucinations and abnormal movements) require discontinuation of medication.[9] To avoid potential drug–food interactions and absorption issues, stimulants should be given 30 to 60 minutes before eating.

Growth suppression or delay is a major concern for parents of children taking stimulants. Growth delay appears to be transient and to resolve by mid-adolescence, but more data are needed to resolve this issue. Another concern is risk of substance abuse with stimulant use. A diagnosis of ADHD alone increases the risk of substance abuse in adolescents and adults. However, stimulant use has not been shown to further increase this risk but actually may decrease this risk, provided ADHD is treated adequately.[11]

The choice of ADHD medication should be made based on the patient's condition, prescriber's familiarity with the medications, ease of administration, and cost. Stimulants should be used as first-line agents in most ADHD patients, although studies in groups of patients have shown no clear advantage of one stimulant over another.[4]

Table 42–2

Patient Monitoring and Management of Selected Adverse Effects of ADHD Medications

Drug	Adverse Effects	Management	Monitoring
Stimulants			
Methylphenidate Dexmethylphenidate Dextroamphetamine Amphetamine Lisdexamfetamine	GI upset, nausea, decreased appetite, potential growth delay	Administer after breakfast and lunch Encourage high-calorie meals/beverages and snacks after dinner Divide dose Change to shorter-acting stimulant Discontinue on weekends and during holidays	Height, weight, blood pressure, pulse ECG if warranted Eating and sleeping patterns Evaluate every 2–4 weeks until stable dose is achieved; then evaluate every 3 months
	Insomnia	Move dose(s) earlier in the day and discontinue later day dose if problem persists Change to a shorter-acting stimulant Consider adjunct hypnotic (eg, melatonin) or alternate medication (eg, guanfacine, bupropion)	
	Headache	Decrease dose Change to longer-acting stimulant or nonstimulant (eg, atomoxetine) Consider analgesic (eg, acetaminophen)	
	Irritability, dysphoria, agitation	Early onset (peak related): Decrease dose or change to longer-acting stimulant Late onset (withdrawal related): Change to longer-acting stimulant Evaluate for comorbidity and treat if present	
	Tics	Decrease dose Change to a different stimulant or a nonstimulant (eg, guanfacine, atomoxetine) Add an antipsychotic (eg, risperidone)	
Nonstimulants			
Atomoxetine	Increased blood pressure and pulse, nausea, vomiting, fatigue, and insomnia	Decrease dose or change to another medication (eg, guanfacine, bupropion)	Same as above but with baseline and routine liver function tests for hepatotoxicity
	Hepatotoxicity, suicidal thoughts	Discontinue or change to another medication	
Clonidine and guanfacine	Sedation	Decrease dose Administer closer to bedtime	Same as above
Bupropion	GI upset, restlessness, sleep disturbances, tremor	Decrease dose or change to another medication (eg, guanfacine)	Height, weight, blood pressure, pulse every month
	Tics, rash, seizures	discontinue medication	Eating and sleeping patterns

ECG, electrocardiography; GI, gastrointestinal.

Patient Encounter Part 1

Rorin, an 8-year-old boy with combined type ADHD comes to your clinic. Three months ago, Rorin's dose of generic Concerta increased from 18 mg to 36 mg daily. At school he still often is in trouble for not listening to teachers, losing interest easily, not remaining seated, talking excessively, blurting out answers, interrupting others, not participating in groups, being disruptive and easily distracted, and hitting other children. The beneficial effects of generic Concerta wear off by 4 PM and no adverse effects have occurred.

Wt: 31.8 kg or 70 lb (86th percentile)

Allergies: None known

Ht: 132 cm or 4'4" (70th percentile)

BP: 95/63 mm Hg

P: 83 beats/min

What other information should be collected and possible comorbid conditions investigated before continuing therapy for ADHD?

Which of Rorin's symptoms are suggestive of ADHD?

What help or suggestions could you offer Rorin's caregivers?

What change to Rorin's stimulant therapy should be made at this clinic appointment?

▶ *Nonstimulants*

LO 4

Atomoxetine Atomoxetine is approved for the treatment of ADHD in both children and adults. In clinical studies, it demonstrated superior efficacy over placebo and either equivalent efficacy compared with a suboptimal immediate-release methylphenidate dose or inferior to Concerta.[12] KEY CONCEPT Atomoxetine may be used as a second- or third-line medication for ADHD.

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinephrine.[12] Atomoxetine is metabolized through the cytochrome P450 (CYP) 2D6 pathway. Concurrent use of certain antidepressants (ie, fluoxetine, paroxetine) may inhibit this enzyme and necessitate slower dose titration of atomoxetine. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine's half-life is increased significantly in this population.[13] The recommended dosing for atomoxetine depends on patient weight and is given once or twice daily[13] (see Table 42–1). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers.[13] Onset of therapeutic effect of atomoxetine may take up to 2 to 8 weeks, significantly longer than with stimulants.[14] Common side effects of atomoxetine are similar to those of stimulants.[12] It can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in children[12] (see Table 42–2). Atomoxetine's labeling includes warnings about severe hepatotoxicity and increased association with suicidal thinking.

Atomoxetine can be given once daily in many patients. It appears to lack any abuse potential and is not a controlled substance.[15] One big disadvantage of atomoxetine is cost compared with other ADHD medications, despite a generic being approved by the FDA in May 2017 (Table 42–3).

Because of the high cost, lack of long-term efficacy data, and few comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to stimulant therapy.

LO 4

Bupropion Bupropion is a monocyclic antidepressant that weakly inhibits the reuptake of norepinephrine and dopamine. Some studies suggest it may be effective for symptoms of ADHD in children, and may be as effective as methylphenidate in children and adults.[16,17] Other evidence suggests that bupropion lacks efficacy and has high-incidence withdrawal effects.[18] Bupropion is generally well tolerated with minimal side effects (eg, insomnia, headache, nausea, and tremor) which typically disappear with continuation of therapy and with slow titration of dose. Bupropion can worsen tics and movement disorders. It is a rational choice in an ADHD patient with comorbid depression.[17] However, seizures have been associated with bupropion at high doses. Seizures risk can be minimized by reducing the dose or switching to a longer-acting formulation. Bupropion can increase the risk of suicidal ideation and is contraindicated in patients with seizure and eating disorders.

LO 4

Clonidine and Guanfacine Clonidine and guanfacine are central α_2-adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both of these agents are less effective than stimulants in treating ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.[19] The effects of immediate-release guanfacine typically last 3 to 4 hours longer than immediate-release clonidine, and the drug requires less frequent dosing. Extended-release formulations of guanfacine (Intuniv) and clonidine (Kapvay) were developed to minimize dosing frequency and improve treatment of anger, hostility, and irritability in patients with ADHD. Similar to other nonstimulants, these two dosage forms can also be used in patients who are intolerant to stimulants. However, use of these dosage forms is limited because of a lack of comparative trials to stimulants. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation generally subsides after 2 to 3 weeks of therapy.[20,21] Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heartbeats, and sudden death have been reported.

Pharmacoeconomic and Treatment Adherence Considerations

LO 5

Annual health care costs for people with ADHD was almost 60% higher than people without ADHD.[19] The financial burden of ADHD is attributed to the direct cost of pharmacotherapy, office visits, diagnostic measurements, therapy monitoring, and indirect costs (eg, lost work time and productivity). When selecting a treatment, the cost burden to the patient's family should be considered. Short-acting stimulants may be more cost effective in many patients compared with longer-acting stimulant formulations (see Table 42–3), but in certain circumstances, longer-acting stimulant formulations may provide a greater benefit owing to increased adherence to the medication and prolonged control of symptoms of ADHD. All intermediate-acting and various long-acting (Concerta, Ritalin LA, Metadate CD, Focalin XR, and Adderall XR) stimulant formulations are now available as generic products, making them potentially more affordable. In addition, some nonstimulant ADHD medications (eg, bupropion and immediate-release α_2-adrenergic agonists) appear to be less costly than many stimulant formulations; however, these agents have not been consistently proven to have superior efficacy over stimulants. Decisions on selection of specific ADHD medications should not be based solely on cost but also on efficacy and safety along with adherence to the prescribed regimen.

Table 42–3

Cost[a] of 30-Day Supply of Selected ADHD Medication Regimens

Medications	Regimens	Cost[a]
Short-Acting Rapid-Onset Stimulants		
Methylphenidate		
Generic	5-, 10-, or 20-mg tablet twice daily	$
Dexmethylphenidate		
Generic	2.5-, 5-, or 10-mg tablet twice daily	$
Dextroamphetamine		
Generic	5-mg tablet twice daily	$$
Intermediate-Acting Slower-Onset Stimulants		
Methylphenidate		
Methylin ER	10- or 20-mg ER tablet daily	$$
Dextroamphetamine[b]		
Generic	10- or 15-mg capsule daily	$$
Dextroamphetamine/amphetamine		
Generic	5-, 7.5-, 10-, 12.5-, 15-, 20-, or 30-mg tablet daily	$
Long-Acting Rapid-Onset Stimulants		
Methylphenidate		
Concerta (brand and generics)[b]	18-, 27-, 36-, or 54-mg tablet daily	$$$
Metadate CD (brand and generics)[c]	10-, 20-, 30-, or 40-mg capsule daily	$$
Ritalin LA (brand and generics)[c]	10-, 20-, 30-, or 40-mg capsule daily	$$
Quillivant XR[c]	10-, 20-, 25-, or 30-mg of suspension daily	$$$
Aptensio XR	10-, 15-, 20-, 30-, 40-, 50-, or 60-mg capsule daily	$$$
Cotempla XR-ODT	8.6-, 17.3-, or 25.9-mg oral disintegrating tablet daily	$$$
Dextroamphetamine/amphetamine		
Adderall XR (brand and generics)	5-, 10-, 15-, 20-, 25-, or 30-mg capsule daily	$$
Dexmethylphenidate		
Focalin XR (brand and generics)[c]	5-, 10-, 15-, 20-, 25-, 30-, 35-, or 40-mg capsule daily	$$$
Amphetamine		
Dyanavel XR	5-, 10-, 12.5-, 15-, or 20-mg of suspension daily	$$$
Long-Acting Slower-Onset Stimulants		
Lisdexamfetamine		
Vyvanse	10-, 20-, 30-, 40-, 50-, 60-, or 70-mg capsule/chew tab daily	$$$
Amphetamine		
Evekeo	5- or 10-mg tablet once or twice daily	$$$
Dextroamphetamine/amphetamine		
Mydayis	12.5-, 25-, 37.5-, or 50-mg ER cap	$$$
Nonstimulants		
Atomoxetine		
Generic	10-, 18-, 25-, 40-, 60-, 80-, or 100-mg capsule daily	$$
Clonidine		
Generic	0.1-, 0.2-, or 0.3-mg tablet twice daily	$
Generic ER	0.1-mg tablet twice daily	$$$
Guanfacine		
Generic	1- or 2-mg tablet twice daily	$
Generic ER	1-, 2-, 3-, or 4-mg tablet daily	$
Bupropion		
Generic	75-mg tablet twice daily	$
Generic	150- or 200-mg SR tablet twice daily	$
Generic	150-mg XL tablet daily	$

[a]Cost based on brand regimen specified without a dispensing fee or discount for a 30-day supply. (From GoodRx.com or various online State Maximum Allowable Costs [SMAC])

[b]Ascending release (early then gradual/continuous).

[c]Bimodal release (early then late; mimics twice daily dosing of shorter-acting stimulant counterpart).

$, less than $60; $$, $60–$140; $$$, greater than $140.

CD, controlled release (biphasic immediate release with extended release); ER, extended release; LA, long-acting; ODT, orally disintegrating tablet; SR, sustain release; XR, extended release.

Patient Encounter Part 2

Rorin returns to clinic the following month. Previously Medicaid paid for Rorin's generic Concerta but that benefit has lapsed and the family cannot afford to pay.

What medication(s) for ADHD will maximize efficacy, minimize potential side effects, and offer an acceptable cost for Rorin's family?

What are important counseling points to discuss with the parents before starting a different ADHD medication?

OUTCOME EVALUATION

Carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized patient outcomes is desired, such as (a) family and social relationships, (b) disruptive behavior, (c) completing required tasks, (d) self-motivation, (e) appearance, and (f) self-esteem. Elicit evaluations of the patient's behavior from family, school, and social environments in order to assess these outcomes. Using standardized rating scales (eg, Conners Rating Scales—Revised, Child Behavior Checklist-Attention Problem scale, and Conners Abbreviated Symptoms Questionnaire, Vanderbilt) leads to favorable diagnostic precision.[22] Assess eating and sleeping patterns, height, weight, pulse, and blood pressure at baseline and after initiation of pharmacotherapy every 2 to 4 weeks to determine efficacy of treatment and potential effects on growth and cardiac system. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children being considered for ADHD pharmacotherapy, obtain baseline electrocardiograms (ECGs) when known or suspected cardiac disease exists or the clinician judges it necessary.[23] Recent evidence suggests that overall cardiac risk with ADHD pharmacotherapy is low but presence of risk factors is associated with increased risk of serious cardiac events.[24] Typically, therapeutic benefits will be seen within days of initiating stimulants and within 1 or 2 months of starting bupropion and atomoxetine. When a maintenance dose has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents,

Patient Encounter Part 3

Rorin returns to clinic in a month after having received generic Adderall tablets at his last clinic appointment. As an outpatient, he has been titrated from generic Adderall 5 mg twice daily to 10 mg twice daily without any adverse effects. His grades, performance, and behaviors in the classroom have greatly improved. Other children have started to tease Rorin when he goes to the principal's office at noon for his second dose. This is very humiliating to Rorin and he is refusing to take a dose at school anymore.

What medication change appears best in order to maintain the beneficial effects he has seen, help him avoid peer ridicule, maintain adherence, and minimize personal cost to his family?

What monitoring parameters should be followed in order to assess efficacy and safety of treatment?

Patient Care Process

Collect Information:

- Current and past medication use including prescription and nonprescription products
- Identify allergies
- Medication history, physical assessment (blood pressure, pulse, height, and weight), ECG (baseline and periodically in children with known or suspected cardiac disease) neurological assessment, home assessment
- Signs and symptoms of hyperactivity, impulsivity, and/or inattention from patient, parents, teachers, and/or other people spending significant amount of time with the patient
- Patient and family lifestyle habits (subacademic performance, poor sleep hygiene, inadequate nutrition), beliefs system, functional goals, socioeconomic factors (insurance vs ability to pay for prescriptions)

Assess the Information:

- Determine if medications or lifestyle habits could be contributing to signs and symptoms of ADHD
- Evaluate medications for indication, side effects, adherence and effectiveness, interactions, and drug-related problems
- Assess overall health status, signs and symptoms of ADHD
- Identify patient/family cost effectiveness/burden of therapy and ability to remain adherent to therapy

Develop a Care Plan:

- Address any drug-related problems, interactions, adherence issues
- Patients < 6 years old, consider behavioral modification before pharmacotherapy
- Patients > 6 years old, consider low-dose stimulant (see Table 42–1)
- If initial stimulant therapy is not effective after 2 to 4 weeks, consider switching to a different stimulant (see Table 42–1)
- Try at least two stimulant medications before considering nonstimulant pharmacotherapy
- Reevaluate the diagnosis if all pharmacotherapy treatment attempts fail

Implement the Care Plan:

- Initiate medication at appropriate dose (see Table 42–1) and titrate to effect as tolerated (see Table 42–2), while considering cost (see Table 42–3)
- Emphasize medication adherence
- Educate patient/family on effectiveness and safety (see Table 42–2)

Follow-up: Monitor and Evaluate:

- Evaluate effectiveness and safety of stimulant therapy monthly for the first 3 months
- Evaluate every 3 months once on maintenance dose
- Monitor height and weight in children and blood pressure in adults quarterly
- Evaluate for improvement in function, use rating scales for consistent evaluation

reevaluate for other possible causes of behavior dysfunction. Counsel patients and their families that treatment generally is long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

Abbreviations Introduced in This Chapter

ADHD	Attention-deficit hyperactivity disorder
CYP	Cytochrome P450
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders,* 5th edition,
ECG	Electrocardiogram

43 Diabetes Mellitus

Julie Sease

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Discuss the incidence of diabetes mellitus (DM).
2. Distinguish clinical differences in type 1, Latent Autoimmune Diabetes of Adulthood, type 2, and gestational diabetes.
3. List screening and diagnostic criteria for DM.
4. Discuss therapeutic goals for blood glucose (BG) and blood pressure (BP) for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Discuss the signs, symptoms, and treatment of hypoglycemia.
9. Define *diabetic ketoacidosis* and discuss treatment goals.
10. Develop a comprehensive therapeutic monitoring plan for a patient with diabetes based on patient-specific factors.

INTRODUCTION

Diabetes mellitus (DM) describes a group of chronic metabolic disorders. KEY CONCEPT DM is characterized by hyperglycemia that may result in long-term **microvascular** and neuropathic complications. These complications contribute to DM being the leading cause of (a) new cases of blindness among adults, (b) end-stage renal disease, and (c) nontraumatic lower limb amputations. Macrovascular complications (coronary artery disease, peripheral vascular disease, and stroke) are also associated with DM.

EPIDEMIOLOGY

LO 1

DM affects an estimated 30.3 million persons in the United States, or 9.4% of the population.[1] Although an estimated 23.1 million persons have been diagnosed, another 7.2 million have DM but are unaware they have the disease.

DM is characterized by a complete lack of insulin, a relative lack of insulin, or **insulin resistance** as well as disorders of other hormones. These defects result in an inability to use glucose for energy. The increasing prevalence of DM is partly caused by three influences: lifestyle, ethnicity, and age.

Lifestyle

A sedentary lifestyle coupled with greater consumption of high-fat, high-carbohydrate foods, and larger portion sizes have resulted in increasing rates of obesity. Current estimates indicate that 36.5% of the US population is obese when obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2.[2] Only 1 in 5 adults currently meet physical activity guidelines set forth by the Centers for Disease Control and Prevention (CDC) and persons living in the American South are less likely to be physically active than those living in other areas of the country.[3]

Ethnicity

Certain ethnic groups are at a disproportionately high risk for developing type 2 DM (T2DM). The prevalence of DM is 15.1% among American Indians/Alaska Natives, 12.7% among non-Hispanic blacks, and 12.1% among persons of Hispanic ethnicity; whereas, among non-Hispanic whites, the prevalence is only 7.4%.[1] Socioeconomic status, when examined as a function of education level, also plays a role in the development of DM. The rate of DM is 12.6% for persons with less than a high school education versus 7.2% for those with education beyond high school.

Age

The third factor contributing to the increased prevalence of T2DM is age. In 2015, 9.9 million people in the United States who were 65 years of age or older had been diagnosed with DM compared with only 3 million between the ages of 18 and 44.[1] As the population ages, the incidence of T2DM is expected to increase.

KEY CONCEPT Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age. As a result, patients over 30 years of age who newly develop T1DM may be misdiagnosed as having T2DM. Autoimmune destruction of the β-cells causes insulin deficiency. T2DM accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and is often preceded by an increased risk for diabetes (previously

known as **prediabetes**). A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving **glucagon**, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed.

ETIOLOGY

LO 2

T1DM is an autoimmune disease in which insulin-producing β-cells in the pancreas are destroyed, leaving the individual insulin deficient.[4] Individuals with T1DM may develop islet cell antibodies, insulin autoantibodies, glutamic acid decarboxylase autoantibodies, protein tyrosine phosphatase autoantibodies, or zinc transporter protein autoantibodies, though most laboratories do not have reliably sensitive or specific assays to measure all five. As more β-cells are destroyed, glucose metabolism becomes compromised because of reduced insulin release after a glucose load. At the time of diagnosis of T1DM, it is commonly believed that most patients have an 80% to 95% loss of β-cell function.[5] The remaining β-cell function at diagnosis creates a "honeymoon period" during which smaller amounts of insulin are required to manage glucose levels. After this, remaining β-cell function is lost, and patients become completely insulin deficient and require more exogenous insulin.

KEY CONCEPT Latent autoimmune diabetes in adults (LADA), slow-onset type 1 or type 1.5 DM, is a form of autoimmune T1DM that occurs in individuals older than the usual age of T1DM onset.[6] Patients often are mistakenly thought to have T2DM because the person is older and may respond initially to treatment with oral BG–lowering agents, possibly taking years to eventually require exogenous insulin. These patients do not have insulin resistance, but antibodies are present in the blood that are known to destroy pancreatic β-cells. **C-peptide**, a surrogate marker for insulin secretion, may be used to establish or verify a diagnosis of T1DM.[4] When C-peptide levels are drawn, a simultaneous BG level should also be taken.

Categories of increased risk for DM include impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or hemoglobin A_{1c} (A_{1c}) between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol hemoglobin [Hgb]).[7] IFG is defined as having a fasting blood glucose (FBG) level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L). IGT is defined by a postprandial BG level between 140 and 199 mg/dL (7.8 and 11.0 mmol/L).

LO 2

T2DM is usually slow and progressive in its development. Risk factors include:

- First-degree family history of DM (ie, parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino or Hispanic American, Asian American, African American, and Pacific Islanders)
- Previously identified IFG, IGT, or A_{1c} between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb)
- Hypertension (≥ 140/90 mm Hg or on therapy for hypertension)
- High-density lipoprotein (HDL) cholesterol less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes
- History of cardiovascular disease
- History of polycystic ovarian syndrome
- Other conditions associated with insulin resistance (eg, **acanthosis nigricans**)

Gestational diabetes mellitus (GDM) is defined as glucose intolerance in women during pregnancy. Clinical detection of and therapy for GDM are important because blood sugar levels within range produces significant reductions in adverse maternal, fetal, and neonatal outcomes.

Diabetes insipidus is unrelated to DM despite the similar nomenclature.[8] Four types of diabetes insipidus exist including central, nephrogenic, dipsogenic, and gestational. Central diabetes insipidus results from damage to a patient's hypothalamus or pituitary causing irregular production, storage and/or release of vasopressin leading to excessive elimination of fluid by the kidneys. Nephrogenic diabetes insipidus occurs when the kidneys no longer respond appropriately to the action of vasopressin. Dipsogenic diabetes insipidus results from a hypothalamic dysfunction which causes increased thirst and liquid intake in the affected patient. Gestational diabetes insipidus occurs during pregnancy and results either from placental destruction of the mother's vasopressin or from prostaglandin's action on the kidneys causing them to lose sensitivity to the action of vasopressin.

DM from other causes includes genetic defects in β-cell function, genetic defects in insulin action, diseases of the exocrine pancreas such as cystic fibrosis, and drug- or chemical-induced diabetes. Drugs that may cause increased BG include glucocorticoids, pentamidine, nicotinic acid, β-adrenergic agonists, thiazides, phenytoin, and γ-interferon.[9]

PATHOPHYSIOLOGY

Normal Carbohydrate Metabolism

The body's main fuel source is glucose. Cells metabolize glucose completely through glycolysis and the Krebs cycle, producing adenosine triphosphate (ATP) as energy.[10] Glucose is stored in the liver and muscles as glycogen. **Glycogenolysis** converts stored glycogen back to glucose.[11] Glucose also may be stored in adipose tissue, which may subsequently undergo lipolysis yielding free fatty acids.[10] In the fasting state, free fatty acids supply much of the energy needs for the body except for the central nervous system, which requires glucose to function normally.[11] Proteins also can be converted to glucose through **gluconeogenesis**.[10] Homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids, and amino acids to maintain a BG level sufficient to provide an uninterrupted supply of glucose to the brain.[11]

Insulin and glucagon are produced in the pancreas by cells in the islets of Langerhans. β-Cells make up 70% to 90% of the islets and produce insulin and **amylin**, whereas α-cells produce glucagon.[10] The main function of insulin is to decrease BG levels. Glucagon, along with other counterregulatory hormones such as growth factor, cortisol, and epinephrine, increases BG levels.[11] Although BG levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, normally maintain fasting values between 79 and 99 mg/dL (4.4–5.5 mmol/L).

▶ *Normal Insulin Action*

Fasting insulin levels in the circulation average from 43 to 186 pmol/L (6–26 μIU/mL).[10] After food is consumed, BG levels rise, and the insulin-secretion response occurs in two phases.

An initial burst, known as *first phase insulin response,* lasts approximately 5 to 10 minutes and serves to suppress hepatic glucose production and cause insulin-mediated glucose disposal in adipose tissue. This bolus of insulin minimizes hyperglycemia during meals and during the postprandial period. The *second phase of insulin response* is characterized by a gradual increase in insulin secretion, which lasts 60 to 120 minutes and stimulates glucose uptake by peripheral insulin-dependent tissues, namely muscle. Slower release of insulin allows the body to respond to the new glucose entering from digestion while maintaining BG levels. Basal insulin secretion is the low rate of continuous insulin secreted by the pancreas to maintain normal FBG levels.

Amylin is a naturally occurring hormone that is cosecreted from β-cells with insulin. People with DM have either a relative or complete lack of amylin. Amylin has three major mechanisms of action: suppression of postmeal glucagon secretion; regulation of the rate of gastric emptying from the stomach to the small intestine, which increases satiety; and regulation of plasma glucose concentrations in the bloodstream.

▶ *Impaired Insulin Secretion*

A pancreas with normal β-cell function is able to adjust insulin production to maintain normal BG levels.[11] In T2DM, more insulin is secreted to maintain normal BG levels until eventually the pancreas can no longer produce sufficient insulin.[10] The resulting hyperglycemia is enhanced by extremely high insulin resistance, pancreatic burnout in which β-cells lose functional capacity, or both. Impaired β-cell function results in a reduced ability to produce a first-phase insulin response sufficient to signal the liver to stop producing glucose after a meal.[12] Progressive β-cell decline is hypothesized to result from ongoing glucotoxicity and lipotoxicity. A recent study showed that early resolution of glucotoxicity through use of basal insulin in those at risk for developing DM reduced the incidence of diabetes diagnosis.[13]

▶ *Insulin Resistance*

Insulin resistance is the primary factor that differentiates T2DM from other forms of diabetes. Insulin resistance may be present for several years prior to the diagnosis of DM and can continue to progress throughout the course of the disease.[10] Resistance to insulin occurs in adipose tissue, skeletal muscle, and the liver.[9] Insulin resistance in the liver poses a double threat because the liver becomes nonresponsive to insulin for glucose uptake, and hepatic production of glucose after a meal does not cease, leading to elevated fasting and postmeal BG levels.

Table 43–1

Five Components of Metabolic Syndrome[14]

Risk Factor	Defining Level
1. Abdominal obesity	Based on ethnic group[a]
Plus any two of the following:	
2. Triglycerides	≥ 150 mg/dL (1.70 mmol/L) or treated
3. HDL cholesterol	
• Men	< 40 mg/dL (1.03 mmol/L) or treated
• Women	< 50 mg/dL (1.29 mmol/L) or treated
4. Blood pressure	≥ 130 or ≥ 85 mm Hg or treated
5. Fasting glucose	≥ 100 mg/dL (5.6 mmol/L) or diagnosed type 2 diabetes

[a]102 cm (40 in) for males and 88 cm (35 in) for females likely to be used clinically.

HDL, high-density lipoprotein.

▶ *Metabolic Syndrome*

Insulin resistance has been associated with a number of other cardiovascular risks, including abdominal obesity, hypertension, dyslipidemia, hypercoagulation, and hyperinsulinemia.[14] The clustering of these risk factors has been termed **metabolic syndrome**. Criteria defining the metabolic syndrome as established by the International Diabetes Federation are summarized in Table 43–1.[14] Patients having these additional risk factors are at much higher cardiovascular risk than would be expected from individual components of the syndrome.

Clinical Presentation and Diagnosis

Characteristic	T1DM	T2DM	LADA
Usual age of onset	Childhood or adolescence	Adult	Over 30
Speed of onset	Abrupt	Gradual	Gradual
Family history	Negative	Positive	Positive
Body type	Thin	Obese or history of obesity	Thin
Metabolic syndrome	No	Often	No
Autoantibodies	Present	Rare	Present
Symptoms	Polyuria, polydipsia, polyphagia, rapid weight loss	Asymptomatic	Polyuria, polydipsia, polyphagia, rapid weight loss
Ketones at diagnosis	Present	Uncommon	Dependent upon β-cell function at time of diagnosis
Acute complications	Diabetic ketoacidosis (DKA)	Rare	DKA possible
Microvascular complications at diagnosis	Rare	Common	Dependent on length of disease at time of diagnosis
Macrovascular complications at or before diagnosis	Rare	Common	Dependent on length of disease at time of diagnosis

▶ *Incretin Effect*

When nutrients enter the stomach and intestines, incretin hormones are released, which stimulate insulin secretion.[15] This so-called **incretin effect** is mediated by two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), with GLP-1 being studied the most. GLP-1 is secreted by the L cells of the ileum and colon primarily, and GIP is secreted by the K cells. GLP-1 secretion is caused by endocrine and neural signals started when nutrients enter the gastrointestinal (GI) tract. Within minutes of food ingestion, GLP-1 levels rise rapidly. A glucose-dependent release of insulin occurs, and the dipeptidyl peptidase-4 (DPP-4) enzyme cleaves GLP-1 rapidly to an inactive metabolite. Much of the research on glucose-lowering products involves prolonging the action of GLP-1. Other glucose-lowering effects of GLP-1 include suppression of glucagon, slowing gastric emptying, and increasing satiety.

▶ *Selective Sodium-Dependent Glucose Cotransporter-2 (SGLT2)*

Glucose is filtered by the kidney at a rate of approximately 162 grams per day.[16] The SGLT2 transporter reabsorbs the majority (90%) of the filtered glucose in the convoluted proximal tubule. The SGLT1 transporter reabsorbs the remaining glucose in the descending proximal tubule. The end result is that no glucose is excreted in the urine when BG levels are normal. In patients with DM, rather than allowing glucose to be dumped into the urine to assist with the correction of hyperglycemia in the blood, the kidney holds onto glucose. Renal tubular cells from T2DM patients show increased levels of SGLT2, thereby offering a mechanism by which the kidney of a patient with DM achieves its increased ability for glucose reabsorption.

CLINICAL PRESENTATION AND DIAGNOSIS

Screening

LO 3

Currently, the American Diabetes Association (ADA) recommends routine screening for T2DM every 3 years in all adults starting at 45 years of age.[7] Testing for T2DM should be considered, regardless of age, in adults who have a BMI greater than or equal to 25 kg/m^2 (or BMI ≥ 23 kg/m^2 for Asian Americans) and one or more additional risk factors. The ADA does not currently recommend widespread screening for T1DM, although measurement of islet autoantibodies may be appropriate for high-risk individuals, including those who have relatives with T1DM. See Table 43–2[7] for complete screening guidelines.

Gestational Diabetes

LO 3

All pregnant women who have risk factors for T2DM should be screened for undiagnosed T2DM at their first prenatal visit using standard diagnostic criteria. Any woman found to have diabetes at that early point in pregnancy is considered to have T2DM, not GDM. All other pregnant women not currently known to have DM should be screened for GDM. Two possible strategies exist for GDM screening. They are a "one-step" 2-hour 75-gram **oral glucose tolerance test** (OGTT) and a "two-step" process which includes a 1-hour 50-gram nonfasting screen followed by a 3-hour 100-gram OGTT for those with a 1-hour screening glucose of greater than or equal to 140 mg/dL (7.8 mmol/L). The diagnostic criteria for the "one-step" 2-hour 75-gram OGTT are listed in Table 43–3.[7] Any woman diagnosed with GDM should be retested at 4 to 12 weeks postpartum using the OGTT with nonpregnant diagnostic criteria.

Table 43–2

American Diabetes Association (ADA) Screening Recommendations for Diabetes[7]

Asymptomatic Type 1

The ADA does not recommend screening for T1DM because of the low incidence in the general population and due to the acute presentation of symptoms

Asymptomatic Type 2

1. The ADA recommends screening for T2DM every 3 years in all adults beginning at 45 years of age
2. Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (BMI ≥ 25 kg/m^2 for the general population and ≥ 23 kg/m^2 for Asian Americans) and have additional risk factors:
   - Habitually inactive
   - First-degree relative with diabetes
   - Member of a high-risk ethnic population (eg, African American, Latino, Native American, Asian American, Pacific Islander)
   - Previous diagnosis of GDM
   - Hypertensive (≥ 140/90 mm Hg or on therapy)
   - HDL cholesterol level < 35 mg/dL (0.91 mmol/L) and/or triglyceride level > 250 mg/dL (2.83 mmol/L)
   - Polycystic ovary syndrome
   - Previous IGT or IFG or A_{1c} ≥ 5.7% (0.057 or 39 mmol/mol Hgb)
   - Other clinical conditions associated with insulin resistance (eg, acanthosis nigricans)
   - History of cardiovascular disease

Type 2 in Children and Adolescents

Criteria:
- Overweight (BMI > 85th percentile for age and sex, weight for height > 85th percentile, or weight > 120% of ideal for height)

Plus any two of the following risk factors:
- Family history of T2DM in first- or second-degree relatives
- Race or ethnicity (Native American, African American, Latino or Hispanic American, Asian American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary disease)
- Maternal history of diabetes or GDM during child's gestation

Age of initiation:
Age 10 years or at onset of puberty, if puberty occurs at a younger age

Frequency of testing:
Every 3 years
Test method: FPG or OGTT possibly more suitable than A_{1c}

GDM

1. Screen for undiagnosed T2DM at first prenatal visit in those with risk factors using standard criteria
2. All women not already known to have diabetes should be screened with an OGTT between weeks 24 and 28 of gestation

A_{1c}, hemoglobin A_{1c}; BMI, body mass index; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; Hgb, hemoglobin; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Diagnostic Criteria

LO 3

Diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options (Table 43–4).[7] For a diagnosis, confirmation of an initial abnormal value must be made using a new blood sample unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria,

Table 43–3

Diagnosis of Gestational Diabetes Mellitus With a 75-g Glucose Load[7]

	Plasma Glucose	
Time	**mg/dL**	**mmol/L**
Fasting	92 or more	5.1 or more
75-g glucose load		
1 hour	180 or more	10.0 or more
2 hours	153 or more	8.5 or more

A positive diagnosis of diabetes is made when any of the listed glucose values are exceeded. The test should be done in the morning after an 8-hour fast.

Note: These values are based on American Diabetes Association guidelines.

and polyphagia. Either A_{1c}, fasting plasma glucose (FPG), or OGTT are appropriate tests for detecting and confirming DM. Use of the same type of test for initial screening and confirmation is recommended, but diagnostic results from two different testing options can also be used.

The categorization thresholds of glucose status for FPG determination and the OGTT are listed in Table 43–5.[7] IFG and IGT may coexist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas postprandial glucose (PPG) levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or a decreased first-phase insulin response. The OGTT identifies people with either IFG or IGT and therefore potentially more people at increased risk for DM and cardiovascular disease. The OGTT is a more cumbersome test to perform than either the A_{1c} or FPG; however, the efficacy of interventions for primary prevention of T2DM has been demonstrated among patients with IGT, not among those with IFG or specific A_{1c} levels.

Table 43–4

American Diabetes Association Criteria for Diagnosis of Diabetes[7]

Symptoms of diabetes plus a casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

FPG ≥ 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.

or

Two-hour postload glucose ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.

or

A_{1c} ≥ 6.5% (0.065; 48 mmol/mol Hgb). The test should be performed in a laboratory using a method that is NGSP certified to the DCCT assay.

A_{1c}, hemoglobin A_{1c}; DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hgb, hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use.

Table 43–5

American Diabetes Association Categorization of Glucose Status[7]

	mg/dL	mmol/L
FPG		
Normal	< 100	< 5.6
IFG (prediabetes)	100–125	5.6–6.9
Diabetes	≥ 126	≥ 7.0
2-hour postload plasma glucose (OGTT)		
Normal	< 140	< 7.8
IGT (prediabetes)	140–199	7.8–11.0
Diabetes	≥ 200	≥ 11.1

FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

TREATMENT

Goals of Therapy

LO 4

KEY CONCEPT DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neuropathic complications; preserving β-cell function;

Patient Encounter Part 1

A 38-year-old white male presents to his provider for a follow-up appointment. On questioning, he states that he was told during a recent workplace wellness program screening that his blood sugar was "high." Today, he has no particular complaint though he does admit to having regular headaches which he treats successfully with acetaminophen over-the-counter.

PMH: Noncontributory

FH: Mother has dyslipidemia and hypertension and is living at age 65; father has hypertension and dyslipidemia and is living at age 68; no siblings and children without chronic health conditions.

SH: Prior history of smoking one half pack per day for 10 years, but quit 6 years ago; denies alcohol or illicit drug use; denies physical activity.

Allergies: Penicillin

Meds: Acetaminophen 500 mg-1000 mg PRN headache

VS: BP 152/86 mm Hg, P 82 beats/min, RR 20 breaths/min, T 37°C (98.6°F), Ht 5'3" (160 cm), Wt 165 lb (75 kg)

ROS: (+) Fatigue, (–) N/V/D, HA, SOB, chest pain

What risk factors does this patient have for diabetes?

Which type of diabetes do his characteristics suggest?

What additional information is needed to diagnose this patient with diabetes?

preventing acute complications from high BG levels; minimizing hypoglycemic episodes; and maintaining the patient's overall quality of life. To achieve the majority of these goals, near-normal BG levels are fundamental; thus, glycemic control remains a primary objective in diabetes management. Two landmark trials, the Diabetes Control and Complications Trial (DCCT)[17] and the United Kingdom Prospective Diabetes Study (UKPDS),[18] showed that lowering BG levels decreased the risk of developing chronic complications. A near-normal BG level can be achieved with appropriate patient education, lifestyle modification, and medications.

▶ *Setting and Assessing Glycemic Targets*

KEY CONCEPT Patients and clinicians can evaluate how well a patient's DM is managed by monitoring daily BG values and the A_{1c} quarterly to biannually. Self-monitoring of blood glucose (SMBG) enables patients to obtain their current BG level at any time easily and relatively inexpensively. The A_{1c} test provides a weighted-mean BG level from approximately the previous 3 months.

Self-Monitoring of Blood Glucose SMBG is the standard method for routinely checking BG levels. Most often, a small drop of blood obtained from a fingertip using a lancet device is used for testing. Some home BG meters require very little blood and can be used for alternative site testing, where small samples can be obtained from the palm, forearm or thigh. Each reading provides a point-in-time evaluation of glucose levels that can vary widely depending on numerous factors, including food, exercise, stress, illness, and time of day.

By examining multiple individual points of data, glucose patterns can be established. Therapy can be evaluated from these patterns, and adjustments can be made to improve overall BG levels. The ADA premeal plasma glucose goals are 80 to 130 mg/dL (4.4–7.2 mmol/L) and peak postprandial plasma glucose goals are less than 180 mg/dL (10.0 mmol/L).[7] The American Association of Clinical Endocrinologists (AACE) supports tighter SMBG levels, with premeal goals of less than 110 mg/dL (6.1 mmol/L) and peak postmeal goals of less than 140 mg/dL (7.8 mmol/L).[19] For patients using multiple daily insulin injections or insulin pump therapy, SMBG may need to be performed six to eight times per day.[7] The optimal frequency of testing in patients using less frequent insulin injections, noninsulin therapies, or medical nutrition therapy (MNT) is less clear.

LO 4

Continuous glucose sensors are now available that work with or independently of insulin pumps. These monitors provide BG readings, primarily through interstitial fluid (ISF). A small sterile disposable glucose-sensing device called a sensor is inserted into the subcutaneous tissues. This sensor measures the change in glucose in ISF and sends the information to a monitor, which stores the results. Some devices allow analysis of data collected over time to aid in clinical decision making. While older continuous glucose sensors require calibration with SMBG measurements, newer sensors allow patients to forego this process.

Hemoglobin A_{1c} Glucose interacts spontaneously with Hgb in red blood cells to form glycated derivatives. The most prevalent derivative is A_{1c}. Greater amounts of glycation occur when BG levels increase. Because a red blood cell has a life span of approximately 3 months, levels of A_{1c} provide a marker reflecting the average glucose levels over this timeframe.[7] The ADA goal for persons with DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas the AACE supports a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) if achievable without resultant hypoglycemia.[7,19] A less stringent A_{1c} goal of less than 8% (0.08; 64 mmol/mol Hgb) may be utilized in some patients such as those with limited life expectancy, long-standing diabetes that is otherwise difficult to control, and those with multiple comorbid conditions including advanced microvascular and/or macrovascular complications. Testing A_{1c} levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those who have had recent changes in therapy. Table 43–6 presents goals for A_{1c} and monitoring parameters for concomitant conditions (such as blood pressure [BP] measurements and complications associated with DM).[7]

LO 4

LO 4

Table 43–6

American Diabetes Association Recommended Goals of Therapy in Adults[7]

Area	Goals
Glycemia	
A_{1c}	< 7% (0.07; 53 mmol/mol Hgb) Evaluate every 3 months until in goal; then every 6 months
Preprandial plasma glucose	80–130 mg/dL (4.4–7.2 mmol/L)
Peak postprandial plasma glucose[a]	< 180 mg/dL (10.0 mmol/L)
Blood Pressure[b]	< 140/90 mm Hg Evaluate at every visit
Lipids	Evaluate at diagnosis and/or age 40, then every 1–2 years thereafter
Monitoring for Complications	
Eyes	Dilated eye examination yearly
Feet	Feet should be examined at every visit
Urinary microalbumin	Yearly

[a]Peak postprandial glucose measurements should be made 1–2 hours after the beginning of the meal.

[b]American College of Cardiology/American Heart Association hypertension guidelines recommend goal of < 130/80 mm Hg for patients with diabetes.

A_{1c}, hemoglobin A_{1c}; Hgb, hemoglobin.

Ketone Monitoring Urine and blood ketone testing is important in people with T1DM, in pregnancy with preexisting diabetes, and in GDM. People with T2DM may have positive ketones and develop DKA if they are ill.

The presence of ketones may indicate a lack of insulin or ketoacidosis, a condition that requires immediate medical attention. When there is a lack of insulin, peripheral tissues cannot take up and store glucose. This causes the body to think it is starving, and because of excessive lipolysis, ketones, primarily β-hydroxybutyric acid and acetoacetic acid, are produced as byproducts of free fatty acid metabolism in the liver. Glucose and ketones are osmotically active, and when an excessive amount of ketones is formed, the body gets rid of them through urine, leading to dehydration. Patients with T1DM should test for ketones during acute illness or stress or when BG levels are consistently elevated above 300 mg/dL (16.7 mmol/L). This commonly occurs when insulin is omitted or when DM is not well managed due to nonadherence, illness, or other reasons. Women with preexisting diabetes before pregnancy or with GDM should check ketones using their first morning urine sample or when any symptoms of ketoacidosis such as nausea,

vomiting, or abdominal pain are present. Blood ketone testing methods that quantify β-hydroxybutyric acid, the predominant ketone body, are available and are the preferred ways to diagnose and monitor ketoacidosis. Home tests for β-hydroxybutyric acid are available. The specific treatment of DKA may include rehydration, correction of electrolyte imbalances, and insulin administration.

General Approach to Therapy

▶ *Type 1 Diabetes Mellitus*

Treatment of T1DM requires providing exogenous insulin to replace the endogenous loss of insulin from the nonfunctional pancreas. Ideally, insulin therapy mimics normal insulin physiology. The basal-bolus approach attempts to reproduce basal insulin response using intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in individuals without diabetes. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a rule, basal insulin makes up approximately 50% of the total daily dose. The remaining half is provided with bolus doses around three daily meals.

Exact doses are individualized to the patient and the amount of food consumed. T1DM patients frequently are started on about 0.6 unit/kg/day, and then doses are titrated until glycemic goals are reached. Most people with T1DM use between 0.6 and 1 unit/kg/day.

Currently, the most advanced form of insulin delivery is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII). See Figure 43–1. Insulin pumps have been linked to improvement in quality of life. Using rapid-acting insulin most often, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and larger boluses of insulin are administered by the patient to account for the consumption of food or correction of hyperglycemia. Insulin pump settings may be adjusted to address exercise, illness, and other factors. Pramlintide, a synthetic analog of the naturally occurring hormone amylin, is another injectable BG–lowering medication that can be used in people with T1DM or in people with T2DM using insulin for treatment. In addition to medication management with insulin, patients with T1DM must also be educated to live a healthy lifestyle including eating a healthy diet and exercising.

▶ *Type 2 Diabetes Mellitus*

Treatment of patients with T2DM has changed dramatically over the past decade with the addition of a number of new drugs and recommendations to maintain tighter glycemic levels.[20,21] Technology available to individuals with T1DM can also be used for those with T2DM. However, lifestyle modifications including education, nutrition, and exercise are paramount to managing the disease successfully.

▶ *Gestational Diabetes*

An individualized meal plan consisting of three meals and three snacks per day is commonly recommended in GDM. Preventing ketosis, promoting adequate growth of the fetus, maintaining satisfactory BG levels, and preventing nausea and other undesired GI side effects are desired goals in these patients. Glucose goals for SMBG for pregnant women as per the ADA include fasting of 95 mg/dL (5.3 mmol/L), 1-hour postprandial of 140 mg/dL (7.8 mmol/L), and 2-hour postprandial of 120 mg/dL (6.7 mmol/L).[7] An abundance of glucose causes excessive insulin production by the fetus, which, if left above glucose target, can lead to the development of an abnormally large fetus. Infant hypoglycemia at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when BG levels are not controlled adequately. Due to concerns that metformin crosses the placenta to the fetus and that glyburide has been identified in cord blood when taken by pregnant women, the ADA currently advocates for insulin as the primary pharmacotherapeutic choice for GDM. Insulin should be used when BG levels are not maintained adequately by diet and physical activity. Insulin detemir, insulin aspart, lispro, and regular insulin carry Category B safety ratings.

Nonpharmacologic Therapy

▶ *Medical Nutrition Therapy (MNT)*

MNT is considered an integral component of DM management and self-management education. People with DM should receive individualized MNT, preferably by a registered dietitian. MNT

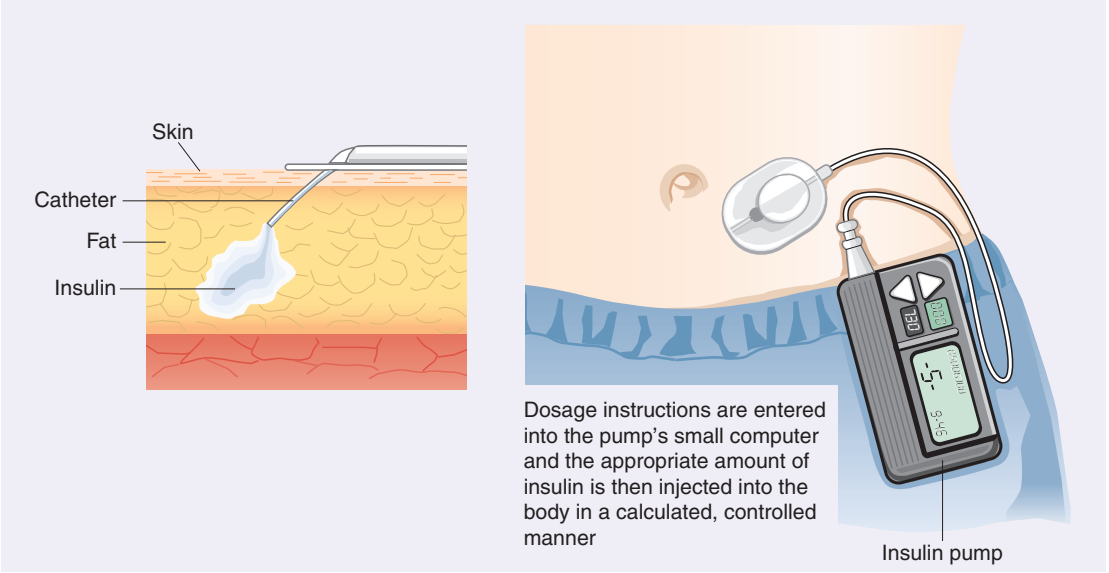

FIGURE 43–1. Insulin pump and placement.

should be provided as an ongoing dialogue customized to take into account cultural, lifestyle, and financial considerations.

LO 5 The primary focus of MNT for patients with T1DM is matching optimal insulin dosing to carbohydrate consumption while maintaining a healthy balance. In T2DM, the primary focus is portion control and controlling BG, BP, and lipids through individualizing limits of carbohydrates, saturated fats, sodium, and calories. Carbohydrates are the primary contributor to postmeal glucose levels. The percentages of fat, protein, and carbohydrate included in each meal should be individualized based on the specific goals of each patient.[7]

► *Dietary Supplements*

There is insufficient evidence of efficacy for improved BG control for any individual herb or supplement.[7] Herbs and supplements commonly touted to improve glucose control include chromium, magnesium, vitamin D, and cinnamon. Patients may inquire about and use dietary supplements. It is important that clinicians respect the patient's health beliefs, address their questions and concerns, and educate them on the differences between dietary supplements and prescribed therapies. Additional information can be found at the National Institutes of Health Office of Dietary Supplements (https://ods.od.nih.gov).

► *Weight Management*

LO 5 Moderate weight loss in patients with T2DM has been shown to reduce cardiovascular risk, as well as delay or prevent the onset of DM in those with prediabetes.[7,22] The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 7% reduction in body weight and an increase in physical activity.[7] A slow but progressive weight loss of 0.45 to 0.91 kg (1–2 lb) per week is preferred.[23] Individual target caloric goals should be set. In the Diabetes Prevention Program, this was done by estimating daily caloric intake needed to maintain a person's current weight and then subtracting 500 to 1000 calories per day (about 2100–4200 kJ per day) depending on initial weight. Metabolic surgeries, such as Roux-en-Y gastric bypass, are recommended for patients with T2DM and a BMI that is or exceeds 40 kg/m^2 regardless of glycemic control.[7] Metabolic surgery is also recommended in those patients with a BMI above 35 kg/m^2 but less than 40 kg/m^2 whose glucose is not adequately controlled. Five drug therapy options have been approved for weight loss in patients with a BMI greater than or equal to 27 kg/m^2 with one or more obesity-related conditions and in patients with a BMI greater than or equal to 30 kg/m^2. Options include orlistat (a lipase inhibitor), lorcaserin (a selective serotonin 5-HT$_{2c}$ receptor agonist), phentermine/topiramate extended release (a sympathomimetic amine anorectic/antiepileptic combination), naltrexone/bupropion (an opioid antagonist/aminoketone antidepressant combination), and liraglutide (a GLP-1 receptor agonist).

► *Physical Activity*

Regular physical activity has been shown to improve BG control by improving insulin sensitivity, and reduce cardiovascular risk factors such as hypertension and elevated serum lipid levels.[22] Physical activity is also a primary factor associated with long-term maintenance of weight loss and overall weight control. Regular physical activity also may prevent the onset of T2DM in high-risk persons.

LO 5 Before initiating a physical activity program, patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity. Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged; gardening and usual housecleaning tasks are good exercises as well. Recommended physical activity goals for patients with T2DM include 150 minutes per week of moderate to vigorous aerobic exercise spread out during at least 3 days of the week with no more than two consecutive days between bouts of aerobic activity and moderate to vigorous resistance training at least 2 to 3 days per week.[7]

► *Psychological Assessment and Care*

Mental health and social state have been shown to have an impact on a patient's ability to carry out DM management care tasks.[7] Clinicians should incorporate psychological assessment and treatment into routine care. The ADA guidelines recommend ongoing psychological screening, including determining the patient's attitudes regarding DM; expectations of medical management and outcomes; mood and affect; general and diabetes-related quality of life; and financial, social, and emotional resources. Patients demonstrating poor self-management should be screened for diabetes-related distress, depression, anxiety, an eating disorder, and/or cognitive impairment.

► *Immunizations*

LO 5 Influenza and pneumonia are common preventable infectious diseases that increase mortality and morbidity in persons with chronic diseases, including DM. Yearly influenza vaccinations, commonly called flu shots, are recommended for all patients with DM 6 months of age or older.[7] Pneumococcal vaccination with the polysaccharide vaccine 23 is also recommended for patients with DM who are 2 years of age or older as a one-time vaccination. At age greater than or equal to 65 years of age, patients should receive the pneumococcal conjugate vaccine. It should be administered no earlier than 1 year after vaccination with the polysaccharide vaccine. Once administered, the conjugate vaccine should then be followed by the polysaccharide vaccine again 12 months later. The 3-dose hepatitis B vaccine series is recommended for those aged 19–59 years and should be considered in those 60 years of age and older.

Pharmacologic Therapy

LO 6 Figures 43–2 and 43–3 summarize treatment algorithms for T2DM per the ADA and AACE, respectively.[7,20,21] While similar, these treatment algorithms differ in that the ADA guidelines do not advocate for the use of several treatment options that the AACE guidelines include; namely, colesevelam, α-glucosidase inhibitors, and bromocriptine. Also, the AACE guidelines take a more aggressive approach, including consideration for starting a patient on two drugs if their presenting A$_{1c}$ is greater than or equal to 7.5% (0.075; 58 mmol/mol Hgb). While the ADA guidelines include metformin alone as the first-line therapy option for T2DM, the AACE guidelines include six other noninsulin initial therapy options as possibilities. As noted earlier, the AACE guidelines also advocate for lower A$_{1c}$ and SMBG goals. Because T2DM generally tends to be a progressive disease, BG levels will eventually increase, making insulin therapy the eventual required therapy in many patients, and therefore insulin should not be used rhetorically as a prophylactic deterrent as this may result in patient trust issues and/or feelings of failure. This is usually done when several oral agents have been used with inadequate glucose-lowering results. Addition of GLP-1 receptor agonists

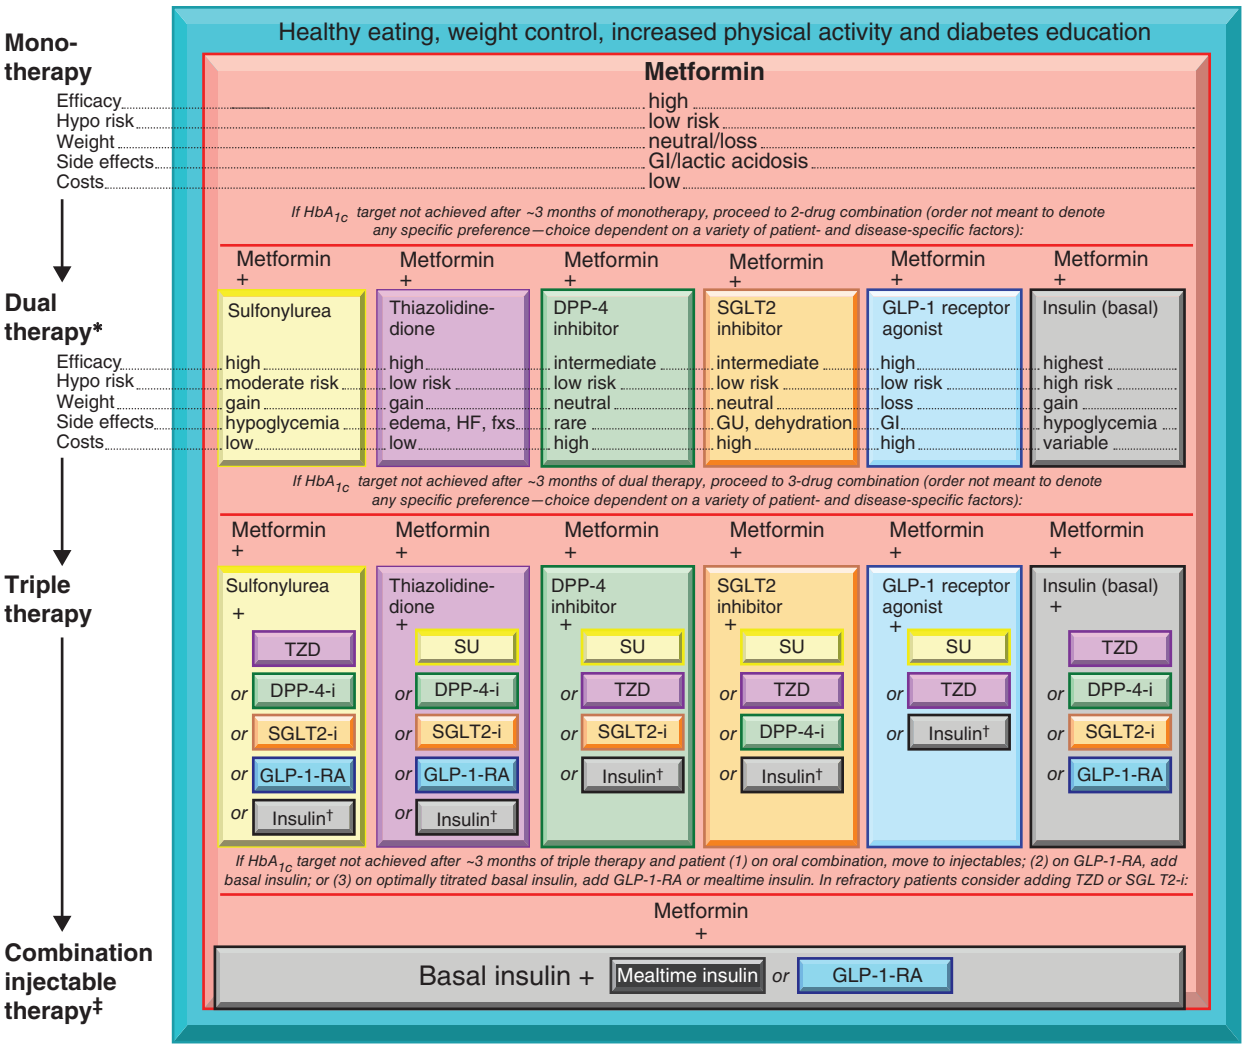

FIGURE 43–2. Patient-centered approach to antihyperglycemic therapy in type 2 diabetes as per the American Diabetes Association/European Association for the Study of Diabetes. Begin with lifestyle changes and add metformin monotherapy at or soon after diagnosis. If hemoglobin A_{1c} (HbA_{1c}) target is not achieved after 3 months, consider one of six treatment options combined with metformin: a SU, TZD, DPP-4-i, SGLT2-i, GLP-1 RA, or basal insulin. Choice is based on patient and drug characteristics. Consider meglitinides in patients with irregular meal schedules or who develop postprandial hypoglycemia on sulfonylureas. *Consider beginning at this stage in patients with HbA_{1c} greater than 9% (0.09; 75 mmol/mol Hgb). †Usually a basal insulin (eg, glargine, detemir, degludec). ‡Consider beginning at this stage if patient presents with glucose greater than 300 mg/dL (16.7 mmol/L). (DPP-4-i, dipeptydal peptidase-4 inhibitor; fxs, fractures; GI, gastrointestinal; GLP-1-RA, glucagon-like peptide-1 receptor agonist; GU, genitourinary; HF, heart failure; Hypo, hypoglycemia; SGLT2-i, sodium-dependent glucose cotransporter-2 inhibitor; SU, sulfonylurea; TZD, thiazolidinedione.) (From Inzucchi SE, Bergenstal RM, Buse JB, et al. Management of hyperglycemia in type 2 diabetes, 2015: a patient-centered approach: update to a position statement of the American Diabetes Association and the European Association for the Study of Diabetes. Diabetes Care. 2015;38:140–149, with permission.)

is recognized by the ADA as an alternative to mealtime insulin in those already receiving maximally titrated basal regimens; in addition to GLP-1 receptor agonists, the AACE guidelines also suggest DPP-4 or SGLT2 inhibitors as options in this scenario. Figure 43–4 is one illustration of a way to start insulin therapy in a patient with T2DM.[21]

KEY CONCEPT Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control through meal planning and physical activity. Table 43–7[19,21,24] lists the oral agents, Table 43–8 lists each noninsulin drug class with site of action and mechanism of action, and Table 43–9 lists the expected A_{1c} reduction for each noninsulin antiglycemic drug class.[9] The various classes of BG-lowering agents target different organs and have different mechanisms of action. Each of these agents may be used individually or in combination with other medications that target different organs for synergistic effects. In addition to single agent products, there are many combination products marketed as well.

LO 6

► *Sulfonylureas*

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β-cells. This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion in a non–glucose dependent manner. Insulin is then

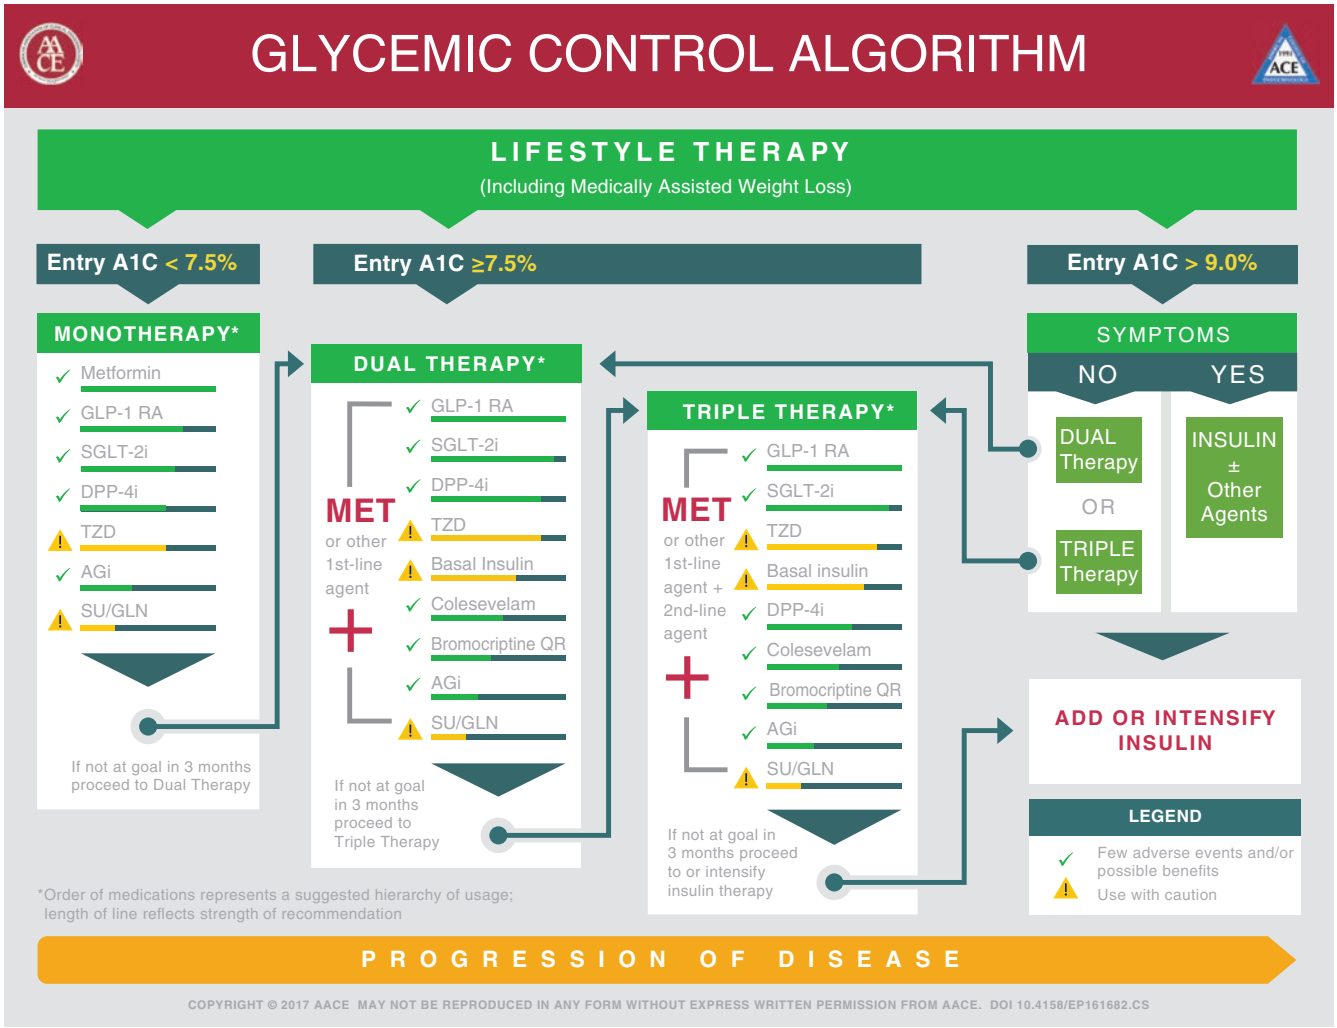

FIGURE 43–3. Algorithm for the metabolic management of type 2 diabetes as per the American Association of Clinical Endocrinologists (AACE). (A_{1c}, hemoglobin A_{1c}; AGi, alpha glucosidase inhibitor; DPP-4i, dipeptidyl peptidase-4 inhibitor; GLN, meglitinides; GLP-1 RA, glucagon-like peptide-1 receptor agonist; MET, metformin; QR, quick release; SGLT-2i, sodium-dependent glucose cotransporter-2 inhibitor; SU, sulfonylurea; TZD, thiazolidinedione.) (Reprinted with permission from American Association of Clinical Endocrinologists © 2018 AACE. Garber AJ, Abrahamson MJ, Barzilay JI, et al. AACE/ACE comprehensive type 2 diabetes management algorithm 2018. Endocr Pract.2018;24:91–120.)

transported through the portal vein to the liver, suppressing hepatic glucose production. These drugs are classified as being either first- or second-generation agents. Both classes of sulfonylureas are equally effective when given at equipotent doses. Today, the vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent.

All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P450 2C9 pathway. First-generation sulfonylureas are more likely to cause drug interactions than second-generation agents. All sulfonylureas, except tolbutamide, require a dosage adjustment or are not recommended in renal impairment.[24] In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

Sulfonylureas' BG-lowering effects can be observed in both fasting and postprandial levels. Monotherapy with these agents generally produces a 1.5% to 2% (0.015–0.02 or 17–22 mmol/mol Hgb) decline in A_{1c} concentrations and a 60 to 70 mg/dL (3.3–3.9 mmol/L) reduction in FBG levels.[9] Secondary failure with these drugs occurs as a result of continued pancreatic β-cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from β-cells at extremely high glucose levels, a phenomenon called glucose toxicity. Common adverse effects include hypoglycemia and weight gain. There may be some cross-sensitivity in patients with sulfa allergy.

▶ *Nonsulfonylurea Secretagogues (Glinides)*

Although producing the same effect as sulfonylureas, nonsulfonylurea secretagogues, also referred to as meglitinides, have a much shorter onset and duration of action. Meglitinides produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the β-cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind.

The primary benefit of nonsulfonylurea secretagogues is in reducing postmeal glucose levels. These agents have demonstrated a reduction in A_{1c} levels between 0.3% and 1% (0.003 and 0.01; 3–11 mmol/mol Hgb).[9] Because they have a rapid onset and short duration of action, they should be taken 15 to 30 minutes before a meal.

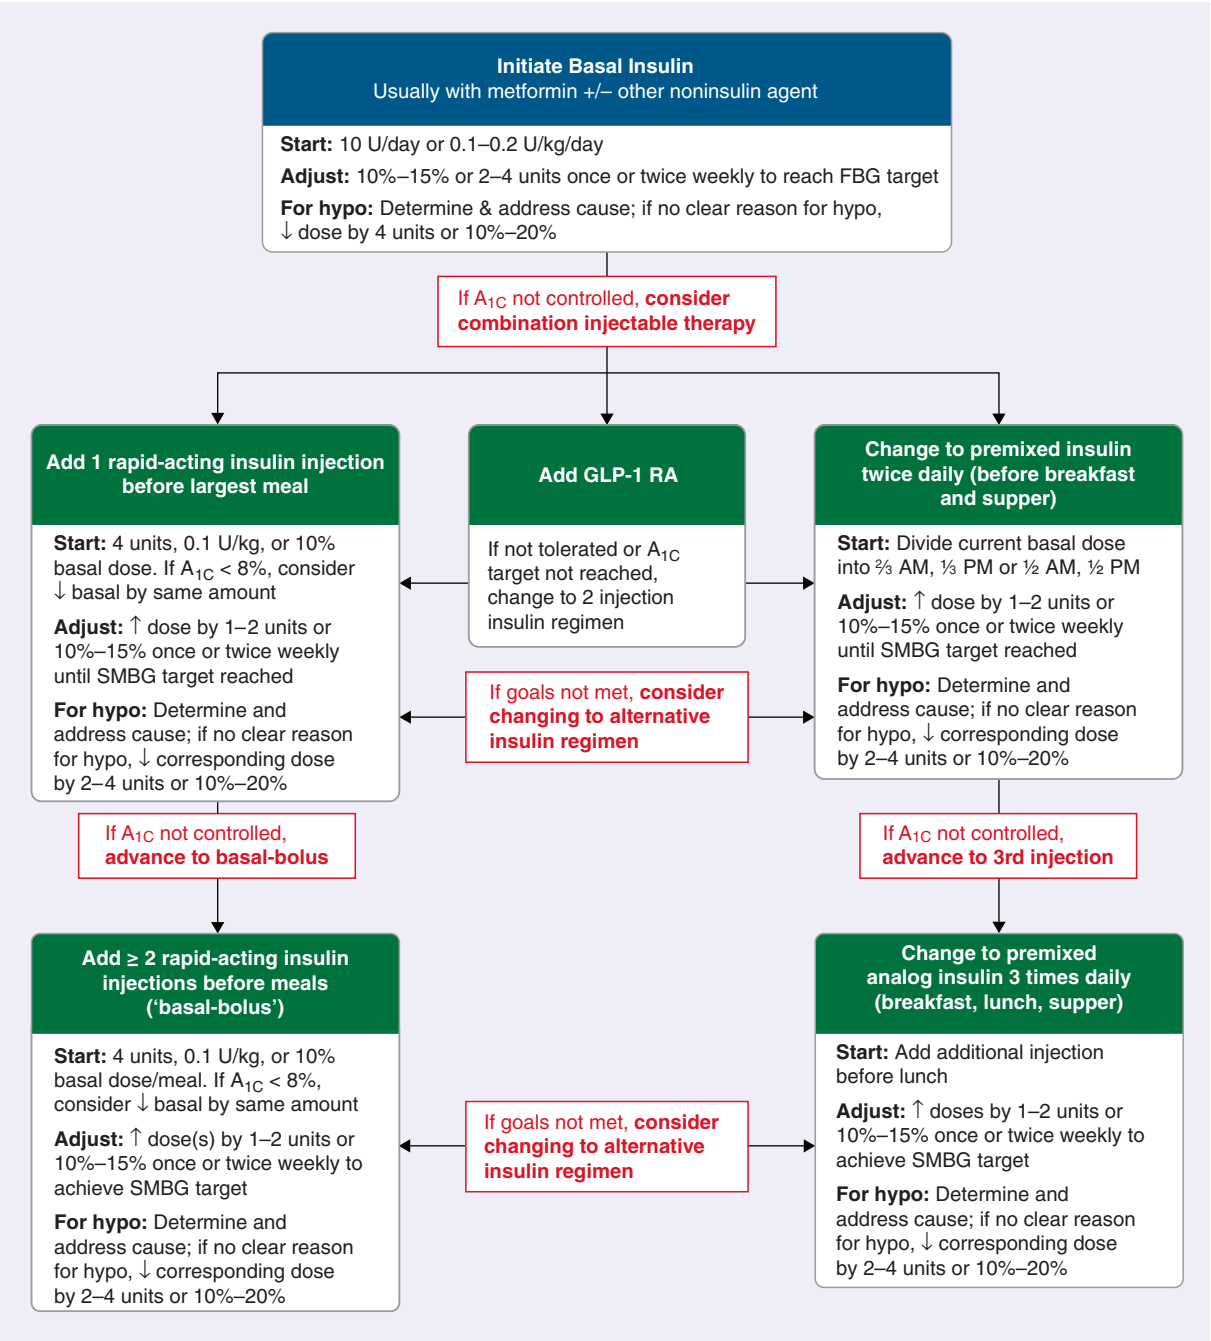

FIGURE 43–4. Initiation and adjustment of insulin regimens. (A_{1c}, hemoglobin A_{1c}; FBG, fasting blood glucose; GLP-1-RA, GLP-1 receptor agonist; hypo, hypoglycemia; kg, kilogram; SMBG, self-monitoring of blood glucose; U, unit(s).) (From American Diabetes Association. Standards of medical care in diabetes—2017. Diabetes Care. 2017;40(Suppl 1):S4–S135, with permission.)

► *Biguanides*

LO 6

Metformin is the only biguanide approved by the Food and Drug Administration (FDA) and currently available in the United States. This agent is thought to lower BG by decreasing hepatic glucose production and increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. Metformin reduces A_{1c} levels by 1.5% to 2% (0.015–0.02; 17–22 mmol/mol Hgb) and FPG levels by 60 to 80 mg/dL (3.3–4.4 mmol/L) when used as monotherapy.[9] Unlike sulfonylureas, metformin retains the ability to reduce FBG levels when they are over 300 mg/dL (16.7 mmol/L). Metformin does not affect insulin release from β-cells of the pancreas, so hypoglycemia is not a common side effect.[24]

Metformin significantly reduced all-cause mortality and risk of stroke in overweight patients with T2DM compared with intensive therapy with sulfonylurea or insulin in the UKPDS.[25] It also reduced diabetes-related death and myocardial infarction compared with a conventional therapy arm. Metformin is considered foundational therapy along with lifestyle modification for T2DM and is often used in combination with other antihyperglycemics for synergistic effects.[7]

Per US labeling, metformin is contraindicated in patients with estimated glomerular filtration rates (eGFR) less than

Table 43–7

Oral Agents for the Treatment of Type 2 Diabetes Mellitus (T2DM)[19,21,24]

Drug Class	Drugs: Trade	Drugs: Generic/ Commercially Available	Target Area	Blood Glucose Affected	Dosing Strategy (All Agents Are Taken Orally)	Adjustment for Renal Impairment: CrCl 30–50 mL/min (0.50–0.83 mL/s)	Adjustment for Renal Impairment: CrCl < 30 mL/min (0.50 mL/s)	Adjustment for Hepatic Impairment	Common Adverse Drug Reactions
α-Glucosidase Inhibitors	Precose	Acarbose/Y	Brush border of small intestine	Postprandial	25 mg three times daily with first bite of each main meal Advance at 4–8 week intervals to a maximum of 100 mg three times daily	SCr > 2 mg/dL (177 µmol/L): Not recommended	SCr > 2 mg/dL (177 µmol/L): Not recommended	No specific dose adjustment recommended	GI (flatulence, diarrhea)
	Glyset	Miglitol/Y			25 mg three times daily with first bite of each main meal Advance at 4–8 week intervals to a maximum of 100 mg three times daily	SCr > 2 mg/dL (177 µmol/L): Not recommended	SCr > 2 mg/dL (177 µmol/L): Not recommended	No adjustment necessary	GI (flatulence, diarrhea)
Meglitinides (should not be used in combination with other insulin secretagogues)	Prandin	Repaglinide/Y	Pancreas	Postprandial	0.5 mg 15–30 minutes before each meal Double preprandial dose every 7 days to a maximum of 4 mg/dose or 16 mg/day (To be taken only if eating)	20–40 mL/min (0.33–0.67 mL/s): Initial dose: 0.5 mg with careful titration	< 20 mL/min (0.33 mL/s): Not studied	Use conservative initial and maintenance doses and use longer intervals between dose adjustments	Hypoglycemia (although less risk than with sulfonylureas)
	Starlix	Nateglinide/Y			120 mg three times daily before meals (To be taken only if eating)	No specific dose adjustment recommended	Use with caution in severe dysfunction	No dose adjustment needed in mild impairment; use with caution in moderate to severe dysfunction	Hypoglycemia (although less risk than with sulfonylureas)
Second-generation sulfonylureas	Micronase	Glyburide/Y	Pancreas	Fasting and postprandial	1.5–3 mg/day with breakfast	Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain

					Increase by 1.5 mg weekly to a maximum of 12 mg/day				
	DiaBeta	Glyburide/Y			2.5–5 mg/day with breakfast Increase by 2.5 mg weekly to a maximum of 20 mg/day	Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain
	Glucotrol	Glipizide/Y			5 mg/day 30 minutes before a meal Increase by 5 mg weekly to a maximum of 40 mg/day; divide dose if > 15 mg/day	No specific dose adjustment recommended	No specific dose adjustment recommended	Initial dose: 2.5 mg/day	Hypoglycemia, weight gain
	Glucotrol XL	Glipizide ER/Y			5 mg once daily before a meal Increase by 5 mg weekly to a maximum of 20 mg/day	No specific dose adjustment recommended	No specific dose adjustment recommended	No specific dose adjustment recommended	Hypoglycemia, weight gain
	Amaryl	Glimeperide/Y			1–2 mg with breakfast Increase by 2 mg every 1–2 weeks to a maximum of 8 mg/day	No specific dose adjustment recommended	< 22 mL/min (0.37 mL/s): Initial starting dose should be 1 mg	No specific dose adjustment recommended	Hypoglycemia, weight gain
Biguanides	Glucophage	Metformin/Y	Liver	Fasting and postprandial	500 mg/day to twice daily with meals. Advance weekly to a maximum of 2000–2550 mg/day	Do not start or, if already taking, continue cautiously if eGFR 30–45 mL/min/1.73 m^2. Consider 50% dose reduction and monitoring of renal function every 3 months.	Contraindicated	Avoid or use cautiously in patients at risk for lactic acidosis (renal impairment or alcohol abuse)	GI (diarrhea, abdominal pain)
	Glucophage ER, Glumetza, Fortamet	Metformin, ER/Y							
	Riomet	Metformin, solution/N			500–1000 mg/day; dose may be increased by 500 mg weekly to a maximum of 2000 mg/day				

(*Continued*)

Table 43–7

Oral Agents for the Treatment of Type 2 Diabetes Mellitus (T2DM)[19,21,24] (*Continued*)

Drug Class	Drugs: Trade	Drugs: Generic/ Commercially Available	Target Area	Blood Glucose Affected	Dosing Strategy (All Agents Are Taken Orally)	Adjustment for Renal Impairment: CrCl 30–50 mL/min (0.50–0.83 mL/s)	Adjustment for Renal Impairment: CrCl < 30 mL/min (0.50 mL/s)	Adjustment for Hepatic Impairment	Common Adverse Drug Reactions
Thiazolidinediones	Actos	Pioglitazone/Y	Peripheral tissue	Fasting and postprandial	15–30 mg/day Increase after 12 weeks to a maximum of 45 mg/day	No adjustment necessary	No adjustment necessary	Clearance lower in Child-Pugh grade B/C; do not start if transaminases > 2.5 × ULN and discontinue if ALT rises to and remains at more than three times ULN	Weight gain
	Avandia	Rosiglitazone/N	Peripheral tissue	Fasting and postprandial	4 mg/day Increase after 8–12 weeks to maximum of 8 mg/day	No adjustment necessary	No adjustment necessary	Do not initiate if active liver disease or ALT > 2.5 times ULN	Weight gain
Dipeptidyl peptidase-4 inhibitors	Januvia	Sitagliptin/N	GI tract (increases GLP-1)	Fasting and postprandial	100 mg/day	50 mg once daily	25 mg once daily	Child-Pugh score 7–9: No dosage adjustment necessary Child Pugh score > 9: Not studied	Upper respiratory, diarrhea
	Onglyza	Saxagliptin/N			2.5 or 5 mg/daily	2.5 mg once daily	2.5 mg once daily	No dose adjustment necessary	UTI, headache
	Tradjenta	Linagliptin/N			5 mg/day	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Headache, arthralgia, nasopharyngitis
	Nesina	Alogliptin/N			25 mg/day	> 30 mL/min (0.50 mL/s) but < 60 mL/min (1 mL/s): 12.5 mg/day	> 15 mL/min (0.25 mL/s) but < 30 mL/min (0.50 mL/s): 6.25 mg/day < 15 mL/min (0.25 mL/s): 6.25 mg/day	No dose adjustment necessary Child Pugh score > 9: Not studied	Headache, increased ALT greater than three times ULN, nasopharyngitis, upper respiratory

Selective sodium-dependent glucose cotransporter-2 inhibitor	Invokana	Canagliflozin/N	Kidney	Fasting and postprandial	100 mg/day in the morning; may increase to 300 mg/day	> 45 mL/min (0.75 mL/s) but < 60 mL/min (1.0 mL/s): 100 mg/day 30 mL/min (0.50 mL/s) to 45 mL/min (0.75 mL/s): not recommended	< 30 mL/min (0.50 mL/s): contraindicated	Mild to moderate: no adjustment necessary Severe: not recommended	Hyperkalemia, genitourinary infection, hypovolemia, renal insufficiency, hypotension
	Farxiga	Dapagliflozin/N			5 mg/day in the morning; may increase to 10 mg/day	< 60 mL/min (1.0 mL/s): not recommended	< 30 mL/min (0.50 mL/s): contraindicated	Mild to moderate: No adjustment necessary Severe: not studied	Genitourinary infection, hypovolemia/ hypotension, dysuria, polyuria, dyslipidemia, mild hypoglycemia, nasopharyngitis
	Jardiance	Empagliflozin/N			10 mg/day in the morning; may increase to 25 mg/day	Not yet available	Not yet available	Not yet available	Genitourinary infection, hypovolemia/ hypotension, dysuria, polyuria, mild hypoglycemia
Dopamine receptor agonist	Cycloset	Bromocriptine mesylate/N	Hypothalamus	Postprandial	0.8 mg once daily within 2 hours of waking; may increase in weekly intervals to 4.8 mg once daily	No dose adjustment necessary	No dose adjustment necessary	No specific dose adjustment recommended, although adjustment may be necessary because of extensive hepatic metabolism	Nausea, headache
Bile acid sequestrant	Welchol	Colesevelam/N	Intestinal lumen	Fasting	1.875 g twice daily or 3.75 g once daily	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Constipation

ALT, alanine aminotransferase; CrCl, creatinine clearance; eGFR, estimated glomerular filtration rate; ER, extended release; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; SCr, serum creatinine; ULN, upper limit of normal; UTI, urinary tract infection.

Table 43–8

Site and Mechanism of Action for Noninsulin Agents

Site of Action	Drug Class	Mechanism of Action
Pancreas	Sulfonylureas	Enhances insulin secretion
	Nonsulfonylurea secretagogues	Enhances insulin secretion
	GLP-1 agonists	Enhances insulin secretion and suppresses glucagon secretion
	Pramlintide	Suppresses glucagon secretion
Liver	Biguanide	Decreases hepatic glucose production and increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Muscle	Biguanide	Increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Adipose tissue	Thiazolidinedione	Increases insulin sensitivity
Intestines	GLP-1 agonists	Increases satiety and regulates gastric emptying
	Pramlintide	Increases satiety and regulates gastric emptying
	Dipeptidyl peptidase-4 inhibitors	Increases endogenous GLP-1
	α-Glucosidase inhibitors	Delays absorption of carbohydrates
Kidney	SGLT-2 inhibitors	Inhibits glucose reabsorption in the kidney's proximal tubule

GLP-1, glucagon-like peptide-1; SGLT-2, sodium-dependent glucose cotransporter-2.

30 mL/min/1.73m^2.[24] It is not recommended for new start in patients whose eGFR is 30 to 45 mL/min/1.73m^2. In those whose eGFR falls to less than 45 mL/min/1.73m^2, a consideration of benefits and risks should be undertaken or a dose reduction to 50% of the maximum dose (or 50% of the patient's current dose) with renal monitoring every 3 months could be chosen. No adjustment is required for patients with an eGFR greater than 45 mL/min/1.73m^2, though more frequent monitoring (every 3–6 months versus annually) is recommended for patients with eGFR greater than 45 but less than 60 mL/min/1.73m^2. Additionally, therapy with metformin should be withheld in patients undergoing radiographic procedures in which a nephrotoxic dye is used if their eGFR is between 30 and 60 mL/min/1.73m^2. Therapy should be withheld the day of the radiographic procedure, and renal function should be assessed 48 hours after the procedure. If renal function is normal, therapy may be resumed. Metformin should also be held 24 hours before surgery and restarted after oral intake is resumed and renal function is evaluated as normal.

Primary side effects associated with metformin therapy are GI in nature, including decreased appetite, nausea, and diarrhea. These side effects can be minimized through use of extended-release products and slow titration of the dose and often subside within 2 weeks.[26] Interference with vitamin B_{12} absorption has also been reported and therefore periodic B_{12} testing is recommended especially in those patients with macrocytic anemia or peripheral neuropathy.[9] Metformin is thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis, a condition which rarely occurs. Patients at greatest risk for developing lactic acidosis include those with renal impairment and those who are of advanced age.[24] Metformin should be withheld promptly in cases of hypoxemia, sepsis, or dehydration. Patients should avoid consumption of excessive amounts of alcohol while taking metformin, and use of the drug should be avoided in patients with liver disease.

► *Thiazolidinediones (TZDs)*

LO 6

TZDs are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR-γ) which increases insulin sensitivity and decreases plasma fatty acids. As monotherapy, TZDs reduce FPG levels by around 60 to 70 mg/dL (3.3–3.9 mmol/L), and the effect on A_{1c} is an up to 1.5% (0.015; 17 mmol/mol Hgb) reduction.[9] The onset of action

Table 43–9

Expected A_{1c} Reduction for Noninsulin Antiglycemic Drug Classes[9]

Drug Class	Efficacy	A_{1c} Reduction (%)	A_{1c} Reduction (mmol/mol Hgb)
Biguanides	High	1.5%–2% (0.015–0.02)	17–22 mmol/mol Hgb
Sulfonylureas	High	1.5%–2% (0.015–0.02)	17–22 mmol/mol Hgb
GLP-1 agonists	High	0.78%–1.6% (0.0078–0.016)	8.8–18 mmol/mol Hgb
Thiazolidinedione	High	up to 1.5% (0.015)	17 mmol/mol Hgb
Dipeptidyl peptidase-4 inhibitors	Intermediate	0.7%–1% (0.007–0.01)	8–11 mmol/mol Hgb
SGLT-2 inhibitors	Intermediate	0.5%–1% (0.005–0.01)	5–11 mmol/mol Hgb
Nonsulfonylurea secretagogues	Intermediate	0.3%–1% (0.003–0.01)	3–11 mmol/mol Hgb
α-Glucosidase inhibitors	Intermediate	0.3%–1% (0.003–0.01)	3–11 mmol/mol Hgb
Central-acting dopamine agonists	Low	0.3%–0.6% (0.003–0.006)	3–7 mmol/mol Hgb
Pramlintide	Low	0.4%–0.5% (0.004–0.005)	5–6 mmol/mol Hgb
Bile acid sequestrants	Low	0.4% (0.004)	5 mmol/mol Hgb

A_{1c}, hemoglobin A_{1c}; GLP-1, glucagon-like peptide-1; Hgb, hemoglobin; SGLT-2, sodium-dependent glucose cotransporter-2.

for TZDs is delayed for several weeks and may require 12 weeks or more before maximum effects are observed.

TZDs may produce fluid retention and edema. Thus, these drugs are contraindicated in situations in which an increased fluid volume is detrimental such as New York Heart Association Class III and IV heart failure. Fluid retention appears to be dose related and increases when combined with insulin therapy. While rare, TZDs can worsen macular edema in the eye. Weight gain of 4 kg (8.8 lb) is common with TZDs and results from both fluid retention and fat accumulation.[9]

Increased rates of upper and lower limb fractures are known to occur with TZD therapy. Premenopausal anovulatory women may begin to ovulate on TZD therapy, and therefore counseling regarding this should be provided to all women capable of becoming pregnant. A slight increased risk for bladder cancer has been noted with pioglitazone therapy, especially among men and smokers.

The safety of TZD therapy in patients with cardiovascular disease is unclear and seems to differ between specific drugs. A meta-analysis reported a significantly greater risk of myocardial infarction with rosiglitazone compared with other oral agents.[27] A subsequent study found rosiglitazone use was associated with a nonsignificant increase in myocardial infarction risk and a nonsignificant reduction in stroke, but a trend toward increased cardiovascular risk in patients with a history of ischemic heart disease.[28] Pioglitazone, added to standard therapy in patients with a history of cardiovascular event or peripheral vascular disease, was shown to decrease the secondary composite endpoint of all-cause mortality, nonfatal myocardial infarction, or stroke.[29]

► α-Glucosidase Inhibitors

LO 6

Acarbose and miglitol are α-glucosidase inhibitors that compete with the enzymes of the small intestines that break down complex carbohydrates. These drugs delay absorption of carbohydrates and reduce postprandial BG concentrations as much as 40 to 50 mg/dL (2.2–2.8 mmol/L); however, A_{1c} reductions range only from 0.3% to 1% (0.003–0.01; 3–11 mmol/mol Hgb).[9] High incidences of GI side effects, including flatulence (42%–74%), abdominal discomfort (12%–19%), and diarrhea (29%–31%), have limited their use.[24] Low initial doses followed by gradual titration may minimize GI side effects. The α-glucosidase inhibitors are contraindicated in patients with chronic intestinal diseases including inflammatory bowel disease. In addition, neither drug in this class is recommended for patients with a serum creatinine (SCr) greater than 2 mg/dL (177 μmol/L).

► Dipeptidyl Peptidase-4 (DPP-4) Inhibitors

LO 6

DPP-4 inhibitors (or gliptins; sitagliptin, saxagliptin, linagliptin, and alogliptin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. They lower BG concentrations by inhibiting DPP-4, the enzyme that degrades endogenous GLP-1, thereby increasing the amount of endogenous GLP-1. The BG-lowering effect of the gliptins is primarily on postprandial levels. Typical A_{1c} reductions are 0.7% to 1% (0.007–0.01; 8–11 mmol/mol Hgb).[9] Common adverse effects include headache and nasopharyngitis. Hypoglycemia is not a common adverse effect with these agents because insulin secretion results from GLP-1 activation caused by meal-related glucose detection and not from direct pancreatic β-cell stimulation. Acute pancreatitis, including hemorrhagic and necrotizing pancreatitis, has been reported in patients taking glipitins.[24]

► Sodium-Dependent Glucose Cotransporter-2 (SGLT2) Inhibitors

LO 6

SGLT2 inhibitors (canagliflozin, dapagliflozin, and empagliflozin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM and may be used as monotherapy or add-on. Inhibition of SGLT2 in the proximal tubules reduces reabsorption of filtered glucose and lowers the renal threshold for glucose which together cause increased urinary excretion of glucose and decreased plasma glucose concentrations.[24] Typical A_{1c} reductions are 0.5% to 1% (0.005–0.01; 5–11 mmol/mol Hgb).[9]

Empagliflozin, added to standard of care, was shown to reduce the composite of cardiovascular death, all-cause mortality, and death from cardiovascular causes.[30] Canagliflozin was evaluated in two trials which enrolled patients with T2DM at high cardiovascular risk.[31] Canagliflozin reduced the risk of primary outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke. An increased risk for amputation was detected in this study, primarily involving the toe or metatarsal. A cardiovascular outcome study is currently ongoing with dapagliflozin.

Possible adverse reactions with SGLT2 inhibitors include urinary tract infections (UTIs) and genital mycotic infections which are increased due to increased glucose excretion that occurs as a function of the drugs' mechanism of action.[24] Osmotic diuresis occurs as well which may result in symptomatic hypotension. Renal function should be monitored at baseline to guide initial dosing and periodically during treatment to assess suitability of continuation. Volume status including BP, hematocrit, serum potassium, serum magnesium, serum phosphate, and low-density lipoprotein (LDL) cholesterol are also recommended monitoring parameters for this class of drug. Cases of euglycemic ketoacidosis have been reported with SGLT2 inhibitors. Before initiation, patients should have their risk for ketoacidosis assessed (some risk factors include insulin deficiency, dose decreases of insulin, caloric restriction, surgery, and infection). Should ketoacidosis occur, the SGLT2 inhibitor should be held or discontinued. Increased risk for bone fracture has also been associated with SLGT2 inhibitor use as well as newly diagnosed bladder cancer with dapagliflozin.

► Central-Acting Dopamine Agonist

LO 6

A quick release formulation of the central-acting dopamine agonist, bromocriptine, is approved for the treatment of T2DM. The mechanism of action for how bromocriptine regulates glycemic control is unknown, but data indicate that bromocriptine administered in the morning improves insulin sensitivity, and this is likely a result of its effect on dopamine oscillations.[9] When used to treat patients with T2DM, bromocriptine should be taken 2 hours after waking in the morning with food.[24] A modest A_{1c} reduction of 0.3% to 0.6% (0.003–0.006; 3–7 mmol/mol Hgb) can be expected from this drug.[9] Main side effects include rhinitis, dizziness, asthenia, headache, sinusitis, constipation, and nausea. Contraindications include syncopal migraine and women who are nursing.[24]

► Bile Acid Sequestrants

LO 6

Colesevelam is the only bile acid sequestrant currently approved as adjunctive therapy to improve glycemic control in conjunction with diet, exercise, and insulin or oral agents for the treatment of T2DM. It acts on the intestinal lumen to bind bile acid, but the drug's exact mechanism that results in plasma glucose lowering is unknown. An A_{1c} reduction of approximately 0.4%

(0.004; 5 mmol/mol Hgb) and an FPG reduction of about 5 to 10 mg/dL (0.3–0.6 mmol/L) can be expected when colesevelam is added.[9] Common adverse effects include constipation and dyspepsia. Drug–drug interactions are possible because of absorption and can be particularly important in patients who are taking levothyroxine, glyburide, oral contraceptives, phenytoin, warfarin, and digoxin. These medications should not be taken together, and they should be separated by at least 4 hours before dosing colesevelam. Malabsorption of fat-soluble vitamins (A, D, E, and K) is also a concern.

▶ *Insulin*

Insulin is the one agent that can be used in all types of DM and has no specific maximum dose, meaning it can be titrated to suit each individual patient's needs. KEY CONCEPT Insulin is the primary treatment to lower BG levels for patients with T1DM, and injected amylin can be added to decrease fluctuations in BG levels. An insulin treatment algorithm for T2DM is found in Figure 43–2.[21]

LO 7

Insulin can be divided into two main classes, basal and bolus, based on their length of action to mimic endogenous insulin physiology. Most formulations are available as U-100, indicating a concentration of 100 unit/mL, though more concentrated insulin formulations have become available in recent years including 200 units/mL (insulin degludec and insulin lispro) and 300 units/mL (insulin glargine), which join the older 500 units/mL regular insulin which has been traditionally available. Insulin is typically refrigerated, though most vials are good for 28 days at room temperature.[24] Insulin products are listed in Table 43–10.[24,32-34]

The most common route of insulin administration is subcutaneous injection using a syringe or pen device. Patients should be educated to rotate injection sites to minimize lipohypertrophy, a buildup of fat that decreases or prevents proper insulin absorption. Additionally, patients should understand that the absorption rate may vary among injection sites (abdomen, thigh, arm, and buttocks) because of differences in blood flow, with absorption occurring fastest in the abdomen and slowest in the buttocks.

Both insulin syringes and pens are now available with shorter needles (4–6 mm, compared to traditional lengths of 8–12.7 mm) that do not require the patient to pinch up their skin before injecting. With the no pinch technique, the needle is injected straight in at a 90-degree angle until flush with the skin. However, these products require a 10-second count to allow enough time for the insulin to be injected. This technique makes injections easier, especially the traditionally more difficult sites such as arms and buttocks.

Bolus Insulins

Regular Regular insulin is unmodified crystalline insulin commonly referred to as natural or human insulin. It is a clear solution that has a relatively short onset and duration of action and is designed to cover insulin response to meals. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Patients should be counseled to inject regular insulin subcutaneously 30 minutes before consuming a meal. Regular insulin, insulin lispro (100 units/mL), insulin aspart, and insulin glulisine can be administered intravenously (IV).

Rapid-Acting Three rapid-acting injectable insulins have been approved in the United States: aspart, glulisine, and lispro (available as 100 units/mL and 200 units/mL). Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. Onset of action of injectable rapid-acting insulins (typically dosed 15 minutes before or immediately prior to meals) varies from 15 to 30 minutes, with peak effects occurring 1 to 2 hours after administration. An inhaled rapid-acting insulin is also available, with peak effect expected to occur around 12 to 15 minutes following a dose and a duration of action of approximately two and one-half to three hours.

Basal Insulins

Intermediate-Duration Neutral Protamine Hagedorn (NPH) insulin is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with a delayed onset but extended duration of action, and is designed to cover insulin requirements in between meals and/or overnight. With the advent of the long-acting insulins, NPH insulin use has declined because of (a) an inability to predict accurately when peak effects occur and (b) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products with NPH insulin, the shorter acting insulin should be drawn into the syringe first.

When utilized in the 500 units/mL (U-500) concentration, regular insulin takes on a different pharmacokinetic/pharmacodynamic profile than when utilized in the 100 units/mL concentration.[9] While its onset of action remains about 30 minutes post injection, its duration of action extends to be more similar to that of NPH. Insulin regular U-500 is now available in a pen device to improve patient safety.[33] The pen device dials in 5-unit increments and takes care of dosing conversion for the patient, meaning that the dose displayed in the pen window is the actual number of units being delivered. Capable of delivering a single dose of up to 300 units at one time, a single pen holds 1500 units total.

Long-Duration Glargine, detemir, and degludec are designed as once-daily-dosing basal insulins which provide a relatively constant insulin concentration over 24 hours.[34] Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Detemir binds to albumin in the plasma, which gives it sustained action. Neither glargine nor detemir completely mimic physiological insulin since, when delivered at high doses, a peak occurs and, when delivered at low doses, the dose may not cover 24 hours.

Recently, insulin glargine at a concentration of 300 units/mL (U-300) became available. This higher concentration product forms a depot with a smaller surface area which creates a more prolonged release than the 100 units/mL (U-100) formulation and a flatter pharmacokinetic/pharmacodynamic response curve. U-300 has been found to result in fewer episodes of hypoglycemia including nocturnal hypoglycemia and decreased weight gain as compared with U-100 glargine. The duration of action for U-300 glargine is approximately 36 hours, about 12 hours longer than that of the U-100 product. Insulin glargine U-300 is available in a pen device which delivers up to 80 units in a single injection.[24] The pen window displays actual units delivered, meaning that no dosing conversion is required. Insulin should not be transferred

Table 43–10

Insulin Agents for the Treatment of Type 1 and Type 2 Diabetes Mellitus[24,32-34]

Generic Name (Insulin)	Brand/Rx Status	Manufacturer	Strength	Onset	Peak (hours)	Duration (hours)	Administration Options
Rapid-Acting Insulin							
Lispro	Humalog/Rx	Eli Lilly	U-100, U-200	15–30 minutes	0.5–2.5	3–4	CSII, IV, SC; 10-mL vial, 3-mL cartridge, and disposable pen
Aspart	Novolog/Rx	Novo-Nordisk	U-100	15–30 minutes	1–3	3–5	CSII, IV, SC; 10-mL vial, 3-mL cartridge, and disposable pen
Glulisine	Apidra/Rx	Aventis	U-100	15–30 minutes	1–2	3–4	CSII, IV, SC; 10-mL vial, 3-mL cartridge, and disposable pen
Recombinant human insulin regular	Afrezza/Rx	MannKind	Not applicable	12–15 minutes	1	2.5–3	Inh; Technosphere insulin particles for oral inhalation
Short-Acting Insulin							
Regular	Humulin R/OTC	Eli Lilly	U-100, U-500	30-60 minutes	2-3	3-6	CSII, IV, SC; U-100 10-mL vial; U-500 20-mL vial
	Novolin R/OTC	Novo-Nordisk	U-100				CSII, IV, SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet*
Intermediate-Acting Insulin							
Neutral protamine Hagedorn	Humulin N/OTC	Eli Lilly	U-100	2–4 hours	4–6	8–12	SC; 10-mL vial, 3-mL cartridge
	Novolin N/OTC	Novo-Nordisk	U-100				SC; 10-mL vial, 3-mL cartridge, 3-mL *InnoLet*
Long-Acting Insulin							
Glargine	Lantus/Rx	Sanofi-Aventis	U-100	4-5 hours	Flat	22–24	SC; 10-mL vial, 3-mL cartridge for *Opticlik* (available in SoloSTAR disposable pen)
	Toujeo/Rx		U-300				SC;1.5-mL SoloSTAR disposable pen
Detemir	Levemir/Rx	Novo-Nordisk	U-100	3–4 hours	Flat	Up to 24	SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet*, 3-mL disposable *FlexPen*
Degludec	Tresiba/Rx	Novo-Nordisk	U-100, U-200	1 hour	Flat	42	SC; 3-ml disposable *FlexTouch* pen
Combination Insulin Products							
Neutral protamine Hagedorn and regular	Humulin 70/30/OTC	Eli Lilly	U-100	30–60 minutes	1.5–16	10–16	SC: 10-mL vial, 3-mL disposable pen SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet*
	Novolin 70/30/OTC	Novo-Nordisk	U-100	30–60 minutes	2–12	10–16	
	Humulin 50/50/OTC	Eli Lilly	U-100	30–60 minutes	2–5.5	10–16	SC; 10-mL vial
Neutral protamine lispro and lispro	Humalog Mix 75/25/Rx	Eli Lilly	U-100	15–30 minutes	1–6.5	15–18	SC; 10-mL vial, 3-mL disposable pen
Neutral protamine aspart and aspart	Novolog Mix 70/30/Rx	Novo-Nordisk	U-100	15–30 minutes	1–4	Up to 24	SC; 10-mL vial, 3-mL cartridge, 3-mL disposable *FlexPen*
Combination Insulin GLP-1 agonist Products							
Degludec and liraglutide	Xultophy/Rx	Novo-Nordisk	U-100 degludec/ 3.6 mg/mL liraglutide	N/A	N/A	N/A	SC; 3-ml pen-injector
Glargine and lixisenatide	Soliqua/Rx	Sanofi	U-100 glargine/ 33 mcg/mL liraglutide	N/A	N/A	N/A	SC; 3-mL pen-injector

CSII, continuous subcutaneous insulin infusion; GLP-1, glucagon like peptide; Inh, inhalation; IV, intravenous; N/A, not applicable; OTC, over-the-counter; Rx, prescription required; SC, subcutaneous.

from the pen to a syringe as incorrect dosing and subsequent adverse effects can occur.

Further search for a more physiologically perfect basal insulin lead to the development of degludec.[34] A modified B chain analogue which forms hexamers and di-hexamers when injected, insulin degludec provides a flatter pharmacokinetic/pharmacodynamic profile than detemir or glargine. Zinc molecules, present in the hexamers, slowly diffuse allowing insulin monomers to be absorbed. This ultra-slow insulin release allows degludec to have a half-life of 25 hours and duration of action that exceeds 42 hours. Though still recommended for daily dosing at the same time each day, degludec's long duration of action means that patients taking it can miss or delay a dose as long as they make sure to keep an 8-hour interval between any two doses.

Combination Products A number of combination insulin products are available commercially.[24,32] These combination products allow some patients to manage their insulin therapy with only two injections per day, and avoids the difficulty and possible errors that can occur when manually mixing insulins. NPH is available in a combination of 70/30 (70% NPH and 30% regular insulin). Three short-acting insulin analog mixtures are also available. Humalog mix 75/25 contains 75% neutral protamine lispro suspension and 25% insulin lispro. Novolog mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. Humalog 50/50 contains 50% neutral protamine lispro and 50% lispro. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and are not commercially available separately.

Insulin Pump Therapy Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily (see Figure 43–1), as well as bolus administration before meals and snacks. Regular or rapid-acting insulin is delivered from a reservoir either by infusion set tubing or through a small canula. Most pump infusion sets are inserted in the abdomen, arm, or other infusion site by a small needle. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. However, they must rotate sites to avoid development of scar tissue. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. More specifically, an individual's ratio is calculated to determine how many units of the specific insulin being used in the pump "covers" for a certain amount of carbohydrates to be ingested at a particular meal. The 450 rule (for regular insulin) or the 500 rule (for rapid-acting insulin) is commonly used. To calculate the ratio using the 500 rule, the patient would divide 500 by his or her total daily dose of insulin. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

In addition to mealtime boluses, correction doses based on premeal glucose readings are also used. The amount of additional insulin for the correction is based on either the 1500 rule for regular insulin or the 1800 rule for rapid-acting insulin. If using rapid-acting insulin, divide 1800 by the patient's total daily insulin dose. The resulting value will represent the reduction in glucose (mg/dL) produced by one unit of insulin. The correction dose would be given in addition to the bolus dose needed based on the patient's carbohydrate-to-insulin ratio and the amount of carbohydrates present in the meal he or she is about to consume.

Insulin pump therapy may be used to lower BG levels in any type of DM; however, patients must be on multiple daily insulin injections and therefore patients with T1DM are always candidates and those with T2DM are sometimes candidates to use these devices. Use of an insulin pump may improve BG levels, reduce wide fluctuations in BG levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules, resulting in improved quality of life.

► *Noninsulin Injectable Agents*

LO 6

Glucagon-Like Peptide 1 (GLP-1) Agonists Exenatide, liraglutide, albiglutide, dulaglutide, and lixisenatide are indicated for the treatment of T2DM to improve glycemic control. These agents are part of the group of drugs known as incretins (Table 43–11).[24,32,35]

GLP-1 agonists lower BG levels by: (a) producing glucose-dependent insulin secretion; (b) reducing postmeal glucagon secretion, which decreases postmeal glucose output; (c) increasing satiety which decreases food intake; and (d) regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly. Typical A_{1c} reductions vary between GLP-1 agonists and are also affected by baseline glucose control. Exenatide immediate release can be expected to lower A_{1c} around 0.9% (0.009; 10 mmol/mol Hgb) while exenatide extended-release lowers A_{1c} around 1.6% (0.016; 18 mmol/mol Hgb).[36] Reductions in A_{1c} from 0.99% to 1.36% (0.0099–0.0136; 11 mmol/mol Hgb to 15 mmol/mol Hgb) have been reported with liraglutide, reductions of around 1.42% have been reported with dulaglutide (0.00142; 16 mmol/mol Hgb), reductions of around 0.79% have been reported with lixisenatide (0.0079; 8.9 mmol/mol Hgb), and reductions around 0.78% (0.0078; 8.8 mmol/mol Hgb) have been reported with albiglutide.[35] GLP-1 agonists typically produce moderate weight loss of around 3 to 4 kg (6.6–8.8 lbs) depending on the drug chosen. Exenatide immediate release has less impact on fasting blood sugar levels as compared with the longer-acting GLP-1 agonists owing to its shorter duration of action.[9] Exenatide and lixisenatide are eliminated renally. Exenatide is not recommended in patients with a creatinine clearance (CrCl) of less than 30 mL/min (0.50 mL/s) and lixisenatide is not recommended in patients with CrCl less than 15 mL/min (0.25 mL/s).[24] No specific dose adjustments are recommended for liraglutide, albiglutide, or dulaglutide in renal impairment. The main side effects of GLP-1 agonist therapy include nausea, vomiting, and diarrhea. These GI adverse effects tend to lessen over time.[9] GLP-1 agonists have been associated with cases of acute pancreatitis. Any patient presenting with symptoms of acute pancreatitis, including abdominal pain, nausea, and vomiting, should have GLP-1 agonist therapy discontinued until pancreatitis can be ruled out. Albiglutide, liraglutide, exenatide extended-release, and dulaglutide packagings contain a black-box warning about thyroid C-cell tumors.[24] They are contraindicated in patients with a personal or family history of medullary thyroid cancer and in those with a history of multiple endocrine tumors. Antibody formation can occur with the GLP-1 agonists leading to treatment failure or increased allergic reaction side effects.

Liraglutide reduced the risk of cardiovascular death as compared with placebo in a clinical trial.[37] Given this potential cardiovascular outcome benefit coupled with their ability to produce weight loss and help control weight gain from insulin therapy, the GLP-1 agonists have had considerable increased utilization in recent years both as monotherapy and as add-on. As such, a market for combination insulin and GLP-1 agonist products has developed. There are now two basal insulin/GLP-1

Table 43–11

Noninsulin Injectable Agents for the Treatment of Diabetes[24,32,35]

Generic Name (Brand)	Type of Diabetes	Dosage Strengths[a]	Starting Dosage	Doses/Day	Titration Interval	Maximum Dose	Time to Effect (minutes)	Comments and Cautions
Pramlintide[b] (Symlin)	T1DM	15, 30, 45, 60 mcg	15 mcg	3	3–7 days	60 mcg	20	Take just before major meals; reduce insulin by 50% Maintenance dose 30–60 mcg Side effects: Hypoglycemia, nausea, vomiting Available in SymlinPen 60 and 120
	T2DM	60, 120 mcg	60 mcg	3	3–7 days	120 mcg	20	
Exenatide[b] (Byetta, Bydureon)	T2DM	Immediate-release: 5 mcg, 10 mcg; Extended-release: 2 mg	Immediate-release: 5 mcg; extended-release: 2 mg	Immediate-release: 2; extended-release: N/A; once-weekly	Immediate-release: 1 month; extended-release: N/A	Immediate-release: 10 mcg; extended-release: 2 mg	Immediate-release: 15–30	Inject immediate-release formulation 15–20 minutes before two meals of the day with 6 hours separating the meals; prefilled disposable pen; may delay absorption of oral drugs; separate doses by 1 hour Extended-release formulation can be administered regardless of meals Side effects: Nausea, vomiting, diarrhea, increased hypoglycemia with sulfonylureas
Liraglutide[b] (Victoza)	T2DM	6 mg/3 mL pen	0.6 mg	1	1 week	1.8 mg	N/A	Can be dosed at any time of day regardless of meals; may delay absorption of oral drugs; separate doses by 1 hour Side effects: Nausea, vomiting, increased hypoglycemia with sulfonylureas
Albiglutide[b] (Tanzeum)	T2DM	30 mg single-dose pen; 50-mg single-dose pen	30 mg	N/A; once weekly	6 weeks	50 mg	N/A	If missed dose occurs within 3 days of the regularly scheduled dose, dose should be administered at that time. If missed dose occurs more than 3 days past scheduled dose, wait until next regularly scheduled dose to administer next dose Side effects: upper respiratory infection, diarrhea, nausea, injection site reaction

Table 43–11

Noninsulin Injectable Agents for the Treatment of Diabetes[24,32,35] *(Continued)*

Generic Name (Brand)	Type of Diabetes	Dosage Strengths[a]	Starting Dosage	Doses/Day	Titration Interval	Maximum Dose	Time to Effect (minutes)	Comments and Cautions
Dulaglutide[b] (Trulicity)	T2DM	0.75 mg single-dose pen and prefilled syringe; 1.5-mg single-dose pen and prefilled syringe	0.75 mg	N/A; once weekly	Not specified	1.5 mg	N/A	If missed dose occurs within 3 days of the regularly scheduled dose, dose should be administered at that time. If missed dose occurs more than 3 days past scheduled dose, wait until next regularly scheduled dose to administer next dose Side effects: nausea, diarrhea, vomiting, abdominal pain, decreased appetite, dyspepsia, fatigue
Lixisenatide[b] (Adlyxin)	T2DM	10 mcg and 20 mcg pen-injector starter kit; 20 mcg pen-injector	10 mcg	1	14 days	20 mcg	N/A	If missed dose, administer within one hour of next meal

[a]Pramlintide supplied as 0.6 mg/mL in 5-mL vials. Exenatide immediate-release supplied as 250 mcg/mL, 1.2 mL for the 5-mcg prefilled pen, and 2.4 mL for the 10-mcg per dose prefilled pen. Exenatide extended-release supplied as 2 mg sterile powder plus 0.65 mL diluent in single use trays. Liraglutide supplied in 6 mg/3 mL prefilled pen, which can be dialed to the desired dose of 0.6, 1.2, or 1.8 mg. Albiglutide supplied in a 30-mg and a 50-mg single-dose pen. Dulaglutide supplied in a 0.75-mg and 1.5-mg single-dose pen and prefilled syringe. Lixisenatide supplied in a 10-mcg and a 20-mcg pen-injector starter kit and a 20-mcg pen-injector for maintenance use.

[b]Generic not available in the United States.

N/A, not applicable; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

agonist combination products available. One contains insulin glargine in combination with lixisenatide and the other contains insulin degludec in combination with liraglutide.

Amylin Pramlintide acetate is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide that is cosecreted with insulin by the β-cells of the pancreas in response to food. Amylin secretion is very low or completely deficient in patients with T1DM and lower than normal in patients with T2DM who require insulin. Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to a reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial postmeal spike in BG is reduced.

Pramlintide is given by subcutaneous injection before meals to lower postprandial BG elevations in patients with types 1 or 2 DM. Pramlintide generally results in an additional A_{1c} reduction of 0.4% to 0.5% (0.004–0.005; 5–6 mmol/mol Hgb) and an average weight loss of 1.5 kg (3.3 lb).[9] Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 30% to 50% before pramlintide is initiated. Primarily, the kidneys metabolize pramlintide, but dosage adjustments in liver or kidney impairment are not required.

Pramlintide has the potential to delay the absorption of orally administered medications. When rapid absorption is needed for the efficacy of an agent, pramlintide should be administered 1 hour after or 3 hours before the drug. Pramlintide should not be used in patients receiving medications that alter GI motility. A disposable pen formulation is now on the market and available as SymlinPen 60 for patients with T1DM and SymlinPen 120 for T2DM.

Treatment of Concomitant Conditions

The ADA standards of medical care address many of the common comorbid conditions, as well as complications that result from the progression of DM.

▶ *Cardiovascular Health*

Cardiovascular disease is the major cause of morbidity and mortality for patients with DM. Interventions targeting smoking cessation, BP control, lipid management, antiplatelet therapy, and lifestyle changes (including diet and exercise) can reduce the risk of cardiovascular events and should be considered as important as glycemic control in the management of a patient with DM. All patients with a history of cardiovascular disease should be prescribed aspirin 75 to 162 mg/day as a secondary prevention strategy.[7] Clopidogrel is an option for patients with atherosclerosis who are allergic to aspirin. The ADA currently recommends that antiplatelet therapy should be considered for patients with DM and no history of heart disease if that patient is 50 years of age or older and has at least one additional cardiovascular risk factor including family history of premature atherosclerotic cardiovascular disease (ASCVD), hypertension, dyslipidemia, smoking, or albuminuria.

The results of a number of trials, including the Action to Control Cardiovascular Risk in Diabetes (ACCORD),[38] Action in Diabetes and Vascular Disease (ADVANCE),[39] and Veterans Affairs Diabetes Trial (VADT)[40] taken together with long-term follow-up information from the UKPDS[41] and DCCT[42,43] trials, have been used to formulate conclusions regarding the effect of glucose lowering on cardiovascular health. Those conclusions are: (1) short-term (3–5 years) intensive glycemic control does not improve the risk of macrovascular complications in patients with long-standing T2DM; and (2) a decrease in macrovascular risk from improved glycemic control may take more than a decade to be realized. Because of the results of these trials, the A_{1c} goal used for most patients with T2DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) may be used for otherwise healthy individuals without cardiovascular disease who are thought to be early in the course of their DM and controlled with lifestyle or metformin only and who have a long life expectancy.[7,19] A more relaxed target of less than 8% (0.08; 64 mmol/mol Hgb) may be employed for those who are older, have numerous medical conditions limiting life expectancy, are at increased risk for hypoglycemia, or have had T2DM for a long period of time.

▶ *Dyslipidemia*

The 2013 American College of Cardiology/American Heart Association (ACC/AHA) Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults recommends statin therapy be considered if a patient falls into one of four statin benefit groups.[44] The ADA guidelines incorporate these statin benefit groups in their recommendations in the following manner:[7]

1. Patients with diabetes and atherosclerosis are recommended to receive high-intensity statin.
2. Patients with diabetes who are less than 40 years old but who have other ASCVD risk factors are recommended to receive moderate- or high-intensity statin.
3. Patients with diabetes aged 40–75 years who have no other ASCVD risk factors are recommended to receive moderate-intensity statin.
4. Patients with diabetes aged 40–75 years who have other ASCVD risk factors are recommended to receive high-intensity statin.
5. Patients with diabetes over 75 years without other ASCVD risk factors are recommended to receive moderate-intensity statin.
6. Patients with diabetes over 75 years with other ASCVD risk factors are recommended to receive moderate- to high-intensity statin.

Refer to Chapter 12, Dyslipidemias, for additional information.

▶ *Hypertension*

KEY CONCEPT Uncontrolled BP plays a major role in the development of macrovascular events and microvascular complications, including retinopathy, nephropathy, and erectile dysfunction, in patients with DM. The 2017 ACC/AHA High Blood Pressure Clinical Practice Guideline recommends patients with diabetes be started on antihypertensive drug therapy at a BP of 130/80 mm Hg.[45] A goal of less than 130/80 mm Hg is recommended. Various first-line antihypertensive agents can be utilized in patients with diabetes included diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and calcium channel blockers. However, when albuminuria is present, ACE inhibitors or ARBs are recommended because of their beneficial effects on renal

LO 4

function. Most patients will require more than one agent to reach BP goal. Renal function and serum potassium levels should be monitored closely in all patients taking an ACE inhibitor, ARB, and/or diuretic. ACE inhibitors and ARBs are contraindicated in patients who are pregnant and in those with bilateral renal artery stenosis.

▶ *Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)*

Patients with HIV are known to be at increased risk for DM.[46] The cause of this increased risk is likely multifactorial with the disease itself playing a role (HIV-related increases in pro-inflammatory cytokines and free fatty acids) as well as typical concomitant disease states (obesity) and adverse effects of antiretroviral therapy used to combat HIV. Protease inhibitors like indinavir increase insulin resistance and decrease insulin secretion. Nucleoside reverse transcriptase inhibitors like stavudine cause lipohypertrophy which is associated with insulin resistance.[7] The ADA currently recommends that patients with HIV undergo screening for DM with an FBG every 6 to 12 months when not receiving antiretroviral therapy and then 3 months after starting or changing antiretroviral therapy.[7] Patients found to have normal FBG on screening should be retested annually. Those found to have prediabetes should be monitored every 3 to 6 months. Use of A_{1c} is not recommended as it is known to underestimate glycemia in patients with HIV. Management of DM in HIV patients includes weight loss through physical activity and nutrition, oral therapy (paying careful attention to drug interactions) or insulin, and even consideration of change in antiretroviral therapy away from the causative agent, though virological control must also be carefully weighed as part of that potential plan.

Patient Encounter Part 2: Follow-Up Visit

The patient returns 8 days later with results from his fasting blood work. The provider also requests an FBG, A_{1c}, and vitals at today's visit. The results are listed below.

VS: BP 148/76 mm Hg, P 70 beats/min, RR 19 breaths/min, T 38°C (100°F)

A_{1c} (today): 8.2% (0.082; 66 mmol/mol Hgb)

FPG (today): 189 mg/dL (10.5 mmol/L)

Labs (2 days ago): Na 136 mEq/L (mmol/L); K 3.6 mEq/L (mmol/L); Cl 98 mEq/L (mmol/L); CO_2 24 mEq/L (mmol/L); BUN 15 mg/dL (5.4 mmol/L); SCr 0.9 mg/dL (80 µmol/L); BG 172 mg/dL (9.5 mmol/L)

The patient is diagnosed with T2DM.

Identify the goals of treatment for this patient.

What nonpharmacologic alternatives are available for this patient for his diabetes?

What are the three general categories of pharmacologic alternatives used to lower blood glucose?

What is the most appropriate initial therapy for this patient in regards to his diabetes?

What additional interventions are recommended for this patient today?

▶ *Antipsychotic Drug Therapy*

An association has been recognized between second-generation antipsychotics and the development of diabetes. Risk seems to be highest with clozapine and olanzapine. The ADA recommends that patients prescribed atypical antipsychotics be screened annually for DM.[7] If a second generation antipsychotic is prescribed, weight, glycemic control, and cholesterol should be carefully monitored.

Treatment of Acute Complications

▶ *Hypoglycemia*

LO 8 Hypoglycemia, or low blood sugar, can be defined by the glucose alert value of less than or equal to 70 mg/dL (3.9 mmol/L).[7,47] Individuals with DM can experience symptoms of hypoglycemia at varying BG levels. Those with uncontrolled glucose can experience pseudohypoglycemia which is when symptoms of hypoglycemia occur even at normal glucose levels. Those with recent low BG levels may have no symptoms even at glucose values below the hypoglycemia threshold, and therefore patients with recurrent hypoglycemia may benefit from a period of more relaxed glycemic targets.[7] LO 8 Typical symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion.

Common causes of hypoglycemia include delayed or inadequate amounts of food intake, especially carbohydrates, excessive doses of medications (eg, sulfonylureas, insulin), exercising when insulin doses are reaching peak effect, or inadequately adjusted drug therapy in patients with impaired renal or hepatic function. LO 8 Patients experiencing symptoms of hypoglycemia should check their BG level, consume 15 g of carbohydrate, wait 15 minutes for symptom resolution, and retest.[47] Examples of 15 g of carbohydrate may include a small box of raisins, 4 oz (~120 mL) of orange juice, 8 oz (~240 mL) of skim milk, or three to four glucose tablets. In patients receiving an α-glucosidase inhibitor in combination with a sulfonylurea or insulin, hypoglycemia should be treated with glucose tablets or skim milk owing to the mechanism of action of the α-glucosidase inhibitors. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by the intramuscular (IM) or subcutaneous route. It is important to contact emergency medical personnel in this particular situation. The patient should be rolled onto his or her side to prevent aspiration because many patients receiving the glucagon injection may vomit.

▶ *Diabetic Ketoacidosis (DKA)*

LO 9 DKA is a reversible but potentially life-threatening medical emergency that results from a relative or absolute deficiency in insulin. Without insulin, the body cannot use glucose as an energy source and must obtain energy via lipolysis. This process produces ketones and leads to acidosis. Although DKA occurs frequently in young patients with T1DM on initial presentation, it can occur in adults as well. Often, precipitating factors such as infection, omission, or inadequate administration of insulin can cause DKA. Signs and symptoms develop rapidly within 1 day or so and commonly include fruity or acetone breath; nausea; vomiting; dehydration; polydipsia; polyuria; and deep, rapid breathing.

LO 9 Hallmark diagnostic criteria for DKA include hyperglycemia (> 250 mg/dL [13.9 mmol/L]), ketosis (anion gap > 12 mEq/L [mmol/L]), and acidosis (arterial pH ≤ 7.3).[48] Typical fluid deficit is 5 to 7 L or more, and major deficits of serum sodium and potassium are common.

DKA severity depends on the magnitude of the decrease in arterial pH, serum bicarbonate levels, and mental state rather than the magnitude of hyperglycemia. Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing serum glucose. Fluid replacement with normal saline at 1 to 1.5 L/hour for the first hour is recommended to rehydrate the patient and ensure the kidneys are perfused.

LO 9

Potassium and other electrolytes are supplemented as indicated by laboratory assessment. The use of sodium bicarbonate in DKA is controversial and generally only recommended when the pH is less than 7. Regular insulin at 0.1 unit/kg/hour by continuous IV infusion is the preferred treatment in DKA to regain metabolic control rapidly. When plasma glucose values drop below 250 mg/dL (13.9 mmol/L), dextrose 5% should be added to IV fluids. During the recovery period, it is recommended to continue administering insulin and allow patients to eat as soon as possible. Dietary carbohydrates combined with insulin assist in the clearance of ketones. See Table 43–12 for DKA management.[48]

LO 9

▶ *Hyperosmolar Hyperglycemic State (HHS)*

HHS is a life-threatening condition similar to DKA that also arises from inadequate insulin, but HHS occurs primarily in older patients with T2DM. DKA and HHS also differ in that HHS lacks the ketonemia and acidosis associated with DKA. Patients with hyperglycemia and dehydration lasting several days to weeks are at greatest risk of developing HHS. Infection, silent myocardial infarction, cerebrovascular accident, mesenteric ischemia, acute pancreatitis, and use of medications that affect carbohydrate metabolism including steroids and thiazide diuretics are known precipitating causes of HHS. Two main diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L) and a serum osmolality of greater than 320 mOsm/kg (mmol/kg).[48] The extreme hyperglycemia and large fluid deficits resulting from osmotic diuresis are major challenges to overcome with this condition. Similar to DKA, the treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. BG levels should be reduced gradually to minimize risk of cerebral edema.

Table 43–12

Management of Diabetic Ketoacidosis[50]

1. Confirm diagnosis (increased plasma glucose, positive serum ketones, metabolic acidosis).
2. Admit to hospital; intensive care setting may be necessary for frequent monitoring or if pH < 7 or unconscious.
3. Assess serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate), acid–base status—pH, HCO_3^-, PCO_2, β-hydroxybutyrate, and renal function (creatinine, urine output).
4. Replace fluids: 0.9% saline 1 L/hour over first 1–3 hours; subsequently, 0.45% saline at 4–14 mL/kg/hour; change to 5% dextrose with 0.45% saline when plasma glucose reaches 250 mg/dL (13.9 mmol/L).
5. Administer regular insulin: IV (0.15 U/kg bolus followed by 0.1 unit/kg/hour infusion); check glucose hourly and double insulin infusion until glucose level falls at steady hourly rate of 50–70 mg/dL (2.8–3.9 mmol/L). Alternatively, could use SC or IM routes, although dosing regimen different. If initial serum potassium is < 3.3 mEq/L (mmol/L), do not administer insulin until the potassium is corrected to > 3.3 mEq/L (mmol/L).
6. Assess patient: What precipitated the episode (eg, nonadherence, infection, trauma, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, chest x-ray, ECG).
7. Measure chemistry (especially K^+, bicarbonate, phosphate, and anion gap) every 2–4 hours until stable.
8. Replace K^+: If K^+ is < 3.3 mEq/L (mmol/L), hold insulin and give 40 mEq (mmol) of K^+ per liter of IV fluid. If K^+ is > 5 mEq/L (mmol/L), do not give K^+ but check level every 2 hours. When K^+ > 3.3 mEq/L (mmol/L) but < 5 mEq/L (mmol/L), ECG normal, urine flow and normal creatinine documented, administer 20–30 mEq/L (mmol/L) of IV fluid to maintain K^+ at 4–5 mEq/L (mmol/L).
9. Continue above until patient is stable, glucose goal is 150–250 mg/dL (8.3–13.9 mmol/L), and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 unit/kg/hour.
10. Administer intermediate- or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and subcutaneous insulin injection.

Cl, chloride; ECG, electrocardiogram; HCO_3, serum bicarbonate; IM, intramuscular; IV, intravenous; K, potassium; Mg, magnesium; Na, sodium; PCO_2, partial pressure of carbon dioxide in the arterial blood; SC, subcutaneous.

Treatment of Long-Term Complications

▶ *Retinopathy*

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. The ADA recommends that patients with T2DM receive a dilated eye examination at the time of diagnosis by an ophthalmologist or optometrist.[7] Examinations should begin within 5 years of diagnosis of T1DM. Once one or more normal examinations occur, the dilated eye examination is recommended to be repeated at least every 2 years. In patients with documented retinopathy, an annual dilated eye examination is recommended. Glucose and BP control are the best strategies for decreasing risk and slowing the progression of retinopathy.

▶ *Neuropathy*

KEY CONCEPT Peripheral neuropathy is a possible complication of DM. The most common types of peripheral neuropathy include chronic sensorimotor distal peripheral neuropathy, which can cause pain, tingling, and numbness in the feet and hands, and autonomic neuropathy, which can lead to hypotension, gastroparesis, sexual dysfunction, and autonomic failure in response to hypoglycemia.[7] Two drugs, pregabalin and duloxetine, have been approved for relief of distal peripheral neuropathy pain. A number of other drugs are also sometimes used including venlafaxine, gabapentin, carbamazepine, tramadol, topical capsaicin, and tricyclic antidepressants.

▶ *Microalbuminuria and Nephropathy*

DM is a leading contributor to end-stage renal disease. Early evidence of nephropathy is the presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in T2DM patients.[7] For patients with T1DM, annual urine protein testing should begin 5 years after the diagnosis of diabetes. The most common form of screening for protein in the urine is a random collection for measurement of the urine albumin-to-creatinine ratio. The desirable value

Patient Encounter Part 3: Follow-Up

The patient returns in 3 months for a follow-up visit. He brings his BG readings from the past week for review in addition to more fasting blood work. BG readings are in units of mg/dL (mmol/L). His most recent medication list is below. There are no changes to his health record from previous visits.

Allergies: Penicillin

Meds: Acetaminophen 500–1000 mg PRN headache; metformin 1000 mg by mouth twice daily

VS: BP 154/96 mm Hg, P 78 beats/min, RR 18 breaths/min, T 37°C (98.6°F)

Labs: Total cholesterol 240 mg/dL (6.21 mmol/L); HDL cholesterol 41 mg/dL (1.06 mmol/L); LDL cholesterol 163 mg/dL (4.22 mmol/L); TG 183 mg/dL (2.07 mmol/L); AST 28 U/L (0.47 µkat/L); ALT 31 U/L (0.52 µkat/L)

Day	FPG	PPG
Monday	118 (6.5)	168 (9.3)
Tuesday	122 (6.8)	187 (10.4)
Wednesday	134 (7.4)	140 (7.8)
Thursday	110 (6.1)	244 (13.5)
Friday	98 (5.4)	257 (14.3)
Saturday	128 (7.1)	297 (16.5)
Sunday	116 (6.4)	240 (13.3)

Are this patient's blood glucose levels within target? What pattern seems to be established?

Which classes of antidiabetic drugs act in a manner that would specifically correct the undesirable glucose pattern?

Based on the information available from this encounter and previous encounters, develop a care plan for this patient. The plan should include (a) identification and assessment of all drug-related needs and/or problems, (b) a detailed therapeutic plan to address each need and problem, and (c) monitoring parameters to assess safety and efficacy.

is less than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine). The terms **microalbuminuria** and macroalbuminuria are being replaced by the term "persistent albuminuria," with the level of albuminuria further defined as either being between 30 and less than 299 mcg of albumin per milligram of creatinine (3.4–33.8 mg/mmol creatinine; previously referred to as microalbuminuria) or greater than or equal to 300 mcg of albumin per milligram of creatinine (≥ 34 mg/mmol creatinine; previously known as macroalbuminuria).

Glycemic control and BP control are primary measures for the prevention of progression of nephropathy. ACE inhibitors and ARBs prevent progression of renal disease in patients with T2DM. Treatment of advanced nephropathy includes dialysis and kidney transplantation.

▶ *Foot Ulcers*

KEY CONCEPT Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral arterial disease (PAD), neuropathies, and foot deformations.

PAD causes ischemia to the lower limbs. This decreased blood flow deprives the tissues of oxygen and nutrients and impairs the ability of the immune system to function adequately. Symptoms of PAD include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the single most important treatment for PAD. In addition, exercising by walking to the point of pain and then resting until pain subsides and resuming can be a vital therapy to maintain or improve the symptoms of PAD. Pharmacologic intervention with antiplatelet therapy (aspirin 160–325 mg/day or clopidogrel 75 mg/day) is indicated in patients with PAD.[49] For those that remain symptomatic, cilostazol 100 mg twice daily may be useful to improve blood flow and reduce the symptoms of PAD.

Neuropathies play a large part in the development of foot ulcers. Loss of sensation in the feet allows trauma to go unnoticed. Autonomic neuropathy can cause changes in blood flow, perspiration, skin hydration, and possibly, bone composition of the foot. Motor neuropathy can lead to muscle atrophy, resulting in weakness and changes in the shape of the foot. To prevent foot complications, the ADA recommends daily visual examination of the feet and a foot check performed at every provider visit as well as a comprehensive foot evaluation each year.[7] Sensory testing with a 10-gauge monofilament can detect areas of neuropathy. Treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Additionally, individuals with diabetes should wear properly fitted, cushioned footwear and padded socks. Table 43–13 provides a list of various microvascular and macrovascular complications as well as their signs and symptoms.

LO 10

▶ *Erectile Dysfunction*

Compared to men who do not have diabetes, men with DM are at two to three times greater risk of erectile dysfunction. Additionally, men with DM may experience this complication several years earlier than men who do not have DM. Improved BG control can minimize risk of erectile dysfunction. Refer to Chapter 51, Erectile Dysfunction, for further information.

Special Situations

▶ *Hospitalized Care*

Current recommendations call for critically ill patients to be started on IV insulin therapy at a threshold of 180 mg/dL (10.0 mmol/L).[7] A goal range of 140 to 180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of patients. More stringent goals may be considered for selected critically ill patients, but only if hypoglycemia can be avoided. Scheduled subcutaneous insulin regimens with basal, nutritional, and correction components are recommended for patients who are not critically ill. Patients who required insulin during hospitalization but had previously not used insulin will need education/training to successfully transition home.

▶ *Sick Days*

Patients should monitor their BG levels more frequently during sick days because it is common for illness to increase BG values.[50] Patients with T1DM should check their glucose and urine for ketones every 4 hours when sick. Patients with T2DM may also need to check for ketones when their BG levels are greater than 240 mg/dL (13.3 mmol/L). Patients should continue to take their medications while sick. T1DM patients may require additional insulin coverage, and some

Table 43–13

Macrovascular and Microvascular Complications Signs and Symptoms

	Complication	Signs and Symptoms
Macrovascular	Coronary heart disease	Stable or unstable angina pectoris, MI, or dysrhythmias; however, many patients have unrecognizable symptoms.
	PAD	Exertional leg pain that can progress to pain at rest and ischemic ulcers. Most cases are asymptomatic.
	Cerebrovascular disease/Stroke	Sudden onset of a focal neurologic deficit such as facial droop, hemiparesis, or isolated weakness of an arm or leg. Dizziness, slurred speech, gait difficulties, and visual loss may also occur.
Microvascular	Retinopathy	Minimal until advanced disease ensues with loss or blurring of vision.
	Nephropathy	Hypertension, which often coincides with the development of microalbuminuria (persistent proteinuria).
	Neuropathy	Numbness, tingling, burning, muscle pain/cramps/weakness that often gets worse at night.
	Foot Care (Neuropathy and/or PAD)	Calluses and corns, tinea pedis, hammertoes, bunions, cracking of skin of the feed and heels.

MI, myocardial infarction; PAD, peripheral arterial disease.

with T2DM who are currently on oral medication regimens may require insulin during an acute illness. Patients should be advised to maintain their normal caloric and carbohydrate intake while ill as well as to drink plenty of noncaloric beverages to avoid dehydration. When having difficulty eating a normal diet, patients may be advised to use nondiet beverages, sports drinks, broths, crackers, soups, and nondiet gelatins to provide normal caloric and carbohydrate intake and avoid hypoglycemia. With proper management, patients can decrease their chance of illness-induced hospitalization, particularly DKA and HHS.

OUTCOME EVALUATION

LO 10

- KEY CONCEPT The success of therapy for DM is measured by the ability of the patient to manage his or her disease appropriately between health care provider visits.
- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.
- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examining the feet for any sores, cuts, or abrasions; checking the skin for dryness to prevent cracking and chafing; and monitoring BG values as directed. Weekly appraisals of weight and BP are also advised.
- Until A_{1c} levels are at goal, quarterly visits with the patient's primary health care provider are recommended. Table 43–6 summarizes the specific ADA goals for

Patient Encounter Part 4: Insulin Therapy

The patient returns to the office for his annual checkup. It has been 5 years since he was first diagnosed with diabetes. His updated information is below. His past medical and family histories are unchanged. He states that he has been adherent to medications and lifestyle changes. He complains that he has burning and tingling constantly in both of his feet.

SH: Prior history of smoking one half pack per day for 10 years, but quit 11 years ago; denies alcohol or illicit drug use

Allergies: Penicillin

Meds: Lisinopril 20 mg by mouth once daily; atorvastatin 20 mg by mouth once daily; acetaminophen 500–1000 mg PRN headache; metformin 1000 mg by mouth twice daily; liraglutide 1.2 mg subcutaneously once daily; multivitamin by mouth once daily

Meal History: Has been consuming approximately 30 to 45 g of carbohydrates per meal three times a day; saturated fat is limited to 12 g/day, and sodium is 2000 mg/day

Physical Activity: Was walking 4 or 5 days per week for 30 minutes at moderate intensity but has not done so recently due to tingling in feet

VS: BP 135/82 mm Hg, P 85 beats/min, RR 20 breaths/min, T 38°C (100°F), Ht 5'3" (160 cm), Wt 155 lb (70.5 kg)

Labs: Na 139 mEq/L (mmol/L); K 5 mEq/L (mmol/L); Cl 103 mEq/L (mmol/L); CO_2 23 mEq/L (mmol/L); BUN 16 mg/dL (5.7 mmol/L); SCr 0.9 mg/dL (80 µmol/L); FPG 180 mg/dL (10.0 mmol/L); A_{1c} 9.7% (0.097; 83 mmol/mol Hgb); AST 28 U/L (0.47 µkat/L); ALT 31 U/L (0.52 µkat/L)

Fasting lipid profile:

- Total cholesterol: 202 mg/dL (5.22 mmol/L)
- LDL cholesterol: 108 mg/dL (2.79 mmol/L)
- HDL cholesterol: 43 mg/dL (1.11 mmol/L)
- Triglycerides: 205 mg/dL (2.32 mmol/L)

What additional pharmacologic options are available for this patient to lower his blood glucose to goal?

Which insulin and starting dose would be most appropriate for this patient?

How could the number of daily injections be reduced for this patient given his current medication regimen after insulin is initiated?

What additional medications, screenings, labs, and/or referrals are recommended for the patient at this point?

What is an important lifestyle modification this patient still needs to make?

Patient Care Process

Collect Information:

- Perform medication history of prescription, over-the-counter, and herbal product use.
- Collect laboratory data including chemistry panel, A_{1c}, lipid panel, and albumin-to-creatinine ratio.
- Measure BP.
- Examine patient for development or progression of DM complications.
- Record SMBG, including FPG and postprandial levels.
- Interview patient to gather information related to quality-of-life measures such as physical, psychological, and social functioning and well-being.

Assess the Information:

- SMBG for glycemic control, including FPG and postprandial levels (see Table 43–6).
  - Are the BG values too high or low?
  - Are there specific times of day or specific days not within glucose goals?
  - Is hypoglycemia occurring?
- Review laboratory data for attainment of goals (see Table 43–6). What goals are not being met?
- Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
  - Is the patient taking medications that may affect glucose control?
- If patient is already receiving treatment for DM, has he/she been adherent to recommended lifestyle modifications and drug therapies? Is the patient having difficulty affording their therapies?
- Assess patient for quality-of-life measures such as physical, psychological, and social functioning and well-being.

Develop a Care Plan:

- Recommend appropriate therapy and develop a plan to assess effectiveness (see Tables 43–7, 43–10, and 43–11, and Figures 43–2, 43–3, and 43–4).

Implement the Care Plan:

- Stress adherence to prescribed lifestyle and medication regimen.
  - Ensure patient has prescription coverage and/or is able to afford prescribed regimen and self-care.
- Provide education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
  - Causes of DM complications and how to prevent them.
  - How diet and exercise can affect diabetes.
  - How to perform SMBG and what to do with the results.
  - When to take medications and what to expect, including adverse effects.
  - What warning sign(s) should be reported to the provider.
- What tests or referrals to other health care team members are needed?

Follow-up: Monitor and Evaluate:

- Set follow-up for SMBG and tolerability/presence of adverse effects based on therapy chosen.
- Follow-up A_{1c} every 3 months until patient reaches goal, then every 6 months. See Table 43–6 for other monitoring parameters and frequency.
- Monitor for macrovascular and microvascular signs and symptoms (Table 43–13).

therapy. The practitioner should review SMBG data and a current A_{1c} level for progress and address any therapeutic or educational issues.

- At a minimum, yearly laboratory evaluation of serum lipids, urinary albumin to creatinine ratio, and SCr should be performed.
- Appropriate monitoring and treatment for DM complications should occur (Table 43–13).

Abbreviations Introduced in This Chapter

A_{1c}	Hemoglobin A_{1c}
AACE	American Association of Clinical Endocrinologists
ACCORD	Action to Control Cardiovascular Risk in Diabetes
ACC/AHA	American College of Cardiology/American Heart Association
ACE	Angiotensin-converting enzyme
ADA	American Diabetes Association
ADVANCE	Action in Diabetes and Vascular Disease
AIDS	Acquired immune deficiency syndrome
ALT	Alanine aminotransferase
ARB	Angiotensin II receptor blocker
ASCVD	Atherosclerotic cardiovascular disease
ATP	Adenosine triphosphate
BG	Blood glucose
BMI	Body mass index
BP	Blood pressure
BUN	Blood urea nitrogen
CDC	Centers for Disease Control and Prevention
Cl	Chloride
CrCl	Creatinine clearance
CSII	Continuous subcutaneous insulin infusion
DCCT	Diabetes Control and Complications Trial
DKA	Diabetic ketoacidosis
DM	Diabetes mellitus
DPP-4	Dipeptidyl peptidase-4
ECG	Electrocardiogram
eGFR	Estimated glomerular filtration rate
FBG	Fasting blood glucose
FDA	Food and Drug Administration
FPG	Fasting plasma glucose
GDM	Gestational diabetes mellitus
GI	Gastrointestinal

GIP	Glucose-dependent insulinotropic peptide
GLP-1	Glucagon-like peptide-1
HDL	High-density lipoprotein
HHS	Hyperosmolar hyperglycemic state
Hgb	Hemoglobin
HIV	Human immunodeficiency virus
IFG	Impaired fasting glucose
IGT	Impaired glucose tolerance
IM	Intramuscular
ISF	Interstitial fluid
IV	Intravenous
K	Potassium
LADA	Latent autoimmune diabetes in adults
LDL	Low-density lipoprotein
Mg	Magnesium
MNT	Medical nutrition therapy
Na	Sodium
NGSP	National Glycohemoglobin Standardization Program
NPH	Neutral protamine Hagedorn
OGTT	Oral glucose tolerance test
PAD	Peripheral arterial disease
PCO_2	partial pressure of carbon dioxide
PPAR-γ	Proxisome proliferator-activated receptor gamma
PPG	Postprandial glucose
SC	Subcutaneous
SCr	Serum creatinine
SGLT2	Sodium-dependent glucose cotransporter-2
SMBG	Self-monitoring of blood glucose
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
TLC	Therapeutic lifestyle change
TZD	Thiazolidinedione
UKPDS	United Kingdom Prospective Diabetes Study
ULN	Upper limit of normal
UTI	Urinary tract infection
VADT	Veterans Affairs Diabetes Trial
WHO	World Health Organization

44 Thyroid Disorders

Michael D. Katz

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Discuss the prevalence of common thyroid disorders, including mild and overt hypothyroidism and hyperthyroidism.
2. Explain the major components of the hypothalamic–pituitary–thyroid axis and interaction among these components.
3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease, and the advantages for use of TSH levels over other tests such as serum T_4 (thyroxine) and T_3 (triiodothyronine) levels.
4. Identify typical signs and symptoms of hypothyroidism and the consequences of suboptimal treatment.
5. Describe clinical use of levothyroxine (LT_4) in the treatment of hypothyroidism.
6. Discuss the issues regarding LT_4 product bioequivalence and reasons for maintaining patients on the same product.
7. Describe the management of hypothyroidism and hyperthyroidism in pregnant women.
8. Identify typical signs and symptoms of Graves disease and consequences of inadequate treatment.
9. Discuss the pharmacotherapy of Graves disease, including advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.
10. Describe the potential effects of selected drugs, including amiodarone, lithium, interferon-α, and tyrosine kinase inhibitors (TKIs) on thyroid function.

INTRODUCTION

Thyroid disorders are common. More than 2 billion people, or 38% of the world's population, have iodine deficiency, resulting in 74 million people with **goiter**. Although overt iodine deficiency is not a significant problem in developed countries, a number of common thyroid conditions exist. The most common are hypothyroidism and hyperthyroidism, which often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, methods of identifying thyroid disorders, and appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

EPIDEMIOLOGY

LO 1

Among 4392 people 12 years of age and older in a sample representing the geographic and ethnic distribution of the US population, hypothyroidism was found in 3.7% (3.4% mild) and hyperthyroidism in 0.5%.[1] The prevalence of hypothyroidism correlated with age and was higher in older age groups, whites, and Hispanics, but was lower in blacks. Compared with the total population, people aged 50 to 79 years had an almost twofold higher prevalence, and those aged 80 years and older had a fivefold higher prevalence. Pregnant women also had a higher prevalence of hypothyroidism than nonpregnant women across all races and ethnicities. The Colorado Thyroid Health Survey assessed thyroid function in 25,862 subjects attending a health fair.[2] Overall prevalence of an abnormal thyroid-stimulating hormone (TSH; thyrotropin) level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were euthyroid (had normal thyroid function or hormone activity), with an equal distribution between subclinical hypothyroidism and hyperthyroidism. The National Health and Nutrition Examination Survey (NHANES) study also found that many patients receiving thyroid medications had an abnormal TSH level. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

PATHOPHYSIOLOGY

The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T_4) and triiodothyronine (T_3). Thyroid hormones are essential for proper fetal growth and development, particularly of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in regulation of energy metabolism. These hormones can affect the function of virtually every organ in the body. The parafollicular C cells of the thyroid gland produce **calcitonin**.

T_4 and T_3 are produced by the **organification** of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by **thyroid peroxidase** and covalently bound to tyrosine residues of **thyroglobulin**. These iodinated tyrosine residues, monoiodotyrosine and diiodotyrosine, couple to form T_4 and T_3. Eighty percent of thyroid hormone is synthesized as T_4 and is stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of TSH (thyrotropin from the anterior pituitary). T_4 and T_3 are transported in the blood by three proteins, 70% bound to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. T_4 is 99.97% protein bound, and T_3 is 99.7% protein bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 to 10 days for T_4 and 24 hours for T_3.

Most of the physiologic activity of thyroid hormones is from the actions of T_3. T_4 can be thought of primarily as a prohormone. Eighty percent of needed T_3 is derived from conversion of T_4 to T_3 in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of T_3 needed to control local metabolic functions. These enzymes also catabolize T_3 and T_4 to biologically inactive metabolites.

LO 2

KEY CONCEPT The production and release of thyroid hormones are regulated by the hypothalamic–pituitary–thyroid axis (Figure 44–1). Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH when there are physiologically inadequate levels of thyroid hormones. TSH promotes production and release of thyroid hormones. As circulating thyroid hormone levels rise to needed levels, negative feedback results in decreased release of TSH and TRH. Release of TRH is also inhibited by somatostatin and its analogs, and release of TSH can also be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

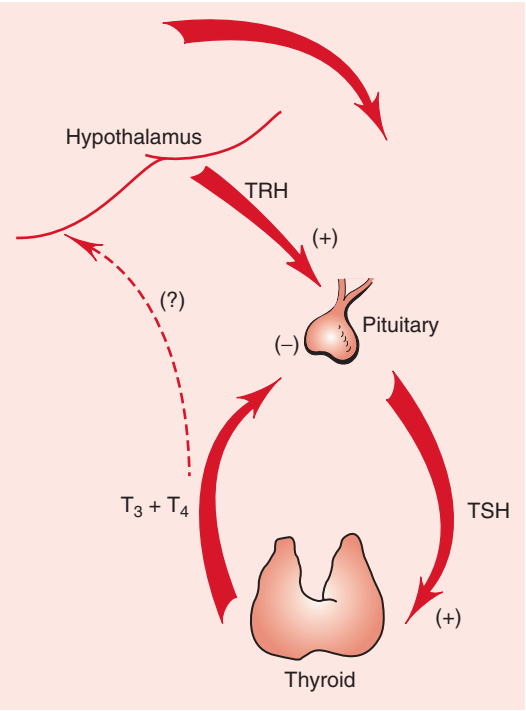

FIGURE 44–1. Hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the neurons within the paraventricular nucleus of the hypothalamus. TRH is released into the hypothalamic–pituitary portal circulation and carried to the pituitary, where it activates the pituitary to synthesize and release thyrotropin (TSH). TSH activates the thyroid to stimulate the synthesis and secretion of thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 inhibit TSH secretion, closing the feedback loop. Negative feedback from T_4 and T_3 to hypothalamic TRH is less certain, hence the question mark.

SPECTRUM OF THYROID DISEASE

There are two general modes of presentation for thyroid disorders: changes in the size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in euthyroid patients are common problems. Patients with a goiter who are biochemically euthyroid often require no specific pharmacotherapy unless the goiter is caused by iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be malignant or may autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter; however, thyroid cancer is discussed briefly in the context of levothyroxine (LT_4) suppressive therapy. Refer to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion, often due to an underlying inflammatory disorder (thyroiditis), can result in hormone deficiency or excess. Although patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that progress slowly over time. Availability of sensitive and specific biomarkers for diagnosis of thyroid hormone disorders has facilitated screening and earlier case-finding and diagnosis, including in those with mild or subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has reduced the incidence of mental retardation and neonatal hypothyroidism dramatically in the United States. However, congenital hypothyroidism owing to iodine deficiency remains a significant worldwide public health problem.

PATIENT ASSESSMENT AND MONITORING

Assessment of patients for thyroid disorders entails a history and physical examination. In many patients with mild or subclinical thyroid disease, there may be an absence of specific signs and symptoms, and physical examination findings may be normal. Various diagnostic tests can be used, including levels of serum thyroid hormone(s), TSH, thyroid antibody levels, and imaging techniques (Table 44–1). Laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical or mild to overt (Figure 44–2).

TSH Levels

KEY CONCEPT In most patients with thyroid hormone disorders, measurement of a serum TSH level is adequate for initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum free thyroxine (FT_4) and triiodothyronine (FT_3) levels may be helpful in distinguishing mild (subclinical) thyroid disease from overt disease. TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.5 milli international units/L (mIU/L) or 1.5 micro international units/mL (μIU/mL) (target range, 0.5–4 mIU/L or μIU/mL), although patients must be individually titrated based on

Table 44–1

Selected Thyroid Tests for Adults

Test	Reference Range	Comments
TSH	0.5–4.5 mIU/L (μIU/mL)	Gold standard; may be lowered by dopamine, dopamine agonists, glucocorticoids, octreotide, recovery from severe nonthyroidal illness
FT_4	0.7–1.9 ng/dL (9.0–24.5 pmol/L)	May be normal in mild thyroid disease
Anti-TPOAb, Anti-TGAb	Variable[a]	Present in autoimmune hypothyroidism; predicts more rapid progression from subclinical to overt hypothyroidism
TSI (TSHR-SAb)	Undetectable	Confirms Graves disease

[a]Anti-TPOAb reference ranges are highly variable from one laboratory to another depending on the method used. Results greater than the upper cutoff are considered abnormal and are consistent with increased risk for autoimmune thyroid disease.

Anti-TPOAb, antithyroid peroxidase antibody; FT_4, free T_4 (thyroxine); Anti-TGAb, antithyroglobulin antibody; TSH, thyroid-stimulating hormone; TSHR-SAb, TSH receptor-stimulating antibodies; TSI, thyroid-stimulating immunoglobulin.

resolution of signs and symptoms as well as biochemical tests. Target TSH may be different in the elderly and in patients being treated with LT_4 for thyroid cancer.

TSH is a highly sensitive bioassay of the thyroid axis. A twofold change in serum-free T_4 levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows it to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism. LO 3 In patients with primary hypothyroidism or hyperthyroidism resulting from gland dysfunction, there is an inverse relationship between the TSH level and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement), and low TSH signifies hyperthyroidism (or iatrogenic overreplacement). There is controversy regarding the normal or laboratory reference ranges for TSH.[3] NHANES showed the mean TSH level in a normal population was 1.46 mIU/L (μIU/mL) (clinical laboratories use either unit of measurement, usually expressed as mIU/L or μIU/mL), but the values were not normally distributed. Although most laboratories quote the upper limit of normal for TSH between 4 and 5 mIU/L (μIU/mL), 95% of subjects had a TSH level of between 0.5 and 2.5 mIU/L (μIU/mL). The population of subjects whose TSH level was 2.5 to 4.5 mIU/L (μIU/mL) may have had mild hypothyroidism, or the non-normal distribution may reflect different normal ranges in a heterogeneous (age, sex, race) population. The mean normal TSH appears to be higher in the elderly with no clinical evidence of hypothyroidism,[3] and there is some evidence that normal TSH ranges are sex and ethnicity specific.[1] The target TSH for most patients being treated for thyroid disorders is not the same as the reference range. Ideally, TSH should be the mean normal value of 1.5 mIU/L (μIU/mL; target range, 0.5–4 mIU/L [μIU/mL]).[3] The upper limit of the target range may be higher in the elderly. Therapy may be titrated within the target TSH range to maximally improve patient signs and symptoms without causing adverse effects of overtreatment or undertreatment.

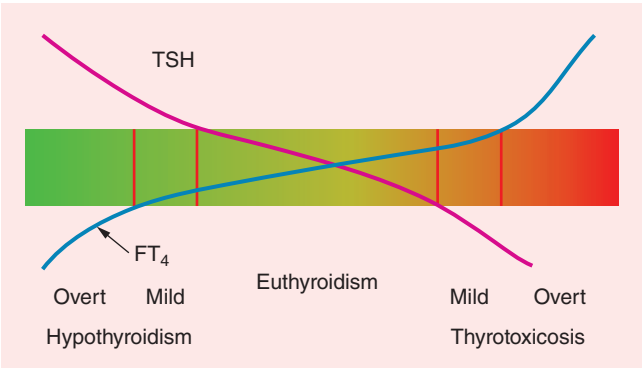

FIGURE 44–2. The continuum of thyroid disorders. (FT_4, free T_4 [thyroxine]; TSH, thyroid-stimulating hormone.)

Serum T_4 and T_3 Levels

Serum T_4 and T_3 levels are used commonly to assess thyroid function. LO 3 Older screening tests of thyroid function measure total serum T_4 or T_3 levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or the degree of protein binding. Since a number of factors can alter protein binding, these older assays are very insensitive and should no longer be used. Free or unbound T_4 (FT_4) and T_3 (FT_3) assays are readily available and more sensitive in identifying thyroid dysfunction than older total assays.[3] However, patients with mild hypothyroidism or hyperthyroidism have normal FT_4 levels despite abnormal TSH levels.

Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. The radioactive iodine uptake (RAIU) is elevated in those with hyperthyroidism and can aid in identifying thyrotoxicosis owing to nonthyroid gland sources. Radionuclide thyroid scans are used in evaluation of thyroid nodules. Because many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase antibodies (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves disease have TSH receptor-stimulating antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function. It is the clinical syndrome that results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, but occasional patients have pituitary or hypothalamic failure. Most studies define hypothyroidism based on a serum TSH level above the upper limit of the laboratory reference range. LO 1 In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, incidence is highly age dependent. In the Colorado Thyroid Health Study, by age 64 years, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, incidence in men approached that of women.[2] Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%.[3] There is a strong correlation between the presence of anti-TPOAb or anti-TGAb and the

risk of developing hypothyroidism. In patients with subclinical hypothyroidism, 2% to 6% per year will progress to overt hypothyroidism, with the risk of progression higher in women, those with higher TSH levels, those with higher levels of anti-TPOAbs and those with low-normal FT_4 levels.[4] Other risk factors for development of hypothyroidism include the postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison disease, other nonendocrine autoimmune diseases such as celiac disease and pernicious anemia, history of treatment for hyperthyroidism, treatment with certain medications including amiodarone or lithium, and an iodine-deficient diet.[5]

Screening

Because prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women older than age 35 years may be cost-effective, though some organizations recommend screening of adults after age 50 or 60 years.[6] Others advocate a case-finding approach, defined as performing a TSH determination in patients based on risk factors or presence of signs and symptoms.[3] However, there are no studies that assess the impact of screening for thyroid disease on morbidity and mortality.[7]

Causes

The most common causes of hypothyroidism are listed in Table 44–2.[3,8-11] Up to 90% of patients with autoimmune thyroiditis (Hashimoto disease) have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Iatrogenic hypothyroidism can occur after thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism, including iodine-containing drugs such as amiodarone and iodinated radiocontrast media, lithium, interferon-α, multikinase and TKIs (imatinib, sunitinib, sorafenib), *p*-aminosalicylic acid, ethionamide, sulfonylureas, valproic acid and other antiepileptic drugs, and aminoglutethimide.[3,8,11] Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary disease often have other signs of pituitary disease, such as hypogonadism, and their TSH levels are low.

Signs and Symptoms

LO 4

Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using serum TSH level to identify patients with hypothyroidism.

Table 44–2

Common Causes of Hypothyroidism[3,8-11]

Primary Hypothyroidism
Autoimmune thyroiditis (Hashimoto disease)
Iatrogenic (irradiation, surgery)
Drugs (amiodarone, radiocontrast media, lithium, interferon-α, tyrosine kinase inhibitors, alemtuzumab)
Silent thyroiditis (including postpartum)
Iodine deficiency and excess
Secondary Hypothyroidism
Pituitary disease
Hypothalamic disease

Clinical Presentation and Diagnosis of Hypothyroidism[3,5,8-10]

Symptoms

Fatigue	Cold intolerance
Lethargy	Hoarseness
Sleepiness	Dry skin
Mental impairment	Decreased perspiration
Depression	Decreased appetite
Weight gain	Constipation
Menstrual disturbances	Arthralgia
Paresthesia	

Signs

Slow movements	Dry skin
Goiter	Weight gain
Slow speech	Nonpitting edema (myxedema)
Hoarseness	Hyporeflexia
Bradycardia	Delayed relaxation of reflexes

Screening/Diagnosis

- TSH level of 4.5 to 10 mIU/L (μIU/mL) may constitute mild or subclinical hypothyroidism.
- TSH level greater than 10 mIU/L (μIU/mL) signifies overt hypothyroidism.
- FT_4 level will be normal (0.7–1.9 ng/dL or 9.0–24.5 pmol/L) in mild or subclinical hypothyroidism and low (< 0.7 ng/dL or 9.0 pmol/L) in patients with obvious signs and/or symptoms.

Mild (Subclinical) Hypothyroidism

Mild or subclinical hypothyroidism is present when a patient has a TSH above the upper limit of the laboratory reference range but usually below 10 mIU/L (μIU/mL), normal FT_4, and no overt hypothyroid signs and symptoms.[4,5,9,10] Many of these patients have autoimmune thyroiditis and anti-TPOAbs and some will progress to overt hypothyroidism. Although patients may not express the typical symptoms of hypothyroidism, many patients do have mild, nonspecific symptoms (eg, fatigue, cold intolerance, constipation). Recent studies have shown subclinical hypothyroidism to be a risk factor for cardiovascular mortality and to be associated with decreased myocardial contractility, decreased exercise tolerance, elevated low-density lipoprotein (LDL) cholesterol, and neuropsychiatric symptoms.[4,12-14]

Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is associated with hypothyroidism, increasing the long-term risk of cardiovascular disease and cardiovascular mortality. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study showed a direct correlation between degree of TSH elevation and rise in serum cholesterol.[2]

Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with LT_4 therapy. Maternal hypothyroidism can have dire consequences for developing fetuses. Fetuses are almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.[3,15]

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

Treatment

▶ *Desired Outcomes*

KEY CONCEPT There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state. Although these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

▶ *Thyroid Hormone Products*

A number of thyroid hormone products are marketed in the United States (Table 44–3). These products include synthetic LT_4 and T_3, combinations of synthetic LT_4 and T_3, and animal-derived products. KEY CONCEPT Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic LT_4 is the treatment of choice for almost all patients with hypothyroidism.[3,8,10,15] LT_4 mimics the normal physiology of the thyroid gland, which secretes mostly T_4 as a prohormone. Peripheral tissues convert T_4 to T_3 as needed based on metabolic demands. If T_3 is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT_4 also has distinct pharmacokinetic advantages over T_3. With a 7- to 10-day half-life, LT_4 provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of T_4 to T_3, addition of T_3 may be warranted. T_3, with a 24-hour half-life, provides a significant peak and trough effect, and many patients have symptoms of thyrotoxicosis after each dose is administered. The use of compounded T_3 or other thyroid hormone products not approved by the Food and Drug Administration (FDA) or dietary supplements marketed for "thyroid health" should be strongly discouraged.[15] For patients who have difficulty adhering to a once-daily regimen, a once-weekly LT_4 regimen is safe and effective.[3,15]

LOS

Animal-derived products such as desiccated thyroid are obtained from pig or cow thyroid and have various degrees of purity. These products contain both LT_4 and T_3, but the amount of T_3 is much higher (T_4:T_3 = 4:1) than what would be found in the human thyroid gland (T_4:T_3 = 14:1). Although some patients want to use desiccated thyroid extract because it is "natural," the products are in no way natural for humans. With strong evidence supporting the safety and efficacy of LT_4 in the treatment of hypothyroidism, there is no rationale for the use of these animal-derived products, and no evidence that desiccated thyroid extract has any benefits over synthetic LT_4.[16] Patients who are treated with these agents should be strongly encouraged to switch to synthetic LT_4. Additionally, patients should be encouraged to not purchase thyroid hormone- or iodine-containing products from health food stores or Internet sites.

Several studies have been published that evaluate use of LT_4 and T_3 combinations in ratios that mimic human physiology. A large number of clinical trials and meta-analyses of studies comparing LT_4 and T_3 combinations with LT_4 monotherapy show no outcome benefit with combination therapy.[15] Except in rare circumstances (eg, patients with impaired T_4-to-T_3 conversion as evidenced by adequate LT_4 dose, continued symptoms and low FT_3 level), there is no rationale for the routine use of LT_4 and T_3 combinations.

Table 44–3

Thyroid Preparations

Drug (Brand Name)	Content	Relative Dose	Comments
Levothyroxine, (Synthroid, Levoxyl, Unithroid), other brands, and generics	Synthetic LT_4; 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, and 300-mcg tablets; 100-, 200-, and 500-mcg vial for injection	60 mcg	Gold standard for treating hypothyroidism; products not therapeutically equivalent; full replacement dose, 1–1.6 mcg/kg/day; when switching from animal product, lower calculated daily dose by 25–50 mcg; IV form rarely needed
Liothyronine (Cytomel)	Synthetic T_3; 5-, 25-, and 50-mcg tablets	15 mcg	Rarely needed in treatment of hypothyroidism; rapid absorption and pharmacologic effect; increased toxicity versus LT_4; no outcome benefit to combining with LT_4
Thyroid (desiccated) USP (Armour, others)	Desiccated pork thyroid glands; contains T_3 and T_4; 15-, 16.25-, 30-, 32.5-, 48.75-, 60-, 65-, 90-, 97.5-, 120-, 130-, 162.5-, 180-, 195-, 240-, 260-, 300-, and 325-mg tablets	65 mg	Nonphysiologic T_4:T_3 ratio; T_3 content may cause toxicity; no advantage over LT_4 monotherapy; no role in modern therapy
Liotrix (Thyrolar)	Synthetic T_4, T_3 in fixed 4:1 ratio; ¼-, ½-, 1-, 2-, 3-strength tablets	12.5/50 mcg T_3:T_4 (1 strength)	Nonphysiologic T_4:T_3 ratio; T_3 content may cause toxicity; no role in modern therapy

IV, intravenous; LT_4, levothyroxine; T_3, triiodothyronine; T_4, thyroxine.

▶ Bioequivalence and LT_4 Product Selection

LO 6

LT_4 products have a long history of bioavailability problems.[3,15,17] Over the years, LT_4 bioavailability has increased, so maintenance doses today are significantly lower than those seen before the early 1980s. Currently, the average bioavailability of LT_4 tablet products is about 70% to 80%. Because of long-standing concerns about LT_4 bioequivalence and because LT_4 products had never undergone formal approval by the FDA under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of LT_4 products submit an Abbreviated New Drug Application (ANDA) to keep their products on the US market after 2001.[15,17,18] Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This action has resulted in many changes in the US LT_4 market, as well as renewed interest in LT_4 bioequivalence. Since 2001, a variety of brand and generic products have been approved by the FDA. Some marketed products carry AB ratings (bioequivalence) to certain other products, using a complex AB1, AB2, AB3, and AB4 system.[18]

For many years, there have been concerns regarding the FDA bioequivalence methodology for LT_4 products. FDA bioequivalence standards allow a –20% to +25% variance in single-dose pharmacokinetic parameters between the test and reference products. Many people believe this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as LT_4. Furthermore, there are unique challenges to performing bioequivalence studies with an endogenous hormone such as LT_4. Because these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous LT_4. Seventy percent of the area under the curve (AUC) in these studies consists of the subjects' endogenous T_4. A study showed the standard FDA bioequivalence methodology would rate 600-, 450-, and 400-mcg LT_4 doses as bioequivalent, and that mathematically removing the subjects' endogenous T_4 level (baseline correction) improves the sensitivity of the analysis.[19] Based on these data, since 2003 the FDA has required that LT_4 bioequivalence data undergo baseline correction. Although this method has improved the ability to identify large differences in LT_4 bioequivalence, small but clinically significant differences will not be identified. In 2008, the FDA adopted stricter criteria for LT_4 tablet shelf-life potency (95%–105% of stated potency vs standard 90%–110%), which may reduce the intrapatient variability seen during long-term LT_4 therapy.

LO 6

More important than bioequivalence is the therapeutic equivalence of LT_4 products. Will patients have the same outcomes if bioequivalent products are used? A study by Dong and colleagues helps to answer this question.[20] Twenty-two well-controlled hypothyroid women were randomly switched to the same dose of four different products every 6 weeks. Non-baseline corrected bioequivalence data showed these products to be bioequivalent. However, as each product switch occurred, more of the subjects had an abnormal TSH level.[21] By the end of the third product switch, 52% had an abnormal TSH level. This is strong evidence that LT_4 products are not therapeutically equivalent even if they are rated as bioequivalent by the FDA.

Evidence does exist that small differences in LT_4 dose can result in large changes in TSH. In one study, when the daily dose was reduced by 25 mcg, 78% had an elevated TSH level.[22] When the daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in LT_4 dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

KEY CONCEPT There is no evidence that one LT_4 product is better than another. However, given the evidence that these products do have differences in bioavailability, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product or otherwise ensuring the product remains constant and not allowing substitution.[15] Although practitioners are pressured by insurance companies and employers to substitute LT_4 products as a cost-saving measure, such switching is not in the best interest of the patient and should not be allowed. If patients are switched to a different product, the prescriber should be notified, and a TSH determination should be done in 6 to 8 weeks to allow dose retitration. LT_4 dose changes significantly increase the cost of care.[23]

▶ Therapeutic Use of LT_4

LO 5

LT_4 replacement is indicated for patients with overt hypothyroidism.[3,5,8-10,15,17] However, the need for treatment is controversial in patients with mild or subclinical disease. There are no prospective clinical trials that show an outcome benefit with treating these patients. A retrospective study in elderly patients showed no outcome benefits with LT_4 therapy.[14] In patients without symptoms who have underlying heart disease, high cardiovascular risk, goiter, positive anti-TPOAb and/or are infertile or pregnant, LT_4 replacement may be considered.[3,9,10,12] Patients with mild or subclinical hypothyroidism do not need to be started on the full LT_4 replacement dose because they still have some endogenous hormone production. Start these patients on 25 to 50 mcg/day and titrate every 6 to 8 weeks based on TSH levels. Over time, it is likely the LT_4 dose will need to be increased slowly as the patient's thyroid gland loses residual function.

In patients younger than age 65 years with overt hypothyroidism, the average LT_4 replacement dose is 1.6 to 1.8 mcg/kg/day (use ideal body weight in obese patients[15]). However, there is wide interpatient variability in the optimal replacement dose, so individual dose titration is necessary. If there is no history of cardiac disease, these patients may be started on the full replacement dose.

The full replacement dose in patients older than age 75 years is lower, about 1 mcg/kg/day.[3,15] In the elderly, the starting dose should be 25 to 50 mcg/day, and the dose should then be titrated to the target TSH value. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy and with each change in dose, recheck the TSH in 6- to 8-week intervals. If the TSH is not in the target range (0.5–2.5 mIU/L [μIU/mL]), change the dose by 10% to 20% and then recheck the TSH 6 to 8 weeks later. As the dose is titrated, assess the patient's symptoms. Many patients will improve quickly, and younger patients will feel best if the TSH is titrated to low-normal to middle-normal levels (0.5–1.5 mIU/L [μIU/mL]).

▶ Risks of Overtreatment and Undertreatment

Patients receiving LT_4 therapy who are not maintained in a euthyroid state are at risk for long-term adverse sequelae. In general, overtreatment and a suppressed TSH are more common than undertreatment with an elevated TSH. Patients with long-term overtreatment are at higher risk for atrial fibrillation and other cardiovascular morbidities, anxiety, depression or mental status changes, and osteoporosis. Elderly patients being treated with LT_4 have a dose-related risk of fractures even if the TSH is not suppressed below normal values.[24] However, patients with

Patient Encounter 1, Part 1

A 76-year-old woman comes to the clinic complaining of fatigue, weakness, dry skin, and constipation for the past 6 months. She thought it was because she was getting old but the symptoms have not improved despite her taking some vitamins with iron. She noticed a 2-kg (4.4-lb) weight gain over the past few months. Her friend gave her an herbal product to give her energy, but she is not sure that it helps. Her current medications include the vitamin and herbal product mentioned above, hydrochlorothiazide for hypertension, lansoprazole for gastroesophageal reflux disease, occasional naproxen for headache, and MiraLAX for constipation.

PE:

VS: Wt 86 kg (189 lb); Ht 5′5″ (165 cm); BMI 31.6 kg/m^2

Skin, HEENT, thyroid, pulmonary, and cardiovascular examinations are normal.

Labs

Serum Cholesterol: 205 mg/dL (5.30 mmol/L); LDL cholesterol 96 mg/dL (2.48 mmol/L)

TSH: 7.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L [μIU/mL])

FT$_4$: 0.96 ng/dL (12.4 pmol/L; reference range, 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L)

Should the patient receive LT$_4$ therapy? Why or why not?

If you think treatment is indicated, what initial dose of LT$_4$ would you choose?

If you think treatment is not indicated, how would you monitor the patient?

What would you tell the patient regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT$_4$ therapy?

untreated subclinical hypothyroidism also have an increased risk of fractures.[25] Although studies have not defined a specific TSH target range for the elderly, these patients should receive close monitoring and dose adjustments to prevent over- and undertreatment. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression and/or other mental status changes, and obstetric complications.

▶ *Alterations in LT$_4$ Dose Requirements*

A number of factors can alter LT$_4$ dose requirements (Table 44–4), including time of administration and drug–drug and drug–food interactions.[3,8,15] LT$_4$ has the greatest and most consistent bioavailability when taken in the evening on an empty stomach.[15,17,26] The most common cause of increased dose requirement is coadministration of LT$_4$ with calcium or iron supplements (including prenatal vitamins) or concomitant use of proton pump inhibitors. In patients who have impaired absorption of standard LT$_4$ dosage forms, use of a liquid or gelcap formulation may improve absorption.[27] Counsel patients that they should take the LT$_4$ dose at least 2 hours before or 6 hours after the calcium or iron dose. The most common reason for decreased dose requirement is aging.

Table 44–4

Factors That Alter LT$_4$ Dose Requirements[3,9]

Increased Dose Requirement	Decreased Dose Requirement
Decreased LT$_4$ Absorption	Aging
Malabsorption syndromes	Delivery of pregnancy
H. pylori infection	Withdrawal of interacting substance
Drugs or Diet	
Bile acid binders	
Caffeine	
Calcium	
Charcoal

LT$_4$, levothyroxine; TBG, thyroxine-binding globulin.

▶ *Patient Monitoring*

Patients on stable LT$_4$ therapy do not need frequent monitoring. In most patients, measuring TSH every 6 to 12 months along with an assessment of clinical status is adequate (Table 44–5). If the patient's clinical status changes (eg, pregnancy), more frequent monitoring may be necessary. LT$_4$ prescriptions should be written as microgram doses to avoid potential errors when written as milligram doses.

Table 44–5

Monitoring Levothyroxine (LT_4) Therapy

- Serum TSH
  - Every 6–12 months or if change in clinical status
  - 6–8 weeks after any dose or product change
  - As soon as possible in pregnancy; then monthly
- Same product prescribed and dispensed with every refill
- Watch for mg/mcg dosing errors
- Assess patient's understanding of disease, therapy, and need for adherence and tight control
- Assess for signs and symptoms of over- and undertreatment
- Identify potential interactions between LT_4, and foods and/or drugs

TSH, thyroid-stimulating hormone.

Patient education is an important component of care. Treatment adherence rate (at least 80% of doses taken) in hypothyroid patients is 68%, slightly less than adherence rates seen in hypertensive patients.[28] Educate patients about the benefits of proper therapy, importance of adherence, consistency in time and method of administration, and importance of receiving a consistent LT_4 product. Some patients take excessive amounts of LT_4 in an effort to "feel better" or as a weight loss treatment. Explain to patients that excessive amounts of LT_4 will not improve symptoms more than therapeutic doses, can cause serious problems, and is not an effective treatment for obesity.

▶ *Special Populations and Conditions*

LO 7

Hypothyroidism and Pregnancy Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects.[3,29] During pregnancy, β-human chorionic gonadotropin (β-hCG) acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development.

Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT_4, typically 25% to 30% or two tablets per week above the prepregnancy dose.[29] The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep TSH in the middle- to low-normal range. After delivery, LT_4 dose usually can be reduced to prepregnancy levels, although patients with preexisting autoimmune thyroiditis may have increased postpartum dose requirements. Because prenatal vitamins contain significant amounts of calcium and iron, remind patients to take the LT_4 dose at least 2 hours before or 6 hours after the vitamin.

Children Congenital hypothyroidism is uncommon in the United States, and all newborns in the United States undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT_4 replacement dose. The replacement dose of LT_4 in children is age dependent. In newborns, the usual dose is 10 to 15 mcg/kg/day. LT_4 tablets may be crushed and mixed with breast milk or formula, but it is best to administer LT_4 to infants and children on an empty stomach.[30] Serum TSH in the mid-to-lower half and FT_4 levels in the mid-to-upper half of the pediatric reference ranges are used for dose titration. By 6 months of age, the required dose is reduced to 5 to 7 mcg/kg/day, and from ages 1 to 10 years, the dose is 3 to 6 mcg/kg/day. After age 12 years, adult doses can be given. In children with subclinical hypothyroidism, treatment can be considered when the serum TSH is over 10 mIU/L (μIU/mL).

Myxedema Coma This is a life-threatening condition owing to severe, long-standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 200 to 400 mcg LT_4 intravenously (IV) initially, using caution in patients with underlying cardiac disease. Although administration of T_3 would provide a more rapid onset of action, there is no evidence that T_3 improves outcomes in patients with myxedema coma. Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. Although there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and risks of a short course of corticosteroids at this dose are low. As patients improve, LT_4 dose can be given orally in a typical full replacement dose. Reduce the full replacement dose by 75% if continued IV therapy is needed.[15]

Patient Encounter 1, Part 2

Thirteen months later, the patient comes to you for routine follow-up stating that she has felt progressively worse since her last visit. Her husband passed away 6 months ago, but she doesn't think she is depressed. She feels more fatigued, and gained 2 more kg (4.4 lb). After her husband died, she elected to "go natural," and started taking more supplements purchased at a health food store. Her most recent TSH determination, obtained 2 days ago, was 12.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L [μIU/mL]).

Why is LT_4 therapy indicated now?

What would you recommend regarding her LT_4 dose and monitoring?

What instructions would you give the patient regarding her LT_4 therapy?

HYPERTHYROIDISM AND THYROTOXICOSIS

Hyperthyroidism is much less common than hypothyroidism. Refer to the Epidemiology section.

Causes of Thyrotoxicosis and Hyperthyroidism

Hyperthyroidism is related to excess thyroid hormone secreted by the thyroid gland. Thyrotoxicosis is any syndrome caused by excess thyroid hormone and can be related to excess hormone production (hyperthyroidism). The common causes of thyrotoxicosis are shown in Table 44–6.[31-33] KEY CONCEPT Graves disease is the most common cause of hyperthyroidism. Thyrotoxicosis in the elderly is more likely caused by toxic thyroid nodules or multinodular goiter than by Graves disease. Excessive intake of thyroid hormone may be caused by overtreatment with prescribed therapy or as a self-remedy for obesity, as thyroid hormones can be obtained easily without a prescription from health food stores or Internet sources. Ingestion of high

Patient Care Process: Hypothyroidism

Collect Information:

- Perform a medication history or medication reconciliation for use of all medications and supplements. Identify adverse drug events, allergies and hypersensitivities.
- Review the medical history and physical assessment findings.
- Speak with the patient and other caregivers as appropriate to identify issues that affect medication access and other aspects of care.

Assess the Information:

- Evaluate for signs and symptoms of hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism). As signs and symptoms of hypothyroidism are nonspecific, clinicians should have a high index of suspicion in higher risk patients including women and the elderly.
- Use serum TSH to identify patients with hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism), and check TSH in pregnant women as soon as pregnancy is determined.
- If patient has been or is already receiving pharmacotherapy to treat thyroid disease, assess efficacy, safety, LT_4 product received (eg, any recent changes in product) and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level and not on therapy, determine if pharmacotherapy is indicated.

Develop a Care Plan:

- Provide synthetic LT_4 replacement to patients with overt hypothyroidism.
- Consider replacement therapy in patients with TSH level of greater than 4.5 but less than 10 mIU/L (µIU/mL) who have nonspecific or subtle symptoms (eg, mild fatigue, lethargy), an elevated cholesterol level, underlying heart disease, or positive anti-TPOAbs.
- Patients with mild hypothyroidism may be started at 25 to 50 mcg/day of LT_4.
- Patients with overt hypothyroidism who are older than 12 and younger than 65 years and do not have cardiac disease may receive the calculated full replacement LT_4 dose of 1.6 mcg/kg/day (based on ideal body weight if obese).
- Elderly patients or those with cardiac disease should be started at a lower LT_4 dose (eg, 12.5–25 mcg/day).
- Provide a brand-name LT_4 product, and do not allow product switches. If the product is switched, check TSH in 6 weeks and retitrate the dose.
- Provide LT_4 prescriptions as microgram, not milligram, doses to avoid errors.
- Make sure patients understand importance of adherence and risks of overuse and underuse of LT_4.
- In pregnant patients, expect to increase LT_4 dose early in first trimester. Maintain TSH in low- to middle-normal range. After delivery, consider reducing LT_4 dose to prepregnancy level, if appropriate.

Implement the Care Plan:

- Educate the patient about any changes in therapy and how to manage and report adverse effects.
- Review proper medication administration with the patient, including issues related to food and concomitant medications.
- Discuss the importance of adherence and risks of over- and undertreatment.
- Determine if the patient has insurance coverage for prescription medications.

Follow-up: Monitor and Evaluate:

- Measure serum TSH 6 to 8 weeks after starting LT_4 or after any dose change. If TSH level is not in target range, alter dose by 10% to 20% increments. Target TSH for patients on LT_4 replacement therapy for hypothyroidism is 0.5 to 2.5 mIU/L (µIU/mL). Younger patients often feel best at a TSH level in the low- to middle-normal range (ie, 0.5–1.5 mIU/L [µIU/mL]).
- Check TSH every 6 to 12 months in stable patients receiving LT_4 replacement.
- Monitor for drug interactions, such as LT_4 absorption problems caused by calcium and iron.
- At each visit, assess for signs and symptoms of overtreatment and undertreatment.
- In pregnant patients, check TSH monthly.

doses of biotin may cause falsely elevated FT_4 levels and a false positive TSHR-SAb assay with subsequent misdiagnosis of Graves disease.[31]

Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. Clinical manifestations of hyperthyroidism may be subtle and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. Clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation, depression, or altered mental status or cognition.

Mild (Subclinical) Hyperthyroidism

Mild (subclinical) hyperthyroidism is defined as a low TSH level with a normal FT_4 level.[12,31-33] Although there may be few or no symptoms in these patients, there are several areas of concern.[12,31] Some patients progress to overt thyrotoxicosis. Patients with subclinical hyperthyroidism have been shown to experience long-term cardiovascular[31,34] and bone sequelae.[35] Mild hyperthyroidism appears to increase cardiovascular morbidity and mortality.[34] Prolonged subclinical thyrotoxicosis speeds the loss of bone mineral density and increases fracture rates in postmenopausal

Table 44–6

Causes of Thyrotoxicosis[33-35]

Primary Hyperthyroidism
Graves disease
Toxic multinodular goiter
Toxic adenoma
Thyroid cancer
Struma ovarii
Iodine excess (including radiocontrast, amiodarone)

Thyrotoxicosis Without Hyperthyroidism
Subacute thyroiditis
Silent (painless) thyroiditis
Excess thyroid hormone intake (thyrotoxicosis factitia)
Drug-induced (amiodarone, iodine, lithium, interferons)

Secondary Hyperthyroidism
TSH-secreting pituitary tumors
Trophoblastic (hCG-secreting) tumors
Gestational thyrotoxicosis

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

women.[31,35] Treatment of patients with mild hyperthyroidism is controversial but should be considered in patients with TSH levels less than 0.1 mIU/L (μIU/mL), Graves disease, postmenopausal women, and patients with underlying cardiovascular disease.[31,36] Patients who do not have a fully suppressed (below the lower limit of detection) TSH or other risk factors for hyperthyroid complications (eg, osteoporosis, atrial fibrillation, heart failure) may undergo observation, with TSH testing every 6 months to identify progression of the hyperthyroid state.

Graves Disease

Graves disease is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos (abnormal protrusion of the eyeball) and other eye findings, and skin findings.[31-33] The prevalence of Graves disease in the United States is approximately 0.4% in women and 0.1% in men. The peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs in at least 80% of patients with clinical Graves disease. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. Although the underlying cause of Graves disease is not known, heredity seems to play a role. Subclinical Graves disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and cytokine therapy.

LO 1

Several features of Graves disease are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients and include exophthalmos, **proptosis**, **chemosis**, **conjunctival injection**, and periorbital edema.[31,32,37] Eyelid retraction causes a typical staring or startled appearance (**Figure 44–3**). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic nerve can be compressed, resulting in permanent vision loss. All patients with suspected or known Graves disease must be evaluated and monitored by an ophthalmologist. Treatment of the underlying hyperthyroid state often, but not always, improves the ophthalmopathy.

LO 8

Clinical Presentation and Diagnosis of Hyperthyroidism[31-33]

Symptoms
- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Palpitations
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Frequent bowel movements or diarrhea

Signs
- Hyperactivity
- Tachycardia
- Atrial fibrillation (especially in elderly adults)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves disease)
- Goiter
- Muscle weakness

Screening/Diagnosis
- Low TSH level (< 0.5 mIU/L [μIU/mL]) signifies thyrotoxicosis.
- FT_4 is elevated in overt hyperthyroidism but may be normal in mild hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves disease will have positive TSHR-SAbs and positive anti-TPOAbs.

LO 8

Dermopathy occurs in 5% to 10% of patients with Graves disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, nonpitting induration of the skin, typically over the pretibial area (pretibial myxedema), the dorsa of the feet, and the shoulder areas. **Clubbing** of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

Treatment

▶ *Desired Outcomes*

Treatment of thyrotoxicosis caused by hyperthyroidism is similar regardless of the underlying cause.[31-33] KEY CONCEPT Goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.

FIGURE 44–3. Features of Graves disease. (**A**) Facial appearance: exophthalmos, eyelid retraction, periorbital edema, and proptosis. (**B**) Thyroid dermopathy over lateral aspects of the shins (*arrow*). (**C**) Thyroid clubbing or acropachy (*arrow*). (From Jameson JL, Weetman AP. Disorders of the thyroid gland. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill; 2004:2114.)

► *β-Blockers*

Because many manifestations of hyperthyroidism appear to be mediated by the β-adrenergic system, β-adrenergic blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Because β-blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Because nonselective agents can impair the conversion of T_4 to T_3, propranolol and nadolol are preferred. An initial propranolol dose of 20 to 40 mg four times daily should be titrated to relieve signs (target resting heart rate < 90 beats/min) and symptoms. β-Blockers should not be used in patients with decompensated heart failure or asthma. A more β-1 specific blocker (eg, metoprolol, atenolol) may be used when a relative contraindication to a β-blocker exists; however, when an absolute contraindication to β-blockers exists, clonidine, verapamil, or diltiazem may be used for heart rate control.

► *Methods to Reduce Thyroid Hormone Synthesis*

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.

Iodide Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum T_4 levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are used most commonly in Graves disease patients before surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38 mg iodide per drop or as Lugol solution, which contains 6.3 mg iodide per drop. The typical starting dose of SSKI is 5 drops every 6 to 8 hours. Iodide therapy should start 7 to 14 days before surgery. Iodide should not be given before radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides also are used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Daily administration of 30 to 100 mg iodide markedly reduces thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, "iodism" (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

LO 9

Antithyroid Drugs The thionamide agents propylthiouracil (PTU) and methimazole (MMI) are used in the United States to treat hyperthyroidism.[31,38] Carbimazole, an MMI prodrug, is used in some countries (10 mg carbimazole = 6 mg MMI). These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase–mediated iodination of tyrosine residues in thyroglobulin. PTU has the added effect of inhibiting conversion of T_4 to T_3. The thionamides also have immunosuppressant effects. In patients with Graves disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal (GI) tract. PTU has a half-life of 1 to 2.5 hours, whereas half-life of MMI is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered.

In most patients, there is no clear efficacy advantage of one thionamide over the other, but in the United States, MMI use has increased dramatically since the mid-1990s in lieu of

PTU.[39] Although PTU has the advantage of inhibiting T_4-to-T_3 conversion, MMI can be given as a single daily dose and may have a better overall safety profile, particularly less hepatotoxicity. MMI is preferred to normalize thyroid function before radioactive iodine therapy, although both thionamides increase the failure rate of radioactive iodine therapy.[40] The usual starting dose of MMI is 10 to 20 mg/day (range 5–40 mg based on initial FT_4 level), and the usual starting dose of PTU is 50 to 150 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, antithyroid drug dose often can be decreased (5–10 mg/day MMI, 100–200 mg/day PTU) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism.

LO 9

Remission of Graves disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. Levels of TSHR-SAb after a course of treatment may have predictive value for the risk of relapse in that antibody-positive patients almost always relapse. However, antibody-negative patients also may relapse after therapy is stopped. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

LO 9

Antithyroid drugs are associated with an overall low rate of adverse effects, although serious adverse effects can occur. In 2010, the FDA released a boxed warning on severe liver injury with PTU.[41] The warning states that PTU should only be used in patients who cannot tolerate MMI. Skin rash, arthralgias, and GI upset are seen in 5% of patients. Although the drug can be continued in the presence of a minor skin rash, development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but potentially serious or fatal adverse effect, occurring in 0.1% to 0.2% of patients. Transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with PTU. Severe hepatocellular damage can occur from PTU, whereas MMI is thought to cause cholestatic jaundice. However, a study in an Asian patient population found a higher rate of drug-induced hepatitis in patients who received MMI, implying there may be genetic differences in hepatotoxicity risk.[42] Antineutrophil cytoplasmic antibody (ANCA) vasculitis is another potentially serious but uncommon reaction that is more common with PTU, and patients may develop a drug-induced lupus syndrome.

KEY CONCEPT Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy. Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves disease. Agranulocytosis occurs in 0.3% of patients, and the incidence may be the same with PTU and MMI therapy. Lower doses of MMI may be associated with a lower incidence.[31] Agranulocytosis, thought to be autoimmune, almost always occurs within the first 3 months of therapy, and occurs suddenly and unpredictably. Patients will present with fever, malaise, and sore throat, and absolute neutrophil count will be less than 1000/mm^3 (1×10^9/L). Patients may develop sepsis and die rapidly. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider administration of filgrastim. The white blood cell count should recover in 1 or 2 weeks. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and unpredictable nature. Most do not recommend routine monitoring of the complete blood count (CBC), although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs and symptoms of agranulocytosis and other serious side effects. Patients should be counseled to report signs and symptoms suggestive of infection, such as fever and sore throat lasting more than 2 or 3 days, bruising, pruritic rash, jaundice, dark urine, arthralgias, abdominal pain, nausea, or fatigue.

Radioactive Iodine Radioactive iodine, typically ^{131}I, produces thyroid ablation without surgery. ^{131}I is well absorbed after oral administration. Iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up the ^{131}I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT_4 replacement will be necessary. Because ^{131}I has a slow onset of action and may cause added release of thyroid hormone, most patients are treated initially with β-blockers and antithyroid drugs to prevent ^{131}I-induced thyroid storm. MMI is the preferred agent before administration of ^{131}I. MMI is discontinued 3 to 5 days before administration of ^{131}I and restarted 3 to 7 days later. MMI is then slowly tapered over the next 4 to 6 weeks as thyroid function normalizes. β-Blockers can be continued during ^{131}I therapy. The dose of ^{131}I is based on the estimated weight of the patient's thyroid gland (typical dose, 10–15 mCi [370–555 MBq]). Radioactive iodine therapy is contraindicated during pregnancy and breastfeeding. Radioactive iodine therapy may acutely worsen Graves ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with the dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy. No long-term carcinogenic effect of ^{131}I has been demonstrated in clinical trials.[31]

LO 9

Surgery Subtotal thyroidectomy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid before surgery, and they are often administered iodide preoperatively to reduce gland vascularity. The overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy. After thyroidectomy, serum calcium and intact parathyroid hormone levels should be monitored for early identification of postoperative hypoparathyroidism. Postoperative administration of 1250 to 2500 mg/day of calcium and 0.5 mcg/day of calcitriol may be given and then tapered over 1 to 2 weeks if the patient does not develop hypoparathyroidism.

► *Special Conditions and Populations*

Graves Disease and Pregnancy Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves disease owing to the TSH agonist effect of β-hCG.[29] Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and

LO 7

Patient Encounter 2, Part 1

A 24-year-old woman comes to the clinic stating, "I'm having trouble sleeping." She first noticed these symptoms a few months ago, which haven't improved despite use of OTC sleep aids. She also feels anxious for no reason and has lost a little weight without trying. Sometimes she can feel her heart beating in her chest when she exercises, but denies chest pain or syncope. Her only medications are a multivitamin product, occasional acetaminophen for headaches, and a hormonal contraceptive. She thinks that her mother had some kind of thyroid problem when she was pregnant with her.

PE:

General appearance: Patient appears slightly anxious and responds appropriately to all questions.

VS: Pulse 101 beats/min, BP 108/73 mm Hg, RR 12 breaths/min, T 37°C (98.6°F)

Skin: Warm, moist, and soft

HEENT: Slightly and symmetrically enlarged thyroid, which is nontender and without appreciable nodules; mild exophthalmos

CV: Apical HR: 105/min, RRR

Exts: No tremor

Diagnostic studies

ECG: Sinus tachycardia

Labs: Electrolytes, CBC normal. TSH less than 0.1 mIU/L (μIU/mL; reference range 0.5–2.5 mIU/L [μIU/mL]); FT_4 4.2 ng/dL (54.1 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs. Pregnancy test is negative.

Should this patient be treated for hyperthyroidism?

What therapeutic options exist for this patient's Graves disease?

What pharmacotherapy would you recommend? What if she were pregnant?

How would you initiate and titrate therapy?

What would you tell the patient regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?

Patient Encounter 2, Part 2

Two years later, the patent is admitted to the hospital for altered mental status and r/o sepsis. For the past year, she had been working in a refugee camp with a non-governmental agency in Jordan. She was unable to obtain her medications and was only taking a local herbal product. Her coworkers in Jordan noticed she was becoming increasingly fatigued, lethargic, and possibly delusional. She was medically evacuated to the United States for further assessment and treatment.

PE:

General appearance: Patient appears sweaty and agitated.

VS: Pulse 144 beats/min, BP 94/68 mm Hg, RR 22 breaths/min, T 40°C (104°F)

Skin: Warm, sweaty, and soft

HEENT: Diffusely enlarged, nontender thyroid without any appreciable nodules; + exophthalmos

CV: Apical HR: 150 beats/min, RRR

Exts: + tremor; Reflexes: biceps, triceps, patellar, and Achilles: 3+/4

GI: Hyperactive bowel sounds

Mental status examination: Patient is only oriented to year and familiar persons. Cannot recall date, time, or location.

Diagnostic studies

ECG: Sinus tachycardia with occasional PACs

Labs: Electrolytes, CBC normal. TSH less than 0.1 mIU/L (μIU/mL; reference range 0.5–2.5 mIU/L [μIU/mL]); FT_4 8.2 ng/dL (105.5 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs. Pregnancy test is negative.

Diagnoses:

1) Thyroid storm.

2) Sepsis: r/o communicable diseases endemic to Jordan such as typhoid.

What are the signs and symptoms of thyroid storm?

How should this patient be treated?

low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of transplacental passage of TSHR-SAbs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. PTU is considered the treatment of choice, particularly in the first trimester. While MMI is thought to have greater teratogenic potential versus PTU, the relative safety of these medications in pregnancy is not clear.[43] Patients receiving prepregnancy MMI are switched to PTU as soon as the pregnancy is confirmed. The lowest possible dose of PTU to maintain maternal euthyroidism should be used. Given the potential maternal adverse effects of PTU (eg, hepatotoxicity), it may be preferable to switch from PTU to MMI for the second and third trimesters.[29,41] Antithyroid therapy in excessive doses may suppress fetal thyroid function. Although PTU and MMI are found in breast milk, nursing mothers should be switched to MMI after delivery because of the risk of hepatotoxicity from PTU in the mother and infant.

Pediatric Hyperthyroidism β-Blockers are administered to children who are symptomatic or have a heart rate greater than 100 beats/min.[29] MMI is the preferred antithyroid drug therapy in children at a dose of 0.2 to 0.5 mg/kg/day.[29] Once a euthyroid state is achieved, MMI dose can be reduced by 50% or more to maintain euthyroidism. As in adults, antithyroid drugs are administered to children with Graves disease for 1 to 2 years. If remission does not occur in that time, long-term antithyroid drug therapy, radioactive iodine,

or surgical therapy is offered. Long-term studies with ^{131}I use in children show no increased risk of thyroid cancer or leukemia.[31]

Thyroid Storm Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis.[29,44] Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and GI disturbances. Thyroid storm is precipitated in a previously hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β-blocker such as IV esmolol, IV or oral iodide, and large doses of PTU (500–1000 mg load; then 250 mg every 4 hours) or MMI (60–80 mg/day). Supportive care with acetaminophen to suppress fever, fluid and electrolyte management, and antiarrhythmic agents are important components of therapy. IV hydrocortisone 300 mg initially and then 100 mg every 8 hours is used often because of the potential presence of adrenal insufficiency.

NONTHYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

A number of changes in the hypothalamic–pituitary–thyroid axis occur during acute illness.[15] These changes are termed *nonthyroidal illness* or *euthyroid sick syndrome*. Type and degree of abnormalities depend on the severity of illness. Mild to moderate medical illness, surgery, or starvation causes a decrease in serum T_3 levels owing to decreased peripheral conversion of T_4 to T_3. Reduced T_3 levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive care unit, frequently have reduced total T_4 levels, although FT_4 levels often are normal. In critically ill patients, there is a correlation between degree of serum T_4 reduction and mortality. In most acutely ill patients who are euthyroid, TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, TSH level may become modestly elevated to

Patient Care Process: Hyperthyroidism

Collect Information:

- Perform a medication history or medication reconciliation for use of all medications and supplements. Identify adverse drug events, allergies and hypersensitivities.
- Review the medical history and physical assessment findings.
- Speak with the patient and other caregivers as appropriate to identify issues that affect medication access and other aspects of care.

Assess the Information:

- A low or undetectable TSH level identifies thyrotoxicosis. See Clinical Presentation and Diagnosis of Hyperthyroidism.
- Via a diagnostic assessment, identify the underlying cause (eg, presence of eye and/or skin findings and presence of TSHR-SAbs may be used to identify Graves disease).

Develop a Care Plan:

- Treat severe or troublesome autonomic signs and symptoms with a nonselective β-blocker such as propranolol 20 to 40 mg four times daily. Titrate β-blocker dose based on signs and symptoms.
- Consider reducing excess thyroid hormone production with an antithyroid drug and/or radioactive iodine. If radioactive iodine is given, make sure that antithyroid drugs are stopped 4 to 6 days before treatment.
- MMI is the antithyroid drug of choice in most patients.
- Refer patients with Graves disease to an ophthalmologist for assessment and monitoring.
- Treat pregnant hyperthyroid women with PTU.
- Address any patient concerns regarding therapy.

Implement the Care Plan:

- Educate the patient about any changes in therapy and how to manage and report adverse effects.
- Review proper medication administration with the patient, including issues related to food and concomitant medications.
- Discuss the importance of adherence and risks of over- and undertreatment.
- Determine if the patient has insurance coverage for prescription medications.
- If patient has been or is currently receiving pharmacotherapy to treat hyperthyroidism, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level, determine if pharmacotherapy or a change in pharmacotherapy is indicated.

Follow-up: Monitor and Evaluate:

- Monitor patients on antithyroid drugs for signs and symptoms of adverse effects.
- After baseline CBC with differential and liver profile, repeat CBC when patient has a febrile illness and repeat liver panel if signs or symptoms of hepatotoxicity occur (some recommend routine monitoring during the first 6 months of therapy).
- Assess any skin rash or development of arthralgias.
- Antithyroid drugs have a delayed effect. After 2 to 4 weeks of therapy, adjust the dose if TSH is not in target range (0.5–2.5 mIU/L [μIU/mL]). When patient is euthyroid, consider reducing dose of antithyroid drug to avoid hypothyroidism.
- Periodic assessment of TSHR-Sabs.
- Consider stopping antithyroid therapy in patients with Graves disease after 12 to 18 months to see if remission has occurred.
- Several months after radioactive iodine, expect that the patient will require permanent LT_4 replacement; thus, evaluate for such.

renormalize serum T_4 levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low T_4 levels, there is no evidence that LT_4 administration has any survival benefit.[3,15,45] Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

THYROID CANCER AND LT_4 SUPPRESSION

KEY CONCEPT The growth and dissemination of thyroid carcinoma are stimulated by TSH. As such, LT_4 is an integral component of thyroid carcinoma management as it suppresses TSH secretion. Early in therapy, patients receive the lowest LT_4 dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival. These patients are purposefully "overtreated" with LT_4, sometimes to a fully suppressed TSH level, and rendered subclinically or mildly hyperthyroid. Postmenopausal women and other individuals at high risk for osteoporosis should receive aggressive osteoporosis therapy to prevent LT_4-induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.

DRUG-INDUCED THYROID ABNORMALITIES

Drugs can affect thyroid function in a number of ways.[3,11] The effects of drugs on thyroid hormone protein binding, LT_4 absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

Amiodarone

Amiodarone is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass.[46] Each 200-mg dose of amiodarone provides 75 mg of iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of T_4 to T_3, inhibits entry of T_3 into cells, and decreases T_3 receptor binding. Amiodarone causes rapid reduction in serum T_3 levels, increases free and total T_4 levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although the serum T_3 and T_4 level changes may remain. Most of these patients are euthyroid because the FT_3 levels are in the low-normal range.

LO 10 Amiodarone can frequently cause thyroid abnormalities in previously euthyroid patients. In a study of amiodarone treatment of persistent atrial fibrillation, 25.8% of patients developed subclinical hypothyroidism, and 5% developed overt hypothyroidism.[47] Hyperthyroidism occurred in 5.3%. Thyroid abnormalities, when they occurred, were seen within 6 months of initiation of amiodarone therapy in almost all patients. Amiodarone-induced hypothyroidism is more common in iodine-sufficient areas of the world. Patients with underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, LT_4 therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with preexisting multinodular goiter or subclinical Graves disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β-blocking activity, palpitations and tachycardia may be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyroiditis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

KEY CONCEPT Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4, FT_3, anti-TPOAbs, and TSHR-SAbs should be performed. TSH, FT_4, and FT_3 should be checked 3 months after initiation of amiodarone and then a TSH at least every 3 to 6 months.

Lithium

LO 10 Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy.[48] Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require LT_4 replacement even if lithium is discontinued.

Interferon-α

LO 10 Interferon-α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection.[3,11] Patients may develop a transient thyroiditis with hyperthyroidism before becoming hypothyroid. The hypothyroidism may be transient as well. Asians and patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If LT_4 replacement is initiated, it should be stopped after 6 months to reevaluate the need for replacement therapy.

Tyrosine Kinase Inhibitors

LO 10 TKIs are targeted antineoplastic agents used in several types of malignancies, including thyroid cancer.[11,15] Several TKIs have significant effects on thyroid function, both in previously hypothyroid patients on LT_4 replacement and in previously euthyroid patients. Imatinib has been shown to cause a fourfold increase in TSH levels in patients being treated for thyroid cancer. Sunitinib and sorafenib have been associated with primary hypothyroidism in 20% to 40% of treated patients. Some sorafenib patients developed mild hyperthyroidism before becoming hypothyroid. Patients receiving TKI therapy should have baseline and periodic thyroid function monitoring.

OUTCOME EVALUATION

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.
- Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient's clinical status and abnormal laboratory values but also on achievement of a long-term, stable euthyroid state. Maintaining TSH level in the normal range improves symptoms and reduces risk of long-term complications.
- Because pharmacotherapy often is lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid long-term complications. In

hypothyroid patients, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of TSH level.

- Any change in the patient's clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.
- Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, the need for periodic clinical and laboratory monitoring, and the importance of staying on one LT_4 product.
- In hyperthyroid patients, the method of achieving desired outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.
- Patients who receive antithyroid drugs must be monitored for adverse drug events such as hepatotoxicity and agranulocytosis.
- Patients who receive radioactive iodine must be monitored for development of hypothyroidism.
- In patients with thyroid cancer, the desired outcomes with LT_4 therapy are often different from those in hypothyroid patients. LT_4 doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

Abbreviations Introduced in This Chapter

ANCA	Antineutrophil cytoplasmic antibody
ANDA	Abbreviated New Drug Application
Anti-TGAb	Antithyroglobulin antibody
Anti-TPOAb	Antithyroid peroxidase antibody
AUC	Area under the (time-concentration) curve
β-hCG	β-Human chorionic gonadotropin
CBC	Complete blood count
CNS	Central nervous system
FDA	Food and Drug Administration
FT_3	Free T_3
FT_4	Free T_4
GI	Gastrointestinal
hCG	Human chorionic gonadotropin
IV	Intravenous
LDL	Low-density lipoprotein
LT_4	Levothyroxine
MMI	Methimazole
NHANES	National Health and Nutrition Examination Survey
NTI	Narrow therapeutic index
PTU	Propylthiouracil
RAIU	Radioactive iodine uptake
SSKI	Saturated solution of potassium iodide
T_3	Triiodothyronine
T_4	Thyroxine
TBG	Thyroxine-binding globulin
TKI	Tyrosine kinase inhibitor
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone (thyrotropin)
TSHR-SAb	Thyroid-stimulating hormone receptor-stimulating antibodies
TSI	Thyroid-stimulating immunoglobulin

45 Adrenal Gland Disorders

Devra K. Dang, Christina M. Polomoff, and Judy T. Chen

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of adrenal insufficiency.
3. Describe the pharmacologic management of acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for adrenal insufficiency.
5. Recognize the clinical presentation of Cushing syndrome and the physiologic consequences of cortisol excess.
6. Describe the pharmacologic and nonpharmacologic management of Cushing syndrome.
7. Recommend strategies to prevent the development of hypercortisolism and hypocortisolism.
8. Recommend therapy monitoring parameters for Cushing syndrome.

INTRODUCTION

The adrenal glands are important in the synthesis and regulation of key human hormones. They play a crucial role in water and electrolyte homeostasis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated with adrenal gland dysfunction: glucocorticoid insufficiency (eg, Addison disease) and glucocorticoid excess (Cushing syndrome). Other adrenal disorders such as **congenital adrenal hyperplasia**, **pheochromocytoma**, hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

LO 1

The adrenal gland is located on the upper segment of the kidney. It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines epinephrine (also called adrenaline) and norepineprhine (also called noradrenaline), which are involved in the regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones (**Figure 45–1**).

The zona glomerulosa is responsible for the production of the mineralocorticoids aldosterone, 18-hydroxy-corticosterone, corticosterone, and deoxycorticosterone. Aldosterone promotes renal sodium retention and potassium excretion. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the **renin-angiotensin-aldosterone system**.

The zona fasciculata is the middle layer and produces the glucocorticoid hormone cortisol. Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, generally beginning to rise at approximately 3 to 4 AM and peaking around 6 to 8 AM. Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 PM, and reach their nadir around midnight. The normal rate of cortisol production is approximately 8 to 25 mg/day. Cortisol plays a key role in the body's response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions such as alcoholism, depression, anxiety disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (eg, exogenous estrogen administration). Cortisol is converted in the liver to an inactive metabolite known as cortisone.[1]

The zona reticularis produces the androgens androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of dehydroepiandrosterone (DHEA-S). Only a small amount of testosterone and estrogen is produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

Adrenal hormone production is controlled by the hypothalamus and pituitary. Corticotropin-releasing hormone (CRH) is secreted by the hypothalamus and stimulates secretion of adrenocorticotropic hormone (ACTH; also known as corticotropin) from the anterior pituitary. ACTH in turn stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol levels are reached, a negative feedback is exerted on the secretion of CRH and ACTH, thereby decreasing overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative feedback mechanism.

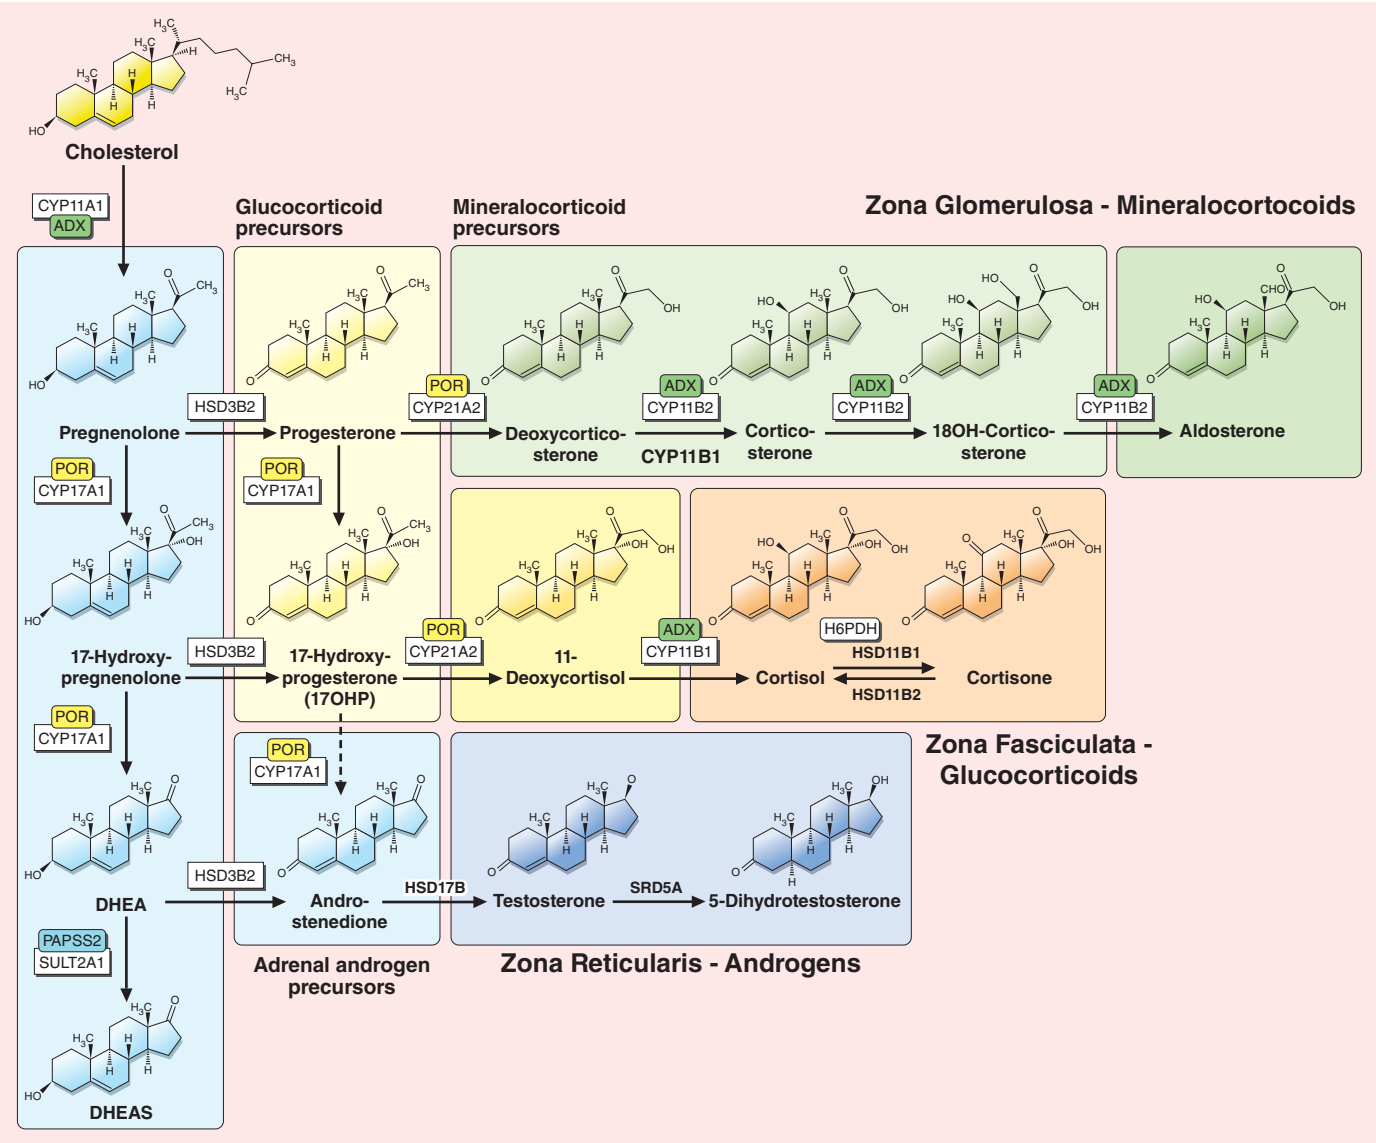

FIGURE 45–1. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the middle zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones. The zona glomerulosa is responsible for the production of mineralocorticoids such as aldosterone. The zona fasciculata produces cortisol and the zona reticularis produces androgens. (ADX, adrenodoxin; CYP11A1, side chain cleavage enzyme; CYP17A1, 17-alpha-hydroxylase/17,20 lyase; CYP21A2, 21-hydroxylase; CYP11B1, 11-beta-hydroxylase; CYP11B2, aldosterone synthase; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; H6PDH, hexose-6-phosphate dehydrogenase; HSD11B1, 11-beta-hydroxysteroid dehydrogenase type 1; HSD11B2, 11-beta-hydroxysteroid dehydrogenase type 2; HSD3B2, 3-beta-hydroxysteroid dehydrogenase type 2; HSD17B, 17-beta-hydroxysteroid dehydrogenase; PAPSS2, PAPS synthase type 2; POR, P450 oxidoreductase; SRD5A, 5-alpha-reductase; SULT2A1, DHEA sulfotransferase.) (Adapted, with permission, from Arlt W. Disorders of the adrenal cortex. In: Longo DL, Fauci AS, Kasper DL, et al., eds. Harrison's Principles of Internal Medicine. New York City: McGraw-Hill, 2011.)

Figure 46–1 in Chapter 46 depicts hormonal regulation with the hypothalamic-pituitary-adrenal (HPA) axis.

ADRENAL INSUFFICIENCY

Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary, depending on the etiology (Table 45–1).[1-5] The estimated prevalence of primary adrenal insufficiency and secondary adrenal insufficiency are approximately 60 to 143 and 150 to 280 cases per 1 million persons, respectively. Whereas primary adrenal insufficiency is usually diagnosed in the third to fifth decade of life, secondary adrenal insufficiency is commonly detected during the sixth decade.[1,6] Adrenal insufficiency is more prevalent in women than in men, with a ratio of 2.6:1.[1] Chronic adrenal insufficiency is rare.

Pathophysiology

Primary adrenal insufficiency, also known as Addison disease, occurs when the adrenal glands are unable to produce cortisol. It occurs from destruction of the adrenal cortex, usually from

Table 45–1

Etiologies of Adrenal Insufficiency[1-5]

Primary Adrenal Insufficiency (Addison disease)
- Autoimmune—accounts for 70%–90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
  - Cytomegalovirus
  - Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, *Blastomyces dermatitidis* infection)
  - HIV (human immunodeficiency virus), AIDS (Acquired Immunodeficiency Syndrome)
    - Mycobacterial, cytomegaloviral, *Pneumocystic jiroveci*, and *Toxoplasma gondii* infection
  - Sarcoidosis
  - Tuberculosis
- Bilateral adrenal hemorrhage or infarction—usually due to anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection. Causes acute adrenal insufficiency.
- Adrenalectomy
- Adrenoleukodystrophy (in men)
- Adrenomyeloneuropathy
- Infiltrative disorders: amyloidosis, hemochromatosis
- Genetic causes
  - Congenital adrenal hyperplasia
  - Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

Secondary Adrenal Insufficiency
- Cushing syndrome
- Panhypopituitarism
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

Tertiary Adrenal Insufficiency
- Hypothalamic dysfunction

Drug-Induced (Most Common Cause of Secondary and Tertiary Adrenal Insufficiency)
- Chronic glucocorticoid administration at supraphysiologic doses
- Steroidogenesis inhibitors
- Megestrol acetate—has glucocorticoid-like activity
- Mifepristone (RU 486) —antagonizes glucocorticoid receptors
- Tyrosine kinase inhibitors
- Inducers of cytochrome P450 enzymes that increase cortisol metabolism (2B1, 2B2, 3A4)

an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.[4] KEY CONCEPT Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action. Primary adrenal insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally, primary adrenal insufficiency may be accompanied by a reduction in aldosterone and androgen production.

Secondary adrenal insufficiency occurs as a result of pituitary gland dysfunction, whereby decreased production and secretion of ACTH leads to a decrease in cortisol synthesis. Tertiary adrenal insufficiency is a disorder of the hypothalamus that results in decreased production and release of CRH, which in turn decreases pituitary ACTH production and release. In

Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency[1,3,4,6]

LO 2

General
- Symptoms develop gradually, especially in the early stages, may be vague, and mimic other medical conditions.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus or autoimmune thyroiditis.

Symptoms (Percent Prevalence)
- Weakness and fatigue (99%).
- Anorexia, nausea, and diarrhea (56%–90%); may range from mild to severe with vomiting and abdominal pain.
- Hypoglycemia may occur.
- Amenorrhea may occur.
- Salt craving occurs in approximately 22% with Addison disease due to aldosterone deficiency.

Signs
- Weight loss (97%).
- Hypotension (< 110/70 mm Hg) and orthostasis (87%).
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only) due to aldosterone deficiency.
- Hyponatremia and hypochloridemia levels due to aldosterone deficiency. Hyponatremia can also be present in secondary insufficiency due to cortisol deficiency and increased antidiuretic hormone secretion leading to subsequent water retention.
- Increased serum blood urea nitrogen (BUN) and creatinine due to dehydration.
- Hyperpigmentation of skin and mucous membranes (92%). Usually observed around creases, pressure areas, areolas, genitalia, and new scars. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, due to increased ACTH levels, occurs in most patients with primary but not secondary or tertiary insufficiency.
- Personality changes (irritability and restlessness) due to cortisol deficiency.
- Loss of axillary and pubic hair in women due to decreased androgen production.
- Blood count abnormalities (normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia) due to cortisol and androgen deficiency.

Laboratory Tests (Table 45–2[1,3,4,7])
- Decreased basal and stress-induced cortisol levels.
- Decreased aldosterone level (in primary insufficiency only).
- Lack of increase in cortisol and aldosterone level after ACTH stimulation.

Other Diagnostic Tests
- Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining etiology.
- Presence of anti-adrenal antibodies is suggestive of an autoimmune etiology.

Table 45–2

Tests for Diagnosing Adrenal Insufficiency[1,3,4,7]

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Screening and Diagnostic Tests for Adrenal Insufficiency				
Unstimulated serum cortisol measurement	Measure serum cortisol at 6–8 AM	Serum cortisol level peaks in the early morning	Serum cortisol < 3 mcg/dL (83 nmol/L)	• Evaluate result in context of those from other test(s) • Can be performed in conjunction with the rapid ACTH stimulation test (measure baseline serum cortisol before administering 250 mcg of cosyntropin)
Rapid ACTH stimulation test (also called cosyntropin stimulation test)	Measure serum cortisol 30–60 minutes after administering cosyntropin 250 mcg IM or IV	Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency	Serum cortisol concentration < 18–20 mcg/dL (497–552 nmol/L)	• Used as gold standard test for diagnosing primary adrenal insufficiency • False negative results may occur if ACTH deficiency is of recent onset (< 1 month) • If measured serum cortisol concentration is low, measure plasma ACTH, aldosterone, and renin concentrations to differentiate between primary and secondary or tertiary adrenal insufficiency (see below) • A normal response does not exclude mild secondary adrenal insufficiency or recent onset ACTH deficiency. Additional testing (eg, insulin tolerance or metyrapone test) may be required
Insulin tolerance test (insulin-induced hypoglycemia test)	Administer insulin IV to induce hypoglycemia then measure serum cortisol during symptomatic hypoglycemia (confirm that blood glucose is < 40 mg/dL [2.2 mmol/L])	Evaluates ability of entire HPA axis to respond to stress (hypoglycemia)	Serum cortisol concentration < 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency	• If the result of the rapid ACTH stimulation test is normal, either this or the overnight metyrapone test is still needed to evaluate for secondary adrenal insufficiency. The insulin tolerance test is considered the gold standard • Contraindicated in patients with a seizure history, aged > 60 years, or with cardiovascular or cerebrovascular disease • Requires close medical supervision • Contraindicated in adrenal crisis and primary adrenal insufficiency
Overnight metyrapone test	Administer metyrapone at midnight then measure serum cortisol at 8 AM the next day	Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol, 11-deoxycortisol. Patients with adrenal insufficiency do not exhibit this	Normal response is a decrease in serum cortisol to < 5 mcg/dL (138 nmol/L) and an increase in 11-deoxycortisol to > 7 mcg/dL (202 nmol/L). Response not seen in secondary adrenal insufficiency	• Distinguishes between normal individuals and patients with secondary adrenal insufficiency • Contraindicated in adrenal crisis and primary adrenal insufficiency
Tests for Differential Diagnosis of Primary, Secondary, and Tertiary Adrenal Insufficiency				
Plasma ACTH concentration	Measure plasma ACTH	In primary adrenal insufficiency, hypocortisolism leads to elevated plasma ACTH concentration via positive HPA axis feedback	• Primary adrenal insufficiency: elevated plasma ACTH • Secondary or tertiary adrenal insufficiency: plasma ACTH low or inappropriately normal	• Evaluate result of test in combination with those from the plasma aldosterone and plasma renin tests

(*Continued*)

Table 45–2

Tests for Diagnosing Adrenal Insufficiency[1,3,4,7] *(Continued)*

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Plasma aldosterone concentration	Measure plasma aldosterone from same blood samples as those used in ACTH stimulation test	Patients with primary adrenal insufficiency may experience a reduction in aldosterone production	• Primary adrenal insufficiency: low plasma aldosterone • Secondary or tertiary adrenal insufficiency: aldosterone concentration is usually normal (≥ 5 ng/dL [139 pmol/L])	• Evaluate result of test in combination with those from plasma ACTH and plasma renin tests
Plasma renin concentration or activity	Measure plasma renin concentration or activity	Mineralocorticoid deficiency occurs in primary adrenal insufficiency but is usually not present in secondary or tertiary adrenal insufficiency	• Primary adrenal insufficiency: elevated plasma renin • Secondary or tertiary adrenal insufficiency: plasma renin concentration or activity is usually normal	• Evaluate result of test in combination with those from plasma ACTH and plasma aldosterone concentration tests

ACTH, adrenocorticotropic hormone or corticotropin; HPA, hypothalamic-pituitary-adrenal; IM, intramuscularly; IV, intravenously.

contrast to Addison disease, aldosterone production is unaffected in the secondary and tertiary forms of the disease. Chronic adrenal insufficiency often has a good prognosis if diagnosed early and treated appropriately.

Acute adrenal insufficiency (ie, adrenal crisis) results from the body's inability to sufficiently increase endogenous cortisol during periods of excessive physiologic stress. Adrenal crisis can occur when patients with chronic adrenal insufficiency do not receive adequate glucocorticoid replacement during stressful conditions such as those experienced during surgery, infection, fever, acute illness, invasive medical procedures, or trauma. Acute adrenal insufficiency can also result from bilateral adrenal infarction due to hemorrhage, embolus, sepsis, or adrenal vein thrombosis. Patients who are critically ill may also experience impaired HPA axis function, with an overall prevalence rate of 10% to 20%, and as high as 60% in those experiencing septic shock. These patients are also at risk for the life-threatening consequences of an adrenal crisis. To better recognize this condition, the term *critical illness–related corticosteroid insufficiency* was coined by the

Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)[1,4,6]

LO 2

General

- Onset of symptoms is acute and precipitated by excessive physiologic stress or abrupt discontinuation of supraphysiologic doses of chronic glucocorticoid.

Symptoms

- Severe weakness and fatigue.
- Abdominal or flank pain.

Signs

- Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous (IV) hydration and may require use of vasopressors.
- Tachycardia
- Nausea, vomiting
- Fever
- Confusion
- Hypoglycemia
- Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

Laboratory Tests

- The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in diagnosis (Table 45–2). The insulin tolerance test is contraindicated due to preexisting hypoglycemia. The metyrapone test is also contraindicated since metyrapone inhibits cortisol production.

Note: Due to the life-threatening nature of this condition, empiric treatment should be started before laboratory confirmation in patients who present with the clinical picture of acute adrenal crisis.

American College of Critical Care Medicine Task Force.[8] Additionally, abrupt discontinuation or rapid tapering of glucocorticoids, given chronically in supraphysiologic doses, may lead to adrenal crisis. This condition results from prolonged suppression of the HPA axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (eg, ketoconazole) or increase metabolism (eg, the cytochrome P-450 [CYP] 3A4 inducer rifampin) of cortisol.[4] Regardless of the etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment since manifestations such as circulatory collapse can lead to life-threatening sequelae.

Treatment

▶ *Chronic Adrenal Insufficiency*

LO 3

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. KEY CONCEPT Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison disease. Glucocorticoids with sufficient mineralocorticoid activity are generally required. However, the addition of a potent mineralocorticoid such as fludrocortisone, along with adequate salt intake, is sometimes needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production is often unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may only require replacement therapy until the HPA axis recovers. Hydrocortisone is often prescribed because it most closely resembles endogenous cortisol with its relatively high mineralocorticoid activity and short half-life, and allows the design of regimens that simulate the normal circadian cycle.[3] Other glucocorticoids, however, can be used. Table 45–3 lists the pharmacologic characteristics of commonly used glucocorticoids.[9] Because the primary source of DHEA and androgens is the adrenal cortex, women with adrenal insufficiency may experience decreased libido and energy. Therefore, DHEA supplementation has been advocated as an option for female patients experiencing these effects from adrenal insufficiency. However, a meta-analysis that included 23 randomized controlled trials found that DHEA supplementation was not associated with significant improvement in libido or sexual function.[10] The use of DHEA remains controversial and requires further study. Management strategies for chronic adrenal insufficiency are outlined below:[1-3,6,11,12]

LO 3

- For the treatment of primary adrenal insufficiency (Addison disease) in adults, hydrocortisone (15–25 mg) or cortisone acetate (20–35 mg) in two or three divided oral doses per day is recommended, with the highest dose given in the morning at awakening to mimic the early morning rise in endogenous cortisol. In a two-dose regimen, the second dose is taken in the early afternoon (2 hours after lunch); and in a three-dose regimen, the second dose is taken at lunch and the third dose is taken no closer than 4 to 6 hours before bedtime. This will avoid insomnia and allow for the lowest concentration in the blood at around midnight. In patients with concerns about adherence, oral prednisolone 3 to 5 mg/day, administered once or twice daily, may be given. Dexamethasone, a long-acting glucocorticoid is not recommended due to risk of Cushingoid side effects from difficulty in dose titration.

LO 4

Doses of the glucocorticoid replacement therapy may need to be increased or decreased in patients taking CYP 3A4 inducers or inhibitors, respectively. Glucocorticoid therapy at physiologic replacement doses should not lead to development of Cushing syndrome; however, careful monitoring should still be performed, and the smallest effective dose used. Patients should be educated regarding the need for increased glucocorticoid dosage during excessive physiologic stress. In addition, administer oral fludrocortisone at a starting daily dose of approximately 0.05 to 0.1 mg in the morning, and

Table 45–3

Pharmacologic Characteristics of Major Corticosteroids[9]

Corticosteroid	Glucocorticoid (Anti-Inflammatory) Potency	Mineralocorticoid (Sodium-Retaining) Potency	Duration of Action[a]	Equivalent Dose (mg)[b]
Glucocorticoid				
Cortisol	1	1	S	20
Cortisone	0.8	0.8	S	25
Prednisone	4	0.8	I	5
Prednisolone	4	0.8	I	5
Methylprednisolone	5	0.5	I	4
Triamcinolone	5	0	I	4
Betamethasone	25	0	L	0.75
Dexamethasone	25	0	L	0.75
Mineralocorticoid				
Fludrocortisone	10	125	I	[c]

[a]S, short (ie, 8–12 hour biological $t_{1/2}$); I, intermediate (ie, 12–36 hour biological $t_{1/2}$); L, long (ie, 36–72 hour biological $t_{1/2}$).

[b]These dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration.

[c]This agent is not used for glucocorticoid effects.

Adapted, with permission, from Shimmer BP, Funder JW. ACTH, adrenal steroids, and pharmacology of the adrenal cortex. In: Brunton LL, Chabner BA, Knollmann BC, eds. Pharmacological Basis of Therapeutics, 12th ed. New York City: McGraw-Hill; 2011: Figure 42–2.

Patient Encounter 1, Part 1: Presentation and Medical History

A 52-year-old female presents to the primary care clinic with complaints of fatigue, weakness, and intermittent nausea and diarrhea which have gradually worsened over the past year. She states that despite craving salty foods, she has lost 10 pounds (4.5 kg) in the last 6 months.

PMH:

- Tuberculosis—completed treatment course
- History of candidal vulvovaginitis
- Depression

FH: Father with type 1 diabetes

SH: Denies smoking, alcohol use or illicit drug use

Current Meds:

- Citalopram 20 mg once daily
- Loperamide 2–4 mg as needed for diarrhea (nonprescription)

PE:

VS: Sitting BP 104/66 mm Hg, P 70 beats/min, standing BP 92/64 mm Hg, RR 14 breaths/minute, Wt 139 pounds (63 kg)—10 pound (4.5 kg) loss in last 6 months, Ht 5'3" (160 cm)

Skin: Hyperpigmentation in creases of palms

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Labs (fasting): Serum electrolytes: sodium 132 mEq/L (mmol/L), potassium 5.3 mEq/L (mmol/L), chloride 95 mEq/L (mmol/L), bicarb 30 mEq/L (mmol/L), blood urea nitrogen (BUN) 28 mg/dL (10 mmol/L), creatinine 1.3 mg/dL (115 µmol/L), glucose 63 mg/dL (3.5 mmol/L)

Which signs or symptoms of adrenal insufficiency does the patient exhibit?

Does her presentation offer any clues as to etiology or classification of adrenal insufficiency?

Which tests would be most useful for determining etiology and confirming diagnosis of adrenal insufficiency?

monitor for resolution of postural hypotension, dizziness, salt-craving, dehydration, hyponatremia, and hyperkalemia; increase the dose if needed. Conversely, consider decreasing the dose if adverse reactions from mineralocorticoid administration such as hypertension, hypokalemia, fluid retention and other significant adverse events occur. In patients receiving hydrocortisone, it should be noted that this drug also possesses mineralocorticoid activity; and patients should be educated to avoid licorice and grapefruit juice as they can enhance hydrocortisone's mineralocorticoid effect. Patients taking concurrent phenytoin may need a higher dose as it can induce fludrocortisone's metabolism. All patients with Addison disease should also maintain adequate sodium intake. Lastly, although controversial (as indicated above), consider giving DHEA 25 to 50 mg/day (as a single oral dose in the morning) for a 6-month trial to premenopausal female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement. In these patients, monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people).

- Patients with secondary and tertiary adrenal insufficiency are treated with oral hydrocortisone or another glucocorticoid as described for primary adrenal insufficiency. However, patients with secondary and tertiary adrenal insufficiency may require a lower dose. Some patients (eg, patients with drug-induced adrenal insufficiency or adrenal insufficiency following treatment for Cushing syndrome) will only require glucocorticoid replacement temporarily, which can be discontinued after recovery of the HPA axis. Fludrocortisone therapy is generally not needed.

► *Acute Adrenal Insufficiency*

LO 3 KEY CONCEPT During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement. The 2016 Endocrine Society's Clinical Practice Guideline on the Diagnosis and Treatment of Primary Adrenal Insufficiency recommends that adults receive a rapid infusion of 1 liter isotonic saline within the first hour or 5% glucose in isotonic saline, followed by continuous IV isotonic saline guided by individual patient needs. For hypoglycemia, dextrose 0.5 to 1 g/kg or 2 to 4 mL/kg of D25W (maximum single dose 25 g) should be infused slowly. Glucocorticoid replacement can be accomplished by hydrocortisone 100 mg IV followed by hydrocortisone 200 mg/day as a continuous infusion for 24 hours, reduced to 100 mg/day the following day.[12] After achieving hemodynamic stability, hydrocortisone can be tapered to a lower maintenance dose by the fourth or fifth day and fludrocortisone can be added if needed. The dose can be increased to 200 to 400 mg/day if there are complications.[1] For the treatment of patients with critical illness-related corticosteroid insufficiency, see the 2017 consensus statements from the Society of Critical Care Medicine and European Society of Intensive Care Medicine.[13]

LO 3 KEY CONCEPT Patients with known adrenal insufficiency should be educated about the need for additional glucocorticoid replacement and prompt medical attention during periods of physiologic stress. Although the dosage of glucocorticoid is generally individualized, a common recommendation is to

Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, the patient is diagnosed with Addison disease.

How should her chronic primary adrenal insufficiency be treated?

What monitoring parameters (therapeutic and toxic) should be implemented?

Patient Care Process: Adrenal Insufficiency

Collect Information:

- Perform a medication history of prescription and nonprescription medications.
- Identify allergies.
- Review the medical history and physical assessment findings.
- Identify lifestyle habits, health goals, and socioeconomic factors that affect care.

Assess the Information:

- Evaluate for typical clinical manifestations of chronic or acute adrenal insufficiency.
- Determine if the patient has any etiologies of adrenal insufficiency.
- Assess results from the rapid ACTH stimulation test for presence of adrenal insufficiency (Table 45–2).
- Assess follow-up tests which differentiate between primary, secondary, and tertiary adrenal insufficiency (Table 45–2).

Develop a Care Plan:

- Determine whether patient will require mineralocorticoid replacement therapy in addition to glucocorticoid supplementation.
- Determine if the patient not previously diagnosed with adrenal insufficiency is presenting with acute adrenal crisis, in which case immediate treatment with injectable hydrocortisone and IV saline and dextrose solutions should be initiated prior to confirmation of diagnosis.
- Determine and correct the underlying cause of the acute adrenal crisis (eg, infection).
- Devise a strategy for patients with chronic adrenal insufficiency that includes supplemental doses of glucocorticoid when varying degrees of physiologic stress are experienced (eg, minor infection, pending surgery).
- Monitor patient for signs of an acute adrenal crisis and develop a plan to treat this emergency condition.

Implement the Care Plan:

- Educate patient and caregivers on causes of adrenal insufficiency, how to recognize clinical manifestations, the need to notify all health care providers of condition.
- Inform patients how to prevent an acute adrenal crisis: adhere to therapy, do not abruptly stop glucocorticoid treatment, need to increase the glucocorticoid dose during different severity levels of physiologic stress, including childbirth.
- Discuss when to self-administer parenteral glucocorticoid and seek emergency care.
- Suggest wearing or carrying a medical alert (eg, bracelet, card).
- Review dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

Follow-up: Monitor and Evaluate:

- Monitor for adequacy of treatment and adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
- Determine duration of treatment for patients with secondary and tertiary adrenal insufficiency.

double the maintenance dose of hydrocortisone if the patient experiences fever, or undergoes invasive dental or diagnostic procedures.[3] Patients who experience vomiting or diarrhea may not adequately absorb oral glucocorticoids and may benefit from parenteral therapy until symptoms resolve. Prior to surgery, additional glucocorticoid replacement (higher dose and parenteral route) must be given to prevent adrenal crisis. The dose and protocol varies depending on the type of surgery (eg, larger doses for major surgery compared to minor surgery).

Outcome Evaluation

LO 4

- Monitor weight, blood pressure, and serum electrolytes, along with symptom resolution and general well-being, in patients with adrenal insufficiency treated with glucocorticoid therapy; adjust dosages accordingly as needed.
- Monitor for adverse drug reactions related to glucocorticoid administration.
- Monitor for progression of the underlying etiology of adrenal insufficiency in patients with secondary or tertiary adrenal insufficiency.

HYPERCORTISOLISM (CUSHING SYNDROME)

Epidemiology and Etiology

Cushing syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing syndrome from endogenous causes is a rare condition, with an estimated incidence of two to five cases per 1 million persons per year.[14] Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing syndrome.

Pathophysiology

Cushing syndrome can be classified as ACTH-dependent or ACTH-independent (Table 45–4).[1,15-17] ACTH-dependent Cushing syndrome results from ACTH-secreting (or rarely CRH-secreting) adenomas. The term *Cushing disease* refers specifically to Cushing syndrome from an ACTH-secreting pituitary adenoma. ACTH-independent Cushing syndrome is due either to excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or to exogenous

Table 45–4

Etiologies of Cushing Syndrome[1,15-17]

ACTH-Dependent
- ACTH-secreting pituitary tumor (Cushing *disease*)—70% of endogenous cases
- ACTH-secreting non-pituitary tumors (ectopic ACTH syndrome)—15% of endogenous cases; usually from small cell lung carcinoma and bronchial carcinoids; also from pheochromocytoma, or from thymus, pancreatic, ovarian, or thyroid tumor. The tumor is usually disseminated (difficult to localize).
- CRH-secreting non-pituitary tumors (ectopic CRH syndrome)—rare

ACTH-Independent—15% of endogenous cases
- Unilateral adrenal adenoma
- Adrenal carcinoma
- Bilateral nodular adrenal hyperplasia—rare (< 1%)

Drug-Induced Cushing Syndrome (ACTH-independent)—most common cause of Cushing syndrome
- Prescription glucocorticoid preparations (most routes of administration)
- Nonprescription and herbal products with glucocorticoid activity (eg, nonprescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts or other byproducts)
- Other drugs with glucocorticoid activity (eg, megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone.

glucocorticoid administration. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent conditions because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. ACTH and cortisol concentrations are elevated episodically in ACTH-dependent disease due to random hypersecretion of ACTH.[4] In general, patients with Cushing syndrome due to endogenous or exogenous glucocorticoid excess present with similar clinical manifestations. However, patients with ectopic ACTH syndrome may not exhibit the typical signs and symptoms of hypercortisolism due to the acute onset nature of the underlying disease process.[1,9]

Cushing disease and adrenal **carcinomas** cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess such as acne, menstrual irregularities, and **hirsutism**, and cause **virilization** in women.[4] Drug-induced Cushing syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other routes such as inhalation, dermal, nasal, and intra-articular have also been implicated.[15] Over-the-counter products, including dietary supplements, should also be evaluated since they may contain corticosteroids. Drug-induced Cushing syndrome has been reported with the use of Chinese herbal products adulterated with corticosteroids.[18,19] The risk of glucocorticoid-induced Cushing syndrome appears to increase with higher doses and/or longer treatment durations.[15]

LO 5 Left untreated, patients with Cushing syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly fourfold increase in mortality.[20] Mortality in patients with Cushing is mostly attributed to cardiovascular disease. Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, atherosclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported.[20] Prevention and management of these conditions are discussed elsewhere in this text. Children may experience linear growth retardation from reduced growth hormone secretion and inhibition of epiphysial cartilage development in long bones.[14,20]

Treatment

The goal of treatment in patients with Cushing syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. KEY CONCEPT Surgical resection is considered the treatment of choice for Cushing syndrome from endogenous causes if the tumor can be localized and if there are no contraindications. The treatment of choice for Cushing syndrome from exogenous causes is gradual discontinuation of the offending agent.

▶ *Nonpharmacologic Therapy*

LO 6 **Transsphenoidal pituitary microsurgery** is the treatment of choice for Cushing disease. Removal of the pituitary tumor can bring about complete remission or cure in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary irradiation or bilateral adrenalectomy is usually reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission following pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing disease in whom the ACTH-producing lesion cannot be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients will require lifelong glucocorticoid and mineralocorticoid supplementation.[5,21] **Nelson syndrome** may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson syndrome may involve pituitary irradiation or surgery.[4]

LO 6 The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery due to atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until recovery of the remaining adrenal gland is achieved. Patients with adrenal carcinomas have a poor prognosis, with a five-year survival of 20% to 58%, because of the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, or bilateral laparoscopic adrenalectomy are the treatment options commonly utilized to manage this condition.[1,5]

▶ *Pharmacologic Therapy*

LO 6 KEY CONCEPT Pharmacotherapy is indicated when the ectopic ACTH-secreting tumor cannot be localized; to control hypercortisolism to prepare for surgery; and in patients who: (1) are not surgical

Clinical Presentation and Diagnosis of Cushing Syndrome[1,14,15,22]

LO 5

General

- Onset of signs and symptoms range from gradual to rapid, depending on etiology.
- Differential diagnoses include diabetes mellitus and the metabolic syndrome because these conditions share several similar characteristics with Cushing syndrome (eg, obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing syndrome can be differentiated from these conditions by identifying the classic signs and symptoms described below.
- True Cushing syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, anxiety disorder, obsessive-compulsive disorder, alcoholism, obesity, uncontrolled diabetes, eating disorders, and physiologic stress—the so-called pseudo-Cushing states.

Signs and Symptoms (Percent Prevalence)

General appearance

- Weight gain and obesity, manifesting as truncal obesity (90%)
- Rounded and puffy face ("moon facies") (75%)
- Dorsocervical ("buffalo hump") and supraclavicular fat accumulation
- Hirsutism (75%)

Skin changes from atrophy of dermis and connective tissue

- Thin skin
- Facial plethora (70%)
- Skin striae ("stretch marks" that are usually red or purple in appearance and > 1 cm) (50%)—not common in patients older than 40 years of age
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation—typically with ectopic ACTH syndrome

Metabolic

- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20%–50%)
- Hyperlipidemia (70%)
- Polyuria (30%)
- Kidney stones (15%–50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

Cardiovascular

- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Peripheral edema

Genitourinary

- Menstrual irregularities (typically amenorrhea) (70%)
- Erectile dysfunction (85%)

Other

- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis—usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- Glaucoma, cataracts
- Impaired wound healing and susceptibility to opportunistic infections
- Hypothyroidism

Laboratory Tests

- Diagnosis is often complex and generally requires the involvement of endocrinologists and specialized testing centers.
- Initial screening tests are listed in Table 45–5.[1,22] Typically, a combination of two screening tests is used to establish the preliminary diagnosis.
- After the diagnosis is confirmed, additional tests (eg, midnight serum cortisol or combined dexamethasone suppression plus CRH test) can be performed to determine the etiology or rule out false positive/negative results.

Other Diagnostic Tests

Imaging studies and inferior petrosal sinus sampling may be needed to distinguish between pituitary, ectopic, and adrenal tumors.

candidates; (2) have failed surgery or had a relapse after surgery; or (3) have Cushing disease awaiting the onset of effect of pituitary radiation.[23] The drugs used are classified according to their mechanism and site of action (Table 45–6[21-26]). The most widely used therapeutic class is the adrenal steroidogenesis inhibitors, which can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol.[23] Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement, and in some cases mineralocorticoid supplementation, may be needed during and after treatment.

LO 6

KEY CONCEPT In drug-induced Cushing syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.[15]

KEY CONCEPT Glucocorticoid doses less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to suppression of the HPA axis.[5,25] However, in patients receiving pharmacologic doses of glucocorticoids for prolonged periods, gradual tapering to near physiologic levels (5–7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.[15] Table 45–7 lists strategies to prevent the development of hypercortisolism and hypocortisolism.

LO 7

Table 45–5

First-Line Screening Tests in Patients with Characteristics of Cushing Syndrome[1,22]

Test	Test Procedure and Measurement	Rationale	Typical Finding in Cushing Syndrome	Comments
24-hour urinary-free cortisol	Collect urine over 24 hours and measure unbound cortisol excreted by kidneys	Urinary cortisol is elevated in hypercortisolic states	Elevated urinary-free cortisol (value depends on the assay used)	• Easy to perform but should not be used alone since sensitivity and specificity depend on assay used • To exclude periodic hypercortisolism, 2 or more samples should be obtained (with urinary creatinine measurement to assess completeness of collection) • Distinguishes the effects of Cushing syndrome (elevation) from obesity (no elevation). However, false positive in other pseudo-Cushing states, physiologic stress, if fluid intake ≥ 5 liters/day, or taking carbamazepine or fenofibrate (if measured by HPLC) • False negative if moderate to severe renal function, or subclinical hypercortisolism
Overnight dexamethasone suppression test (DST)	Give 1 mg oral dexamethasone at 11 PM, then measure plasma cortisol at 8–9 AM the next morning	Dexamethasone administration suppresses morning plasma cortisol in normal individuals	Plasma cortisol < 1.8 μg/dL (50 nmol/L) is not suggestive of Cushing syndrome	• Simple to perform and inexpensive • Can be used in conjunction with, or instead of, the urinary-free cortisol test • False positive if pseudo-Cushing states, physiologic stress, pregnancy, estrogen treatment (including contraceptives), uremia, taking inducers of dexamethasone metabolism (phenytoin, alcohol, etc.), or decreased dexamethasone absorption • False negative if subclinical hypercortisolism, slow metabolism of dexamethasone (eg, CYP3A4 inhibitors), or liver or renal impairment • In pseudo-Cushing states, the 48-hour 2-mg DST (administer 0.5 mg dexamethasone every 6 hours for 48 hours then measure serum cortisol at 8 or 9 AM after the last dose) is preferred
Late-night salivary cortisol	Collect salivary cortisol concentration at 11 PM	Loss of circadian rhythm of cortisol secretion (no nadir at night) in Cushing syndrome but not in pseudo-Cushing states	Elevated late-night salivary cortisol	• Easiest screening test to perform (sample can be collected at home by patient) • To exclude periodic hypercortisolism, two or more samples (on two separate evenings) should be obtained • False positive possible with cigarette smoking, chewing tobacco, licorice ingestion, in pseudo-Cushing states • Adjust collection time in shift workers and others with bedtime significantly after midnight

CYP, cytochrome P450; HPLC, high-performance liquid chromatography.

Patient Encounter 2

A 32-year-old female presents to a clinical pharmacist for diabetes education. She was recently diagnosed with type 2 diabetes. She also has a diagnosis of hypertension, dyslipidemia, depression, asthma, eczema, and seasonal allergies. She complains of thirst, polyuria, and fatigue. She also reports increased facial acne over the past few months. Physical examination reveals an obese (BMI 38 kg/m^2) woman with truncal obesity, dosocervical fat, and facial plethora. Her current medications include metformin, lisinopril, escitalopram, albuterol inhaler, fluticasone nasal spray, and mometasone 0.1% cream. She has been treated several times this year with methylprednisolone therapy for reoccurring rashes from poison ivy. The clinical pharmacist suggests evaluation for possible Cushing syndrome.

Which findings are suggestive of Cushing syndrome?

Aside from Cushing syndrome, what are some major differential diagnoses for clinical presentation?

The patient is diagnosed with drug-induced Cushing syndrome after evaluation and diagnostic testing by the endocrinologist. What patient education points should be provided?

Table 45–6

Pharmacologic Treatments for Cushing Syndrome[21-26]

Drug	Mechanism of Action	Dosage[a]: Initial, Usual, Maximum, Dosing Adjustment for Renal and/or Hepatic Failure	Common and/or Major Adverse Reactions	Comment
Inhibitors of Adrenal Steroidogenesis				
Ketoconazole[b] (oral administration)	Inhibits several CYP enzymes including 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase. Also inhibits cholesterol synthesis	*Adults*: 400–1600 mg/day; every 6–8 hour dosing Extensively metabolized by liver and dosing adjustment should be considered in severe liver disease. Dosing adjustment not needed in renal disease	Generally well-tolerated. Symptoms of adrenal insufficiency (eg, nausea, vomiting, decreased appetite, fatigue). Gynecomastia, decreased libido, and impotence (due to inhibition of testosterone synthesis). Hepatotoxicity	• Effective in a majority of causes; rapid clinical improvement seen • Monitor efficacy with urinary cortisol • Monitor liver transaminases for hepatotoxicity • Useful in women with hirsutism and patients with hyperlipidemia • Requires gastric acidicity for dissolution and absorption, therefore not useful in patients with achlorhydria and those taking proton pump inhibitors or round-the-clock antacids or histamine-2 receptor blockers • Is a CYP3A4 substrate and a strong CYP3A4 inhibitor. Also has other CYP interaction potential. Coadministration with certain medications can lead to QT prolongation and dysrhythmia
Metyrapone[b] (oral administration)	Inhibits 11β-hydroxylase. Also suppresses aldosterone synthesis	*Adults*: 500 mg/day to 6 g/day; every 6–8 hour dosing Dosages in special populations (liver and kidney disease, elderly patients) have not been established	Generally well-tolerated. Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension	• Used in Cushing disease, ectopic ACTH syndrome, and adrenal carcinoma • Also used as a test to diagnose adrenal insufficiency
Etomidate[b] (intravenous infusion administration)	Inhibits 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase	*Adults*: Bolus and titrate Extensively metabolized in the liver to inactive metabolites. Because of changes in protein binding, dosing adjustment may be needed in kidney and liver disease	Injection site pain, nausea, vomiting, myoclonus, hypotension	• Is a general anesthetic • Generally reserved for patients with more severe symptoms and in emergency settings
Adrenolytic Agent				
Mitotane (oral administration)	Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses. Inhibits 11β- hydroxylase and cholesterol side-chain cleavage. Reduces aldosterone synthesis	*Adults*: Starting dose: 250 mg; 500 mg/day to 8 g/d. Elderly patients may require a dose decrease Primarily metabolized by the liver and dosing adjustment may be needed in liver disease	GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia. Hyperlipidemia requiring lipid-lowering treatment. Adrenal insufficiency requiring glucocorticoid replacement therapy	• FDA-approved for treatment of inoperable adrenal cortical carcinoma. Can be used in other types of Cushing syndrome • Efficacy takes several weeks • Lower rate of relapse when used with pituitary radiation. Also enables lower doses and therefore lower rate of adverse reactions • Hypocortisolism (if occurs) may persist several weeks/months after discontinuation as drug is stored in fatty tissues • Strong inducer of CYP3A4

Peripheral Glucocorticoid Antagonist				
Mifepristone (RU 486) (oral administration)	Antagonizes glucocorticoid receptors	*Adults*: 300–1200 mg/day Maximum 300 mg/day with concomitant strong CYP450 inhibitors Do not exceed 600 mg/day in renal impairment or mild-to-moderate hepatic impairment. Do not use in severe hepatic impairment	Nausea, fatigue, headache, hypokalemia, arthralgia, vomiting, peripheral edema, hypertension, dizziness, decreased appetite, endometrial hypertrophy, prolonged QT interval. Has abortifacient and embryotoxic properties	• FDA-approved for control of hyperglycemia secondary to hypercortisolism in adult patients with endogenous Cushing syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery • Increases cortisol and ACTH levels via antagonism of negative feedback of ACTH secretion • Requires cautious use since limited clinical experiences and cannot use cortisol or ACTH levels to monitor efficacy of treatment • Quicker effectiveness compared to other drug treatment options • Is a CYP3A4 substrate. Also inhibits CYP3A and has other CYP interaction potential
Somatostatin Analog				
Pasireotide (subcutaneous injection)	Binds to somatostatin receptor subtype 5 over-expressed in corticotroph tumor cells resulting in inhibition of ACTH secretion	*Adults*: 0.6–0.9 mg twice daily Moderate hepatic impairment (Child Pugh B): initial 0.3 mg twice a day, maximum 0.6 mg twice a day. Avoid in severe hepatic impairment (Child Pugh C). No dosage adjustment needed in renal impairment	Hyperglycemia, GI pain, nausea, diarrhea, headache, fatigue, bradycardia, QT prolongation, liver test elevations, cholelithiasis, pituitary hormone (other than ACTH) inhibition	• FDA-approved for treatment of adult patients with Cushing disease for whom pituitary surgery is not an option or has not been curative • Measure response based on 24-hour urinary-free cortisol level and/or improvement in signs and symptoms

[a]Dosing guidelines (including age ranges) and safety for children have not been definitively established.

[b]These medications do not have FDA-approved indications for the treatment of Cushing syndrome in either adults or children.

ACTH, adrenocorticotropic hormone or corticotropin; CYP, cytochrome P450; FDA, Food and Drug Administration; GI, gastrointestinal.

Table 45–7

Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism

To Prevent Hypercortisolism and Development of Cushing Syndrome

- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal)
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning)[4]
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism

To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis

- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:[4]
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, and then
  - Change glucocorticoid to every other day administration, in the morning
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent)
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress
- Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate
- Avoid concurrent administration of drugs that can induce glucocorticoid metabolism
- Educate patients about:
  - The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy
  - How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency
  - Need to wear or carry medical identification regarding their condition (eg, card, bracelet)

HPA, hypothalamic-pituitary-adrenal.

Patient Care Process: Cushing Syndrome

Collect Information:

- Perform a medication history of prescription and nonprescription medications.
- Identify allergies.
- Review the medical history and physical assessment findings.
- Identify lifestyle habits, health goals, and socioeconomic factors that affect care.

Assess the Information:

- Determine whether the patient is taking any glucocorticoids (from prescription or herbal/dietary supplement sources) that may have induced Cushing syndrome.
- Review relevant lab tests (eg, 24-hour urinary-free cortisol, overnight dexamethasone suppression test [DST], late-night salivary cortisol).
- Establish diagnosis and etiology based on diagnostic testing.

Develop a Care Plan:

- Evaluate patient for appropriateness of surgery, radiation, and/or pharmacologic therapy depending on etiology.
- If etiology is exogenous administration of glucocorticoid, attempt taper.
- If etiology is endogenous, determine if patient is an appropriate candidate for surgical resection of the tumor or has contraindications to surgical resection such as advanced disease (metastatic adrenal carcinoma).
- Assess response and complications associated with surgery including[21]:
  - Measuring plasma cortisol postsurgery to determine if the patient displays persistent hypercortisolism (surgical treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
  - In patients demonstrating hypocortisolism:
    i. Monitor for signs and symptoms of glucocorticoid withdrawal (headache, fatigue, malaise, myalgia).
    ii. Monitor for signs and symptoms of adrenal insufficiency and develop a treatment plan.
    iii. Monitor morning cortisol or response to ACTH stimulation every 3–6 months to assess for HPA axis recovery. Discontinue glucocorticoid replacement therapy when cortisol concentrations are greater than 19 mcg/dL (524 nmol/L) on either test.
    iv. Monitor cortisol, ACTH, low-dose dexamethasone suppression, or other tests to assess for risk of relapse of hypercortisolism.
- If surgical resection does not achieve satisfactory disease control or is not indicated, evaluate the patient for pituitary radiation or bilateral adrenalectomy with concomitant pituitary radiation.

(*Continued*)

Patient Care Process: Cushing Syndrome (*Continued*)

- Evaluate patients with adrenal adenomas for unilateral adrenalectomy.
  - Give glucocorticoid and mineralocorticoid replacement (permanently in the case of bilateral adrenalectomy).

Implement the Care Plan:

- Educate patient and caregivers on causes and possible sequelae of Cushing syndrome, how to recognize clinical manifestations, and the need to notify all health care providers of condition.
- Inform patients on how to reduce modifiable cardiovascular and metabolic complications.
- Review advantages and disadvantages of treatment options including possible adverse consequences.
- Highlight the importance of adherence to therapy.
- Discuss the need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate.

Follow-up: Monitor and Evaluate:

- Monitor for response to therapy, need for dose adjustments, and presence of adverse drug reactions.
- Once disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing syndrome, as relapse may occur.
- Monitor patients treated with surgery or pituitary radiation for development of pituitary hormone deficiency.

Outcome Evaluation

LO 8

- Monitor patients receiving surgical, medical, or radiation therapy for resolution of the clinical manifestations of hypercortisolism. Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve following radiation therapy.
- Monitor for normalization of serum cortisol concentrations.
- Patient Care Process discusses additional evaluation strategies.

ACKNOWLEDGMENTS

The authors and editors wish to acknowledge and thank Dr. Frank Pucino and Dr. Karim Calis, co-authors of this chapter in the first, second, third, and fourth editions of this book.

Abbreviations Introduced in This Chapter

ACTH	Adrenocorticotropic hormone or corticotropin
AIDS	Acquired immunodeficiency syndrome
BUN	Blood urea nitrogen
CRH	Corticotropin-releasing hormone
CT	Computed tomography
CYP	Cytochrome P450
DHEA	Dehydroepiandrosterone
DHEA-S	Sulfated form of dehydroepiandrosterone
DST	Dexamethasone suppression test
FDA	Food and Drug Administration
GI	Gastrointestinal
HIV	Human immunodeficiency virus
HPA	Hypothalamic-pituitary-adrenal
HPLC	High performance liquid chromatography
IM	Intramuscular
IV	Intravenous or intravenously
MRI	Magnetic resonance imaging

46 Pituitary Gland Disorders

Judy T. Chen and Devra K. Dang

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the mediators and primary effects of pituitary hormones.
2. Identify clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify clinical features of children and adults with growth hormone (GH) deficiency and select appropriate pharmacotherapy for these patients.
6. Recommend monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving GH therapy.
7. List common etiologies of hyperprolactinemia.
8. Identify clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary, referred to as the "master gland," is a small endocrine gland located at the base of the brain and is responsible for the regulation of many other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe and the posterior pituitary lobe. The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons.

The posterior pituitary is innervated by nervous stimulation from the hypothalamus, resulting in the release of specific hormones to exert direct tissue effects. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored and released from the posterior pituitary lobe. The anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. It synthesizes and secretes six major hormones. Figure 46–1 summarizes the physiologic mediators and effects of each of these hormones.

Hormonal Feedback Regulatory Systems

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert a negative feedback on other hormones in the hypothalamic–pituitary axis (see Figure 46–1). This negative feedback serves to maintain body system homeostasis. In general, high circulating hormone concentrations inhibit the release of hypothalamic and anterior pituitary hormones.

Damage and destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, growth hormone (GH) deficiency, hypoprolactinemia, or panhypopituitarism. A tumor (adenoma) located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient's clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, GH deficiency, and hyperprolactinemia. The following hormones are discussed elsewhere in this textbook: adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), antidiuretic hormone (or vasopressin; ADH), and oxytocin.

GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or GH, the most abundant hormone produced by the anterior pituitary lobe, is regulated primarily by the hypothalamic–pituitary axis. The hypothalamus releases growth hormone–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas somatostatin inhibits it.[1] Release of GH into the circulation stimulates the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs are the peripheral GH targets. There are two types of IGFs, IGF-I and IGF-II. IGF-I is responsible for growth of bone and other tissues, whereas IGF-II is primarily responsible for regulating fetal growth. High concentrations of IGF-I inhibit GH secretion through somatostatin, thereby inhibiting GHRH secretion at the hypothalamus.[1] The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion.

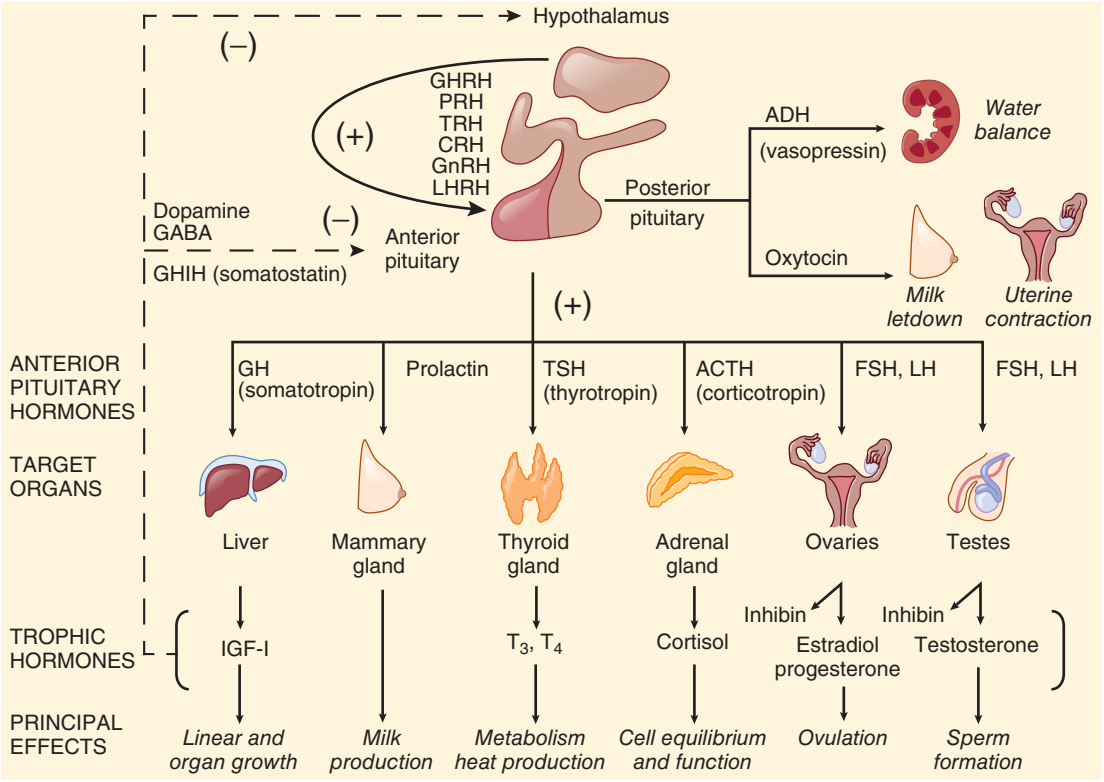

FIGURE 46–1. Hypothalamic–pituitary–target-organ axis. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. These trophic hormones regulate the activity of endocrine glands. Subsequently, increased serum concentration of the trophic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in men and the ovaries in women during pregnancy. Inhibin directly inhibits pituitary production of follicle-stimulating hormone (FSH) through a negative feedback mechanism. Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure. (–), inhibit; (+), stimulate. (ACTH, adrenocorticotropic hormone [corticotropin]; ADH, antidiuretic hormone [vasopressin]; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; GH, growth hormone [somatotropin]; GHIH, growth hormone -inhibiting hormone [somatostatin]; GHRH, growth hormone -releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor-I; LH, luteinizing hormone; LHRH, luteinizing hormone -releasing hormone; PRH, prolactin-releasing hormone; T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone [thyrotropin].)

The effects of IGF-I in peripheral tissues are both GH dependent and GH independent.[2] GH is an anabolic hormone with direct "anti-insulin" metabolic effects. By stimulating protein synthesis and shifting the body's energy source from carbohydrates to fats, GH promotes a diabetic state (Table 46–1).[2] GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

Table 46–1

Effects of Growth Hormone[2]

	Effect(s)
Lipid metabolism	Increases breakdown of fat (lipolysis) Increases circulating fatty acid concentrations
Protein metabolism	Increases lean body mass Increases muscle mass
Carbohydrate metabolism	Decreases glucose utilization Increases insulin resistance Hyperglycemia Increases hepatic glucose output

In healthy individuals, GH is secreted in a pulsatile manner with several short bursts occurring mostly during the night. The amount of GH secretion fluctuates throughout a person's lifetime. Secretion of GH is lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years.[1] These changes are parallel to an age-related decline in lean muscle mass and bone mineral density.

Growth Hormone Excess

▶ *Epidemiology and Etiology*

Acromegaly affects both genders equally, and the average age of presentation is 44 years. Approximately 125 to 295 people per 1 million are affected, with an estimated annual incidence of five cases per 1 million people.[3] In more than 95% of cases, overproduction of GH is caused by a benign pituitary adenoma, whereas malignant adenomas are rare. Most pituitary adenomas occur spontaneously as a result of a sporadic genetic mutation acquired during life. Depending on tumor size, pituitary adenomas are classified as: (a) microadenomas if they are 10 mm or less in diameter; or (b) macroadenomas if they are greater

FIGURE 46–2. Before and after photographs of a patient with acromegaly. Compare the photographs **(A)** before the onset of acromegaly and **(B)** after approximately 20 years when the diagnosis was well established. Notice the coarsening of facial features, with an enlarged nose, lips, and forehead.

than 10 mm. Although these tumors can produce GH, they more commonly secrete GHRH, resulting in excessive GH and IGF-I production.

▶ *Pathophysiology*

Acromegaly is a rare disorder that manifests gradually over time and typically occurs after fusion of the epiphyses (growth plates) of the long bones.[4] The facial and hand features of an acromegalic patient are depicted in Figures 46–2 and 46–3. Gigantism refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth. Because the signs and symptoms of acromegaly are insidious, diagnosis of this disorder is often delayed for up to 10 years after the initial presentation of symptoms.[4] Therefore, it is important for practitioners to be vigilant in identifying this disease in the early stages.

Diagnosis of acromegaly is based on both clinical and biochemical findings. Because GH fluctuates throughout the day, a single random measurement is never a reliable diagnostic tool to evaluate GH excess.[1] GH is suppressed after administration of a 75-g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH. Therefore, measurement of serum GH secretion in response to an oral glucose tolerance test (OGTT) is the primary biochemical test for diagnosing acromegaly.

FIGURE 46–3. Photograph of hands from a patient with acromegaly. Soft tissue swelling and enlargement of the hand in a woman with acromegaly resulting in increased ring and glove size.

If the nadir GH concentration is greater than 0.4 ng/mL (mcg/L; 18 pmol/L) 2 hours after the test or the random GH concentration is greater than 1 ng/mL (mcg/L; 45 pmol/L), the patient is diagnosed with acromegaly.[5,6] In addition to clinical presentation, an elevated IGF-I serum concentration helps to confirm the diagnosis. IGF-I concentrations are often represented as age- and sex-matched population values.[5] They are relatively stable and correlate positively with mean GH concentrations,[1] thus making elevations in IGF-I concentrations an ideal and reliable biochemical marker to monitor disease activity and response to therapy.[4,5]

▶ *Treatment*

Desired Outcomes Patients with untreated acromegaly experience a two- to threefold increase in mortality rate primarily because of cardiovascular and pulmonary diseases.[4,6] KEY CONCEPT Prolonged exposure to elevated GH and IGF-I can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure to prevent cardiovascular, pulmonary, metabolic, respiratory, and neuropathic complications.[5,6] Normalization of GH and IGF-I concentrations lowers the mortality risk and may improve overall life expectancy. The goals of therapy are as follows.[4,6,8]

- Reduce fasting morning GH and IGF-I concentrations as close to normal as possible
- Reduce tumor size to relieve tumor mass effect
- Prevent tumor recurrence
- Preserve normal pituitary function
- Improve clinical signs and symptoms
- Alleviate significant morbidities
- Reduce mortality rates to those of the general population

LO 3

Surgical Treatment According to the Endocrine Society[6] and the American Association of Clinical Endocrinologists (AACE) treatment guidelines for acromegaly,[4] KEY CONCEPT surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with GH-producing pituitary adenomas. When

Clinical Presentation and Diagnosis of Acromegaly[4-7]

LO 2

General

The patient will experience slow development of soft tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years.

Symptoms

- Headache and compromised visual function (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures.
- Weakness, low blood sugar, or weight loss caused by disruption of adrenal function (ie, ACTH deficiency) by effect of tumor mass on the pituitary.
- Fatigue and weight gain caused by disruption of thyroid function (ie, TSH deficiency) by effect of tumor mass on the pituitary.
- Absence of regular menstrual periods (amenorrhea), impotence, and decreased libido caused by disruption of the gonadotropin secretion (ie, LH and FSH).
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I concentrations.

Signs

- Coarsening of facial features
- Increased hand volume
- Increased ring and shoe size
- Increased spacing between teeth
- Increased acne or oily skin
- Enlarged tongue
- Deepening of voice
- Thick, irregular, and patchy skin discoloration
- Enlarged nose, lips, and forehead (frontal bossing)
- Abnormal protrusion of the mandible (prognathia) and bite abnormalities
- Inappropriate secretion of breast milk (galactorrhea)
- Abnormal enlargement of various organs (organomegaly) such as liver, spleen, and heart
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue

Laboratory Tests

- Random GH concentration greater than 1 ng/mL (mcg/L; 45 pmol/L) or nadir GH concentration greater than 0.4 ng/mL (mcg/L; 18 pmol/L) after an OGTT and elevated IGF-I concentration compared with age-matched control values.
- Loss of other hormonal functions caused by tumor mass compression of the anterior pituitary.
- Measure prolactin concentration in all patients because prolactin cosecretion is common.
- Glucose intolerance may be present in up to 50% of patients.

Additional Clinical Sequelae

- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 90% of patients.
- Respiratory disorders and sleep apnea occur in up to 60% of patients.
- Type 2 diabetes mellitus develops in 25% of patients.
- Increased risk for the development of esophageal, colon, and stomach cancer.

Other Diagnostic Tests

- Perform magnetic resonance imaging (MRI) examination of the pituitary to locate the tumor and validate the diagnosis.
- Obtain serum prolactin concentrations to assess for hyperprolactinemia and hypopituitarism.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

Adapted from Jordan JK, Sheehan AH, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 10th ed. New York: McGraw-Hill; 2017.

performed by experienced surgeons, greater than 85% of patients with microadenomas and fewer than 50% of patients with macroadenomas achieve remission.[6] Complete resection of a macroadenoma may be difficult if the tumor has already invaded the surrounding nerves and tissues. In such cases, debulking of the tumor along with adjunctive radiation and/or pharmacotherapy may improve treatment outcome. Infrequent surgical complications include meningitis, serious visual impairment, spinal fluid leakage, diabetes insipidus, and hypopituitarism.[6] Relative contraindications to surgery include patient frailty, acromegaly-associated comorbidities, and medically unstable conditions such as airway difficulties, severe hypertension, or uncontrolled diabetes.

Pharmacologic Therapy Pharmacologic therapy is often necessary for patients in whom surgery is not an option (Figure 46–4).[8] Somatostatin analogs, GH receptor antagonists, and dopamine agonists are the primary pharmacologic therapies used for the management of acromegaly (Table 46–2).[4,6,8,9] Pharmacologic therapy avoids hypopituitarism and other surgical risks.

LO 4

Somatostatin Analog (GH-Inhibiting Hormone) KEY CONCEPT

LO 4

Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery is not appropriate, or as an adjuvant therapy until patients achieve a sustained response to radiation therapy.[6,8] These agents mimic endogenous somatostatins and bind to somatostatin receptors in the pituitary to cause potent inhibition of GH, insulin, and glucagon secretion. Long-term treatment can sustain GH suppression, alleviate soft tissue manifestations, and reduce tumor size. The long-acting preparations of somatostatin analogs are considered the cornerstone of therapy because of improved patient adherence and acceptability over the first-generation octreotide. Somatostatin analogs normalize GH and IGF-I concentrations in approximately 55% of patients[4] and modestly reduce pituitary tumor size in more than half of the patients with acromegaly.[6] Optimal dose titration

Patient Encounter 1, Part 1

A 68-year-old Caucasian woman complains of frequent headaches, and she has not seen her primary care provider for years prior due to lack of insurance. The patient has noticeably large facial features, and manly arms, hands, and legs. She states that she has always been somewhat bothered by her more masculine features, but brushed it off because she grew up with several brothers.

PMH: Uncontrolled hypertension for 10 years; uncontrolled type 2 diabetes mellitus for 4 years; sleep apnea for 20 years

FH: Positive for diabetes in patient's mother and four brothers

Allergies: Penicillin (rash)

SH: Unemployed and uninsured, cleans hallways at her apartment building to cover rent and utility; recently quit smoking

Meds: Losartan-hydrochlorothiazide 100-25 mg once daily; metformin 1000 mg twice daily; insulin glargine 40 units once daily; insulin aspart 12 units with dinner; aspirin 81 mg once daily

Based on the information available, what signs and symptoms are suggestive of acromegaly?

What comorbidities are present in this patient as a result of untreated acromegaly?

What diagnostic tests should be performed to confirm the patient's diagnosis of acromegaly?

of somatostatin analogs is important in disease control.[6] Their efficacy and safety have been demonstrated in long-term studies (up to 9 years with octreotide and 4 years with lanreotide).[10-12] The long acting release (LAR) formulation of pasireotide has been demonstrated to provide superior efficacy compared to octreotide or lanreotide in achieving clinical and biochemical control.[9] Because somatostatin analogs can achieve substantial relief of clinical symptoms with significant reduction in tumor size,[13] it is important to monitor patients for tumor recurrence if treatment is discontinued.[4,6] Use of somatostatin analogs before surgery is not routinely recommended due to insufficient data to suggest additional benefits over surgery alone.[14]

Somatostatin analogs are generally well tolerated. Transient gastrointestinal (GI) disturbances are common but usually subside within the first months of therapy.[15] Somatostatin analogs inhibit gallbladder contractility and decrease bile secretion; therefore, their major adverse effect is development of **biliary sludge** and asymptomatic **gallstones (cholelithiasis)**.[15] Somatostatin analog–induced gallstones are generally asymptomatic; therefore, prophylactic therapy or routine abdominal ultrasound monitoring are usually not needed.[6,15] Additionally, somatostatin analogs may alter the balance of counterregulatory hormones (ie, glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia. Higher incidence of hyperglycemia and diabetes has been reported with pasireotide compared to other somatostatin analogs.[9] Somatostatin analogs also may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism. Proactive monitoring of thyroid function and glucose metabolism is recommended.

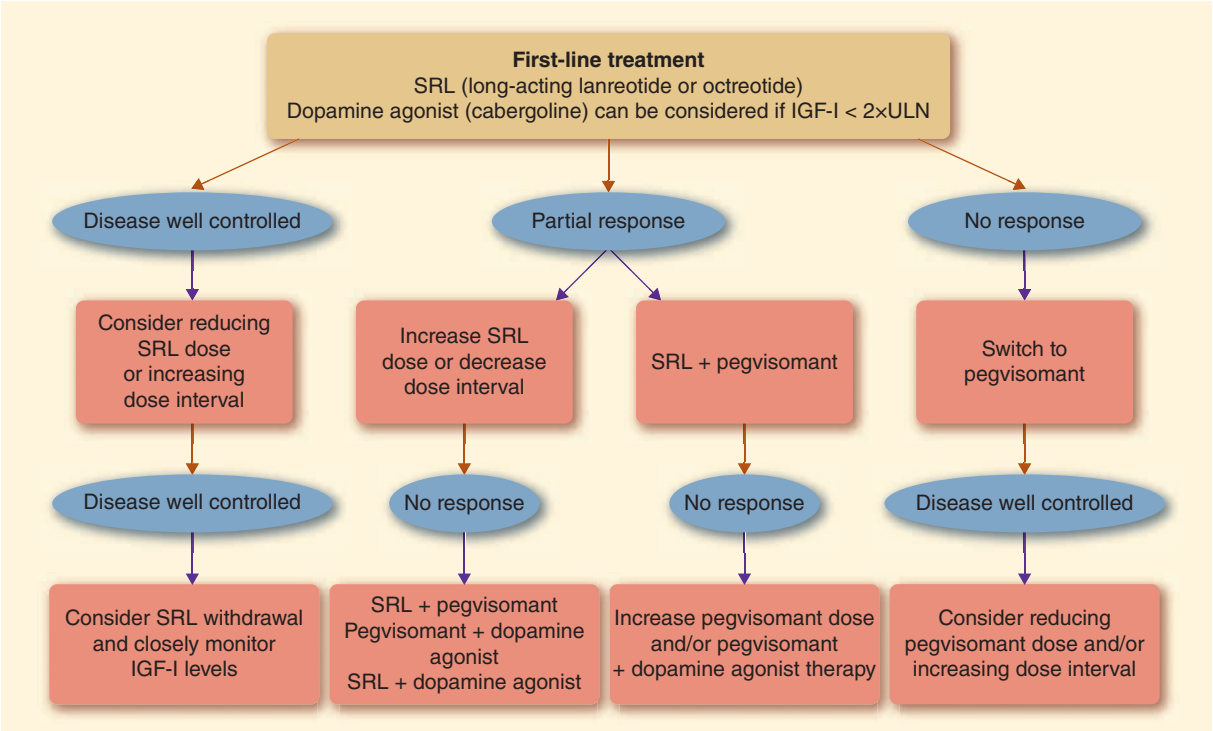

FIGURE 46–4. Medical management of patients with acromegaly.[8] A proposed algorithm for the medical management of acromegaly after surgery or as primary treatment strategy when surgery is inappropriate. Radiation therapy as rescue therapy has not been considered in this algorithm because its use is usually determined by a multidisciplinary management team. IGF-I, insulin-like growth factor I; SRL, somatostatin receptor ligan; ULN, upper limit of normal. Expert consensus document: a consensus on the medical treatment of acromegaly. Nat Rev Endocrinol. 2014;10:243–248.)

Table 46–2

Comparison of Various Drugs Within Drug Classes for Treatment of Acromegaly[4,6,8,9]

	Dopamine Agonist	Somatostatin Analog					GH Receptor Antagonist
Medication	Cabergoline	Octreotide (Sandostatin)	Octreotide LAR (Sandostatin LAR)	Lanreotide SR	Lanreotide Autogel (Somatuline Depot)	Pasireotide (Signifor LAR)	Pegvisomant (Somavert)
Starting dose	1 mg/week orally	50 mcg SC thrice daily	20 mg IM every 4 weeks	60 mg IM every 2 weeks	90 mg deep SC every 4 weeks[a]	40 mg IM every 4 weeks	10 mg SC daily after initial loading dose of 40 mg
Maximal dose	4 mg/week orally	200 mcg SC thrice daily	40 mg IM every 4 weeks[b]	120 mg IM every 7 days	120 mg deep SC every 4 weeks	60 mg IM every 4 weeks	40 mg SC daily[c]
Dosage in hepatic insufficiency	Dosage reduction may be recommended for patients with severe hepatic failure	—	Cirrhosis: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate to severe impairment: starting dose 60 mg every 4 weeks	Moderate impairment: starting dose 20 mg every 4 weeks, maximal dose of 40 mg every 4 weeks. Severe hepatic impairment: avoid use	Discontinue therapy if liver function tests are elevated at least five times the upper limit of normal or transaminase at least three times the upper limit of normal with any increase in serum total bilirubin
Dosage in renal failure	None	Dialysis dependent: adjustment may be necessary; no guidelines available	Dialysis-dependent renal impairment: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate to severe impairment: starting dose, 60 mg every 4 weeks	None	None
Side effects	Nausea, GI cramps, headache, drowsiness, dizziness, fatigue	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, hyperglycemia, fatigue, gallstones, abdominal pain	Headache, fatigue, GI cramps, abnormal liver enzymes, injection site reactions, sweating
Monitoring suggestions	GH, IGF-I, and prolactin concentration 4–6 weeks after each dose change	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	Liver function tests (serum transaminase, total bilirubin, alkaline phosphatase) monthly for 6 months, then biannually for the next year; MRI every 6 months, then yearly if no growth; IGF-I (not GH) after first year, then yearly

[a]In the United States, initiate lanreotide at 90 mg every 28 days for 3 months and then titrate accordingly based on response.

Different labeled dosing guidelines exist for the United Kingdom and Canada.

[b]Product labeling recommends a maximum of 30 mg IM every 4 weeks.

[c]Alternative dose administration protocol of twice a week or once a week has been used.[4]

GH, growth hormone; GI, gastrointestinal; IGF-I, insulin-like growth factor-I; IM, intramuscularly; LAR, long-acting release; MRI, magnetic resonance imaging; SC, subcutaneously; SR, slow-release.

Adapted from AACE Medical Guidelines for Clinical Practice for the diagnosis and treatment of acromegaly. Endocr Pract. 2004;10:213–225 by permission of publisher, American Association of Clinical Endocrinologists (AACE) Corp.

Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with use of somatostatin analogs. Because of the potential adverse effects of the somatostatin analogs, concomitant use with insulin, oral hypoglycemic agents, β-blockers, or calcium channel blockers may require careful dosage adjustment. Somatostatin analogs may also alter the bioavailability and elimination of cyclosporine, and monitoring of cyclosporine serum concentration is necessary.

GH-Receptor Antagonist The advent of a GH-receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered GH-receptor antagonist that blocks the action of GH. Pegvisomant is indicated for treatment of acromegaly in patients who have an inadequate response to surgery or radiation therapy. The effects of pegvisomant work independently of tumor characteristics, somatostatin, and dopamine receptors. To date, pegvisomant is the most effective agent in normalizing IGF-I concentration in acromegaly.[16] Long-term safety and efficacy of pegvisomant (up to 5 years) from an ongoing postmarketing surveillance registry (ACROSTUDY) suggest a reasonable benefit/risk balance.[17] In patients who were relatively unresponsive to other medical or surgical therapies, normal IGF-I concentrations were achieved in 63% of the patients treated with pegvisomant (mean dose of 18 mg/day)[17] and in 69% to 100% of patients treated with pegvisomant and somatostatin analog therapy.[18] Pegvisomant therapy has favorable effects on glucose tolerance and insulin sensitivity and may be considered as a treatment option if patients also present with diabetes as a comorbidity.[6] However, use of pegvisomant is associated with significant dose-dependent increases in GH despite declining IGF-I concentrations. The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH concentration may be indicative of tumor growth. Although the incidence of pituitary tumor enlargement is low (3.2%), careful monitoring with periodic imaging scans is nonetheless warranted.[17] KEY CONCEPT LO 4 Pegvisomant is recommended in patients who have inadequate response to somatostatin analogs, or as an adjuvant for patients who have only a partial response to somatostatin analogs.[4,6,8] Patients at risk of visual damage from large tumors impinging on the optic chiasm may consider alternative pharmacologic therapy.[6]

The long-term use of pegvisomant appears to be well tolerated with a low incidence of adverse effects, including self-limiting injection-site reactions (2.2%) and elevated liver enzymes (2.5%).[17] Although elevations of liver enzymes often are self-limiting and not associated with symptoms,[4,6] hepatotoxicity has been reported in clinical trials, particularly in patients receiving combined pegvisomant and somatostatin analogs.[16] Therefore, serum transaminases, total bilirubin, and alkaline phosphatase should be assessed before initiating therapy and periodically thereafter. Use caution when administering pegvisomant to patients with elevated liver function tests, and therapy should be discontinued in patients who present with clinical signs and symptoms of hepatic injury.

Dopamine Agonists Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist used for acromegaly, bromocriptine, achieved normal IGF-I concentrations in fewer than 10% of patients.[19] The large doses of bromocriptine required to achieve the desired response are often associated with dose-limiting toxicity such as GI discomfort and orthostatic hypotension. Cabergoline is the preferred dopamine agonist for treatment of acromegaly due to its improved tolerability and extended duration of action. Cabergoline can effectively reduce GH and IGF-I concentrations in approximately 30% of patients but its efficacy appears to decrease over time.[6] Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options. KEY CONCEPT LO 4 Cabergoline may be considered for patients with modest elevation of GH and IGF-I concentrations less than two times the upper limit of normal (ULN). It may also be used as adjunctive therapy in patients unresponsive to monotherapy with somatostatin analogs or pegvisomant.[6,8] Although cardiac valvular abnormalities have been observed in patients using higher doses of cabergoline for Parkinson disease, patients receiving treatment for acromegaly do not seem to carry increased risk of cardiac valve disease.[4,6,19,20] Nonetheless, echocardiographic monitoring for potential cardiac abnormalities is reasonable for patients who require prolonged, high-dose (> 2 mg/week) cabergoline therapy.[6]

Combination Therapy For patients who are resistant to monotherapy, combination therapies have been beneficial with improved efficacy and reduced side effects associated with individual medication. Addition of pegvisomant or cabergoline may be considered in patients with inadequate response to somatostatin analog.[6,18]

Radiation Therapy LO 3 Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapy.[6] Treatment involves the use of radiation to destroy rapidly growing tumor cells and often results in a reduction in tumor size. A major complication of radiation therapy is hypopituitarism, requiring lifelong hormone replacement.[4] There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy may take 10 to 20 years before its full effects become evident.[4] Owing to this delay in onset of effectiveness, pharmacologic therapy with a somatostatin analog often is indicated as bridge therapy.[4,6] Men and women who desire to have children should be warned that pituitary irradiation therapy may impair fertility because of subsequent gonadotropin deficiency.[4]

Management of Acromegaly in Pregnancy Due to limited safety data, use of pharmacologic therapy during pregnancy is reserved for tumor and headache control. Substitute long-acting formulation of somatostatin analogs and pegvisomant with short-acting octreotide approximately 2 months prior to conception.[6] Monitoring of IGF-I and GH level during pregnancy is limited in patients with acromegaly because conventional assays are not usually able to distinguish between the variant forms of GH.[6]

▶ *Outcome Evaluation*

- Lifelong biochemical assessment is critical for determining therapeutic outcomes. Although some patients may experience a rapid decline in GH concentrations after surgery, stabilization of IGF-I concentrations usually occurs 3 months after surgery but rarely may be delayed for up to 12 months. Fully assess pituitary function at 12 weeks or later after surgery.[4] Monitor random GH and IGF-I concentrations every 3 to 6 months postoperatively to assess treatment response.[4] Obtain IGF-I concentrations annually in all postsurgical patients to monitor for potential pituitary tumor

recurrence.[4,6] Measure nadir GH level after glucose load in patients with GH greater than 1 ng/mL (mcg/L; 45 pmol/L).[6]

- Assess MRI 12 weeks after surgery and 3 to 6 months after starting medical therapy.[21] Because up to 10% of pituitary tumors may recur within 15 years after surgery, continual postoperative monitoring is recommended.[22]
- For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term somatostatin analogs. Reevaluate IGF-I and GH concentrations at 3-month intervals to determine therapeutic response and inquire about symptoms of gallbladder disease (eg, intermittent pain in the upper right abdomen) during follow-up appointments.[4,6] If normalization of GH and IGF-I concentrations is not fully achieved after 1 year, perform MRI 6 months later and annually thereafter to monitor tumor mass.[4]
- For patients treated with a GH receptor antagonist, GH concentrations are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely elevated GH concentrations. Therefore, monitor IGF-I concentrations to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I concentrations every 6 months.[4,6] Concern for tumor growth requires careful monitoring of tumor size; therefore, perform MRI every 6 months during the first year of therapy. If there is no evidence of growth, then monitor annually thereafter.[6] Because of the potential for hepatotoxicity with pegvisomant therapy, it is mandatory to monitor liver enzymes prior to initiation of therapy, monthly during the first 6 months, then biannually thereafter.[6] More frequent monitoring of liver enzymes is warranted in patients with elevated liver enzymes at baseline.[4] Discontinue pegvisomant if liver function test (LFT) is more than threefold elevated.[6]
- For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I concentrations may take up to 3 months to achieve. After stable control of biochemical markers is achieved with dopamine agonists or somatostatin analogs, monitor GH and IGF-I concentrations annually.[4] Measure GH, prolactin, and IGF-I level 4 to 6 weeks after dose change.[4]
- Monitor GH and IGF-I annually 1 to 3 months after medication withdrawal to assess efficacy of radiation therapy.[6] Assess for hypopituitarism and replace any hormone deficits.[6]

Growth Hormone Deficiency

▶ *Epidemiology and Etiology*

In the United States, GH deficiency affects approximately 50,000 adults, with around 6000 new cases diagnosed annually.[23] Approximately 10,000 to 15,000 children have growth failure owing to GH deficiency. Children may present with GH deficiency at any time during their developmental stages. The evaluation for GH deficiency in a child of short stature should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders, has occurred. Several medications, such as somatostatin analogs, gonadotropin-releasing hormone (GnRH) agonists, methoxamine, phentolamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamine derivatives, may induce GH insufficiency.[24]

▶ *Pathophysiology*

GH deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus–pituitary axis. GH deficiency may be an isolated condition or occasionally be accompanied by another endocrine disorder

Patient Encounter 1, Part 2

PE:

VS: BP 158/100 mm Hg, P 104 beats/min, RR 18 breaths/min, T 37°C (98.6°F), Ht 168 cm (5'6"), Wt 82 kg (180 lbs), BMI 29.1 kg/m^2

ROS: (+) HA, (+) deepening of voice

HEENT: Visual field defects; head is elongated with bony prominence of the forehead, nose, and lower jaw; large fleshy nose

CV: RRR, normal S_1 and S_2; no murmurs, rubs, or gallops, (–) chest pain, palpitation, orthopnea, and leg swelling

Pulm: (–) SOB, (–) cough

GI: (–) Nausea, vomiting, and abdominal pain

Abd: Soft, nontender, nondistended; (+) bowel sounds, (–) hepatosplenomegaly

Neuro: A & O × 3. Normal reflexes

Psychiatric: Depressed mood. Spacy, sweet, and needs extra help understanding instructions.

Available Labs: Electrolytes and renal function are within normal limits. Fasting blood glucose concentration is 268 mg/dL (14.9 mmol/L), glycated hemoglobin A_{1c} ($HgbA_{1c}$) is 10.4% (0.104; 90 mmol/mol), (+) microalbuminuria. GH concentration 2 hours after an OGTT is 83.6 ng/mL (mcg/L; 3779 pmol/L). Elevated IGF-I concentration at 998 ng/mL (mcg/L; 131 nmol/L). TSH is slightly low at 0.40 µU/mL (mU/L) and free T_4 (FT_4) is within normal range at 1.1 ng/dL (14.2 pmol/L).

MRI: (+) 9 mm benign pituitary adenoma extending toward the optic chiasm; no invasion into the cavernous sinus

Given that the patient doesn't want surgery, what pharmacologic treatment options are available?

Since the patient is uninsured without a source of income, what factors need to be considered when choosing a pharmacologic treatment option?

Provide monitoring parameters to assess efficacy and safety to the patient starting on pegvisomant.

Patient Care Process: Acromegaly

Collect Information:

- Review the available diagnostic data to determine pituitary tumor size and location.
- Perform complete medication history. Identify allergies to medications and other substances.
- Determine treatment options the patient has tried in the past.
- Review the medical history, relevant laboratory tests, and physical assessment findings.
- Speak with patient and review records to identify signs and symptoms of acromegaly, preferences and beliefs, health goals, socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms and biochemical disease markers to determine the severity of acromegaly.
- Determine if the patient has a coexisting prolactin secreting tumor and impact of the tumor on the optic tract.
- Assess presence of acromegaly complications. Identify any significant comorbidities associated with acromegaly that require immediate treatment or early diagnosis.
- Evaluate patient for presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
- Assess if the patient has any contraindications or allergies to therapies (see Table 46–2).

Develop a Care Plan:

- If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors (see Figure 46–4).
- Determine if selected drug doses are optimal (see Table 46–2). Consider if the patient's therapy requires any dose adjustments.

Implement the Care Plan:

- Discuss potential effectiveness and disadvantages of existing treatment options.
- Address any patient concerns about acromegaly, its management, and possible complications.
- Determine whether the patient has insurance coverage and preferred treatments covered.
- Educate patient about changes in drug therapy, proper medication administration techniques, potential new adverse effects, and how to manage and report adverse effects that occur.
- Discuss importance of medication adherence and how to reduce the modifiable cardiovascular and metabolic risk factors.
- Use motivational interviewing strategies and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Monitor patient's biochemical markers (GH and IGF-I concentrations) and complications to surgical intervention.
- Review adherence to treatment plan using multiple sources of information.
- Review physical examination, lab tests, and results of other diagnostic tests to assess changes in clinical status and complications.
- Evaluate safety and efficacy of pharmacologic therapy and the degree of disease control.
- Determine whether the patient is experiencing any adverse reactions or drug interactions.
- Routinely assess acromegaly complications; include blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy x-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function, and sleep apnea.

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Children[7,23]

LOS

General

The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and sex.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

Laboratory Tests

- Patients will exhibit a peak GH concentration of less than 10 ng/mL (mcg/L; 452 pmol/L) after a GH stimulation test.
- Reduced IGF-I concentration also may be present.
- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia and hypothyroidism also may be noted.

Other Diagnostic Tests

- Perform MRI or computed tomography (CT) scan of the hypothalamic–pituitary region to detect structural or developmental anomaly.
- Perform radiography of the left wrist and hand for children older than 1 year of age to estimate bone age (knee and ankle for children younger than 1 year of age).

Adapted from Jordan JK, Sheehan AH, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 10th ed. New York: McGraw-Hill; 2017.

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Adults[25,28,32,34]

LO 5

General

The patient likely will have a history of childhood-onset GH deficiency; hypothalamic or pituitary disorder; or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

Symptoms

- Reduced strength and exercise capacity
- Defective sweating
- Psychological problems
- Low self-esteem
- Depression
- Fatigue or listlessness
- Sleep disturbance
- Anxiety
- Social isolation
- Emotional lability and impaired self-control
- Poor marital and socioeconomic performance

Signs

- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass
- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function as evidenced by abnormal echocardiography or stress test results

Laboratory Tests

- Patients will exhibit a peak GH concentration of less than 5.1 ng/mL (mcg/L; 231 pmol/L) after a GH stimulation test. ITT is the gold standard stimulation test. Low or low-normal IGF-I concentration also may be present. Presence of three or more pituitary hormone deficiencies with a low IGF-I concentration does not require further stimulation test.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

(eg, panhypopituitarism). Because GH is frequently undetectable with random sampling, a stimulation or provocative test usually is performed to confirm the diagnosis. The gold standard for diagnosis of adults with GH deficiency is the insulin tolerance test (ITT), with glucagon as an alternative if GHRH is unavailable.[25] Adults exhibiting a peak GH concentration of less than 5.1 ng/mL (mcg/L; 230 pmol/L) after two ITT simulation tests would warrant treatment.[25] In prepubertal children, measurement of IGF-I concentrations may be useful in evaluating GH deficiency.[26] The diagnosis of GH deficiency in children, often without the need for provocative testing, is established if the child exhibits all three conditions: (1) auxological criteria, (2) hypothalamic-pituitary defect, and (3) deficiency of at least one additional pituitary hormone.[27] Failure of linear growth is an almost universal presenting feature of childhood GH deficiency.

Childhood GH deficiency may or may not continue into adulthood. Most adults with GH deficiency have overt pituitary disease and present with nonspecific clinical disorders distinct from pediatric GH deficiency. Adult GH deficiency presumably is associated with an increased risk of death from cardiovascular diseases.[25]

▶ *Treatment*

Desired Outcomes The goal of treatment for GH deficiency is to correct associated clinical symptoms.[24] In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, the goal is to achieve normal physiologic GH concentrations in an attempt to reverse metabolic, functional, and psychological abnormalities.[25,28]

LO 5

Pharmacologic Therapy KEY CONCEPT Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults. It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism (see Table 46–1).[2] GH therapy requires subcutaneous or intramuscular administrations. Because two-thirds of GH secretion normally occurs during sleep, it is recommended to administer GH injections in the evening.[29] Many preparations of synthetic GH (somatropin) are available with a variety of injection devices to make administration more appealing and easier. Zomacton is only approved for use in children, and other somatropin products such as Humatrope, Norditropin, Genotropin, Omnitrope, and Saizen are approved in both children and adults.

KEY CONCEPT Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines. GH secretion decreases with age; therefore, older adults with GH deficiency often require substantially lower replacement doses than younger individuals. The optimal therapeutic approach is to initiate GH therapy at lower doses and titrate according to clinical response, adverse effects, and IGF-I concentrations.[30,31] Table 46–3 lists the recommended GH replacement doses for children and adults.[25,27,30] Conventional weight-based regimens are not recommended in adults due to lack of evidence supporting higher dosages in heavier individuals and greater potential for adverse effects.[25,28,32] For elderly patients, lower GH replacement doses often are adequate because of increased GH sensitivity.[28,32] Women with intact hypothalamic–pituitary–gonadal axis or on estrogen therapy (or oral contraceptives) generally require a higher GH dose than men due to decreased GH concentrations associated with estrogen.[30,32] Carefully monitor patients requiring replacement therapy with estrogens, thyroid hormones, or glucocorticoids because of potential interactions with GH

LO 5

LO 5

Table 46–3

Dose Recommendation for Growth Hormone Deficiency in Children and Adults[25,27,30]

	Growth Hormone Replacement Dose	Dose Titration
Children[27]	**Starting Dose**	• Evaluate every 3–6 months based on height and height velocity. • Monitor IGF-I and IGFBP-3 yearly. • Monitor TSH and T_4 for hypothyroidism. • Reduce dose if serum IGF-I concentration is substantially above normal after 2 years of therapy.
Prepubertal children	22–35 mcg/kg/day with individualization on subsequent dosing	
During puberty	Individualized dosing	• Against routine increase in dose to 700 mcg/kg/week.
Adults[25,30]	**Starting Dose**	• Increase dose by 0.1–0.2 mg/day based on clinical response, serum IGF-I concentrations, and side effects at 1- to 2-month intervals. Longer time intervals and smaller dose titration may be necessary in older adults.
Age < 30 years	0.4–0.5 mg/day[a]	
Age 30–60 years	0.2–0.3 mg/day	
Age > 60 years	0.1–0.2 mg/day	
Diabetes or glucose intolerance (overweight, obese, or history of gestational diabetes)	0.1–0.2 mg/day	
Hepatic impairment	—	• Clearance may be reduced in patients with severe hepatic dysfunction; specific dosing suggestions are not available.
Renal impairment	—	• Patients with chronic renal failure tend to have decreased clearance; specific dosing suggestions are not available.

[a]Might require a higher dose for patients transitioning from pediatric treatment.

IGFBP-3, insulin-like growth factor-bind protein 3; IGF-I, insulin-like growth factor-I; T_4, thyroxine; TSH, thyroid-stimulating hormone.

therapy.[28] The potency of GH products is generally expressed as 3 international units (IU or mU) per 1 milligram of protein.[25] Selection of an injection device depends on patient preference due to lack of differences in clinical outcomes among the various injection systems.[30]

Evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.[23] Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated to normalize body composition and metabolic process; improve cardiac risk profile, bone mineral density, quality of life, and psychological well-being; and increase muscle strength and exercise capacity.[25,32] However, evidences for reduction in cardiovascular risks and mortality are still lacking with long-term use of GH replacement therapy.[33]

Practitioners should begin GH therapy as soon as possible to optimize long-term growth, especially for young children in whom GH deficiency is complicated by fasting hypoglycemia.[23] Selection of the optimal GH replacement dose will need to be individualized depending on response, financial resources, and product availability. Although the appropriate time to discontinue therapy remains controversial in childhood GH deficiency, it is reasonable to continue GH replacement until the child has reached satisfactory adult height, achieved documented epiphyseal closure, or failed to respond to therapy.[23] It is recommended that the GH dose in pediatric patients does not continue beyond achievement of a growth velocity below 2 to 2.5 cm/year.[27] Management of the transition between pediatric and adult GH replacement remains a challenge because limited data are available.[27] The secretion of GH during adolescence is normally lower than during puberty but higher than during adulthood. Therefore, for patients in a transition phase who may be restarting GH therapy, the initial dose for an adolescent is approximately the average of the pediatric dose required for growth and the adult dose.[30] Starting GH therapy at a low dose and gradually titrating upward may decrease the potential for adverse effects. The optimal duration of treatment with GH therapy remains unclear, but lifelong therapy may be required. However, GH replacement should be discontinued if therapeutic benefit is not achieved after 2 years of therapy.[30]

In both children and adults, treatment with GH may mask underlying central hypothyroidism and adrenal insufficiency.[35] Treatment with GH also may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Adults are more susceptible to dose-related adverse effects of GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, which may necessitate dose reductions in up to 40% of adults.

Children treated with GH replacement therapy rarely experience significant adverse effects. Benign increases in intracranial pressure related to GH therapy may manifest as headaches, visual changes, or altered concentrations of consciousness. This condition is generally reversible upon discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence. Presently, there is no compelling evidence that GH replacement therapy is associated with an increased risk of cancers in children without prior history or risk factors.[36,37] It remains unclear if the risk is affected in high-risk patients. Survivors of childhood cancer may have an increased risk of abnormal growth of tissues with GH treatment but it does not appear to increase the risk of cancer reoccurrence.[36] The risk of cancer was unrelated to duration or cumulative dose of GH treatment, but the cancer mortality risk increases significantly with increasing daily dose of GH in previous cancer survivors.[37]

Nevertheless, GH replacement therapy is contraindicated in all patients with active malignancy.[30] In children with a history of malignancies, it would be prudent to wait for a 1-year tumor-free period (5 years for adults) before initiating GH therapy.[23,36] Any patients treated for a prior malignancy should be monitored carefully for tumor recurrence.[23] Because deaths have been reported with use of GH in children with **Prader-Willi syndrome** who are severely obese or suffer from respiratory impairments, use of GH is contraindicated in these individuals.

Evidence from the long-term surveillance study, Safety and Appropriateness of Growth hormone treatments in Europe (SAGhE), remains inconclusive regarding GH therapy and its risk of increased morbidity.[33] Therefore, further surveillance monitoring is warranted.

▶ *Outcome Evaluation*

LO 6

- Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.[23,38] Every effort should be made to maximize height before the onset of puberty. After final adult height is reached and GH is discontinued for at least 1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.[25,30,38]
- Although GH and IGF-I concentrations do not always correlate with growth response, measure IGF-I concentrations yearly to assess adherence to therapy and patient response. If the IGF-I concentrations are substantially above the normal range 2 years after GH replacement therapy, the dose should be reduced.[38] IGF-I concentration may be used as a guide to gradually reduce replacement dose after epiphyseal closure.
- Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.[23,38]
- In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose. Measure IGF-I serum concentrations 1 to 2 months during dose titration and semiannually thereafter.[25] If therapy is not observed after at least 1 year of treatment, therapy may be discontinued.[25,28,30]
- Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.
- Evaluate psychological well-being.
- Assess patients' bone mineral density every 2 to 3 years.[30]
- When maintenance therapy is achieved, assess body composition (body mass index [BMI], waist circumference, waist-to-hip ratio), metabolic status (fasting glucose concentration, free thyroxine serum, hemoglobin A_{1c}), cardiac risk factors (eg, fasting lipid profile), hypothalamic–pituitary–adrenal axis function (eg, morning serum cortisol response to ACTH stimulation), and testosterone concentrations at 6- to 12-month intervals.[28,30]

PROLACTIN

Prolactin is an essential hormone for normal production of breast milk after childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus–pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal conditions, secretion of prolactin is predominantly under inhibitory control by dopamine. Increases of hypothalamic thyrotropin-releasing hormone in primary hypothyroidism can stimulate the release of prolactin.

Patient Care Process: GH Deficiency in Children

Collect Information:

- Obtain a thorough history and physical examination (weight and height) that may indicate the possible presence of GH deficiency.
- Obtain GH and IGF-I concentrations.
- Review imaging tests of the hypothalamic–pituitary region to detect any anomalies.
- Speak with caregivers to identify signs and symptoms of GH deficiency, preferences and beliefs, health goals, socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the child's growth characteristics and compare the physical height with a population standard (eg, Centers for Disease Control and Prevention Growth Charts).
- Exclude other identifiable causes of growth failure.
- Assess presence of other pituitary hormone deficiency.
- Assess risk factor for development of malignancy (history of cancer or active cancer).
- Assess if the patient has any contraindications, allergies, or drug interactions to GH therapy.

Develop a Care Plan:

- Calculate the appropriate GH therapy at the lower dosing range based on patient weight (see Table 46–3).

Implement the Care Plan:

- Initiate GH therapy based on patient preference (see Table 46–3).
- Discuss with caregivers and child the potential effectiveness and disadvantages of existing GH treatment options.
- Address any patient concerns about long-term complications of GH deficiency, its management, and possible adverse effects of GH therapy.
- Educate regarding potential for lifelong replacement therapy.
- Use motivational interviewing strategies and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Review child's medication adherence.
- Monitor response (increase in height and change in height velocity) and adverse effects of GH therapy (intracranial hypertension, slipped capital femoral epiphysis, and scoliosis progression). Individualized dose based on child's response.
- Continue GH therapy until child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
- Review and retest the child using adult GH deficiency diagnostic criteria when the child reaches final adult height.

Patient Care Process: GH Deficiency in Adults

Collect Information:

- Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency, history of childhood GH deficiency, or presence of other pituitary hormone deficiencies.
- Obtain GH and IGF-I concentrations after appropriate provocative testing.
- Review imaging tests of the hypothalamic–pituitary region to detect any anomalies.
- Perform complete medication history. Identify allergies to medications and other substances.
- Speak with patient to identify sign and symptoms of GH deficiency, preferences and beliefs, health goals, socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms to determine the severity of GH deficiency.
- Assess presence of other pituitary hormone deficiency.
- Assess presence of metabolic abnormalities and cardiovascular and fracture risks.
- Assess risk factor for development of malignancy (history of cancer or active cancer).
- Assess if the patient has any contraindications, allergies, or drug interactions to GH therapy.

Develop a Care Plan:

- Determine if GH therapy is indicated. Initiate the appropriate GH therapy at the lower dosing range based on patient characteristics (see Table 46–3).

Implement the Care Plan:

- Initiate GH therapy based on patient preference and characteristics (see Table 46–3).
- Discuss with patient the potential effectiveness and disadvantages of existing GH treatment options.
- Address any patient concerns about long-term complications of GH deficiency, its management, and possible adverse effects of GH therapy.
- Discuss with patient how to reduce the modifiable cardiovascular, metabolic, and fracture risk factors.
- Educate regarding potential for lifelong replacement therapy.
- Use motivational interviewing strategies and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Review medication adherence.
- Assess the efficacy and adverse effects of GH therapy and consider if the patient's therapy requires any dose adjustments based on IGF-I concentration, patient response, and adverse effects.
- Monitor for improvement of metabolic, cardiovascular, bone mineral density, mood, and body composition parameters to assess response to GH therapy.

Hyperprolactinemia

▶ *Epidemiology and Etiology*

LO 7

Hyperprolactinemia affects women of reproductive age more than men, and the estimated prevalence in women treated with hyperprolactinemia is 90 cases per 100,000 person years.[39] The etiologies of hyperprolactinemia are presented in Table 46–4.[7,24,39] Any medications that antagonize dopamine or stimulate prolactin release can induce hyperprolactinemia.[7,24] Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are the most common pituitary tumors. They are classified as microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or larger in diameter.[39] In general, microprolactinomas rarely increase in size, but macroprolactinomas have the potential to enlarge and invade the surrounding tissues.[40]

▶ *Pathophysiology*

LO 8

Hyperprolactinemia is a condition of elevated serum prolactin. It is the most common endocrine disorder of the hypothalamic–pituitary axis. High prolactin concentrations inhibit the release of gonadotropin-releasing hormone by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary (see Figure 46–1). High prolactin concentrations result in reduced gonadal hormone concentrations, often leading to reproductive dysfunction and galactorrhea (inappropriate breast milk production).

In combination with clinical symptoms, one or more serum prolactin concentrations greater than 25 ng/mL (mcg/L; 1087 pmol/L) will confirm the diagnosis of hyperprolactinemia in women.[39] A number of physiologic factors such as eating, exercise, and stress can transiently elevate prolactin concentrations.[7] If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin concentration.[7,24,39] Although medication-induced hyperprolactinemia is typically associated with prolactin concentrations of 25 to 100 ng/mL (mcg/L; 1087–4348 pmol/L), metoclopramide, risperidone, and phenothiazines have been associated with concentrations greater than 200 ng/mL (mcg/L; 8696 pmol/L). However, prolactin concentrations greater than 500 ng/mL (mcg/L; 21739 pmol/L) are almost always associated with the presence of a macroprolactinoma.[39]

▶ *Treatment*

Desired Outcomes Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are as follows[39]:

- Normalize prolactin concentration
- Restore normal gonadal function and fertility
- Prevent development of osteoporosis
- If a pituitary tumor is present:
  - Ablate or reduce tumor size to relieve tumor mass effect
  - Preserve normal pituitary function
  - Prevent progression of pituitary tumor or hypothalamic disease

General Approaches to Treatment Management of drug-induced hyperprolactinemia is to discontinue the offending

LO 7

Table 46–4

Causes of Hyperprolactinemia[7,24,39]

Physiologic Causes
Pregnancy
Stress (including exercise and hypoglycemia)
Breast stimulation
Breastfeeding
Coitus
Sleep
Meal
Increased prolactin production
Ovarian: Polycystic Ovarian Syndrome
Oophorectomy (removal of an ovary)
Pituitary tumors
Adenomas
Microprolactinoma (< 10 mm diameter)
Macroprolactinoma (≥ 10 mm diameter)
Hypothalamic stalk interruption (prevent dopamine from reaching the pituitary)
Hypophysitis (inflammation)
Ectopic tumors
Hypothalamic Prolactin Stimulation
Primary hypothyroidism
Adrenal insufficiency
Reduced Prolactin Elimination
Chronic renal failure
Hepatic cirrhosis
Neurogenic Causes
Chest wall injury (eg, surgery, herpes zoster)
Spinal cord lesions
Abnormal Molecules
Macroprolactinemia
Medications
Dopamine antagonists: antipsychotics,[a] phenothiazines, metoclopramide, domperidone
Dopamine-depleting agents: reserpine, α-methyldopa
Prolactin stimulators: serotonin reuptake inhibitors, dexfenfluramine, estrogens, progestins, antiandrogens, gonadotropin-releasing hormone analogs, benzodiazepines, tricyclic antidepressants, monoamine oxidase inhibitors, protease inhibitors, histamine$_2$ receptor antagonists
Other: isoniazid, cocaine, opioids, verapamil
Seizures
Idiopathic (Unknown)

[a]Atypicals (olanzapine and clozapine) other than risperidone may cause an early but transient elevation in prolactin.

Data from Jordan JK, Sheehan AH, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 10th ed. New York: McGraw-Hill; 2017.

agent, if clinically feasible, and replace it with an appropriate alternative that does not cause hyperprolactinemia.[39] When the offending agent cannot be discontinued or dosage cannot be reduced, cautious use of hormone replacement, oral contraceptives, pharmacologic treatment for osteoporosis, aripiprazole, or dopamine agonists may be considered depending on the patient's clinical circumstances.[41] Treatment options for the management of hyperprolactinemia include: (a) clinical observation, (b) pharmacologic therapy with dopamine agonists, (c) transsphenoidal pituitary adenomectomy, and (d) radiation therapy. Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.[39] KEY CONCEPT

LO 9

Dopamine agonists are the first-line treatment of choice for all patients with symptomatic hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.[39] However, in patients with underlying psychiatric symptoms, use of dopamine agonists in addition to an antipsychotic therapy may exacerbate the underlying psychosis and should be used with caution in consultation with a mental health clinician.[41]

Pharmacologic Therapy Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for management of hyperprolactinemia. Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin concentration, restoring gonadal function, decreasing tumor size, and improving visual fields.[39,42] Patients with macroprolactinomas generally require a higher dose to normalize prolactin concentrations compared with patients with microprolactinomas.[43]

LO 9

Two dopamine agonists—bromocriptine and cabergoline—are used for the management of hyperprolactinemia (Table 46–5).[44] Because these two dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P-450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors, azole antifungals, and some macrolide antibiotics. Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders.

Bromocriptine Bromocriptine directly binds to the D_2 dopamine receptors. It normalizes prolactin concentration in 68% of patients and reduces tumor size in 62% of patients.[42] Treatment with bromocriptine may also restore menses and fertility in women and improve testosterone secretion, sperm count, and erectile function in men. It may also improve visual field defects associated with macroadenomas.[42] Adverse effects such as nausea, dizziness, and orthostatic hypotension often limit 5% to 10% of patients from continuing treatment. To reduce risk of adverse effects and improve patient adherence, bromocriptine may be initiated at bedtime or be administered vaginally (2.5 mg/day) at low dose.[40,45]

Cabergoline Cabergoline has a higher affinity for D_2 dopamine receptors than bromocriptine and possesses a long half-life, allowing for once- or twice-weekly administration. Cabergoline appears to be better tolerated than bromocriptine, and may be more effective in normalizing prolactin concentrations and restoring menses.[46] It is also effective in treating hyperprolactinemia in patients who are resistant to or intolerant of bromocriptine and in men and women with microprolactinomas and macroprolactinomas.[39,46] Given its favorable safety and efficacy profile and ease of administration, cabergoline has replaced bromocriptine as first-line therapy for the management of hyperprolactinemia.[39] Withdrawal of pergolide from the US market due to increased risk for valvular heart disease raised concerns about the safety of cabergoline. However, to date, cabergoline use in patients with hyperprolactinemia[47] or prolactinoma[48] has not been associated with clinically significant valvular heart disease.

Clinical Presentation and Diagnosis of Hyperprolactinemia[7,39]

LO 8

General

Hyperprolactinemia most commonly affects women of reproductive age and is very rare in men.

Signs and Symptoms

Premenopausal women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Clinical presentation is associated with the degree of prolactin elevation:
  - Prolactin greater than 100 ng/mL (mcg/L; 4348 pmol/L): hypogonadism, galactorrhea, and amenorrhea
  - Prolactin 51 to 75 ng/mL (mcg/L; 2217–3261 pmol/L): oligomenorrhea (infrequent menstruation)
  - Prolactin 31 to 50 ng/mL (mcg/L; 1348–2174 pmol/L): decreased libido and infertility
- Increased body weight may be associated with a prolactin-secreting pituitary tumor.
- The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
- Excessive hair growth (hirsutism) and acne also may be present owing to relative androgen excess compared with low estrogen concentrations.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotence, decreased sperm production, infertility, gynecomastia, and rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

Laboratory Tests

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (mcg/L; 870 pmol/L) in men or 25 ng/mL (mcg/L; 1087 pmol/L) in women with at least three measurements.
- Obtain β-human chorionic gonadotropin (β-hCG) concentration to exclude pregnancy.
- Obtain TSH concentration to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

Other Diagnostic Tests

- Perform MRI to locate the tumor, exclude a pseudo-prolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

Additional Clinical Sequelae

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Adapted, with permission, from Jordan JK, Sheehan AH, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 10th ed. New York: McGraw-Hill; 2017.

LO 9

Nonpharmacologic Therapy In a small number of patients who have failed or are intolerant of dopamine agonists, transsphenoidal adenomectomy may be necessary.[39] Surgical treatment is also considered in patients with nonprolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.[43] Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications.[42] Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.[39] However, normalization of prolactin concentration with radiation therapy may take 20 years to show full benefit, and

Table 46–5

Comparison of Dopamine Agonists for Treatment of Hyperprolactemia[44]

	Bromocriptine (Parlodel)	Cabergoline
Starting dose	0.625–1.25 mg/day at bedtime	0.5 mg/week or 0.25 mg twice/week
Titrating dose	1.25 mg increments at 1-week interval	0.25 mg twice weekly increment, up to 1 mg twice weekly every 2 to 4 months
Usually effective dose	2.5–15 mg/day	1–2 mg/week
Maximal dose	20 mg/day	4.5 mg/week
Dosing frequency	Two to three divided doses per day	Once or twice weekly
Dosage in hepatic insufficiency	May be required in acute hepatitis or cirrhosis; no guidelines are available	Dose reductions may be recommended for patients with severe hepatic failure (Child-Pugh scores of 10 or higher)
Dosage in renal failure	None	None
Adverse effects	Dizziness, headache, syncope, nausea, vomiting, gastrointestinal cramps, orthostatic hypotension, nasal congestion	Similar but orthostatic hypotension less common
Cost	Moderately expensive	More expensive

Patient Encounter 2, Part 1

A 27-year-old woman presented to primary care clinic 8 months ago with complaints of infrequent menstruation and infertility. Since she started cabergoline for hyperprolactinemia 6 months ago, she was excited to see return of her regular menses for several months until she realized her last menstrual period was 5 weeks ago.

PMH: Depression for 5 years

FM: Mother has depression, post-traumatic stress disorder, hypertension; father with high cholesterol and coronary artery disease.

SH: Married, dental assistant; sexually active (occasional use of condoms)

Meds: Prenatal vitamin one tablet daily; cabergoline 1-mg tablet weekly; naproxen 220 mg one to two tablets as needed for menstrual cramps and headache

ROS: Negative, other than in history of present illness

PE:

HEENT: Ophthalmic examination reveals normal visual acuity and fields. (–) goiter

VS: BP 128/78 mm Hg, P 76 beats/min, RR 19 breaths/min, T 37.1°C (98.8°F)

CV: RRR, normal S1, S2; no murmurs, rubs, or gallops

Breasts: (–) Galactorrhea with no abnormalities

Abd: Soft, nontender, nondistended; (+) bowel sounds; (–) hepatosplenomegaly

Rectal: Heme (–) stool

Prolactin: Elevated prolactin at 79 ng/mL (mcg/L; 3434 pmol/L) 7 months ago; prolactin at 30 ng/mL (mcg/L; 1304 pmol/L) today.

Imaging: MRI revealed a 4-mm pituitary tumor (7 months ago)

What signs and symptoms were suggestive of hyperprolactinemia in this patient?

What other tests would also be appropriate to obtain based on patient's history and diagnosis?

radiation-induced hypopituitarism may require lifelong hormone replacement.

Management of Hyperprolactinemia in Pregnancy Most women with hyperprolactinemia require dopamine agonist therapy to achieve regular ovulatory cycles and pregnancy. Because restoration of the ovulatory cycle may occur immediately after initiation of therapy, it is necessary to caution patients regarding their potential to become pregnant and ensure adequate contraception when beginning therapy.[43]

Overall, there is reassuring evidence that bromocriptine use during pregnancy does not increase fetal malformations, spontaneous abortions, preterm deliveries, or multiple births.[39,49] Although experience during pregnancy is limited, cabergoline does not appear to be teratogenic.[44] Despite these data, continuation of dopamine agonists during pregnancy is generally not recommended. KEY CONCEPT Women who become pregnant while taking a dopamine agonist should discontinue treatment to minimize fetal exposure.[39]

LO 9

Patient Encounter 2, Part 2

Labs: Electrolytes, renal and thyroid functions are within normal limits.

β-human chorionic gonadotropin (β-hCG): 7800 mIU/mL (U/L)

Given this additional information, what nonpharmacologic and pharmacologic treatment options are available for the patient at this time?

Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry about a 31% risk of tumor enlargement and potentially can jeopardize vision.[39] Therefore, monitor female patients with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. If tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater experience with this drug during pregnancy.[39]

▶ *Outcome Evaluation*

- Assess patients for tolerability to dopamine agonists.
- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months to assess therapeutic efficacy and assist with dose titration.
- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy.[39]
- When the prolactin concentration is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin concentration every 6 to 12 months.
- If the prolactin concentration is well controlled with dopamine agonist therapy for 2 years with significant tumor reduction, gradually taper therapy to the lowest effective dose or consider discontinuing therapy.[39] Check prolactin concentration after each dose reduction.
- If the prolactin concentrations remain unchanged for 1 year at the reduced dose, dopamine agonist therapy may be discontinued.
- In patients with macroprolactinomas, monitor visual field at baseline and repeat the test 1 month after initiation of a dopamine agonist.
- Repeat the MRI in 1 year after initiating therapy or in 3 months in patient with macroprolactinoma or if an increase in symptoms or rise in prolactin concentration suggests the presence of tumor growth.[39]
- Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

ACKNOWLEDGMENTS

The authors and editors wish to acknowledge and thank Dr. Frank Pucino and Dr. Karim Calis, co-authors of this chapter in the first, second, third, and fourth editions of this book.

Patient Care Process: Hyperprolactinemia

Collect Information:

- Review the available diagnostic data to determine tumor size and location.
- Perform complete medication history. Identify allergies to medications and other substances.
- Review the medical history, relevant laboratory tests, and physical assessment findings.
- Speak with patient and review records to identify signs and symptoms of hyperprolactinemia, preferences and beliefs, health goals, socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms and prolactin level to determine the severity of hyperprolactinemia.
- Exclude other common causes of hyperprolactinemia (Table 46–4).
- Review patient's medication list to exclude medication-induced hyperprolactinemia (Table 46–4).
- Determine if the patient has a coexisting prolactin secreting tumor and impact of the tumor.
- Assess presence of hyperprolactinemia complications.
- Assess if the patient has any contraindications, allergies, or drug interactions to dopamine agonists.
- Determine the patient's plan regarding pregnancy because this influences treatment selection.

Develop a Care Plan:

- Initiate the appropriate dopamine agonist at the lowest effective dose for management of hyperprolactinemia (see Table 46–5). Consider if the patient's therapy requires any dose adjustments.

Implement the Care Plan:

- Discuss potential effectiveness and disadvantages of existing treatment options.
- Address any patient concerns about long-term complications of hyperprolactinemia, its management, and possible adverse effects of existing dopamine agonists.
- Educate patient about risks associated with hyperprolactinemia.
- Use motivational interviewing and coaching strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Evaluate safety and efficacy of dopamine agonist. When appropriate, be sure to make dose adjustments (Table 46–5).
- Monitor patient adherence to treatment plan using multiple sources of information.
- Monitor patient prolactin level. If the prolactin concentration remains normal for 2 years, reassess the need to continue treatment.
- Consider bone mineral density tests in patient with long-term hypogonadism.

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ACTH	Adrenocorticotropic hormone or corticotropin
ADH	Antidiuretic hormone or vasopressin
β-hCG	β-Human chorionic gonadotropin
BMI	Body mass index
CRH	Corticotropin-releasing hormone
CT	Computed tomography
CYP3A4	Cytochrome P-450 subfamily IIIA polypeptide 4
DEXA	Dual-energy x-ray absorptiometry
FSH	Follicle-stimulating hormone
FT_4	Free T_4
GABA	γ-Aminobutyric acid
GH	Growth hormone or somatotropin
GHIH	Growth hormone–inhibiting hormone or somatostatin
GHRH	Growth hormone–releasing hormone
GI	Gastrointestinal
GnRH	Gonadotropin-releasing hormone
$HgbA_{1c}$	Glycated hemoglobin A_{1c}
IGF	Insulin-like growth factor
IGF-I	Insulin-like growth factor-I
IGF-II	Insulin-like growth factor-II
IGFBP-3	Insulin-like growth factor-binding protein-3
IM	Intramuscular
ITT	Insulin tolerance test
LAR	Long-acting release
LFT	Liver function test
LH	Luteinizing hormone
LHRH	Luteinizing hormone–releasing hormone
MRI	Magnetic resonance imaging
MSH	Melanocyte-stimulating hormone
OGTT	Oral glucose tolerance test
PRH	Prolactin-releasing hormone
SAGhE	Safety and Appropriateness of Growth hormone treatments in Europe
SC	Subcutaneous
SR	Slow release
SRL	Somatostatin receptor ligan
T_3	Triiodothyronine
T_4	Thyroxine
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone or thyrotropin
ULN	Upper limit of normal

47 Pregnancy and Lactation: Therapeutic Considerations

Ema Ferreira, Évelyne Rey, Caroline Morin, Katherine Theriault, and Marie-Lou Tardif

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the principles of embryology and teratology.
2. Identify known teratogens and drugs of concern during lactation.
3. Compare the main sources of drug information relevant to pregnancy and lactation.
4. Evaluate and communicate the risks of a drug when taken during pregnancy or lactation.
5. Apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.
6. Recommend the appropriate dose of folic acid to prevent congenital anomalies.
7. Describe physiologic changes during pregnancy and their impact on pharmacokinetics.
8. Choose an appropriate treatment for common conditions in a pregnant or lactating woman.

INTRODUCTION

This chapter will provide general principles to understand the scientific data on medication use during pregnancy and lactation, to choose appropriate treatment and adjust their dosage for a variety of conditions prevalent during pregnancy, and to counsel women in a helpful and supportive way.

EPIDEMIOLOGY AND ETIOLOGY

Background Risks of Anomalies in Pregnancy

Table 47–1 describes the baseline risks of congenital anomalies and some obstetrical complications. This information is essential to evaluate risks associated with medication use and to counsel pregnant women.

Causes of Congenital Anomalies

Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small. Medications are associated with less than 1% of all congenital anomalies, although they may also interact with genetic factors.[3,4] It is important to evaluate and optimize drug use in pregnant women and women planning a pregnancy.

Other causes of anomalies include genetic causes in 25% of cases (inherited disease, gene mutation, chromosomal disorder), maternal infections (1%), maternal conditions (1%–3%; eg, pregestational diabetes, obesity), multifactorial heredity (23%–50%), and unknown causes (34%–43%).[3] Theoretical concerns regarding paternal exposure to genotoxic medication are reported, but currently no medication taken by a man has been proven teratogenic.[4]

PATHOPHYSIOLOGY

Age of Pregnancy

LO 1

The age of pregnancy can be defined as gestational or postconceptional age (PCA).[4] Gestational age (GA) is the term used in clinical practice. It is calculated from the first day of the last menstruation or by ultrasound dating.

PCA, calculated from the day of conception, is 14 days shorter than GA if the menstrual cycle is 28 days. Some references in

Table 47–1

Occurrence of Some Obstetrical Complications and Risk of Congenital Anomalies in the General Population[1-3]

	Risk of Occurrence in Population (%)
Spontaneous abortion/miscarriage (pregnancy loss that occurs after the pregnancy is known and before 20 weeks of GA; risk increases with higher maternal age)	10–15
Congenital anomalies (percentage of live births):	
• Minor malformations	14
• Major malformations at birth	3
• Major malformations at 2 years old	6
Preterm birth (< 37 completed weeks gestation)[a]	9.6
Low birth weight (< 2500 g)[a]	8.0

[a]United States data from 2014.

GA, gestational age.

Table 47–2

Phases of Embryonic and Fetal Development[3,4]

Phase of Development	Stage of Pregnancy[a]	Development Description	Potential Complications
Implantation and predifferentiation	0–14 days after conception (14–28 days after LMP)	Very little contact between the blastocyst and mother's blood Pluripotent cells, capacity to repair a damage Cells are fragile, miscarriage before pregnancy is detected if too many are destroyed	Spontaneous abortion; even if stopped during this period, long half-life drugs could affect organogenesis
Organogenesis (embryogenesis)	From day 14 until the 9th week after conception (From day 28 until the 11th week after LMP)	Organs are being formed; most critical period for structural anomalies Organs are being formed at different times; sensitivity for each organ differs Refer to Figure 47–1 for the time frame of organ formation	Major or minor structural anomalies; Spontaneous abortion; neurologic impairment
Fetogenesis	After the organogenesis and until birth	The fetus grows Organs begin to function (eg, glomerular filtration) Active cell growth, proliferation, and migration (eg, CNS)	Fetal growth retardation; functional deficit (eg, renal insufficiency), neurologic impairment; spontaneous abortion, stillbirth; neonatal complications

[a]Stage of pregnancy based on a menstrual cycle of 28 days.

LMP, last menstrual period; CNS, central nervous system.

the field of teratology and embryology refer to PCA to describe stages of pregnancy.

Principles of Embryology

Pregnancy is divided into three development phases: implantation and predifferentiation, organogenesis (or embryogenesis), and fetogenesis. Table 47–2 describes these phases and possible drug effects if taken during these phases, and Figure 47–1 illustrates the critical periods of human in utero development. KEY CONCEPT The risk of birth defects is usually higher during organogenesis.

▶ *Teratogens*

LO 2

KEY CONCEPT Health professionals should know which medications have teratogenic risk. A teratogen is an exogenous agent that can modify normal embryonic or fetal development.[3] Teratogenicity can manifest as structural anomalies, functional deficit, cancer, growth restriction, neurologic impairment, or death (spontaneous abortion, stillbirth).

In utero exposure to medication near delivery can also lead to transient neonatal complications, such as withdrawal or side effects (eg, opioids, selective serotonin reuptake inhibitors, antipsychotics, lithium).[4,5]

Teratogenic exposure is a term preferred over *teratogen* as it considers level (dose) and timing of exposure during pregnancy to determine whether it could lead to a higher risk of a specific malformation.[6]

Criteria have been proposed to determine whether a causal relationship between congenital anomalies and a medication is plausible when analyzing scientific documentation (teratogenic effect).[6] Exposure to the medication must have happened during the critical period of development of the organ for which a malformation is noticed (Figure 47–1). Also, a pattern of anomaly or a specific syndrome must be reproducible in at least two studies conducted in different populations. A rare anomaly associated with a rare exposure is also indicative of a teratogenic effect (eg, ear anomalies and isotretinoin).

Other criteria, listed below, are considered:

- Strength of the association
- Same effects observed in animal studies

Patient Encounter Part 1

A 35-year-old woman comes to your office after a positive urine pregnancy test. You collect the following data:

Estimated Gestational Age: 5 weeks, regular menstrual cycles of 28 days

PMH: Type 2 diabetes mellitus (T2DM) diagnosed 3 years ago, hypercholesterolemia, obesity (BMI 37 kg/m^2)

FH: T2DM, hypertension

SH: Afro-American origin. Nursing assistant. No use of alcohol, tobacco, or illicit substances. Not very active, but tries to respect low-carb diet

Meds: Metformin 1 g orally twice daily with meals, linagliptin 5 mg orally daily in the morning, glargine insulin 10 units subcutaneously at night

Allergy: None

ROS: Morning nausea; tiredness

VS: Wt 209 lb (95 kg), Ht 63 in (160 cm), BP 110/72 mm Hg with large cuff, pulse 70 beats/min, RR 12 breaths/min

How will you confirm gestational age?

What prenatal workup would you perform at this time?

What is the appropriate counseling at this time?

What are the risks of drugs taken in the first weeks of pregnancy? What resources will you use to find the appropriate information?

What do you recommend for her pharmacologic treatment?

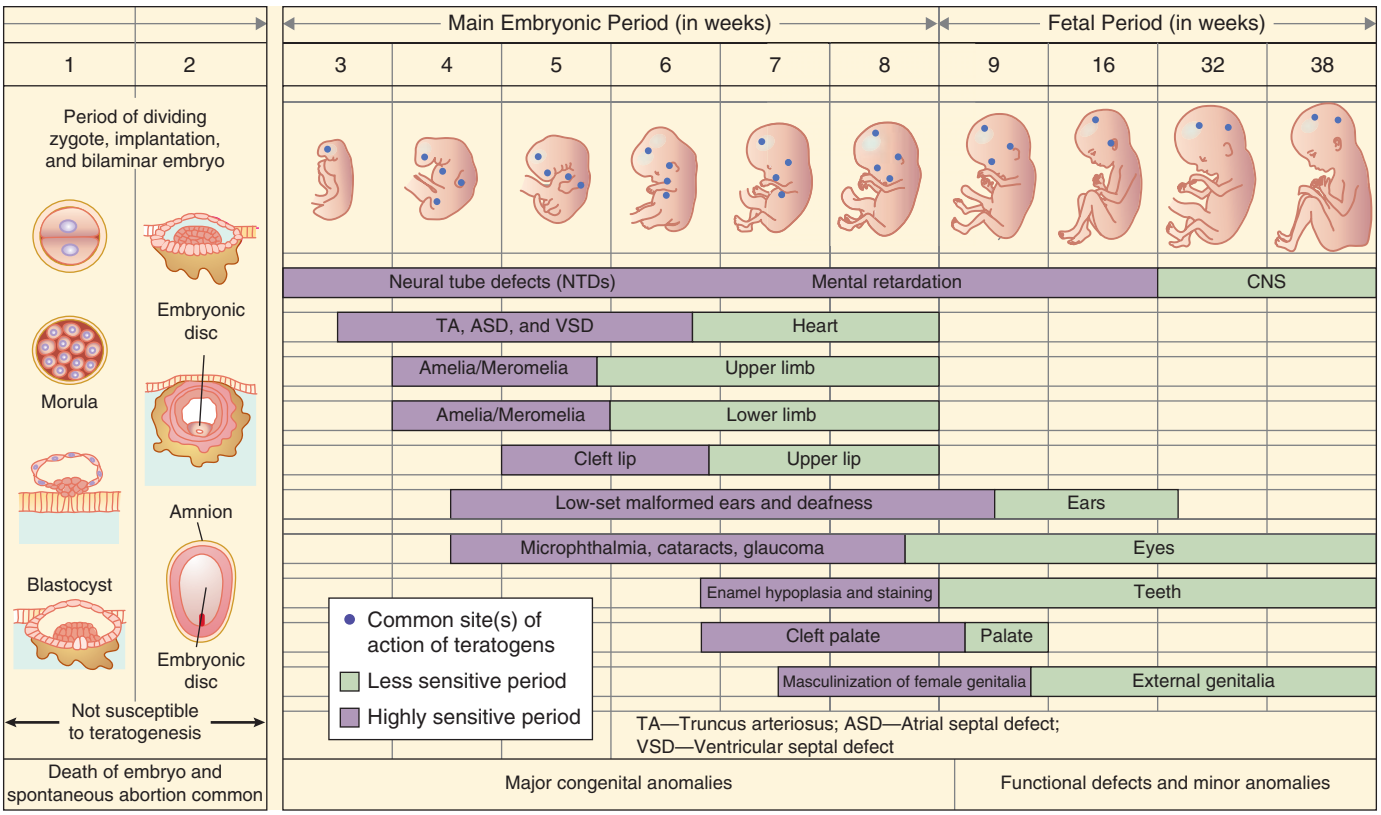

FIGURE 47–1. Embryonic and fetal development. The horizontal bars represent potential sensitivity to teratogens. The colored areas represent the more critical times. Embryonic period is in postconceptional weeks. (Reprinted with permission from Moore KL. The Developing Human. New York: Elsevier, p. 976: copyright 1974.)

- Biological plausibility based on pharmacologic effect
- Higher incidence of the anomaly in the population with the period of use of the medication (eg, thalidomide and limb anomalies)
- Dose–response relationship

LO 1 LO 2 With these criteria, there are approximately 30 medications or classes of medications that are considered teratogens (Table 47–3). Others are not necessarily safe: we must be careful not to interpret a lack of data as an absence of risk. A medication on this list is not necessarily contraindicated as severity and occurrence of malformations vary from one agent to another. Some can be used when benefits outweigh potential risks.

RISK EVALUATION

Desired Outcomes

The goal of drug use during pregnancy and lactation is to treat conditions effectively when necessary while minimizing risk to the developing embryo/fetus or the neonate.

Medication and Pregnancy

▶ *Data Published on Medication Safety During Pregnancy*

Most available data on drug safety during pregnancy come from postmarketing reports: case reports or case series, epidemiological research using population/prescription databases or using questionnaires, manufacturer registries, or specialized pregnancy registries. Clinicians are encouraged to refer their patients taking medication to a pregnancy registry; a list of pregnancy registries is available on the Food and Drug Administration (FDA) website (www.fda.gov/pregnancyregistries).

Animal studies, now mandatory before marketing a medication, can identify high-risk medications and prevent congenital anomalies. However, they have limitations; different species do not share the same pharmacodynamics and pharmacokinetics, and usually much higher doses than those used in clinical settings are tested.[8]

▶ *Sources of Information on the Use of Drugs During Pregnancy and Lactation*

KEY CONCEPT Health care professionals should be able to compare the main sources of drug information relevant to pregnancy and lactation. Some specialized information sources provide data on the use of medications during pregnancy and lactation (Table 47–4).

LO 3

The new FDA regulation, the Pregnancy and Lactation Labeling Rule (PLLR), has been effective since June 30, 2015.[9] This rule requires that the labels of all prescription drugs and biologic products approved after June 30, 2001 include narrative summaries of the risk of using them during pregnancy and lactation, with presentation of data supporting the summaries, and asks for an update of the information presented when it is outdated. It replaces the categories A, B, C, D, and X that were proposed before. Letters have long been criticized by experts because it is much too simplistic and can lead to a misinterpretation of risk.

Drugs that were approved before June 30, 2001 do not have to include in their label the information requested by the PLLR, but they have to remove the categories A, B, C, D, and X.

Table 47–3

Medications with Proven Teratogenic Effects in Humans[4-7]

Drug or Drug Class	Teratogenic Effects	Critical Period[a]
Alkylating agents	Malformations of many different organs	Organogenesis
Amiodarone	Transitory hypothyroidism (risk of 17%, goiter in some cases) or transitory hyperthyroidism	From 12th week after LMP
Androgens (danazol, testosterone)	Masculinization of genital organs in female fetus	From 9th week after LMP
Angiotensin converting enzyme inhibitors; angiotensin II receptor antagonists	Renal failure, anuria, oligohydramnios, pulmonary hypoplasia, intrauterine growth restriction, limbs contracture, skull hypoplasia	After the first trimester
Anticonvulsants (first generation)	NTD (carbamazepine and valproic acid); oral cleft, skeletal, urogenital, craniofacial, digital, and cardiac malformations	Organogenesis for structural anomalies
• Carbamazepine • Phenytoin • Phenobarbital • Valproic acid, divalproex	Major malformations: up to 5%–10% depending on the agent used, with variation with dosage used (10%–15% or more for valproic acid). Valproic acid: abnormal neurologic development	Valproic acid: whole pregnancy for neurologic impairment
Corticosteroids (systemic)	Oral cleft (risk of 3–4/1000 vs 1/1000 in general population)	Organogenesis (most critical period for palate formation: 8 and 11 weeks after LMP)
Diethylstilbestrol	Girls: cervical or vaginal adenocarcinoma, incidence: 1/1000. Structural genital anomalies (eg, of cervix, vagina) Boys: genital anomalies, spermatogenesis anomalies	First and second trimesters
Fluconazole high doses	Skeletal and craniofacial malformations, cleft palate, cardiac anomaly (with chronic dose ≥ 400 mg/day; not reported with 150 mg single dose)	Not defined, but cases are reported where exposure was throughout pregnancy
Iodine (supraphysiologic dosage)	Hypothyroidism, goiter	From 12th week after LMP
Isotretinoin, other systemic retinoids (acitretin, bexarotene, etretinate), and high dose of vitamin A (vitamin A > 10,000 IU/day not recommended)	Spontaneous abortion, CNS, skull, eyes and ears malformations, micrognathia, oral cleft, cardiac malformations, thymus anomalies, mental retardation: estimated risk at 25%–30% (may be higher for neurologic development impairment) Isotretinoin and bexarotene: discontinue 1 month before pregnancy, isotretinoin prescribed under a special program called iPLEDGE Acitretin: discontinue 3 years before pregnancy	Organogenesis (risk of teratogenic effect after organogenesis not excluded)
Lithium	Cardiac malformations: risk of 0.9%–6.8% (higher risks in small studies) (baseline risk ~1%) Includes Ebstein anomaly: risk estimated at 0.05%–0.1%	Cardiac organogenesis (5–10 weeks after LMP)
Methimazole/propylthiouracil	Methimazole: aplasia cutis, choanal atresia, esophageal atresia, omphalocele, minor facial anomalies, growth delay; risk of 2%–4% Methimazole/propylthiouracil: fetal hypothyroidism in 1%–5% of newborns, goiter	Organogenesis Second and third trimesters
Methotrexate	Spontaneous abortion, CNS, and cranial malformations (large fontanelles, hydrocephalia, incomplete cranial ossification, craniosynostosis), oral cleft, ear, skeletal and limb malformations, mental retardation; discontinue at least one ovulatory cycle before pregnancy	Organogenesis (8–10 weeks after LMP for structural anomalies but some exceptions reported)
Misoprostol	Moebius syndrome ± limb anomalies ± CNS anomalies Abortion, preterm birth	Organogenesis Throughout pregnancy for abortion/preterm birth
Mycophenolate mofetil, mycophenolic acid	Anomalies including ear anomalies, oral cleft, micrognathia, ophthalmic, cardiac, and digital anomalies (risk of structural anomalies estimated from 20%–25%); spontaneous abortion (30%–50%)	Organogenesis (risk unknown after)
Nonsteroidal anti-inflammatory drugs	In utero closure of ductus arteriosus (constriction is rare before 27 weeks, 50%–70% at 32 weeks [GA]) and neonatal pulmonary hypertension Renal toxicity and oligohydramnios possible after prolonged use from second half of second trimester from 20 weeks of gestational age	Third trimester
Penicillamine	Cutis laxa Joints and CNS anomalies Risk probably low	Not defined
Tetracyclines	Teeth discoloration	From 16 weeks after LMP

(*Continued*)

Table 47–3

Medications with Proven Teratogenic Effects in Humans[4-7] (*Continued*)

Thalidomide	Limb anomalies (amelia, phocomelia) Cardiac, urogenital, gastrointestinal, and ear malformations Risk of 20%–50% Prescribed under a special program called STEPS (System for Thalidomide Education and Prescribing Safety)	34–50 days after LMP
Trimethoprim	Cardiac and urogenital malformations, NTD, oral cleft; overall risk probably < 6%	Organogenesis
Warfarin/acenocoumarol	Before 6 weeks: baseline risk of anomalies Taken between 6 and 12 weeks: nasal hypoplasia, epiphysis dysplasia, vertebral malformations, rarely ophthalmic anomalies, scoliosis, hearing loss; risk estimated of 6%–10% and possibly dose-dependent 12 weeks after LMP: rarely, heterogeneous CNS anomalies	Between weeks 6 and 12 after LMP; some risks persist after

[a]Stages of pregnancy in this table are calculated after last menstrual period (gestational age) and not after conception to be more clinically useful.
CNS, central nervous system; LMP, last menstrual period; NTD, neural tube defect.

Manufacturers of medication approved between June 30, 2001 and June 30, 2015 have a 3- to 5-year period to comply with the PLLR.[9]

▶ *Communication of Information*

Communication of data on medication use during pregnancy can be challenging[10]:

- Data may be limited or contradictory.
- Taking medications during pregnancy is a source of anxiety.
- Pregnant women tend to overestimate their risk of an anomaly associated with medication use and to underestimate their risk associated with undertreating their condition.

Table 47–4

LO 4 LO 5

KEY CONCEPT Health care professionals should be able to evaluate and communicate the risks of a drug when taken during pregnancy or lactation. The objective is to give precise data that will help the patient make an informed decision for her health and baby's health. Information should include a well-grounded assessment of risks, including baseline risks in the general population, risks associated with the medication, and risks of not treating the disease during pregnancy.[10]

When discussing risks[10]:

- Use absolute numbers instead of relative numbers.
- Use negatively and positively framed information at the same time (eg, 3% chance of having a malformed child; 97% chance of having a child without malformation).
- Use the same denominator when discussing probabilities.

To determine a woman's risk of birth defects, obtain good medical, obstetrical, and pharmacotherapeutic histories (including over-the-counter medications and natural health products) and exposures to alcohol, tobacco, and other recreational drugs.[13]

KEY CONCEPT With all this information, the health care professional should be able to apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.

▶ *Preconception Care*

Adverse pregnancy outcomes, including prematurity, low birth weight, and birth defects, are major health concerns. Late start in prenatal care can delay the identification and modification of risk factors that can affect pregnancy outcomes. Strategies to improve pregnancy outcomes include treating nutritional deficiencies, adequate folic acid, avoiding alcohol, substance and smoking, optimizing the management of chronic illnesses and genetic disorders, screening for infections, vaccination, pregnancy planning, and reaching a healthy weight.[11]

▶ *Folic Acid*

Anencephaly and spina bifida, with an estimated annual prevalence of 6.5 cases per 10 000, are the most common neural tube defects (NTDs) from an inadequate closure of the embryonic neural tube early in pregnancy.[12] Multivitamins containing folic acid reduce NTD and other congenital anomalies including oral clefts and cardiovascular, limb, and urinary tract malformations.[13]

KEY CONCEPT All women of childbearing age should be counseled on the appropriate dose of folic acid to prevent congenital anomalies.

LO 6 The American College of Obstetricians and Gynecologists (ACOG) and the US Preventive Services Task Force recommend that all women capable of pregnancy take 0.4 to 0.8 mg of folic acid daily, beginning 1 month before pregnancy and through the first 2 to 3 months, to prevent NTD.[12] Women at higher risk of NTD (eg, personal or family history of NTDs, use of antiseizure medications [valproic acid and carbamazepine], maternal diabetes, obesity, and mutations in folate-related enzymes) should take higher daily doses of folic acid (eg, 1–5 mg).[12]

► *Impact of Physiologic Changes During Pregnancy on Pharmacokinetics*

KEY CONCEPT Several physiologic changes during pregnancy have an impact on pharmacokinetics.

Absorption Decreased gastrointestinal transit can delay drug peak effect, prolonging the time of contact of drugs with the intestinal mucosa, and possibly enhancing absorption of certain drugs. Higher gastric pH may affect absorption of weak bases or acids. Pregnancy physiologic changes may also increase skin, tissue, and lung absorption.[14]

Distribution Volume of distribution increases for most drugs during pregnancy due to plasma volume expansion and the presence of amniotic fluid, the placenta, and the fetus, thus decreasing maximal drug concentrations. In addition, hypoalbuminemia and decreased protein binding increase free fraction (active portion) of some medications.[14]

Metabolism During pregnancy, the activity of some isoenzymes is increased (eg, CYP3A4, CYP2A6, CYP2D6, CYP2C9), while activity of others is decreased (eg, CYP1A2, CYP2C19). Net impact on drug effect is often unpredictable since there is a wide interindividual variability, and some drugs are metabolized by several isoenzymes.[14]

Renal Elimination Renal blood flow and glomerular filtration increase significantly during pregnancy. The impact of this is more important for drugs that are eliminated in the urine, which results in a decrease in their half-lives.

LO 7 Table 47–5 shows clinical recommendations based on pharmacokinetic changes during pregnancy for several drugs.[4,14]

Medication and Lactation

According to the latest policy statement from the American Academy of Pediatrics (AAP), mothers should breast-feed exclusively for 6 months and continue for 1 year if possible.[15]

► *Drug Transfer into Breast Milk*

To study drug effects, breast-fed infant's serum drug levels could be measured to evaluate safety; however, these data are often unavailable. In most instances, the approximate quantity of drug ingested by the breast-fed infant is estimated using published measured drug concentrations in breast milk. With these data, the percentage of pediatric dose or, if a pediatric dose is not available, the relative infant dose (percentage of weight-adjusted

Table 47–5

Altered Pharmacokinetics During Pregnancy: Clinical Implications and Management[4,14]

Drugs	Pharmacokinetic Changes	Recommendations and Monitoring[a]
Aminoglycosides	↑ V_d, ↑Cl, ↓ $t_{1/2}$	Monitor peaks and troughs; increase doses if necessary
Antiretrovirals	Variable Cl and C_{max}	Monitor clinical response; drug levels can be useful to adjust some drug dosages
Caffeine	↑ $t_{1/2}$ ↓ Cl (T_1, T_2, T_3)	Risk of more frequent and prolonged side effects; decrease caffeine consumption
Carbamazepine	↑ Cl ↓ $t_{1/2}$	Measure free fraction (preferably); increase dose according to clinical response and levels
Digoxin	↑ Cl ↓ C_{max}	Adjust according to clinical response and plasma levels; digoxin-like immunoreactive substance might interfere with measurement
Fluoxetine and other SSRIs	↑ Cl (T_3)	Increase dose according to clinical response
Heparin LMWH	↑ Cl (T_1, T_2, T_3)	For high-risk women (mechanical valves, new clot on therapeutic dosing) or CKD, follow anti-XA levels. Use twice daily administration for high-risk women.
Lamotrigine	↑ Cl (T_1, T_2, T_3)	For epilepsy: measure drug levels at least every trimester; increase dose according to clinical response and levels
Levothyroxine (T_4)	↓ff	Increase dose at the beginning of pregnancy; follow TSH levels every 4–6 weeks until 20 weeks and once in early T3
Lithium	↑ Cl (T_1, T_2, T_3) ↓ $t_{1/2}$	Measure drug levels every trimester and monthly in T3; increase dose according to levels if necessary
Nicotine	↓ $t_{1/2}$ ↑ Cl (T_2, T_3)	Higher doses might be required (smoking cessation) at T2 and T3; however, higher nicotine plasma levels possible (increased transdermal absorption)
Nifedipine	↑ Cl (T_3)	Monitor clinical effect; increase doses/frequency if necessary. Use twice daily for extended release formulation if > 40 mg/day
Phenytoin	↓ C_{total}, ff ↑ Cl (T_3) ↓ $t_{1/2}$	Measure free fraction; adjust dose according to clinical response, levels and signs of toxicity.
Valproic acid	↓ C_{total} ↑ ff	Measure free fraction if prepregnancy reference level available; dose will remain the same in most cases. Increase dose according to clinical response and levels

[a]Resume prepregnancy dosage after delivery in case of dosage adjustment for altered pharmacokinetics.

↑, increase; ↓, decrease; ↔, unchanged; C_{max}, maximum serum concentration; CKD, chronic kidney disease; Cl, clearance; ff, free fraction; T, trimester; $t_{1/2}$, elimination half-life; LMWH, low-molecular-weight heparin; C_{total}, total concentration; SSRI: selective serotonin reuptake inhibitor.

maternal dose) can be calculated, assuming an average of 150 mL/kg/day of milk ingested by a breast-fed infant.

$$\text{Percentage of pediatric dosage} = \frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Usual initial pediatric dose (mg/kg/day)}} \times 100$$

$$\text{Weight adjusted maternal dose or relative infant dose} = \frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Maternal dose adjusted by weight (mg/kg/day)}} \times 100$$

In the latter equation, maternal dose refers to the dose used by patients in a published study or a case report, not to the dose of your actual patient.

Usually, a percentage of less than 10% of the pediatric dose or, when a pediatric dose is not available, a percentage of less than 10% of weight adjusted maternal dose is generally accepted as safe in full-term healthy infants unless a drug has a toxic side-effect profile.[16]

▶ *Drug Pharmacokinetics*

If clinical data are unavailable on drug transfer into breast milk, drugs that are highly protein bound, have a high molecular weight, have a short half-life, have no active metabolites, and are well tolerated by children could be preferred.[16] In addition, drugs that are not orally absorbed should not cause systemic adverse effects in the breast-fed infant.

▶ *Drugs of Concern During Breast-Feeding*

LO 2

KEY CONCEPT Most drugs are safe during breast-feeding. However, some drugs are of concern and require a more thorough assessment by the clinician (Table 47–6). One should also consider additive side effects of several medications.

LO 8 CONDITIONS PREVALENT IN PREGNANCY AND LACTATION

KEY CONCEPT When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy.

KEY CONCEPT Evaluate the need for treatment, including benefits and risks, and possibility of delaying treatment after pregnancy or breast-feeding.

For chronic diseases, please refer to the relevant chapter under "Special populations."

Iron-Deficiency Anemia

Anemia during pregnancy is defined as a hemoglobin level less than 11 g/dL (110 g/L; 6.83 mmol/L).[17] Maternal symptoms include fatigue, palpitations, and decreased resistance to exercise and infections. Fetal risks are prematurity, low birth weight, and perinatal death. All pregnant women should be screened for anemia, and those with iron deficiency should be treated with oral iron preparations in addition to prenatal vitamins.[17] Iron supplementation decreases the prevalence of maternal anemia at delivery and reduce transfusion requirements. It is unclear whether supplementing nonanemic pregnant women will improve perinatal outcomes but it reduces maternal fatigue.[17]

Nausea and Vomiting of Pregnancy (NVP)

As many as 80% of pregnant women suffer from nausea or vomiting.[18] Taking prenatal vitamin for 3 months before pregnancy may reduce the incidence and severity of NVP. Nonpharmacologic measures, such as lifestyle (rest, avoidance of nausea triggers) and

Table 47–6

Drugs of Concern During Breast-Feeding[4,5,16]

Drug or Class	Comments
Drugs that can decrease the breast milk production	
Clomiphene	Has been used to suppress lactation
Ergot derivatives (bromocriptine, cabergoline, ergotamine)	Have been used to suppress lactation
Estrogens	Contraceptives with ethinylestradiol should be delayed for 3–6 weeks postpartum to decrease effect on lactation and to prevent thrombosis
Pseudoephedrine	Do not use in women with low milk production; a few doses will probably not have effect
Drugs for which use during breast-feeding may expose the neonate to a significant quantity and may necessitate a strict follow-up	
β-Blocking agents (acebutolol, atenolol, sotalol)	Neonatal β-blockade reported Concern for acebutolol, atenolol, and sotalol, but other β-blocking agents such as metoprolol, propranolol, and labetalol are safe
Amiodarone	May accumulate (long half-life); possible neonatal thyroid and cardiovascular toxicity
Antineoplastics	Neonatal myelosuppression possible
Chloramphenicol	Severe adverse effects reported when used to treat babies (blood dyscrasia, grey baby syndrome)
Ergotamine	Symptoms of ergotism (vomiting and diarrhea) reported
Illicit drugs	Unknown contents and effects
Lamotrigine	A breast-fed infant could have blood concentrations between 10% and 50% of maternal blood concentrations (variable but can be in therapeutic range); monitor for CNS side effects (sedation, hypotonia, weight gain, and poor sucking) and rash
Lithium	Up to 50% of maternal serum levels have been measured in infants; cases of infant toxicity (lethargy, cyanosis, electrocardiogram anomalies, dysthyroidism, tremors) reported; if breast-feeding, monitor infant serum lithium, creatinine, urea, and TSH levels every 4–12 weeks and other side effects (jitteriness, feeding problems, signs of dehydration)
Phenobarbital/ primidone	Drowsiness and reduced weight gain reported; up to 25% of a pediatric dose can be ingested via breast milk; monitor for CNS adverse effects (sedation, hypotonia, weight gain, and poor sucking)
Radioactive iodine-131	No breast-feeding for days to weeks to achieve nonsignificant radiation levels (long radioactive half-life); monitor radioactive levels in milk before allowing breast-feeding; for diagnostic purposes, prefer Tc99m or iodine-123
Tetracyclines	Chronic use may lead to dental staining or decreased epiphyseal bone growth (theoretical)

CNS, central nervous system.

dietary changes (small/frequent meals, fluid restriction during meals, avoiding spicy/fatty foods, consuming crackers upon rising, high protein snacks) should be used as first-line management. Acupuncture and acupressure also can be helpful.[18]

Early treatment with pyridoxine (vitamin B6) or a combination of pyridoxine and doxylamine is recommended to prevent progression to more severe NVP such as *hyperemesis gravidarum*. When insufficient, metoclopramide, diphenhydramine, or ondansetron can be prescribed (Table 47–7).[18]

Pain

Pregnant or lactating women experience pain from preexisting conditions or from temporary pathologies (eg, musculoskeletal conditions, fibromas, migraine, etc).

The general principles of treatment are[4,5,19]

- Maximize nonpharmacological measures
- Acetaminophen is the safest analgesic during pregnancy
- Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) during the third trimester; short-term (< 72 hours) courses can be used under medical supervision during the first and second trimesters.
- Opiates are not associated with a higher risk of malformations. However, close neonatal monitoring is necessary due to possible withdrawal if opiates are taken regularly near delivery.
- Pregnancy and lactation safety data are limited for some medications (eg, pregabalin, gabapentin) and their use should be evaluated on a case-by-case basis
- For migraine, sumatriptan can be used when other medications are not sufficient or indicated.

Urinary Tract Infections

Urinary tract infections, even asymptomatic, are associated with preterm birth, low birth weight, and preeclampsia, and treatment reduces these risks.[20] Untreated bacteriuria leads more often to pyelonephritis due to physiologic changes of the urinary tract.[20] Screening for asymptomatic bacteriuria is performed in the first trimester,[20] but may be repeated in high-risk women (eg. preexistant diabetes mellitus [DM], sickle cell disease, and neurogenic bladder). Uropathogens are the same for nonpregnant women,[20] including multidrug-resistant strains; antibiograms are warrant. Differential diagnosis of dysuria includes sexually transmitted infections.

Antimicrobial therapy is considered for asymptomatic women with ≥ 10^8 colony forming unit (cfu)/L or symptomatic women with ≥ 10^5 cfu/L of a uropathogen on a clean-catch mid-stream specimen. Treatment options include β-lactams and nitrofurantoin (Table 47–7). Trimethoprim-sulfamethoxazole should be avoided during organogenesis (congenital malformations) and near term (theoretical risk of **kernicterus**).[5] Quinolones are reserved for resistant infections due to theoretical concerns of arthropathy.[5] Initiate in-hospital intravenous (IV) antibiotics for pyelonephritis.

Repeat urine culture 7 days after treatment then monthly. Suppressive prophylaxis (Table 47–7) up to 6 weeks after delivery is indicated for persistent bacteriuria despite two treatment courses, recurrent cystitis, or after a single pyelonephritis episode.[20]

Preterm labor

Preterm birth is defined as a delivery before 37 completed weeks (< 259 days). Preterm birth, especially before 32 weeks of pregnancy, is the major cause of short- and long-term neonatal mortality and morbidity. In case of a premature delivery threat, depending on the gestational age, start: antenatal corticosteroids for fetal pulmonary maturation, antibiotic to lower the risk of neonatal group B streptococcal disease, and magnesium sulfate for fetal neuroprotection. **Tocolytics** can be administered in preterm labor and antibiotic in preterm premature rupture of membranes (PPROM) to prolong pregnancy.

► *Antenatal Corticosteroids*

Administration of antepartum corticosteroids to the mother to accelerate the maturation of the fetal lungs decreases incidence and severity of neonatal respiratory distress syndrome, intraventricular hemorrhage, **necrotizing enterocolitis**, and death.[21] Provide a single course of antenatal corticosteroids (betamethasone or dexamethasone) to women between 24 0/7 weeks and 33 6/7 weeks of gestation at risk of delivery within 7 days (Table 47–7).[21] It may also be considered starting at 23 0/7 weeks or between 34 0/7 weeks and 36 6/7 weeks if they did not receive a previous course. A single repeat course can be considered after 7 to 14 days if at less than 34 0/7 weeks and, at risk of delivery within 7 days.[21]

► *Tocolytic Agents*

Tocolytics are used when preterm labor occurs before 33 6/7 weeks to delay delivery in order to complete a course of corticosteroids and allow transfer of the mother to a center with neonatal intensive care facilities. Tocolytics include magnesium sulfate, β-mimetics (terbutaline), prostaglandin inhibitors (indomethacin), oxytocin receptor blockers (atosiban, not available in the United States), and calcium channel blockers (nifedipine) (Table 47–7).[22,23] Tocolytic agents can prolong pregnancy for up to 48 hours. Magnesium sulfate is associated with significant maternal adverse effects, and indomethacin cannot be used after 32 weeks of pregnancy.[22]

FDA issued a warning regarding the use of terbutaline for tocolysis due to the risk of serious maternal adverse effects. Accordingly, its use should be limited to short-term inpatient use.[22]

► *Neuroprotection*

Magnesium sulfate given to women at imminent risk of delivery before 32 0/7 weeks gestation decreases the incidence of subsequent neurologic morbidities like cerebral palsy (Table 47–7).[22,24,25]

► *Antibiotics for PPROM*

In the presence of PPROM, 2 days of parenteral ampicillin/erythromycin followed by 5 days of oral amoxicillin and erythromycin are associated with a delay of delivery and reduction in maternal and neonatal morbidity (Table 47–7).[25] Women with PPROM should receive an adequate intrapartum Group B *Streptococcus* (GBS) prophylaxis for the first 48 hours to prevent neonatal infection (refer to section on GBS infection).[25,26]

► *Progesterone*

Progesterone is used to reduce the risk of preterm birth in women with singleton gestation and a prior spontaneous singleton preterm delivery. Administration of progesterone is also recommended in women with a very short cervix (≤ 20 mm) by transvaginal ultrasound before or at 24 weeks of gestation (Table 47–7).[27]

Group B *Streptococcus* Infection

Ten percent to 30% of pregnant women are colonized by GBS at term. IV antibiotics are effective in reducing the incidence

Table 47–7

Medication Dosing Recommendations During Pregnancy and Lactation[4,12,17,19-22,24–42]

Drug	Dosage	Comments
Micronutrients and Vitamins		
Folic acid	0.4–0.8 mg po daily 1–5 mg po daily	Dosage necessary to reach RDA: 0.6 mg (pregnancy), 0.5 mg (breast-feeding) If higher risk of having a child with NTD
Iron	60–200 mg (elemental iron) po per day (divided doses if > 60–100 mg of elemental iron)	Doses to treat iron-deficiency anemia
Nausea and Vomiting		
Diphenhydramine or dimenhydrinate	25–50 mg po four times daily as needed	Will likely cause sedation. Do not drive under the effect of these medications
Doxylamine	12.5 mg po three to four times daily as needed	
Pyridoxine	25 mg po three times daily as needed	Dose up to 200 mg daily have been used
Doxylamine + pyridoxine	Two pills at bedtime, one pill in the morning, and one pill in the afternoon (up to eight pills daily)	
Metoclopramide	5–15 mg po three to four times daily as needed	
Ondansetron	4–8 mg po three times daily as needed	
Urinary Tract Infections		
Asymptomatic bacteriuria and uncomplicated acute cystitis		
Nitrofurantoin	100 mg po four times daily for 3–7 days (Furadantin, Macrodantin) 100 mg po twice daily (macrocrystalline—Macrobid) for 3–7 days	
Cefadroxil	1000 mg po twice daily for 3–7 days	
Cefprozil	500 mg po twice daily for 3–7 days	
Cephalexin	500 mg po twice daily for 3–7 days	
Amoxicillin	500 mg po three times daily for 3–7 days	Check for local resistance before prescribing
Acute pyelonephritis		
Ampicillin + gentamicin	1–2 g IV every 6 hours + 1.5 mg/kg/dose IV every 8 hours	Switch to oral antibiotic after 48 hours afebrile and treat for a total of 10–14 days, for example: • Cephalexin 500 mg po four times daily • Cefprozil 500 mg po twice daily • Amoxicillin clavulanate 875/125 mg po twice daily
Cefazolin	1–2 g IV every 8 hours	
Cefuroxime	0.75–1.5 g IV every 8 hours	
Ceftriaxone	1–2 g IV or IM every 24 hours	
Prophylaxis		
Nitrofurantoin	50–100 mg po at bedtime	Start after the end of the treatment for pyelonephritis and continue until 4–6 weeks after delivery
Cephalexin	250 mg po at bedtime	Nitrofurantoin should be preferred to prevent resistance to cephalosporins
Fetal Lung Maturation		
Betamethasone	12 mg IM every 24 hours for two doses	A single rescue course may be considered after at least 1 or 2 weeks of treatment if gestational age is < 34 0/7 weeks and the woman is likely to give birth within the next week
Dexamethasone	6 mg IM every 12 hours for four doses	
Tocolytic agents		
Indomethacin	50 mg oral load, then 25–50 mg po every 6 hours up to 48 hours	Avoid after 32 weeks of pregnancy; reports of increased risk of maternal postpartum hemorrhage, and neonatal complications (eg, premature closure of the ductus arteriosus, renal insufficiency, patent ductus arteriosus, necrotizing enterocolitis) are worrisome
Magnesium sulfate	4 g IV over 30 minutes, then continuous IV infusion of 2 g/hour up to 48 hours	Contraindicated in women with myasthenia gravis; maternal pulmonary edema and cardiac arrest have been reported Monitor blood magnesium levels Use with caution if renal impairment, contraindicated if renal failure
Nifedipine (short acting)	10–30 mg oral load (divided over at least 1 hour if > 10 mg used), then 10–20 mg every 4–8 hours up to 48 hours	Avoid in women with hypotension and preload-dependent cardiac lesions such as aortic insufficiency

(*Continued*)

Table 47–7

Medication Dosing Recommendations During Pregnancy and Lactation[4,12,17,19-22,24-42] (*Continued*)

Drug	Dosage	Comments
Magnesium sulfate For neuroprotection or prevention of eclampsia.	4 g IV over 30 minutes, then continuous IV infusion of 1 g/hour	Contraindicated in women with myasthenia gravis; maternal pulmonary edema and cardiac arrest have been reported; treatment limited to 24 hours for neuroprotection Monitor blood magnesium levels Use with caution if renal impairment; contraindicated if renal failure
Preterm Premature Rupture of Membranes		
Ampicillin	2 g IV every 6 hours for 48 hours followed by amoxicillin	Ampicillin/amoxicillin are used with erythromycin
Amoxicillin	250 mg po three times daily for 5 days	
Erythromycin base	250 mg IV every 6 hours for 48 hours followed by 333 mg three times daily for 5 days	
Preterm Labor Prevention		
17-α-hydroxyprogesterone	250 mg IM each week	Start at 16–24 weeks' gestation if previous preterm delivery
Progesterone (micronized)	100 mg (capsules) or 90 mg (8% gel) intravaginally daily (previous preterm delivery) 200 mg intravaginally daily (short cervix)	Start at 16–24 weeks' gestation if previous preterm delivery and before 24 weeks if short cervix
Group B *Streptococcus*		
Penicillin G	5 million units IV initially, then 2.5–3 million units IV every 4 hours until delivery	First choice
Ampicillin	2 g IV initially, then 1 g IV every 4 hours until delivery	
Cefazolin	2 g IV initially, then 1 g IV every 8 hours until delivery	
Clindamycin	900 mg IV every 8 hours until delivery	Only if isolate proven sensitive to clindamycin and erythromycin, or sensitive to clindamycin and testing for inducible clindamycin resistance is negative
Vancomycin	1 g IV every 12 hours until delivery	If other options are inappropriate
Cervical ripening/ Induction of labor		
Misoprostol	25 mcg (1/4 of 100 mcg tablet) vaginally every 3–6 hours	Check for uterine tachysystole with or without fetal heart rate changes
Dinoprostone	0.5 mg gel in cervical canal, or 1–2 mg gel vaginal	Do not use if previous uterine surgery including cesarean section
	10 mg extended-release vaginal insert in posterior fornix	Check for uterine tachysystole with or without fetal heart rate changes
Oxytocin	Low-dose regimen: 0.5–2 mU/min, with 1–2 mU/min increase every 15–40 minutes according to contractions High-dose regimen: 6 mU/min with 3–6 mU/min increases every 15–40 minutes according to contractions	Check for uterine tachysystole and water intoxication
Postpartum hemorrhage treatment		
Oxytocin	10 units IM or 10–40 units per 500–1000 mL as continuous intravenous infusion	Use normal saline or lactated Ringer; cautious with bolus if cardiac disease
Carbetocin (prophylaxis)	100 mcg IM or IV over 1 minute	
Methylergonovine	0.2 mg IM every 2–4 hours	Do not use in women with hypertension, preeclampsia or cardiovascular disease
Carboprost tromethamine	0.25 mg IM or intramyometrial every 15–90 minutes up to eight doses	Use with caution if asthma
Misoprostol	600–1000 mcg PO or PR	
Tranexamic acid	1g IV over 10 minutes (repeat once if bleeding persists)	
Hyperthyroidism		
Methimazole	5–15 mg po once or twice daily (total daily dose: 10–30 mg)	Second and third trimesters
Propylthiouracil	50–100 mg po one to three times daily (100–600 mg divided in three daily doses)	First trimester; risk of hepatotoxicity
Severe Hypertension		
Labetalol	Start with 10–20 mg IV over 2 minutes; repeated 20–80 mg every 15–30 minutes (max 300 mg/24 hours) Or 1–2 mg/min IV drip Oral formulation can be acceptable if woman is asymptomatic and no other option is available	Can exacerbate asthma symptoms May cause fetal bradycardia

(*Continued*)

Table 47–7

Medication Dosing Recommendations During Pregnancy and Lactation[4,12,17,19-22,24–42] (*Continued*)

Drug	Dosage	Comments
Nifedipine (short acting)	5–10 mg po; could be repeated after 30 minutes	May cause headache, flushing, dizziness, reflex tachycardia, and maternal pulmonary edema
Hydralazine	5 mg IV or IM; repeated 5–10 mg IV every 30 minutes (max 20 mg IV or 30 mg IM) Or 0.5–10 mg/hour IV drip	May cause reflex tachycardia, headaches
Nonsevere Hypertension		
First choices		
Methyldopa	500–3000 mg in 2–4 daily doses—max 750 mg per dose	May cause drowsiness, depression, hemolytic anemia, positive antinuclear antibodies
Labetalol	100–1200 mg divided in two to four daily doses	Can exacerbate asthma symptoms. May cause tiredness, headaches, hepatotoxicity
Nifedipine extended release	20–120 mg po in one to two daily doses (twice daily if > 40 mg daily)	May cause tachycardia, headaches, lower limb edema
Second choices		
Hydralazine	10–50 mg po two to four times daily	May cause reflex tachycardia, headaches, lupus-like syndrome; avoid monotherapy
Metoprolol	50–200 mg dived in two daily doses	Can exacerbate asthma; may cause fetal bradycardia
Clonidine	0.05–0.2 mg po (maximum: 0.8 mg daily divided in two daily doses)	May cause drowsiness
Hydrochlorothiazide	12.5–50 mg po once daily	May cause hypokalemia, dehydration
Bacterial Vaginosis		
Metronidazole	250 mg po three times daily for 7 days or 500 mg orally twice a day for 7 days 0.75% vaginal gel, once or twice daily for 5 days	Can be used in all trimesters For metronidazole and clindamycin, use oral formulation during pregnancy if treatment aim is to prevent PTB
Clindamycin	300 mg po twice daily for 7 days 2% cream, 5 g intravaginally at bedtime for 7 days 100-mg ovules intravaginally at bedtime for 3 days	
Vulvovaginal Candidiasis: refer to Chapter 83		
6–7 days treatments for intravaginal antifungical azoles are recommended during pregnancy to prevent recurrent episodes; shorter courses are appropriate during breast-feeding. Fluconazole is an acceptable alternative if intravaginal azoles cannot be used or during lactation.		
Mastitis		
Outpatient Treatment		
Dicloxacillin	500 mg po four times daily	Treat for 10–14 days
Cephalexin	500 mg po four times daily	
Amoxicillin 875 mg + clavulanate 125 mg	One tablet po twice daily	
Inpatient Treatment for More Severe Cases		
Oxacillin	2 g IV every 4 hours	Treat IV for 24–48 hours until afebrile then continue with outpatient treatment
Nafcillin	2 g IV every 4 hours	
Clindamycin	600–900 mg IV every 8 hours	
Vancomycin	1 g IV every 8–12 hours	If MRSA suspected or proven
Breast Candidiasis		
Mother		
Clotrimazole, miconazole, or nystatin	Topical cream	After each feeding and for 1 week after symptoms have resolved; also treat infant even if asymptomatic
Fluconazole	200–400 mg po for one dose followed by 100–200 mg po daily	If topical treatment not efficacious, add fluconazole; use until 1 week after symptoms have resolved (minimum of 2 weeks); also treat infant even if asymptomatic
Infant		
Nystatin oral solution	100,000–200,000 units (1–2 mL) to be swabbed into infant's mouth four times daily, after feedings	
Clotrimazole or miconazole topical cream	Apply in a thin layer in infant's mouth four times daily, after feedings	
Other Treatments for Candidiasis		
Gentian violet 0.5%–1% solution	To be swabbed into infant's mouth once daily for 5 days before a feeding	Can stain clothes and skin If nipples or mouth are not violet after application and the feeding, reapply the treatment

IM, intramuscular; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; NTD, neural tube defect; po, orally; PR, per rectum; RDA, recommended daily allowance.

Clinical Confirmation and Associated Problems of Pregnancy and Lactation

Confirmation of Pregnancy

Positive urine or blood human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

Pregnancy Dating and Gestational Age

Calculated from the first day of the last menstrual period (LMP).

An ultrasound between 10 + 0 and 13 + 6 weeks determines gestational age based on crown-rump length and identifies multiple pregnancies.

Due dates typically are estimated at 40 weeks of gestation; however, infants delivered between 37 and 42 weeks are considered full term.

Pregnancy Symptoms

First trimester: Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation

Second trimester: Frequent urination, heartburn, constipation, dry skin, edema, linea nigra, melasma

Third trimester: Backache, edema, shortness of breath, insomnia

Routine Pregnancy Visits

In an uncomplicated pregnancy, visits should occur monthly until 28 weeks of gestation, every 2 to 3 weeks from 28 to 36 weeks of gestation, and then weekly until delivery.

Assess for each of the following at each visit:

- Blood pressure
- Weight
- Urine protein (dipstick)
- Uterine size
- Fetal heart rate
- Fetal movement

Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)

- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Blood type, Rh, red blood cell antibody screening
- Human immunodeficiency virus
- Venereal Disease Research Laboratory (VDRL) slide test for syphilis
- Rubella immunity
- Varicella immunity
- Hepatitis B surface antigen
- Urinalysis with culture for bacteriuria
- Gonorrhea and chlamydia
- Cervical cytology
- Screens for Down syndrome and NTDs (between 11 and 20 weeks)
- Gestational diabetes screening (at 24–28 weeks)
- Group B streptococcus (GBS) screening (at 35–37 weeks)
- Women at high risk for these conditions should be tested at the first visit:
  - Hypothyroidism
  - Type 2 diabetes
  - Sickle cell disease or thalassemia
  - Hepatitis C
  - Tuberculosis
  - Bacterial vaginosis

of early-onset neonatal GBS infection when administered to high-risk groups including women with GBS vaginal/rectal colonization, GBS bacteriuria in the current pregnancy, and those who previously delivered a neonate with GBS disease.[26]

All women should be screened for colonization using a vaginal-rectal swab between 35 and 37 weeks. If treatment is indicated, it should be started at the time of membrane rupture or onset of labor, whichever comes first and continued until delivery (Table 47–7). All women with unknown status should be treated if labor or PPROM occur before 37 weeks. IV penicillin G or ampicillin, or if penicillin-allergic, cefazolin (nonanaphylactic) or clindamycin (anaphylaxis), can be used (refer to Table 47–7 to know when clindamycin can be used). If sensitivity to clindamycin is unknown, vancomycin should be administered.[26]

Induction of Labor

Induction of labor aims to achieve a vaginal delivery by stimulating uterine contractions before spontaneous labor. Cervical ripening is the process of cervical softening, thinning, and dilating, when the cervix is not favorable to delivery.

Mechanical methods for ripening include cervical dilators (hygroscopic dilator, Foley catheter) and extraamniotic saline infusion.[28,29] Pharmacological methods include prostaglandin E1 (eg, vaginal misoprostol) and E2 (eg, vaginal or cervical dinoprostone). Prostaglandins are used both for cervical ripening and induction of labor. The controlled-release vaginal dinoprostone is easily removed in case of uterine tachysystole, which help to reverse it. Prostaglandins should not be used in women with a previous cesarean section due to the increased risk of uterine rupture.[29]

When the cervix is deemed favorable, nonpharmacological options for producing contractions are membranes sweeping, nipple stimulation, and amniotomy.[28]

Oxytocin is the most frequently used pharmacological method of labor induction.[28] If a prostaglandin has been used, oxytocin needs to be delayed 30 to 60 minutes after the removal of dinoprostone controlled-release insert, 4 hours after the last dose of misoprostol, and 6 to 12 hours after the administration of dinoprostone gel.[28] A rare but serious complication of high cumulative dose of oxytocin is water intoxication due to its antidiuretic action.[29]

Postpartum Hemorrhage

Postpartum hemorrhage is defined by the ACOG as blood loss greater than or equal to 1000 mL or blood loss with signs or symptoms of hypovolemia within 24 hours after birth, regardless

of route of delivery.[30] A blood loss greater than 500 mL after vaginal delivery is considered abnormal. Uterine atony accounts for up to 80% of primary postpartum hemorrhage, but other etiologies like genital or cervical trauma, retained placenta, and coagulopathies are also implicated.[30]

Oxytocin and carbetocin (long-acting analog of oxytocin) can prevent excessive blood loss associated with delivery and caesarian section. Of the treatment of postpartum hemorrhage, uterotonics (oxytocin, methylergonovine, carboprost tromethamine, and misoprostol) are effective in the presence of uterine atony. Methylergonovine should not be administered to women suffering from hypertension or coronary artery disease. Carboprost tromethamine should be used with caution in asthmatic women.[30] ACOG recommends that tranexamic acid, an antifibrinolytic agent, should be administered when uterotonics fail, and recent data indicate that it reduces mortality when given within 3 hours of birth.[30,31]

Nonpharmacologic approach, like uterine massage or compression (tamponade), is also used. More invasive procedures ranging from transfusion to hysterectomy are used in unresponsive postpartum hemorrhages.[30]

Thyroid Disorders

Thyroid hormones increase by 50% from 7 to 16–20 weeks' gestation, then plateau until delivery. Thyroxine-stimulating hormone (TSH) reference range shifts downward by 0.5 mIU/L (μIU/mL) because of the beta-human chorionic gonadotropin (β-hCG) effect. Universal screening of thyroid disorders in pregnancy is debated.[32] See Chapter 44 for further discussion on thyroid disorders.

Gestational (subclinical) hypothyroidism is defined by a TSH above normal pregnancy range, and is linked to adverse pregnancy outcomes. Replacement therapy is suggested for positive antithyroid peroxidase antibodies (anti-TPOAbs) and TSH above 2.5 mIU/L (strongly if above 4.0 mIU/L) or negative antibodies and TSH above 4.0 mIU/L (strongly if above 10.0 mIU/L).[32] For prepregnancy hypothyroidism, increase levothyroxine (LT_4) by 30%. Once treatment is initiated, monitor TSH every 4 to 6 weeks until 20 weeks and once in the early third trimester to aim TSH under 2.5 mIU/L. Resume prepregnancy dosage at delivery.

Gestational hyperthyroidism is self-remitting and not associated with adverse outcomes. In Graves' disease, propylthiouracil (PTU) is used until week 16 and methimazole thereafter (Tables 47–3 and 47–7).[32] Administer at the lowest effective dose to target FT_4 at or moderately above the reference range. Monitor fetus and neonate to detect signs of hypothyroidism (if antithyroid drugs) or hyperthyroidism (if mother is positive for thyroid-stimulating hormone receptors-stimulating antibodies [TSHR-Sabs]).

Monitor TSH levels 6 to 8 weeks after delivery in women with thyroid disorders. Both LT_4 and antithyroid drugs can be used during lactation.[16,32]

Hypertension

Preexisting and gestational hypertension increase the risk of maternal and perinatal morbidity and mortality. Preeclampsia, caused by impaired placentation, may present with hypertension and multiple maternal complications or fetal distress. Delivery leads to cure, although transient flare or de novo preeclampsia occur postpartum.[33,34] Timing of delivery depends on maternal and fetal status and gestational age, but is not deferred past 37 weeks.[34] IV magnesium sulfate is used in prevention of **eclampsia** (Table 47–7).[24,33,34]

Treat severe hypertension (systolic above 160 mm Hg or diastolic above 110 mm Hg) promptly to avoid target-organ damage (Table 47–7).[34,35] Threshold for treatment of nonsevere hypertension (130–155/85–105 mm Hg) is still debated. In nonpreeclamptic hypertension, tight control benefits mother without harming the fetus.[36] Methyldopa, labetalol, and extended release nifedipine are first-line treatments[33] (Table 47–7). Angiotensin-converting enzyme inhibitors (ACEi), angiotensin II receptor antagonists, or renin inhibitors are contraindicated past the first trimester.[33]

To prevent preeclampsia and growth restriction in high-risk women, initiate low-dose aspirin (75–160 mg daily) early in pregnancy and calcium supplements (1.5–2.0 g elemental calcium/day) if low calcium intake in usual diet.[34]

Women with hypertension around pregnancy and delivery should be instructed to monitor blood pressure up to 10 days postpartum and on thresholds or symptoms requiring consultation.[33,34] Appointment 6 to 12 weeks postpartum is recommended to ensure correction of hypertension and proteinuria, and for counseling on future pregnancies and long-term care.

Preexisting Diabetes Mellitus

For gestational diabetes mellitus (GDM) discussion, see Chapter 43. Hyperglycemia is teratogenic. Women of childbearing age with preexistent diabetes should achieve a preconception hemoglobin A_{1c} less than 7% (ideally < 6.5%) to minimize risks of spontaneous abortions and malformations.[37] Refer to folic acid recommendations above.

Women with preexisting DM should be screened for diabetic nephropathy and retinopathy.[37] Type 1 diabetes mellitus (T1DM) are tested for gestational hypothyroidism and anti-TPOAbs. Low-dose aspirin is indicated to reduce preeclampsia risks.[34]

Optimal control of glycemia throughout pregnancy reduces risks of macrosomia, delivery complications, fetal demise, preeclampsia, and neonatal complications.[37] Self-monitoring of blood glucose (SMBG) goals during pregnancy are fasting less than 95 mg/dL (5.3 mmol/L), premeal less than 100 mg/dL (5.6 mmol/L), 1 hour postmeal less than 140 mg/dL (7.8 mmol/L), or 2 hour postmeal less than 120 mg/dL (6.7 mmol/L). Standard treatment is insulin. Oral hypoglycemics are not as efficacious, cross the placenta, and long-term safety data are missing.[5,37] Continue medication until the patient is safely switched to insulin.

Intrapartum glucose is maintained between 70 mg/dL (3.9 mmol/L) and 110 mg/dl (6.1 mmol/L) to avoid fetal acidosis and neonatal hypoglycemia. Postpartum, resume 2/3 of prepregnancy insulin dosage. Metformin and insulin are safe during breast-feeding.[5]

Anticoagulation

Thromboembolic risk increases during pregnancy and up to 12 weeks postpartum. Anticoagulation with low-molecular-weight heparins or unfractionated heparin may be required antepartum and/or postpartum for some women, even when not anticoagulated before pregnancy.[5,7] Dosage is specific to the underlying condition.

Warfarin is associated with a dose-dependent embryopathy when used between 6 and 12 weeks' gestation and with fetal and maternal bleeding when used near delivery (Table 47–3).[5,7] Its use is still recommended during pregnancy (except during those periods), in addition to low-dose aspirin, for prosthetic heart valves, which are highly thrombogenic.[7] Warfarin and heparins are safe to use during breast-feeding.[16]

Patient Encounter Part 2

The first trimester urine culture screening reports more than 10^8 cfu/L of sensitive *Escherichia coli*. The patient was successfully treated with oral amoxicillin for 3 days, and urine culture a week later was negative. At 18 weeks, she presents with pollakiuria and dysuria without fever or systemic symptoms. She tested negative for chlamydia and gonorrhea in the first trimester. Urinalysis shows leucocytes and glycosuria, and urine culture is positive for *Proteus mirabilis* at more than 10^5 cfu/L susceptible to amoxicillin. She denies past repeated urinary tract infections, symptoms after sexual intercourse, or new sexual partner. Home blood glucose monitoring is at target in the fasting state and 1-hour post meals, but is elevated around 108 mg/dL (6.0 mmol/L) before lunch and dinner.

Meds: Insulin glargine 20 units subcutaneously at bedtime, insulin aspart 10 units subcutaneously before every meal, aspirin 81 mg orally at bedtime, and multivitamin containing folic acid 1 mg.

What treatment do you recommend at this time?

Bacterial Vaginosis

Bacterial vaginosis is associated with spontaneous abortion, PPROM, chorioamnionitis, preterm birth, postcesarean wound infection, postpartum endometritis, and pelvic inflammatory disease.[38,39] Oral or topical treatment with metronidazole or clindamycin is recommended for symptomatic pregnant and lactating women.[38,39] Oral metronidazole or clindamycin is recommended to prevent preterm delivery in women at high risk (Table 47–7).[39] Culture should be performed 1 month after completion of therapy since the cure rate is approximately 70%.[39]

Vulvovaginal Candidiasis

Only symptomatic vulvovaginal candidiasis should be treated in pregnant or lactating women (Table 47–7).[38]

Patient Encounter Part 3

At 37 weeks' gestation, the patient presents with rapidly progressing edema, unusual headache, blurry vision, and blood pressure persistently slightly over 140/90 mm Hg. Her reflexes are brisk. Dipstick urinalysis shows 2+ protein. Serum uric acid is mildly elevated, but remaining preeclampsia workup (complete blood count [CBC], liver enzymes, lactate dehydrogenase, and creatinine) is normal. Nonstress test is reassuring. Cervix is closed. The fetus had an estimated fetal weight at 40th percentile and was in cephalic position. Vaginal-rectal swab was negative for group B *Streptococcus* (GBS).

Meds: Insulin glargine 10 units subcutaneously at awakening, 25 units subcutaneously at bedtime, insulin aspart 15 units subcutaneously before every meal, aspirin 81 mg orally at bedtime, and multivitamin containing folic acid 1 mg.

What is your diagnosis and what will you recommend now?

Sexually Transmitted Infections

Table 47–8 presents the management of sexually transmitted infections during pregnancy and lactation, associated risks, and recommended follow-up.[38] Treatment of all recent sexual partners is mandatory.

Enhancement of Lactation

Insufficient milk production is diagnosed when breast-feeding cannot meet neonate's requirements. Several factors affect milk production including fatigue, stress, smoking, premature delivery, cesarean section, pain, and some medications (Table 47–6). Optimization of breast-feeding techniques is the first-line strategy. Prolactin is the main hormone linked to milk production. No drug is currently approved by the FDA or recommended by the American Academy of Breastfeeding for lactation enhancement, but dopamine antagonists, metoclopramide, and domperidone (not available in the United States), which increase prolactin levels, are used for this purpose.[40] Metoclopramide's maternal adverse effects include fatigue, irritability, headache, and extrapyramidal symptoms. Domperidone has been associated with abnormal heart rhythm and sudden cardiac death in susceptible individuals; caution is advised when prescribing it with other drugs that prolong the QT interval or that inhibit its metabolism or for women with underlying cardiac conditions.[41] Very few adverse effects in the infant have been reported.

Mastitis

Bacterial mastitis, seen typically within the first 6 weeks of breast-feeding, is characterized by localized signs of inflammation and engorgement. Fever, shivering, and malaise can occur. Most commonly encountered bacteria are *Staphylococcus aureus* (including methicillin-resistant), followed by *Streptococcus*, *Staphylococcus epidermidis*, and *E. coli*.[42]

Cold or warm compresses and more frequent breast-feeding/breast pumping should be encouraged. Antibiotics (Table 47–7) and analgesics (eg, acetaminophen, NSAIDs) can be used to relieve pain.[16,42] Confirm abscess suspicion with ultrasound before surgical drainage.

Breast Candidiasis

Candidiasis (most commonly *Candida albicans*) presents with severe and persistent nipple pain, usually more intense during and immediately after breast-feeding. Breast-fed infant can be symptomatic or asymptomatic. It is recommended to breast-feed more frequently for a short period of time. Clothes and towels in contact with breasts and infant's mouth should be washed in hot water. Antifungal treatment must be given to mother and neonate simultaneously (Table 47–7). Analgesics (eg, acetaminophen, NSAIDs) can be used.[42]

Patient Encounter Part 4

After 10 hours of labor, the patient delivers vaginally a 6.6 lb (3.0 kg) baby. She plans to breast-feed.

What treatment plan do you recommend after delivery?

What surveillance do you suggest for the newborn/baby?

Can she breast-feed while taking her medications?

Table 47–8

Management of Sexually Transmitted Infections During Pregnancy and Lactation[38,39]

	Indications for Treatment	Associated Risks During Pregnancy	When to Repeat Testing During Pregnancy	Other
Chlamydia trachomatis	All women with a positive test, even if asymptomatic	Preterm labor; neonatal infection	Third trimester: < 25 years of age, those at increased risk of infection	Repeat testing 3–4 weeks and 3 months after therapy
Treatment	First choice: Azithromycin 1 g po once Alternative choices: Amoxicillin 500 mg po three times daily for 7 days Erythromycin base 500 mg po four times daily for 7 days or 250 mg po four times daily for 14 days Doxycycline 100 mg po twice daily for 7 days only during lactation (contraindicated during pregnancy)			
Gonorrhea	All women with a positive test, even if asymptomatic	Preterm labor, neonatal infection	Third trimester: if first screening positive or if at risk of reinfection	Repeat testing 2 weeks and 3 months after treatment
Treatment (uncomplicated infection of pharynx, cervix, urethra, rectum)	First choice: ceftriaxone 250 mg IM once + azithromycin 1 g po once Second choice during breast-feeding: ceftriaxone 250 mg intramuscularly once + doxycycline 100 mg po twice daily for 7 days (doxycycline contraindicated pregnancy)			
Genital Herpes Simplex	Active lesions, disseminated; Starting at 36 weeks: prevention of recurrence at term	Neonatal infection, especially if acquired near time of delivery (30%–50%)	No routine testing recommended	Cesarean section if active genital lesions at delivery; evaluate newborn for herpes infection
Treatment	**First episode:** Acyclovir: 400 mg po three times daily for 7–10 days, or 200 mg five times daily for 7–10 days Valacyclovir: 1000 mg po twice daily for 7–10 days **Recurrent episodes:** Acyclovir: 400 mg po three times daily for 5 days, or 800 mg twice daily for 5 days, or 800 mg three times daily for 2 days Valacyclovir: 500 mg po twice daily for 3 days **Suppressive therapy:** start at 36 weeks of gestation (or earlier if at risk of preterm delivery) until delivery Acyclovir: 400 mg po three times daily Valacyclovir: 500 mg po twice daily			
Syphilis	All women with confirmed positive serology	In utero fetal and neonatal infection; congenital malformations	At 28–32 weeks and at delivery if at risk of reinfection, if untested before, if positive serology in the first trimester, or if was previous stillborn at more than 20 weeks	Therapy is efficacious to treat the fetus and to prevent transmission; be aware of Jarisch-Herxheimer reaction; fetal evaluation should include ultrasounds
Treatment	Desensitize penicillin-allergic patients Primary, secondary, or early latent: Benzathine penicillin G 2.4 million units IM once Late latent or of unknown duration or tertiary: Benzathine penicillin G 2.4 million units IM three times at 1-week interval			
Trichomoniasis	Symptomatic women	PPROM, preterm birth, low birth weight; neonatal infection		Therapy does not decrease perinatal mortality
Treatment	Metronidazole 2 g po for one dose			

IM, intramuscular; IV, intravenous; po, orally; PPROM, preterm premature rupture of membranes.

Patient Care Process

Collect Information:

- Complete medical and obstetrical history.
- Inquire about disorders evolution and last follow-up with the treating physician.
- Conduct medication history (past/current treatments, compliance, efficacy, and safety).
- Verify immunization status.
- Assess for pregnancy signs and symptoms.
- Perform physical examination.
- Evaluate nutritional status and socioeconomic environment.
- Perform first trimester routine lab testing.
- Order serum drug levels.

(*Continued*)

Patient Care Process (*Continued*)

Assess the Information:

- Evaluate benefits and risks for mother and fetus of continuing medications.
- Assess efficacy, safety, and patient adherence, and screen for drug interactions.
- Evaluate whether safer and more effective alternative are available.

Develop a Care Plan:

- Choose treatments with evidence of benefit and safety data during pregnancy or that cannot be delayed until after delivery and or after breast-feeding is finished (Table 47–7).
- Address patient concerns (risks of medication or of relapse if condition is untreated, prescription coverage and access to care).
- Treat pregnancy symptoms (eg, nausea) if needed.
- When possible, use nonpharmacologic treatments.

Implement the Care Plan:

- Recommend appropriate folic acid and multivitamins.
- Counsel of lifestyle (healthy diet, exercise, avoidance of tobacco, alcohol, and illicit or unnecessary drugs).
- Encourage breast-feeding. If breast-feeding, choose drugs with the best safety profile.
- Communicate information to all other health care professionals to ensure continuing of care.

Follow-up: Monitor and Evaluate:

- Assess compliance, effectiveness, and safety of treatment at each prenatal visit.
- Review and repeat assessments as necessary.
- Monitor infants for birth defects, developmental delays, or unusual reactions, and report suspected drug-related reactions to the FDA or pharmaceutical companies.

Abbreviations Introduced in This Chapter

AAP	American Academy of Pediatrics
ACEi	Angiotensin-converting enzyme inhibitors
ACOG	American College of Obstetricians and Gynecologists
anti-TPOAbs	Antithyroid peroxidase antibodies
β-hCG	Beta-human chorionic gonadotropin
CNS	Central nervous system
DM	Diabetes mellitus
GA	Gestational age
GBS	Group B *streptococcus*
GDM	Gestational diabetes mellitus
LMP	Last menstrual period
LT_4	Levothyroxine
NSAID	Nonsteroidal anti-inflammatory drug
NTD	Neural tube defect
OTIS	Organization of Teratology Information Specialists
PCA	Postconceptional age
PPROM	Preterm Premature Rupture of Membranes
PTU	Propylthiouracil
SMBG	Self-monitoring of blood glucose
STEPS	System for Thalidomide Education and Prescribing Safety
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
T_4	Thyroxine
TSH	Thyroxine-stimulating hormone
TSHR-Sabs	Thyroid-stimulating hormone receptors-stimulating antibodies
VDRL	Venereal Disease Research Laboratory

48 Contraception

Julia M. Koehler and Kathleen B. Haynes

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Discuss the physiology of the female reproductive system.
2. Compare the efficacy of oral contraceptives with that of other methods of contraception.
3. State the mechanism of action of hormonal contraceptives.
4. Discuss adverse effects, risks, and contraindications associated with the use of contraceptives, and recommend strategies for minimizing or eliminating such risks.
5. Describe advantages and disadvantages of various contraceptives, including oral and nonoral formulations.
6. Cite important drug interactions that may occur with oral contraceptives.
7. Provide appropriate patient education regarding the use of oral and barrier methods of contraception.
8. Discuss how emergency contraception may be employed to prevent unintended pregnancy.

INTRODUCTION

Historically, the 1950s was an important time in the control of human fertility. It was during that decade that the first combination hormonal contraceptives (CHCs) were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. CHCs are the most commonly used reversible form of contraception in the United States today, with an estimated 9.7 million women users.[1] Studies of women of childbearing age (15–44 years) in the United States estimate that 62% are currently using a contraceptive method.[1] Since the introduction of oral contraceptives, many additional contraceptive forms have been developed and are available for use in the United States, including transdermal systems, transvaginal systems, and intrauterine devices (IUDs). These additional forms of contraception offer women effective and potentially more convenient alternatives to oral contraceptives.

EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.37 million pregnancies occur annually in the United States.[2] It is estimated that nearly half of all pregnancies that occur each year in the United States are unintended.[2,3] A survey of women who had unintended births in the United States between 1998 and 2002 revealed that approximately 60% were not using any form of contraception.[1] In addition, many women who do use contraceptives use their chosen method of contraception imperfectly, and this also increases the risk of unintended pregnancy. For patients with certain medical conditions, such as epilepsy, hypertension, ischemic heart disease, sickle cell disease, lupus, or thromboembolic mutations, unintended pregnancy can further increase the risk for adverse health events.[4,5] The provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential in order to reduce the risk of unintended pregnancy and, for some women, the associated increase in risk for adverse health-related events.

Exposure to sexually transmitted infections (STIs) is also a concern for women who are sexually active. It is estimated that 20 million people in the United States become newly infected annually with an STI.[6] Given that not all methods of contraception protect the user against STIs, the provision of proper patient education by health care professionals regarding this risk is absolutely essential.

PHYSIOLOGY

LO 1

The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual.[4] The follicular phase begins the cycle, and ovulation generally occurs around day 14. The luteal phase then begins and continues until menstruation occurs.[4] The menstrual cycle is regulated by a negative-feedback hormone loop between the hypothalamus, anterior pituitary gland, and ovaries[4] (Figure 48–1).

Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulosa cells lining the follicle to grow and produce estrogen. LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulosa cells to cells that secrete progesterone after ovulation.

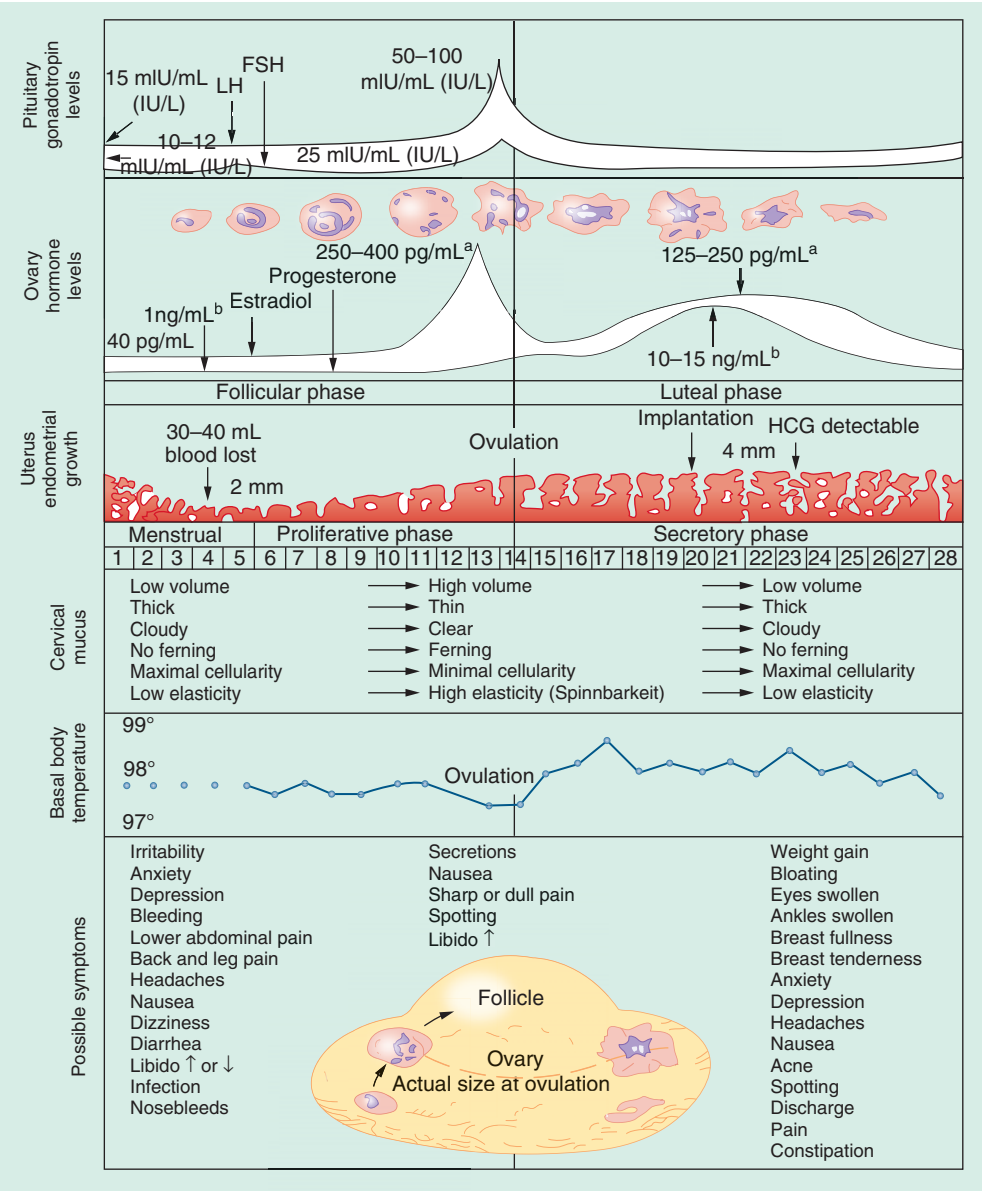

FIGURE 48–1. Menstrual cycle events. [a]Estradiol: 40 pg/mL = 147 pmol/L; 250 to 400 pg/mL = 918 to 1468 pmol/L; 125 to 250 pg/mL = 459 to 918 pmol/L. [b]Progesterone: 1 ng/mL = 3.18 nmol/L; 10 to 15 ng/mL = 32 to 48 nmol/L. (FSH, follice-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, leutinizing hormone.) (Adapted with permission from Shulman LP. The menstrual cycle. In: Hatcher RA, Trussel J, Nelson AL, Cates W Jr, Kowal D, Policar M. Contraceptive Technology, 20th rev. ed. New York: Ardent Media, 2011:29–44.)

Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoan penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity—implantation—occurs.

PREVENTION OF PREGNANCY: CONTRACEPTIVES AND DEVICES

Goals of Contraception/Desired Outcome

The most common goal of contraception is the prevention of pregnancy. However, some patients use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

Choice of Contraceptives: Important Considerations

When helping a patient with contraceptive selection, the most important goal is finding an option the patient is comfortable with and the clinician feels is beneficial for the patient. It is imperative to explain the side effects, safety concerns, and noncontraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals vary for each patient. It must be determined whether the goal is to postpone conception, space out the next pregnancy, or avoid further pregnancy altogether. Also, a clinician must understand the patient's desire to have or not have a regular bleeding pattern, because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients may be evaluated by a

health care professional to rule out medical contraindications to certain contraceptives, although a physical examination is not required and pharmacists can prescribe contraceptives in some states. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STIs. Women not in a monogamous relationship must consider their risk of STIs as a factor in their contraceptive decision. Some barrier methods protect against STIs, but hormonal contraceptives do not prevent STIs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that interrupts sexual activity, then a diaphragm would be an inappropriate choice. Preference of the sexual partner may also be important. Certain agents such as male condoms require the male partner to play an active role in contraception. Patients must also consider their religious beliefs and cultural practices as some forms of birth control may violate certain religious rules or cultural beliefs.

Cost may also be an issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

Efficacy of Contraceptives

LO 2

The unintended pregnancy rate for women who do not use any form of contraception is unknown. Therefore, it is difficult to determine the true efficacy of contraceptives in preventing unwanted pregnancy. Table 48–1 shows the percentage of women who experience unintended pregnancy within 1 year of contraceptive use with ongoing sexual activity.[4]

Oral Contraceptives (Combination)

CHCs contain a synthetic estrogen and one of several steroids with progestational activity. Most oral contraceptives contain one of three types of estrogen: ethinyl estradiol (EE), which is pharmacologically active; mestranol, which is converted by the liver to EE; or estradiol valerate, which is metabolized to estradiol and valeric acid. Many different progestins are found in the various oral contraceptives. These include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, drospirenone, and dienogest.

LO 3

The primary mechanism by which CHCs prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the ovaries occurs in a cyclic manner, which determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of CHCs is most active in inhibiting FSH release.[4] However, at sufficiently high doses, estrogens also may cause inhibition of LH release. In low-dose CHCs (≤ 35 mcg EE), the progestin component causes suppression of LH.[4] Ovulation is prevented by this suppression of the midcycle surge of both FSH and LH and mimics the physiologic changes that occur during pregnancy.

LO 3

Although suppression of FSH and LH is the primary mechanism by which CHCs prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy. Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of cervical

Table 48–1

Unintended Pregnancy Rates

Method	Percentage of Women Experiencing Unintended Pregnancy Within First Year of Use: Typical Use[a]	Percentage of Women Experiencing Unintended Pregnancy Within First Year of Use: Perfect Use[b]	Percentage of Women Continuing Use at 1 Year[c]
No method	85	85	
Spermicides	28	18	42
Withdrawal	22	4	46
Fertility awareness–based methods	24		47
Standard days method		5	
Two-day method		4	
Ovulation method		3	
Symptothermal method		0.4	
Sponge			
Parous women	24	20	
Nulliparous women	12	9	
Diaphragm	12	6	57

NuvaRing	9	0.3	67
Depo-Provera	6	0.2	56
IUD			
ParaGard (copper T)	0.8	0.6	78
Mirena (LNG-IUS)	0.2	0.2	80
Liletta	0.15		
Skyla	0.4		
Implanon	0.05	0.05	84
Nexplanon	0.05	0.05	84
Female sterilization	0.5	0.5	100
Male sterilization	0.15	0.1	100

[a]Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, periodic abstinence, the diaphragm, the male condom, the pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth corrected for underreporting of abortion.

[b]Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[c]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

IUD, intrauterine device.

mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm.[4] Thus, in addition to inhibiting ovulation, CHCs induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.[4]

Table 48–2 contains a partial listing of the many oral contraceptives available in the United States.[7] Since the mid-1960s, EE has been the primary estrogen used in most CHCs. However, the amount of EE used in CHCs has decreased progressively since that time, and most now contain 35 mcg or less

Table 48–2

Some Available Oral Contraceptives

Estrogen (mcg/tablet)	Progestin (mg/tablet)	Examples of Brand Names
Monophasic Preparations		
EE (20)	Norethindrone acetate (1)	Junel 1/20, Junel Fe 1/20, Junel Fe 24, Larin 1/20, Larin Fe 1/20, Larin 24 Fe, Loestrin 21 1/20, Loestrin Fe 1/20, Lomenia 24 Fe, Mibelas 24 Fe, Microgestin 1/20, Microgestin Fe 1/20, Minastrin 24 Fe, Tarina Fe 1/20, Taytalla
EE (20)	Levonorgestrel (0.09)	Amethyst
EE (20)	Levonorgestrel (0.1)	Aviane, Falmina, Lessina, Lutera, Orsythia, Sronyx, Vienva
EE (20)	Drospirenone (3)	Beyaz,[a] Gianvi, Loryna, Nikki, Vestura, Yaz
EE (20)	Desogestrel (0.15)	Azurette
EE (25)	Norethindrone (0.8)	Generess Fe, Kaitlib Fe
EE (30)	Desogestrel (0.15)	Apri, Desogen, Emoquette, Enskyce, Reclipsen
EE (30)	Levonorgestrel (0.15)	Altavera, Kurvelo, Levora, Marlissa, Portia
EE (30)	Drospirenone (3)	Ocella, Safyral[a], Syeda, Yasmin, Zarah
EE (30)	Norgestrel (0.3)	Cryselle, Elinest, Lo/Ovral-28, Low-Ogestrel
EE (30)	Norethindrone acetate (1.5)	Blisovi 1.5/30, Junel 1.5/30, Junel Fe 1.5/30, Larin 1.5/30, Larin Fe 1.5/30, Loestrin 21 1.5/30, Loestrin Fe 1.5/30, Microgestin 1.5/30, Microgestin Fe 1.5/30
EE (35)	Norgestimate (0.25)	Estarylla, Mono-Linyah, MonoNessa, Ortho-Cyclen, Previfem, Sprintec
EE (35)	Norethindrone (0.4)	Balziva, Briellyn, Femcon Fe, Gildagia, Ovcon-35, Philith, Vyfemla, Wymza Fe, Zenchent, Zenchent Fe, Zeosa
EE (35)	Norethindrone (0.5)	Brevicon, Modicon, Necon 0.5/35, Nortrel 0.5/35, Wera
EE (35)	Norethindrone (1)	Alyacen 1/35, Cyclafem 1/35, Dasetta 1/35, Necon 1/35, Norinyl 1/35, Nortrel 1/35, Ortho-Novum 1/35, Pirmella 1/35
EE (35)	Ethynodiol diacetate (1)	Kelnor 1/35, Zovia 1/35
EE (50)	Norgestrel (0.5)	Ogestrel
EE (50)	Ethynodiol diacetate (1)	Zovia 1/50E
Mestranol (50)	Norethindrone (1)	Necon 1/50, Norinyl 1/50
Biphasic Preparations		
EE (10)	Norethindrone acetate (1,0)	Lo Loestrin Fe[b]
EE (20,0,10)	Desogestrel (0.15,0,0)	Bekyree[b], Kariva[b], Kimidess[b], Pimtrea[b], Viorele[b]
EE (35)	Norethindrone (0.5,1)	Necon 10/11
Triphasic Preparations		
EE (20,30,35)	Northindrone acetate (1)	Estrostep Fe, Tilia Fe, Tri-Legest Fe
EE (30,40,30)	Levonorgestrel (0.05,0.075,0.125)	Enpresse, Levonest, Myzilra, Trivora
EE (35)	Norgestimate (0.18,0.215,0.25)	Ortho Tri-Cyclen, Tri-Estarylla, Tri-Linyah, Tri-Nessa, Tri-Previfem, Tri-Sprintec
EE (35)	Norethindrone (0.5,1,0.5)	Aranelle, Leena, Tri-Norinyl
EE (35)	Norethindrone (0.5,0.75,1)	Alyacen 7/7/7, Cyclafem 7/7/7, Dasetta 7/7/7, Necon 7/7/7, Nortrel 7/7/7, Ortho-Novum 7/7/7, Pirmella 7/7/7
EE (25)	Norgestimate (0.18,0.215,0.25)	Ortho Tri-Cyclen Lo, Tri-Lo-Estarylla, Tri-Lo-Marzia, Tri-Lo-Sprintec
EE (25)	Desogestrel (0.1,0.125,0.15)	Caziant, Cyclessa, Velivet
Quadriphasic Preparations		
Estradiol valerate (3,2,2,1)	Dienogest (0,2,3,0)	Natazia
Extended Cycle Preparations		
EE (20)	Levonorgestrel (0.1)	Amethia Lo, Camrese Lo
EE (30)	Levonorgestrel (0.15)	Amethia, Ashylyna, Camrese, Daysee, Introvale, Jolessa, Quasense, Seasonale, Setlakin
EE (20,25,30,10)	Levonorgestrel (0.15,0)	Fayosim, Rivelsa, Quartette
EE (20,10)	Levonorgestrel (0.1)	LoSeasonique
EE (30,10)	Levonorgestrel (0.15)	Seasonique
Progestin-Only Preparations		
None	Norethindrone (0.35)	Camila, Errin, Heather, Jencycla, Jolivette, Nora-BE, Nor-QD, Ortho Micronor

[a]Each tablet also contains 451 mcg of levomefolate calcium.

[b]Some references may classify as monophasic since the variation in hormone content does not occur during the first 3 weeks of the pill pack.

EE, ethinyl estradiol

Data compiled in part from Anonymous. Choice of contraceptives: Med Lett Drugs Ther. 2015;57:127–134.

of EE. In addition, to reduce side effects and improve tolerability associated with oral contraceptive use, newer progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with the progestins of CHCs, the original synthetic progestins were modified to create "third generation" progestins (eg, desogestrel and norgestimate), and "fourth generation" progestins with antiandrogenic properties (eg, drospirenone). Overall, the synthetic progestins found in today's CHCs are extremely potent in their ability to inhibit ovulation and prevent pregnancy.

CHCs are available in monophasic, biphasic, triphasic, and quadriphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all four preparations contain both estrogens and progestins, biphasic, triphasic, and quadriphasic preparations contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce a patient's cumulative exposure to progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the multiphasic preparations offer any significant clinical advantage over monophasic pills.[7]

Most traditional CHCs are packaged as 21/7 cycles (ie, 21 days of active pills and 7 days of placebo). However, newer regimens offer either fewer hormone-free days per traditional, 28-day pill cycle or extended (or in some cases continuous) cycles (84- or 365-day pill cycle), which may allow for fewer withdrawal bleeds per year and fewer menstrual-related side effects (eg, menstrual pain, bloating, headaches) for some women.

▶ *Noncontraceptive Benefits of Combination Hormonal Contraceptives*

In addition to preventing pregnancy, there are several noncontraceptive benefits associated with the use of CHCs.

Reduction in the Risk of Endometrial Cancer The risk of endometrial cancer among women who have used oral contraceptives for at least 1 and 10 years is approximately 40% and 80% less than the risk in women who have never used oral contraceptives, respectively.[4,8] There is additional evidence to suggest that this reduced risk may persist for up to 20 years following discontinuation of oral contraceptives.[4,8]

Reduction in the Risk of Ovarian Cancer When compared with women who have never used oral contraceptives, women who have used oral contraceptives for at least 1 year are less likely to develop ovarian cancer than those who have never used oral contraceptives. While there is evidence to suggest the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives,[9-11] a recent study suggested possible attenuation of the protective effect of CHCs against ovarian cancer with use after 35 years of age.[12] Thus, further study may be needed to determine the influence of age of user on potential protection against this type of cancer.

Improved Regulation of Menstruation and Reduction in the Risk of Anemia Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and dysmenorrhea.[4,7] Also, women who take oral contraceptives have a smaller volume of menstruum and experience fewer days of menstruation each month and consequently experience less blood loss with each menstrual period.[4,13] Some studies suggest that oral contraceptive use decreases overall monthly menstrual flow by 60% or more and conserves hemoglobin and ferritin levels, which may be particularly beneficial in women who are anemic or at risk for anemia.[4] In addition, some CHC formulations contain iron, which may also minimize the risk for anemia. (See **Unique Oral Contraceptives** section.)

Reduction in the Risk of Fetal Neural Tube Defects While CHCs are not 100% effective at preventing pregnancy, it is possible that a woman may conceive while taking a CHC. In addition, many women may become pregnant very soon after discontinuing a CHC. In order to decrease the risk of neural tube defects in the fetuses associated with such pregnancies, CHC formulations that contain a source of folate in every pill are also available.[4]

Relief from Symptoms Associated with Premenstrual Dysphoric Disorder CHCs have been widely used for the treatment of premenstrual dysphoric disorder (PMDD). Current evidence suggests that these agents are most effective at targeting the physical symptoms associated with the disorder and less effective in treating mood-related symptoms.[14] Although multiphasic CHCs have been used effectively in the treatment of PMDD, monophasic preparations may yield fewer mood swings and are generally easier to manage. Several drospirenone-containing CHCs now carry a US Food and Drug Administration (FDA)-approved indication for PMDD, including Yaz, Gianvi, Loryna, Nikki, and Vestura.[7]

Relief of Benign Breast Disease Women who use oral contraceptives are less likely to develop benign breast cysts or fibroadenomas and are less likely to experience progression of such conditions.[4,7]

Prevention of Ovarian Cysts Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.[7]

Decrease in Symptoms Related to Endometriosis CHC use has been linked to a decreased incidence of symptomatic endometriosis. In women who suffer from endometriosis, the extended-cycle CHCs may provide the most effective relief from menstrual pain by reducing the total number of painful episodes per year.[4]

Improvement in Acne Control All CHCs can improve acne by increasing the quantity of sex hormone–binding globulin and thereby decreasing free testosterone concentrations.[7] Third-generation progestins, such as desogestrel and norgestimate, are believed to have less androgenic activity compared with older progestins, and drospirenone is considered to be antiandrogenic.[7] However, it is not clear that CHCs containing any of these progestins confer any advantage over other CHCs with respect to their ability to improve acne control. Ortho Tri-Cyclen, TriNessa, and Tri-Sprintec (EE and norgestimate); Estrostep Fe, Tilia Fe, and Tri-Legest Fe (EE and norethindrone acetate); Yaz, Beyaz, and Safyral (EE and drospirenone) each carry an FDA-approved indication for the treatment of acne.[4,7]

▶ *Potential Risks of Combination Hormonal Contraceptives*

LO 4

Although there are many noncontraceptive benefits associated with the use of CHCs, their use is not without risk or potential for adverse effects.

Sexually Transmitted Infections Because the use of CHCs may decrease the use of selected barrier contraceptive methods (eg, latex condoms) that do protect against STIs, one of the most common potential risks associated with the use of oral contraceptives is the increased risk of acquiring an STI.[5] However,

concerning risks for HIV acquisition studies have failed to show an increased risk and therefore the CDC considers HIV a condition for which there is no restriction for the use of the contraceptive method.

Cardiovascular Events and Hypertension A World Health Organization (WHO) collaborative study found that high-dose (50 mcg or more of EE) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke.[7,15] In this study, women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives.[16-18] Hypertension secondary to oral contraceptive use is thought to occur in up to 3% of women and is believed to be attributed to the effect of estrogens and progestins on aldosterone activity.[4] Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If blood pressure is ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic, the risks outweigh advantages and there should be consideration to discontinue CHCs; if blood pressure is ≥ 160 mm Hg systolic or ≥ 100 mm Hg, then CHC use is not recommended.[5] Estrogen-containing contraceptives are not recommended for smokers who are 35 years of age or older or for women who experience migraine headaches with aura.[5,7]

Venous Thromboembolism It is believed that the estrogen component of CHCs stimulates enhanced hepatic production of clotting factors. CHCs have been associated with a two- to threefold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives.[7] Contraceptive users at greatest risk for the development of VTE include those who are obese, smoke, have hypertension, have diabetes complicated by end-organ damage, are immobile, have experienced recent trauma or surgery, or have a history of prior thromboembolism. It is important to note, however, that the increase in risk of VTE in oral contraceptive users is lower than that associated with pregnancy and the postpartum period.[7,19] Newer, less androgenic progestins, such as desogestrel and fourth generation drospirenone, have been reported to be associated with a higher risk of VTE.[20-23] Currently available studies validating this risk have produced conflicting results. Two studies published in 2011 reported a two- to threefold greater risk of venous thromboembolic events in women using oral contraceptives containing drospirenone when compared with women using levonorgestrel-containing contraceptives.[24,25] A more recent case-control study of > 10,000 women with VTE also found that exposure to drospirenone and desogestrel was associated with a higher risk of VTE compared to exposure to levonorgestrel.[26] Conversely, the results of the International Active Surveillance Study of Women Taking Oral Contraceptives, published in 2014, demonstrated similar rates of venous and arterial thromboembolism in women taking CHCs containing drosperinone, levonorgesterol, or other progestins.[27] In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.[5,7]

Gallbladder Disease In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease and may worsen existing gallbladder disease.[4,5] Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, CHCs containing estrogen should be used with caution in patients with a history of gallbladder disease or current gallbladder disease, especially if known cause is related to CHCs.

Hepatic Tumors Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors.[3] Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination. In cases of benign hepatocellular adenoma and hepatoma (malignancy), the use of CHCs is contraindicated.[5]

Cervical Cancer There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives, particularly among women who test positive for human papilloma virus (HPV), a known risk factor for cervical cancer.[4] It is uncertain whether this increase in risk is directly attributed to the use of oral contraceptives. Data suggest that oral contraceptive users tend to have more sexual partners and use condoms less frequently, and as a result, this may increase their susceptibility to infection with HPV.

KEY CONCEPT Absolute and relative contraindications to the use of oral contraceptives are listed in Table 48–3.[4,5,28]

Adverse Effects of Oral Contraceptives and Their Management

LO 4

As with all medications, there are potential adverse effects with CHCs. KEY CONCEPT Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive. It is also important to individualize the selection of oral contraceptives, because some women are at increased risk for potentially serious side effects.

Common complaints with CHCs include headaches, nausea, vomiting, **mastalgia**, and weight gain, although studies have shown a similar percentage of patients taking placebo experience

Patient Encounter Part 1

A 20-year-old nulliparous woman presents to your clinic requesting information on contraception. She specifically inquires about options that allow for fewer or no menstrual periods. You begin to take a history and determine that the patient is currently sexually active and is not using any method of birth control. She weighs 125 lb (56.8 kg), is 65 in (165 cm) tall, and has a blood pressure of 110/72 mm Hg. She has no history of smoking. She has migraines without aura and anxiety. Her only medication is propranolol. On further questioning, you discover that she has a positive family history of breast cancer (both her mother and maternal grandmother), but no personal history. As you discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

What additional information do you need to know before recommending a contraceptive for this patient?

Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?

What education would you provide to this patient regarding risks associated with oral contraceptive use?

Table 48–3

Conditions with Unacceptable Health Risk or with Theoretical or Proven Risks That Usually Outweigh the Advantages of CHC Use[3,4]

Conditions that represent an unacceptable health risk with CHC use

- History of thromboembolic disease
- History of stroke (or current cerebrovascular disease)
- History of (or current) coronary artery disease, ischemic heart disease, or peripheral vascular disease
- History of carcinoma of the breast (known or suspected)
- History of any estrogen-dependent neoplasm (known or suspected)
- Undiagnosed abnormal uterine or vaginal bleeding
- Pregnancy (known or suspected)
- Breastfeeding < 21 days postpartum
- Heavy smoking (defined as 15 cigarettes or more per day) by women who are 35 years of age or older
- History of hepatic tumors (benign or malignant)
- Active liver disease
- Migraine headaches with focal neurologic symptoms (aura)
- Postpartum (during the first 21 days in women with additional risk factors for thromboembolism, including age ≥ 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

Conditions for which the theoretical or proven risks usually outweigh the advantages of CHC use

- Smoking (< 15 cigarettes per day) at any age
- Migraine headache disorder without focal neurologic symptoms
- Hypertension (NOTE: WHO considers health risk posed by CHC use to be "unacceptable" when either systolic blood pressure is 160 mm Hg or more, or diastolic blood pressure is 90 mm Hg or more)
- Fibroid tumors of the uterus
- Breast-feeding > 21 days postpartum (with other risk factors for VTE such as > 35 years, previous VTE, transfusion at delivery, peripartum cardiomyopathy, obesity, postpartum hemorrhage, postcesarean delivery, preeclampsia or smoking)
- Superficial venous thrombosis (acute or history)
- Multiple sclerosis with prolonged immobility
- Diabetes mellitus
- Family history of dyslipidemia
- Sickle cell disease
- Active gallbladder disease
- Age > 50 years
- Elective major surgery requiring immobilization (planned in the next 4 weeks)
- Postpartum (during days 21 through 42 in women with additional risk factors for thromboembolism, including age ≥ 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

these side effects.[29] Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of CHCs is necessary.

Between 30% and 50% of women complain of breakthrough bleeding or spotting when oral contraceptives are initiated. All side effects tend to resolve by the third or fourth cycle.[4] Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, and poor absorption of the oral contraceptive owing to drug interaction or gastrointestinal problems, should be ruled out. Once these causes have been ruled out, the timing of the spotting must be determined in order to adjust the formulation appropriately.

LO 4 The most common side effects and ways to adjust therapy to minimize these side effects are listed in Table 48–4.[4,7,30]

As highlighted in Table 48–4, many of the side effects of CHCs may be minimized by adjusting the estrogen or progestin content of the preparation.

Progestin-Only Pills

LO 5 For women unable to take estrogen-containing oral contraceptives, there is an alternative: oral contraceptives containing only the progestin, norethindrone. These agents are slightly less effective than CHCs but have other advantages over CHCs. Progestin-only products have not shown the same thromboembolic risk as estrogen-containing products. Therefore, women at increased risk for or with a history of thromboembolism may be good candidates for progestin-only oral contraceptives. Also, these products can minimize menses, and many women have **amenorrhea** after six to nine cycles. These products have also been found safe to use in women who are nursing, so they are a viable option for women who breast-feed and desire hormonal contraception. In such patients, it should not be initiated until 42 days postpartum. Spotting may occur in some women, and this is a common cause for discontinuation. These products should be taken at the same time every day, and there is no pill-free or hormone-free period.

Unique Oral Contraceptives

LO 5 Along with varying doses of estrogen and different progestins, formulation modifications among select CHC products may yield certain benefits in some patient situations.

Lo-Loestrin Fe (norethindrone/EE) is a biphasic product that contains a low-dose estrogen, a high amount of progestin, and medium androgenic activity. Similar to other low-dose estrogen CHCs, Lo-Loestrin Fe may offer a smaller margin of error when pills are missed but provide the potential advantage of fewer estrogen-related side effects (eg, nausea and breast tenderness). Unlike the typical 28-pill packs that contain 21 active tablets and seven placebo tablets, Lo-Loestrin Fe contains 24 combination hormone tablets, two estrogen-only tablets, and two placebo (iron-only) tablets. This product provides a shorter hormone-free interval and may allow for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

There are several monophasic combinations that are packaged as a 91-day treatment cycles with 84 active tablets that are taken consecutively followed by seven placebo tablets. These include Amethia, Ashlynn, Camrese, Daysee, Introvale, Jolessa, Seasonale, and Setlakin (levonorgestrel/EE). The extended cycle length of these products allows for one menstrual cycle per "season," or four per year. This type of formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. These products may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. However, in the SEA 301 clinical trial comparing the efficacy of Seasonale with that of an equivalent-dosage 28-day cycle regimen, 7.7% versus 1.8% of women discontinued prematurely for unacceptable bleeding.[31] The risk of intermenstrual bleeding and/or spotting may be higher for patients taking these extended-cycle combinations than for patients taking typical 28-day-regimen CHCs.[32]

Seasonique and LoSeasonique (levonorgestrel/EE) are also extended cycle preparations that are similar to those mentioned earlier, but instead these preparations contain seven tablets with low-dose estrogen rather than placebo. Menstruation-related

Table 48–4

Management of Adverse Effects of Oral Contraceptives[4,7,30]

Adverse Effect	Cause	Adjustment	Notes
Spotting/bleeding before finishing active pills	Insufficient progestin	Monophasic with increased progestin or triphasic with increasing progestin	
Continued bleeding after menses	Insufficient estrogen	Increase estrogen or triphasic with lower early progestin	
Midcycle bleeding	Difficult to determine	Increase estrogen and progestin	
Increased breakthrough bleeding in general	Insufficient estrogen	Increase estrogen or triphasic formulation	Will increase amount of withdrawal bleeding during menses
Acne, PMDD, hirsutism	Progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone	
Nausea, vomiting	Related to estrogen	Take at bedtime or with food; decrease estrogen or switch to a progestin-only product	Symptoms often resolve in 1–3 months
Constipation, bloating, distention	Related to progestin	Decrease progestin	Symptoms often resolve in 1–3 months
Headache	Must be evaluated because of warning sign for stroke – monitor blood pressure	If determined to not be serious, but still troublesome consider: a. Discontinue oral contraceptive b. Decrease estrogen c. Decrease progestin d. Eliminate pill-free interval for 2–3 cycles (when headaches occur during pill-free interval)	Discontinue oral contraceptive immediately if any neurologic symptoms or blurred vision
Decrease in libido, decreased vaginal lubrication	Insufficient estrogen	Increase estrogen or consider vaginal hormonal ring (NuvaRing)	Feelings of depression may coincide
Dyslipidemia in general	Progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone	Obtain a baseline lipid panel in women with risk factors for dyslipidemia—smoking, hypertension, family history of heart disease
Triglycerides > 350 mg/dL (3.96 mmol/L)	Related to estrogen	Decrease estrogen to 20–25 mcg or a progestin-only formulation[3]	
Mastalgia	Related to estrogen	Decrease estrogen or switch to an extended cycle formulation (see Unique Oral Contraceptives, later) if it occurs prior to menses	
Weight gain, fluid retention	Excess estrogen and progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Decrease estrogen and switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone	
Visual changes or disturbances with contact lenses	Related to estrogen	Use saline eye drops	Referral to ophthalmology if eye drops do not help
Melasma, chloasma	Related to estrogen stimulation of melanocyte production	Consider progestin-only product and use of sunscreen	Women with darker pigmentation are more susceptible; melasma may not be completely reversible on discontinuation

problems that may improve with Seasonique or LoSeasonique include menstrual-related headaches, menorrhagia, and anemia. In addition, endometriosis-related menstrual pain may be relieved by providing a continuous regimen without a pill-free interval.[33]

Yasmin and Yaz (drospirenone/EE) are examples of unique oral contraceptives that contain the progestin drospirenone, that has antiandrogenic properties, but also showed antimineralocorticoid activity such as diuresis and hyperkalemia. Drospirenone has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3-mg dose available in CHC preparations has antimineralocorticoid activity equal to 25 mg of spironolactone. It can affect the sodium and water balance in the body, although it has not shown superior efficacy for side effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or in women taking other medications that may affect serum potassium.

Yaz (drospirenone/EE) is an extended-cycle preparation that contains a low-dose estrogen and antimineralocorticoid and antiandrogenic activity. Yaz also contains 24 active tablets and four placebo tablets, allowing for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

In 2003, the FDA Advisory Committee for Reproductive Health Drugs recommended the development of a CHC tablet containing folic acid in order to minimize the risk of neural tube defects in cases of contraceptive failure. Beyaz and Safyral, which were FDA approved in 2010, are combination tablets containing drospirenone and EE and 451 mcg of levomefolate calcium, the primary metabolite of folic acid. Beyaz is an extended-cycle preparation, which may allow for shorter menstrual periods and fewer menstrual-related symptoms.

In addition to the prevention of pregnancy, Yaz, Beyaz, Safyral; Ortho Tri-Cyclen, TriNessa, and Tri-Sprintec (norgestimate/EE); and Estrostep Fe, Tilia Fe, and Tri-Legest Fe (norethindrone acetate/EE) each carry an approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have not responded adequately to conventional antiacne medication. This can help clinicians to streamline medications by serving dual purposes.

Bekyree, Kariva, Kimidess, Pimtrea, and Viorele (desogestrel/EE) have a unique dosing schedule. After the usual 21 active tablets, there are only two tablets with inert ingredients. The last five tablets in the package have 10 mcg of EE. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established. With each of these products, it is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Ovcon 35 (norethindrone/EE) has all 28 tablets in chewable form and has added spearmint flavoring.

Natazia was approved by the FDA in 2010 and is a quadriphasic CHC containing estradiol valerate and the progestin, dienogest. Estradiol valerate is metabolized endogenously to estradiol, and dienogest is a strong progestin with antiandrogenic activity. Natazia provides a unique estrogen step-down (estradiol valerate dose gradually decreases from 3 mg to 1 mg)/progestin step-up regimen (dienogest dose gradually increases from 0 mg to 3 mg), and this CHC offers the advantage of a shorter hormone-free interval. This results in fewer days of withdrawal bleeding and may help with menstrual-related headaches.

Patient Encounter Part 2: Adverse Effects

After 3 months of taking LoSeasonique, she returns to your clinic complaining of breakthrough bleeding during her sixth week of active pills. She reports no change or increase in frequency of her migraine headaches, and her blood pressure is 108/70 mm Hg. She is frustrated with the breakthrough bleeding and wants to explore other contraceptive options.

What are some potential causes of the breakthrough bleeding that the patient has been experiencing?

What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?

Finally, Quartette, Fayosim, and Rivelsa (levonorgestrel/EE) are extended-cycle, quadriphasic preparations that contain increasing doses of EE throughout the 91-day pill period. The increasing dose of EE is intended to reduce the rate of breakthrough bleeding or spotting.

Drug Interactions with Oral Contraceptives

LO 6

EE is metabolized in the liver primarily via cytochrome P-450 (CYP450) 3A4. KEY CONCEPT When reviewing drug interactions of oral contraceptives, clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives. Refer to Table 48–5 for a list of some of the most common drug interactions seen with oral contraceptives.[4,34]

Nonoral Hormonal Contraceptives

LO 5

KEY CONCEPT As an alternative to oral contraceptive pills, which must be taken daily in order to reliably prevent pregnancy, nonoral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than the pill formulations.

Xulane is a transdermal patch that contains both an estrogen (35 mcg of EE) and a progestin (150 mcg of norelgestromin). A new patch is applied to the abdomen, buttocks, back, or upper (outer) arm once weekly for 3 weeks, followed by 7 patch-free days.[7] Although some women have noted irregular bleeding during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of CHCs. It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg (about 198 lb).[7] Further, manufacturer prescriber information indicates that women who take transdermal contraception are exposed to approximately 60% more estrogen than women who take CHCs with 35 mcg of estrogen.[35] Although the clinical significance of this is not well defined, studies have suggested a link between the use of the patch and an increased risk for VTE. A slightly higher reported incidence of breast discomfort and local skin irritation has also been reported with the patch.[7,36]

NuvaRing is a unique transvaginal delivery system that provides 15 mcg of EE and 120 mcg of etonogestrel for the prevention of ovulation. NuvaRing is inserted into the vagina on or before day 5 of the menstrual cycle and is removed from the vagina 3 weeks later.[7] Seven days after the ring is removed, a new ring should be inserted. In clinical trials, NuvaRing demonstrated comparable efficacy and cycle control to CHCs as well as a similar side-effect profile.[7,37] NuvaRing should not be removed during intercourse.

Depo-Provera is a progestin-only, injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera is extremely effective in preventing pregnancy. However, the incidence of menstrual irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with CHCs. The use of Depo-Provera also has been demonstrated to result in significant loss of bone mineral density (BMD).[38] Although the effect is known to be reversible following product discontinuation, a black-box warning within the product labeling

Table 48–5

Commonly Seen Drug Interactions with CHCs[4,34]

Medication	Mechanism	Clinical Effect
Anticonvulsants (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, topiramate, and felbamate)	Increase metabolism of CHCs via induction of various cytochrome P-450 enzymes	Decrease efficacy of CHCs (EE doses < 35 mcg are not recommended in women on these medications)
Bosentan	Increase metabolism of CHCs via induction of cytochrome P-450 3A4 enzyme	Decrease efficacy of CHCs
Griseofulvin	Increase metabolism of CHCs	Decrease efficacy of CHCs; backup method of contraception is recommended
Lamotrigine	CHCs increase metabolism of lamotrigine via induction of glucuronidation	Decrease efficacy of lamotrigine; dose adjustment may be necessary
Nonnucleoside reverse transcriptase inhibitors (efavirenz, etravirine, nevirapine, rilpivirine)	Increase metabolism of CHCs	Decrease efficacy of CHCs; alternative method of contraception may be considered with efavirenz
Protease inhibitors (atazanavir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, tipranavir)	Increase or decrease in metabolism of CHCs	Decrease efficacy of CHCs or increase side effects of CHCs; alternative method of contraception is recommended with fosamprenavir and may be considered with ritonavir-boosted protease inhibitors, atazanavir and nelfinavir
Rifampin, rifabutin	Increase metabolism of CHCs	Decrease efficacy of CHCs; backup method of contraception is recommended
St. John's wort	Increase metabolism of CHCs via induction of various cytochrome P-450 enzymes	Decrease efficacy of CHCs; avoid use with CHCs
Theophylline	CHCs decrease theophylline clearance by 34% and increase half-life by 33%	Increase side effects of theophylline

CHC, combined hormonal contraception; EE, ethinyl estradiol.

cautions against the risk of potentially irreversible BMD loss associated with long-term use (eg, > 2 years) of the injectable product. Although injectable contraceptives offer no protection against STIs, it is important to note the CDC finds that the risk of HIV acquisition does not outweigh the benefit of contraceptive use in a patient at high risk of HIV infection. Although the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months).[7]

Depo-SubQ Provera 104 is also an injectable contraceptive product that contains only progestin (depot medroxyprogesterone acetate). This product differs from Depo-Provera in that it is given subcutaneously rather than intramuscularly, and it contains only 104 mg of medroxyprogesterone acetate (~30% less hormone) administered every 3 months for the prevention of pregnancy. Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy.[39] This product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera. It is also used for the management of endometriosis-associated pain along with its use for contraception.

Long-Acting Reversible Contraception

The currently available products for long-term reversible contraception (LARC) are listed in Table 48–6. Surveys have shown that LARC has the highest satisfaction rate among patients using reversible contraceptives, and use within the United States is on the rise.[1]

Although the mechanism of action for IUDs is not completely understood, several theories have been suggested. The original theory is that the presence of a foreign body in the uterus causes an inflammatory response that interferes with implantation. It is believed that copper-containing IUDs may interfere with sperm transport and fertilization and prevent implantation. Progestin-containing implantable contraceptives can have direct effects on the uterus, such as thickening of cervical mucus and alterations

Table 48–6

Long-Acting Reversible Contraception

Product	Ingredient	Dosage Form	Duration
Mirena	Levonorgestrel	Intrauterine device	Up to 5 years
Skyla	Levonorgestrel	Intrauterine device	Up to 3 years
Kyleena	Levonorgestrel	Intrauterine device	Up to 5 years
Liletta	Levonorgestrel	Intrauterine device	Up to 4 years
ParaGard T 380A	Copper	Intrauterine device	Up to 10 years
Implanon	Etonorgestrel	Implantable device	Up to 3 years
Nexplanon	Etonorgestrel	Implantable device	Up to 3 years

to the endometrial lining. Paragard T 380A does not prevent ovulation, although the other LARCs can because they are progestin-containing products.

It is important to evaluate a patient to determine whether she is an appropriate candidate for an implantable contraceptive. IUDs are recommended for women who are in a monogamous relationship, are at low risk for acquiring STIs, and have no current **pelvic inflammatory disease** (PID). Contraindications to the use of progestin-containing LARC products include (a) known or suspected pregnancy, (b) hepatic tumors or active liver disease, (c) undiagnosed abnormal genital bleeding, (d) known or suspected carcinoma of the breast or personal history of breast cancer, (e) history of thrombosis or thromboembolic disorders, and (f) hypersensitivity to any components of the products. There are also multiple additional contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (a) anatomically abnormal or distorted uterine cavity, (b) acute PID, (c) postpartum **endometritis** or infected abortion in the past 3 months, (d) known or suspected uterine or cervical malignancy, (e) untreated acute **cervicitis**, (f) previously inserted IUD still in place, (g) increased susceptibility to pelvic infections, and (h) **Wilson disease** (Paragard T 380A only).

The most common adverse effects are abdominal/pelvic cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are **ectopic pregnancy**, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.

Nonpharmacologic Contraceptive Methods

▶ *Barrier Contraceptives*

LO 5

As an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. Although barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are associated with much higher unintended pregnancy rates[7] (see Table 48–1).

Diaphragms and Cervical Caps Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a health care professional, and they must be refitted in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. They must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reapplication of the spermicide is necessary. However, when sexual intercourse is repeated with a cervical cap, reapplication of the spermicide typically is not necessary.[7] Whether or not diaphragms or cervical caps provide adequate protection against STIs remains unclear.[40]

Spermicides Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the most commonly used spermicide in the United States.[4,7] Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, and suppository. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy.[4] To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix.[7] Additionally, film and suppositories must dissolve to be effective. Although the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device.[40] Clinical trials assessing the ability of spermicides to protect against STIs have failed to produce positive results.[4] Further, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for acquisition of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus.[7] In December 2007, the FDA issued a statement requiring manufacturers of nonoxynol-9 products to include a warning on the product label indicating that the spermicide does not provide protection against infection from HIV or other STIs. Patients should be encouraged not to use spermicides alone, but it is recommended with a barrier method.

Condoms Condoms, which are available for both male and female use, act as physical barriers to prevent sperm from coming into contact with ova.[4] Condoms are easy to use, available without a prescription, and inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy.[41] Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy.[7] For latex-sensitive individuals, condoms made from lamb intestine ("natural membrane" condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STIs.[4] As well, synthetic polyurethane condoms may be more likely to break than latex condoms. KEY CONCEPT Both latex and synthetic condoms can provide some protection against many STIs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used.[42] This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STIs. Relative to male condoms, female condoms may offer even better protection against STIs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis.[4] It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.[4]

Sponge The Today Sponge is a small, pillow-shaped polyurethane sponge impregnated with nonoxynol-9.[40] It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms.[42] The sponge is moistened with water and then is inserted and placed over the cervix for up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse.[4] Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.[7]

▶ *Fertility Awareness–Based Methods*

Fertility awareness–based methods (natural methods) represent another nonpharmacologic means of pregnancy prevention.

Patient Encounter Part 3: Missed Doses

The patient calls your clinic in a panic today because she forgot to take her oral contraceptive for the past 2 days, beginning the third week of active pills. Two days have elapsed since she took her last active pill, and she reports having had unprotected sexual intercourse last night. The patient is very concerned about her risk of pregnancy and is interested to learn more about emergency contraception and what her options are.

Given this patient's reported imperfect use of her oral contraceptive, what information can you provide to the patient regarding her risk of pregnancy?

What additional education should be provided to the patient regarding her risk of STIs related to unprotected intercourse?

Provide appropriate patient education regarding the use of various forms of emergency contraception, in the event she decides to use EC.

Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman's "fertile window," or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse.[4] During the fertile window, the couple practices abstinence, or avoidance of intercourse, in order to prevent pregnancy. In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.[4]

Emergency Contraception

Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. Ideally it should be used as soon as possible after unprotected sexual intercourse and within 72 hours (120 hours with ella), but it can still remain effective beyond this time frame. If a woman is already pregnant, EC cannot stop the pregnancy or harm the fetus. It is unknown how EC works although it is theorized it may prevent or delay ovulation or possibly prevent fertilization if ovulation has occurred. It is not recommended that EC be used as a regular form of birth control.

There are six FDA-approved oral agents available for use as EC, with availability from over the counter to prescription-only access. The product known as ella (ulipristal acetate), a progesterone-receptor agonist/antagonist, can delay follicular rupture if taken just before ovulation and may cause endometrial changes to interfere with implantation. The available products are LO 7 listed in Table 48–7 along with information on availability and correct dosage. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. Common side effects include headache, nausea, abdominal pain, dysmenorrhea, fatigue, and dizziness. If severe abdominal pain occurs, patients should be referred to their health care provider for evaluation of risk of an ectopic pregnancy. Patients should also contact their health care provider if their menstrual cycle is more than 1 week late after taking EC.

OUTCOME EVALUATION

Side effects of contraceptives tend to occur in the first few months of therapy. Schedule follow-up visits as needed and at the discretion of the provider. At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen. Strict adherence to the prescribed hormonal contraceptive regimen is essential for effective prevention of unintended pregnancy. KEY CONCEPT When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted. For further information, patients can be referred to https://www.cdc.gov/reproductivehealth/contraception/pdf/Recommended-Actions-Late-Missed_508Tagged.pdf.

Table 48–7

Emergency Contraception

Product	Where Stocked	Availability	Ingredient	Dose	When Recommended[a]
Plan B One-Step	Over the counter	All ages with no identification required	Levonorgestrel	1.5 mg	Within 72 hours of unprotected sex
Take Action	Over the counter	All ages with no identification required	Levonorgestrel	1.5 mg	Within 72 hours of unprotected sex
Next Choice One Dose	Behind the counter	Over the counter for 17 years and older; prescription required for 16 years and younger	Levonorgestrel	1.5 mg	Within 72 hours of unprotected sex
My Way	Behind the counter	Over the counter for 17 years and older; prescription required for 16 years and younger	Levonorgestrel	1.5 mg	Within 72 hours of unprotected sex
Levonorgestrel	Behind the counter	Over the counter for 17 years and older; prescription required for 16 years and younger	Levonorgestrel	0.75 mg (two tablets for a total of 1.5 mg)	Both tablets within 72 hours of unprotected sex
ella	Behind the counter	Only as a prescription	Ulipristal acetate	30 mg	Within 120 hours of unprotected sex

[a]Although these are the preferred time frames for optimal efficacy, these products can be taken after 72 hours.

Patient Care Process

Collect Information:

- Determine goals related to contraceptive use (pregnancy prevention, menstrual regulation, control of acne).
- Based on medical, social (ie, smoking), and family history, determine if patient qualifies for hormonal contraceptives. Rule out pregnancy, and evaluate patient's risk for STIs.
- Conduct thorough medication history to identify potential for drug interactions.

Assess the Information:

- At follow-up visits, assess blood pressure, weight, and menstrual patterns for changes from baseline.
- Assess tolerability of and adherence to the prescribed contraceptive method.
- Assess safety by using the mnemonics, "ACHES"[4] for hormonal contraceptives, and "PAINS" for IUDs:

  ACHES[4]

  A = Abdominal pain

  C = Chest pain

  H = Headaches (especially if associated with focal neurologic symptoms)

  E = Eye problems (blurred vision, ocular pain, visual changes)

  S = Severe leg pain

- Also monitor for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes.

  PAINS

  P = Period late

  A = Abdominal pain, pain with intercourse

  I = Infection, abnormal/odorous vaginal discharge

  N = Not feeling well, fever, chills

  S = String (missing, shorter, longer)

Develop a Care Plan:

- Select a contraceptive option that the patient is comfortable with, that is likely to achieve the patient's desired goal(s), and is not contraindicated.
- Educate regarding the potential for side effects, safety risks, drug interactions, and any noncontraceptive benefits that may result for the chosen method.
- Determine the patient's sexual behavior and evaluate whether the contraceptive method will impact the risk for STIs.
- Evaluate insurance coverage/cost factors.

Implement the Care Plan:

- Instruct the patient to consult a health care professional upon noticing or experiencing any warning signs.
- Stress the importance of adherence (especially if prevention of pregnancy is desired).
- Educate on what to do in the event of missed doses.

Follow-up: Monitor and Evaluate:

- Schedule a follow-up visit 3 to 6 months after initiating a new contraceptive.
- Assess blood pressure, headache frequency, and menstrual bleeding patterns.
- Assess patient tolerance and evaluate for the occurrence of side effects specific to the regimen prescribed.
- Assess adherence to the prescribed regimen.

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
CHC	Combination hormonal contraceptive
CYP450	Cytochrome P-450
EC	Emergency contraception
EE	Ethinyl estradiol
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
HIV	Human immunodeficiency virus
HPV	Human papilloma virus
IUD	Intrauterine device
LARC	Long-acting reversible contraception
LH	Luteinizing hormone
PID	Pelvic inflammatory disease
PMDD	Premenstrual dysphoric disorder
STI	Sexually transmitted infection
TSS	Toxic shock syndrome
WHO	World Health Organization

Kylie N. Barnes, Jacqueline M. Klootwyk and Elena M. Umland

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the underlying etiology and pathophysiology of dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding and how they relate to selecting effective treatment modalities.
2. Describe the clinical presentation of dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding.
3. Recommend appropriate nonpharmacologic and pharmacologic interventions for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding.
4. Identify the desired therapeutic outcomes for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding.
5. Design a monitoring plan to assess the safety and effectiveness of pharmacotherapy for dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding.

INTRODUCTION

Problems related to the menstrual cycle are common among women of reproductive age. The most common menstruation-related disorders include dysmenorrhea, amenorrhea, anovulatory bleeding, and abnormal uterine bleeding. These disorders can negatively affect quality of life, reproductive health, and productivity; they may also lead to adverse long-term health consequences, such as increased risk for osteoporosis with amenorrhea.

DYSMENORRHEA

Dysmenorrhea is pelvic pain, generally described as painful cramping, occurring during or just prior to menstruation. Primary dysmenorrhea occurs with normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.[1]

Epidemiology and Etiology

Dysmenorrhea is the most commonly reported menstrual complaint, with more than one-half of menstruating women reporting pain for at least 1 or 2 days each month.[2] Of women with dysmenorrhea, around 51% report limited daily activities or missing work or school.[3] Risk factors include irregular or heavy menses, age less than 30, menarche prior to age 12, body mass index (BMI) less than 20 kg/m^2, history of sterilization or sexual abuse, and smoking.[1,4] Causes of secondary dysmenorrhea may include endometriosis, pelvic inflammatory disease (PID), uterine or cervical polyps, and uterine fibroids.[4-5]

LO 1

Pathophysiology

LO 1

KEY CONCEPT In primary dysmenorrhea, elevated arachidonic acid levels in the menstrual fluid lead to increased concentrations of prostaglandins and leukotrienes in the uterus. This induces uterine contractions, stimulates pain fibers, reduces uterine blood flow, and causes uterine hypoxia.[3]

Treatment

▶ *Desired Outcomes*

LO 4

Desired treatment outcomes (Figure 49–1) are reduction of pelvic pain, improved quality of life, and fewer missed days from school and work.

▶ *Nonpharmacologic Therapy*

LO 3

Exercise may reduce dysmenorrhea by increasing pelvic blood flow and stimulating the release of beta-endorphins which act as analgesics.[1,3,6] In addition, a low-fat vegetarian diet has been shown to lessen the intensity and duration of dysmenorrhea. Evidence supporting acupuncture, heat therapy, transcutaneous nerve stimulation, yoga, and massage therapy is insufficient to recommend as standards of care.

▶ *Pharmacologic Therapy*

LO 3

Medication management options are summarized in Table 49–1.

Nonsteroidal Anti-inflammatory Drugs

KEY CONCEPT Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line therapy for dysmenorrhea, and up to 80% of patients will respond to them.[7] By inhibiting prostaglandin production, they exert analgesic properties, decrease uterine contractions, and reduce menstrual blood flow. Choice of one agent over another is based on effectiveness, tolerability, and patient preference, as no NSAID has been proven more effective than others.[1,3,4] The most commonly used nonprescription NSAIDs utilized in the United States are naproxen and ibuprofen. Of note, aspirin is not used for the treatment of dysmenorrhea as it is not potent enough in usual dosages.

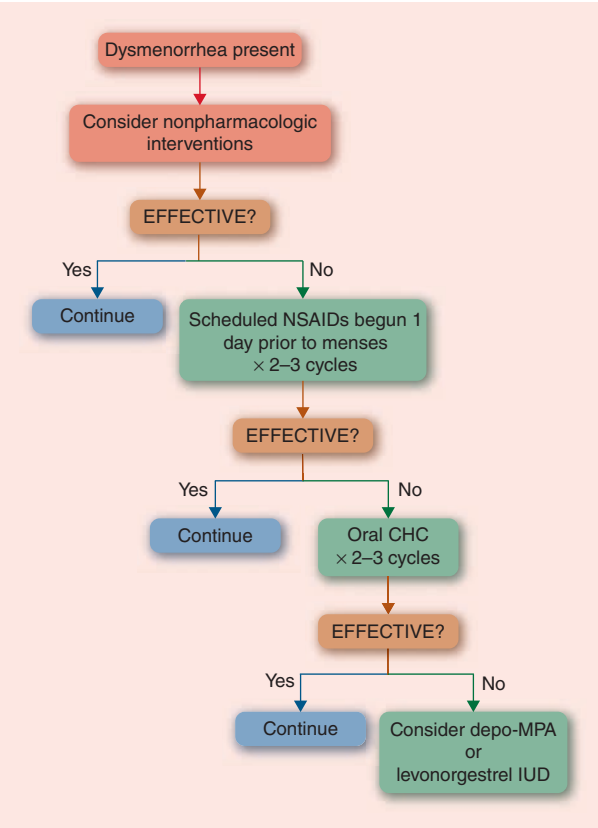

FIGURE 49–1. Treatment algorithm for dysmenorrhea. (CHC, combination hormonal contraceptive; IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal anti-inflammatory drug.) Clinical Presentation and Diagnosis of Dysmenorrhea

LO 2

General

- May be in acute distress depending on the severity of pain.

Symptoms

- Recurrent, crampy pelvic pain (lasting 2–3 days) beginning shortly before or during menses. Pain may radiate into lower back or thighs. Associated symptoms may include nausea, vomiting, diarrhea, headache, dizziness, bloating, and fatigue. Symptoms generally begin in adolescence.

Laboratory Tests

- Gonorrhea, chlamydia cultures or polymerase chain reactions test, wet mount

Other Diagnostic Tests

- Pelvic examination for sexually active females, females reporting severe pain or limitation of activity, or who have not responded to first- and second-line treatments
- Pelvic ultrasound may identify anatomic abnormalities (eg, masses/lesions), ovarian cysts, or endometriomas.

Patient Encounter 1, Part 1

A 17-year-old white woman presents reporting severe, crampy pelvic pain that radiates to her lower back during menses, causing her to miss 1–2 school days each menstrual cycle. Her last menses was 20 days ago, and her first menstrual cycle occurred at age 11. She has never been sexually active. She has been taking acetaminophen as needed for pain. She is a runner, 5'8" (173 cm) tall, and weighs 126 pounds (57.2 kg).

What risk factors does the patient have for primary dysmenorrhea?

What risk factors does the patient have for secondary dysmenorrhea?

NSAID treatment should begin 1 to 2 days prior to the start of menses, or at dysmenorrhea onset, and continued for 2 to 3 days or until pain resolves.[1,4] A loading dose (twice the usual single dose) is recommended, followed by the usual recommended dose.[1,5] For patients which contraindications to NSAID therapy, or with dysmenorrhea unresponsive to initial NSAID treatment, combination hormonal contraceptives (CHCs) should be considered.[4]

Combination Hormonal Contraceptives

CHCs improve mild to severe dysmenorrhea by decreasing endometrial lining and inhibiting ovulation, which decreases the formation of prostaglandins and leukotrienes contributing to menstrual pain.[3-5] Data supporting CHC efficacy, including oral, intravaginal, transdermal patch, and vaginal ring, for treatment of primary dysmenorrhea are limited, although their use is common in clinical practice.[1,4] Two to three months of therapy are often required to achieve full effects, and can take up to 6 months.[4] Both standard (28-day) and extended cycle (91-day) therapies are effective for primary dysmenorrhea.[1,4] Continuous CHC may show more immediate pain relief when compared to cyclic therapy; however, both effects are similar when evaluated at 6 months.[1,4] For dysmenorrhea secondary to endometriosis, CHCs, specifically extended cycle regimens, are considered first-line.[1,4] Additionally, the patch and vaginal ring have both shown comparable efficacy to oral agents.[8] If no response with any agent occurs after 3 months, the patient should be reevaluated.[5]

Progestin-Only Hormonal Contraceptives

Progestin-only agents diminish dysmenorrhea by reducing or eliminating menses over time, thus eliminating prostaglandin release.[5] Three long-acting reversible contraceptive agents are available: depot medroxyprogesterone acetate, etonogestrel implant, and levonorgestrel-releasing IUD. Observational data show women with dysmenorrhea reduced from 60% to 29% after 3 years of levonorgestrel-releasing IUD therapy.[6]

Dysmenorrhea in Adolescents

Dysmenorrhea is the most common gynecologic complaint amongst female adolescents, reported in 60% to 90%, and the most common reason for missed school or work.[6] At diagnosis, a pelvic examination should be performed in adolescents who

Table 49–1

Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
Amenorrhea (primary or secondary)	CEE[a]	0.625–1.25 mg by mouth daily on cycle days 1–26[9]	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema
	Ethinyl estradiol patch[a]	50–100 mcg/24 hours[9]	
	Oral CHC[a]	30–40 mcg formulations	
Amenorrhea (secondary)	Oral medroxyprogesterone acetate[a]	10 mg by mouth on cycle days 14–26[9]	Edema, anorexia, depression, insomnia, weight gain or loss, elevated total and LDL cholesterol, may reduce HDL cholesterol
Amenorrhea (hyperprolactinemia)	Bromocriptine	2.5 mg by mouth two to three times daily[15]	Hypotension, nausea, constipation, anorexia, Raynaud phenomenon
	Cabergoline	0.25 mg by mouth twice weekly[15]	
Anovulatory bleeding	Oral CHC[a]	Optimal dose unknown[19] For acute or severe bleeding, product containing 35 mcg ethinyl estradiol; take one tablet by mouth three times daily × 1 week; then one tablet by mouth daily × 3 weeks.[19] Therapy continuation may be necessary to prevent future occurrences	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Oral medroxyprogesterone acetate[a]	For acute bleeding, 20 mg by mouth three times daily × 1 week; then 20 mg by mouth once daily × 3 weeks[19]	As noted above for oral medroxyprogesterone acetate
Dysmenorrhea	Oral CHC[38,a]	< 35 mcg formulations + norgestrel or levonorgestrel[39]; use of extended-cycle formulations is beneficial for this indication	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Depot medroxyprogesterone acetate[a]	150 mg intramuscularly every 12 weeks	Irregular menses, amenorrhea
	Levonorgestrel IUD[10,a]	20 mcg released daily	Irregular menses, amenorrhea
	NSAIDs—any are acceptable except aspirin or salicylates; the most commonly studied/ cited are included in this table[1,3–5,38]	Ibuprofen 800 mg by mouth three times daily[a] Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses, followed by 275 mg by mouth every 6–12 hours as needed[c] Mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to four times daily as needed[b] Diclofenac 50 mg by mouth three times daily[b] Treatment should begin 1–2 days prior to the expected onset of menses	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness
Abnormal uterine bleeding	Oral CHC[a]	Optimal dose unknown	As noted above
	Levonorgestrel IUD[a]	20 mcg released daily	As noted above
	Medroxyprogesterone acetate (oral)[a]	5–10 mg by mouth on days 5–26 of the cycle *or* during the luteal phase[32]	As noted above
	NSAIDs	Doses as recommended for above; therapy should be initiated with the onset of menses[32]	As noted above
	Tranexamic acid	1300 mg (650 mg × 2) by mouth three times days × 5 days[35–37]	Fatigue, abdominal, back, or muscle pain

(*Continued*)

Table 49–1

Therapeutic Agents for Selected Menstrual Disorders (*Continued*)

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
PCOS-related amenorrhea and/or anovulatory bleeding	If pregnancy is an immediate goal: Clomiphene[6] plus insulin-sensitizing agent Or Letrozole plus insulin-sensitizing agent	Clomiphene: 50 mg by mouth daily × 5 days starting 3–5 days after the start of menses; doses up to 100 mg by mouth daily have been used in significantly obese patients Letrozole: 2.5–7.5 mg by mouth cycle days 3–7[23] Metformin[a,c]: 1500–2000 mg by mouth daily in 2–3 divided doses	Clomiphene: Hot flashes, ovarian enlargement, thromboembolism, blurred vision, breast discomfort Letrozole: Hot flashes, fatigue, dizziness, edema Metformin: Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis
	If pregnancy is not an immediate goal: Insulin sensitizing agent +/- use of CHC containing an anti-androgenic progesterone or levonorgestrel IUD	Metformin[a,c]: 1500–2000 mg by mouth daily in 2–3 divided doses Oral CHC: 35 mcg or less ethinyl estradiol and progesterone with antiandrogenic effects (eg, drospiernone) Levonorgestrel IUD: 20 mcg released daily	As noted above
	Women with side effects or contraindications to estrogen: Medroxyprogesterone acetate (oral)[a]	10 mg by mouth × 10 days[17]	As noted above
	Depot medroxyprogesterone acetate[a]	150 mg intramuscularly every 12 weeks	

[a]Use is contraindicated in patients with severe hepatic impairment.

[b]Not recommended in patients with severe renal impairment.

[c]Use is contraindicated with creatinine clearance < 30 mL/min (0.5 mL/s).

CEE, conjugated equine estrogen; CHC, combination hormonal contraceptive; GI, gastrointestinal; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein; NSAIDs, nonsteroidal anti-inflammatory drugs; PCOS, polycystic ovary syndrome.

have had vaginal intercourse due to high risk of PID. Adolescents who have never had vaginal intercourse do not require a pelvic examination.[4] NSAIDs are the preferred initial treatment in adolescents, followed by hormonal treatment. KEY CONCEPT Adolescents with symptoms unresponsive to NSAID therapy for three menstrual periods should be offered hormonal therapy.[5] If symptoms do not improve within 6 months of NSAIDs and CHC, further evaluation through laparoscopy is indicated. CHC also provides effective contraception, which may be desired for sexually active adolescents.

Patient Encounter 1, Part 2

Additional workup reveals:

PMH: Seasonal allergic rhinitis

PSH: Appendectomy at age 15

FH: Mother and father alive and well; two younger siblings (ages 8 and 13), both alive and well

SH: (–) tobacco use; (–) illicit drug use; (–) alcohol use

Medications: Cetirizine 10 mg once daily as needed for allergies

Past Gynecologic History: Menarche at age 11; never pregnant; (–) sexual activity; (+) history of painful menses beginning at age 12; (+) heavy menstrual flow; menstrual cycle 27–30 days

ROS: (+) fatigue with menses; (–) headaches; (+) mild acne on face, chest, and upper back; (+) moderate to severe pelvic pain radiating to lower back with menses

PE:

General: Thin, white woman, in no acute distress

VS: BP 112/72, P 68, RR 14, Wt 126 lbs (57.2 kg), Ht 5′8″ (173 cm), BMI: 19.2 kg/m^2

HEENT: (–) hirsutism

Breasts: (–) galactorrhea

Pelvic examination: Normal appearance of external genitalia and vagina, cervix without lesions, uterus midposition without masses

Labs: (–) hCG

Given this information, what is your assessment of this patient's condition?

Identify the treatment goals for this patient.

What nonpharmacologic therapies are recommended for this patient?

AMENORRHEA

Amenorrhea is the absence of menses. **Primary amenorrhea** is failure to reach menarche. Evaluation for amenorrhea should occur if there is no pubertal development by age 13, menarche has not occurred within 5 years after initial breast development, or the patient is 15 years or older.[9-11] **Secondary amenorrhea** is the cessation of menses for 3 months in a previously regular menstruating woman, or 6 months in a previously irregular menstruating woman.[9]

Epidemiology and Etiology

KEY CONCEPT Unrecognized pregnancy is the most common cause of amenorrhea; therefore, a urine pregnancy test should be one of the first steps in evaluating amenorrhea. Amenorrhea not related to pregnancy, lactation, or menopause occurs in 3% to 4% of women.[11] Primary amenorrhea is often caused by chromosomal irregularities resulting in primary ovarian insufficiency or anatomic abnormalities.[9] Causes of secondary amenorrhea include **polycystic ovary syndrome** (PCOS), hypothalamic suppression, hyperprolactinemia, or primary ovarian insufficiency.[9] Additional causes include undernutrition or anorexia and excessive exercise.

LO 1

Pathophysiology

Normal menstrual cycle physiology depends on hormonal interactions involving the hypothalamus, anterior pituitary gland, ovary, and endometrium (Figure 49–2).[5,9] Table 49–2 shows causative condition(s) and the organ system(s) involved in the pathophysiology of amenorrhea. Amenorrhea is a potential side effect from using low-dose or extended oral CHCs, depot medroxyprogesterone acetate, or levonorgestrel-releasing IUD.[9,12] Many women experience delayed return of menses after discontinuing hormonal contraception. If resolution of amenorrhea does not occur within 3 to 6 months after discontinuing contraception, evaluation for other conditions should be considered (eg, PCOS).

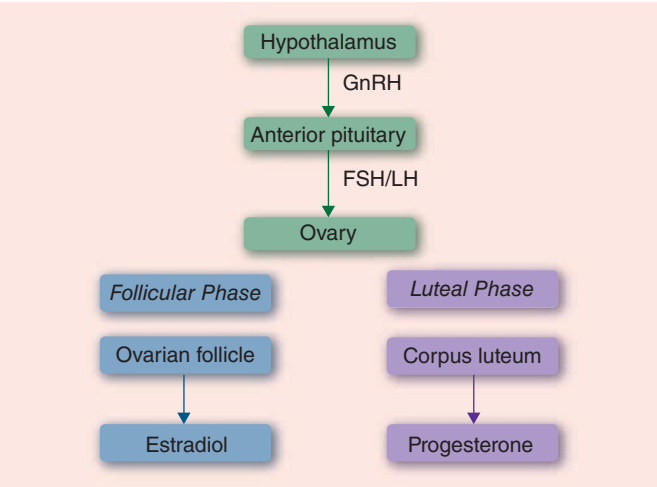

FIGURE 49–2. Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin releasing hormone; LH, luteinizing hormone.) (Data from Umland EM, Klootwyk J. Menstruation-related disorders. In: Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014, with permission.)

Treatment

▶ *Desired Outcomes*

LO 4

Treatment goals include ensuring normal puberty is occurring, restoring the normal menstrual cycle, preserving bone density, preventing bone loss, improving quality of life, and restoring ovulation, thus improving fertility.[9,13] Amenorrhea attributable to hypoestrogenism (eg, premature ovarian insufficiency) can cause hot flashes and dyspareunia, thus reduction of those symptoms becomes an additional goal.

▶ *Nonpharmacologic Therapy*

LO 3

Nonpharmacologic therapy depends on the underlying cause. Amenorrhea secondary to undernutrition or anorexia may respond to weight gain and psychotherapy.[11] If excessive exercise is the cause, exercise reduction is recommended.[9]

▶ *Pharmacologic Therapy*

LO 3

Estrogen/Progestin Replacement Therapy KEY CONCEPT For most conditions associated with primary or secondary amenorrhea, estrogen treatment is recommended. To minimize risk of endometrial hyperplasia and cancer, progestin should also be given to women with an intact uterus. Estrogen's role is to reduce osteoporosis risk, stimulate and maintain secondary sexual characteristics, and improve quality of life.[11] Table 49–1 lists the types and doses of estrogen and progestin therapy for amenorrhea.

Dopamine Agonists In women with hyperprolactinemia with or without a pituitary tumor, dopamine agonists are the preferred treatment.[11] Dopamine agonists restore normal prolactin levels and resolve amenorrhea. Additionally, they restore ovulation in 80% to 90% of women.[14] Bromocriptine and cabergoline are the most commonly studied agents, with cabergoline being more effective in resolving amenorrhea.[14,15]

Progestins Progestins are commonly used to induce withdrawal bleeding in women with secondary amenorrhea. Efficacy varies depending on the formulation used. Withdrawal bleeding occurs with intramuscularly injected progesterone and oral medroxyprogesterone acetate in 70% and 95% of patients, respectively.[16] The usual dose of medroxyprogesterone acetate is 10 mg orally once daily for 7 to 10 days.[9]

Insulin-Sensitizing Agents PCOS-induced amenorrhea may respond well to insulin sensitizing agents.[17] Using metformin for this purpose is discussed in the anovulatory bleeding section.

All patients experiencing amenorrhea should follow a diet rich in calcium and vitamin D to support bone health. Supplemental calcium and vitamin D (1200 mg/800 International Units per day) should be recommended for patients with inadequate dietary consumption.[9] Figure 49–3 illustrates treatment recommendations for amenorrhea.[9]

Amenorrhea in Adolescents

Adolescence is when peak bone mass is achieved. The cause of amenorrhea and appropriate treatment must be identified promptly because hypoestrogenism negatively impacts bone development.[11] Estrogen replacement, typically through a CHC, is recommended. Although recent data suggest that CHCs and depot medroxyprogesterone acetate may reduce bone mineral density (BMD) for short term, their long-term effects on

Table 49–2

Pathophysiology of Selected Menstrual Bleeding Disorders[9,17,19,25,40]

Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea[9,40]		
Uterus	Asherman syndrome	Postcurettage/postsurgical uterine adhesions
	Congenital uterine abnormalities	Abnormal uterine development
Ovaries	Turner syndrome	Lack of ovarian follicles
	Gonadal dysgenesis	Other genetic anomalies
	Premature ovarian failure	Early loss of follicles
	Chemotherapy/radiation	Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma	↑ Prolactin suppresses HPO axis
	Hypothyroidism	TRH causing ↑ prolactin, other abnormalities
	Medications—antipsychotics, verapamil	↑ Prolactin suppresses HPO axis
Hypothalamus	"Functional" hypothalamic amenorrhea	↓ Pulsatile GnRH secretion in the absence of other abnormalities
	Disordered eating	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss
	Excessive exercise	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat
	Anovulation/PCOS	Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Anovulatory Bleeding[17,19]		
Physiologic causes	Adolescence	Immature HPO axis: no LH surge
	Perimenopause	Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation (PCOS, congenital adrenal hyperplasia, androgen-producing tumors)	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance
	Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss, anorexia nervosa)	Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH
	Hyperprolactinemia (pituitary gland tumor, psychiatric medications)	High prolactin
	Hypothyroidism	High TSH
	Premature ovarian failure	High FSH
Abnormal Uterine Bleeding[25]		
Hematologic	von Willebrand disease	Factor VII defect causing impaired platelet adhesion and increased bleeding time
	Idiopathic thrombocytopenic purpura	Decrease in circulating platelets—can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in HPO axis
Uterine	Fibroids	Alteration of endometrium, changes in uterine contractility
	Adenomyosis	Alteration of endometrium, changes in uterine contractility
	Endometrial polyps	Alteration of endometrium
	Gynecologic cancers	Various dysplastic alterations of endometrium, uterus, cervix

↑, high; ↓, low; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic-pituitary-ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary syndrome; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

fractures are unknown. The effects on BMD appear to be reversible; therefore, CHCs are recommended in the adolescent population.[18] Ensuring adequate dietary or supplemental calcium and vitamin D intake in this population is imperative.

ANOVULATORY BLEEDING

Anovulatory uterine bleeding (AUB) is irregular menstrual bleeding from the endometrium ranging from light spotting to heavy blood flow.[19] KEY CONCEPT It includes noncyclic menstrual bleeding due to ovulatory dysfunction (AUB-O), including anovulation or oligo-ovulation.[19] AUB-O is secondary to the effects of unopposed estrogen and does not include bleeding due to an uterine anatomic lesion. Many women pursue medical care to regulate menstrual cycles or improve fertility.

Epidemiology and Etiology

LO 1

AUB is the most common form of noncyclic uterine bleeding. PCOS is the most common cause, occurring in 5% to 10% of women, and is responsible for 55% to 91% of ovulatory dysfunction cases.[17,19] It typically presents with irregular menstrual bleeding, hirsutism, obesity, and/or infertility. Anovulation results from dysfunction at any level of the hypothalamic-pituitary-ovarian (HPO) axis which can be due to physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation or pathologic causes (see Table 49–2).[10,19] Anovulation may also occur at any time during the reproductive years due to a pathologic cause. The most common causes of nonphysiologic ovulatory dysfunction are PCOS, hypothalamic amenorrhea, hyperprolactinemia, and premature ovarian failure.

Clinical Presentation and Diagnosis of Amenorrhea

LO 2

General

- Concerns about cessation of menses and fertility implications
- Generally no acute distress

Symptoms

- Cessation of menses
- Possible reports of infertility, vaginal dryness, decreased libido

Signs

- Absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of thelarche (if occurs before age 10)
- Recent significant weight loss or gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigricans suggest androgen excess

Laboratory Tests

- Pregnancy test
- Thyroid Stimulating Hormone (TSH)
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel
- If premature ovarian failure is suspected, consider follicle-stimulating hormone (FSH) and luteinizing hormone (LH) measurements

Other Diagnostic Tests

- Pelvic ultrasound to evaluate for polycystic ovaries
- May consider progesterone challenge, by administering either progesterone 100–200 mg intramuscular injection or oral medroxyprogesterone acetate 10 mg daily for 5–10 days to see if it induces a menstrual period. If bleeding occurs beyond spotting within 2 weeks after progesterone is given, the amenorrhea is due to anovulation. If no withdrawal bleeding occurs, amenorrhea is due to other causes.

Pathophysiology

LO 1

During a normal ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary gland. The endometrium proliferates and undergoes secretory changes throughout the cycle, first due to ovarian production of estrogen alone, followed by a combination of estrogen and progesterone. The presence of progesterone halts endometrial growth and stimulates endometrial differentiation. At cycle end, if conception and implantation do not occur, estrogen and progesterone withdrawal begins, leading to menstrual flow as the endometrium sloughs. In anovulation, a corpus luteum does not develop, and the ovary fails to secrete progesterone. This causes the endometrium to continue proliferation under the influence of unopposed estrogen, and eventually it becomes thick, vascular, and fragile. The clinical result is unpredictable, heavy, noncyclic bleeding, as sporadic sloughing of the endometrium begins to occur.[19] Chronic anovulatory cycles and unopposed estrogen secretion lead to increased risk of polyps, endometrial hyperplasia, and endometrial carcinoma (see Table 49–2).

Treatment

▶ *Desired Outcomes*

LO 4

The desired outcomes are to stop acute bleeding, restore natural cycle of endometrial growth and shedding, decrease long-term complications of anovulation (eg, osteopenia and infertility), and improve quality of life.[19]

▶ *Nonpharmacologic Therapy*

LO 3

Nonpharmacologic treatment options depend on the underlying cause. For women with PCOS, weight loss may be beneficial. In overweight or obese women, a 5% weight reduction is associated with resumption of menses, improved pregnancy rates, and decreased hirsutism, glucose, and lipid levels.[17] In women who have completed childbearing or who have failed medical management,

Patient Encounter 2

A 38-year-old woman presents for a routine gynecologic examination. She started menarche at age 11; her last period was 4 months ago. Her periods are irregular, and occur every 2 to 4 months. All previous Pap smears have been normal, and she denies a history of sexually transmitted infections. She reports history of one sexual partner, her husband, of 20 years. Currently sexually active, she is not on any form of contraception, and does not desire any more children. Reports history of one pregnancy, after three courses of clomiphene due to "follicles" on her ovaries, after several years of infertility. PMH significant for diabetes and hypertension. Current medications include metformin 1000 mg twice daily and lisinopril 20 mg once daily. On examination, patient is overweight with mild hirsutism.

Labs: (–) hCG; free testosterone 105 ng/dL (3.6 nmol/L; elevated); TSH 2.4 µIU/mL (mIU/L; WNL); prolactin 8 ng/mL (mcg/L; WNL); fasting glucose 122 mg/dL (6.8 mmol/L); total cholesterol 192 mg/dL (4.97 mmol/L); LDL cholesterol 115 mg/dL (2.97 mmol/L), HDL cholesterol 60 mg/dL (1.55 mmol/L); triglycerides 68 mg/dL (0.77 mmol/L)

Pelvic ultrasound: 15 follicles in right ovary, 11 follicles in left ovary; increased ovarian volume of 13 mL

What anovulatory disorder is this patient most likely experiencing?

What signs/symptoms support your conclusion?

What pharmacologic therapies are recommended for this patient?

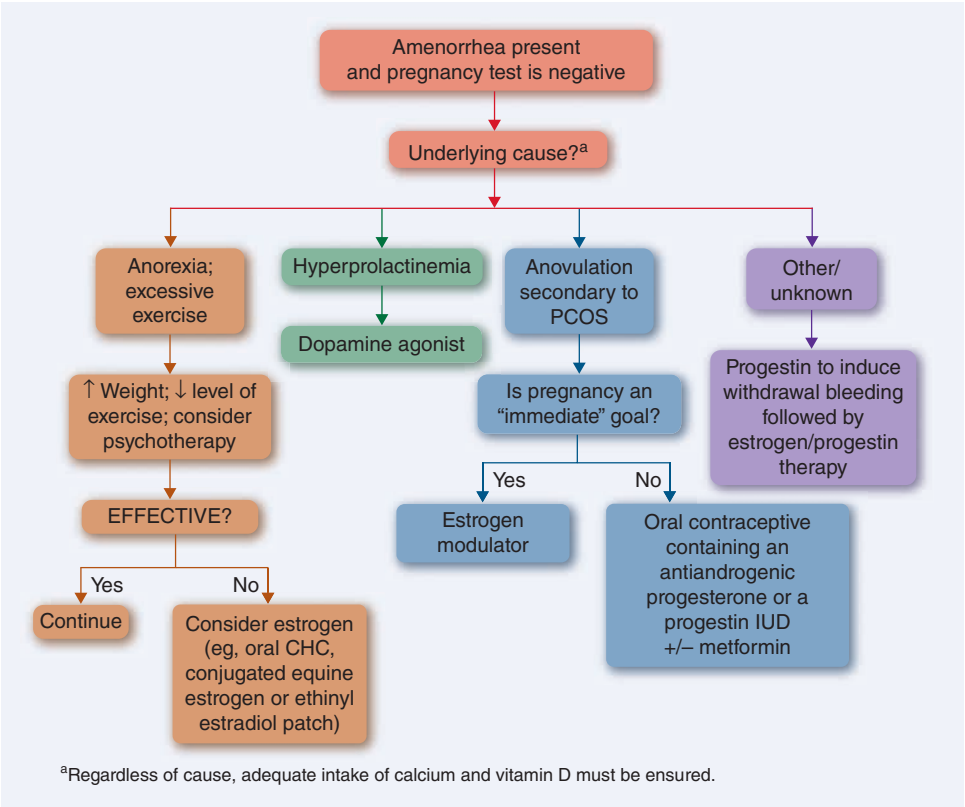

FIGURE 49–3. Treatment algorithm for amenorrhea. (CHC, combination hormonal contraceptive; IUD, intrauterine device; PCOS, polycystic ovary syndrome.) (Data from Umland EM, Klootwyk J. Menstruation-related disorders. In: Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014, with permission.)

endometrial ablation or resection, and hysterectomy are surgical options. The preferred procedure is unclear. For short term, it appears ablation or resection results in less morbidity and shorter recovery periods.[20] However, a significant number of these women undergo hysterectomy within 5 years.[19]

▶ *Pharmacologic Therapy*

LO 3

Estrogen Table 49–1 summarizes therapeutic agents and doses. Estrogen is the recommended treatment for managing acute bleeding episodes because it promotes endometrial growth and stabilization.[19] Long-term therapy with a CHC reduces the risk of endometrial cancer compared to unopposed estrogen therapy.[9] CHCs suppress ovarian hormones and adrenal androgen production and indirectly increase sex hormone–binding globulin (SHBG). This, in turn, binds and reduces circulating androgen.[17,19,21] Women with high androgen levels or signs of hyperandrogenism (eg, hirsutism, acne) are recommended to start low-dose CHCs (35 mcg or less ethinyl estradiol).[19] CHCs with low-dose estrogen and a progesterone that exhibits minimal androgenic side effects (eg, norgestimate or desogestrel) or with antiandrogenic effects (eg, drospirenone) may be considered.[22] However, to date, there is no consensus regarding the best CHC choice for treating PCOS.[17]

Medroxyprogesterone Acetate Women who experience side effects or have contraindication(s) to estrogen, or who have abnormal uterine bleeding due to anovulatory bleeding, should consider progesterone-only products. For women with PCOS, depot and intermittent oral medroxyprogesterone acetate suppress pituitary gonadotropins and circulating androgens, leading to endometrial shedding.[17] If contraception is desired, placement of a levonorgestrel-releasing IUD is an option.

Estrogen Modulators If pregnancy is an immediate goal, clomiphene may be used to induce ovulation. Oral medroxyprogesterone acetate 10 mg/day for 10 days is initiated to induce withdrawal bleeding, followed by clomiphene citrate 50 mg/day for 5 days, cycle days 3 through 5. If ovulation does not

LO 2

Clinical Presentation and Diagnosis of Anovulatory Bleeding

General

- Acute distress may or may not be present.

Symptoms

- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, night sweats, vaginal dryness, dyspareunia)

Signs

- Acne, hirsutism, obesity

Laboratory Tests

- If suspect PCOS: free or total testosterone, fasting glucose, fasting lipid panel
- If suspect perimenopause: TSH and FSH

Other Diagnostic Tests

- Pelvic ultrasound to evaluate for polycystic ovaries

occur, the dose may be increased to 100 mg/day. Approximately 50% of women who are going to conceive using clomiphene do so at the 50 mg/day dose, and another 20% conceive at the 100 mg/day dose.[17]

Recent data have shown beneficial effects with the use of letrozole to improve fertility. In a large trial, when compared to clomiphene citrate, letrozole had a statistically higher live birth rate with a similar adverse effect profile. Additional trials are needed to support this finding.[22,23]

Insulin-Sensitizing Agents Metformin improves insulin sensitivity and is recommended in women who cannot tolerate CHC and have impaired glucose tolerance (IGT) or type-2 diabetes mellitus.[22] KEY CONCEPT In patients with PCOS, metformin reduces circulating androgen concentrations, increases ovulation rates, and improves glucose tolerance, due to the SHBG increase that occurs via increased insulin sensitivity. Additionally, metformin may decrease cardiovascular risk and promote weight loss.[17] Notably, metformin is not recommended as monotherapy to improve ovulation and fertility. Limited data have shown adding metformin to clomiphene may increase pregnancy rates, especially in obese women with PCOS who are resistant to clomiphene monotherapy.[17,22,24] Thiazolidinediones are no longer recommended due to a poor risk-benefit ratio.[22]

Anovulatory Bleeding in Adolescents

Anovulation is the most common cause of AUB in adolescents. Anovulatory bleeding in teenagers can become excessive, persistent, and require medications to treat. The differential diagnosis is similar to adults, and should include evaluation for blood dyscrasias.[19,25] Patients should also be evaluated for PCOS by assessing for signs of hyperandrogenism, including acne and hirsutism.[19]

Blood dyscrasias are treated based on guideline recommendations. Adolescents with chronic anovulation are treated with low-dose CHCs (20–35 mcg of ethinyl estradiol).[19] Extended cycle therapies can be utilized to extend the interval of menstruation, which allows for resolution of anemia, mental recovery from prolonged acute bleeding, and time for additional imaging or consultations as needed. Patients with acute, severe bleeding may require brief hospitalization and treatment with high-dose estrogen. If the patient is overweight or obese, lifestyle changes are also recommended first-line, and if IGT or metabolic syndrome is present, metformin is often recommended.[22]

ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding describes prolonged menstrual bleeding (lasting > 7 days) or cyclic, heavy menstrual bleeding (> 80 mL per cycle).[26-28] It can be difficult to quantify menstrual blood loss in clinical practice. Many women with less than 80 mL of blood loss seek medical attention with concerns of containment flow problems, unpredictable heavy flow, reduced quality of life, anemia, and other dysmenorrhea symptoms.[27]

Epidemiology and Etiology

Abnormal uterine bleeding occurs in an estimated 10% of women, although as high as 30% will seek treatment for the condition.[8]

LO 1 KEY CONCEPT Causes of abnormal uterine bleeding is divided into systemic disorders and reproductive tract abnormalities. KEY CONCEPT Women presenting with heavy menses should be examined to rule out intrauterine pregnancy, ectopic pregnancy, and miscarriage. Additionally, genital tract malignancies and infections may present with abnormal bleeding.[19] Systemic disorders include coagulation dysfunction such as von Willebrand disease, hemophilia, and platelet function disorders, in addition to hypothyroidism.[19,25,26] Specific reproductive tract causes of abnormal uterine bleeding are more common in older childbearing women, and include fibroids, adenomyosis, endometrial polyps, PID, and gynecologic malignancies.[29,30]

LO 2

Clinical Presentation and Diagnosis of Abnormal Uterine Bleeding

General

- Acute distress may or may not be present.

Symptoms

- Reports of heavy/prolonged menstrual flow. Associated symptoms may include dysmenorrhea, fatigue, or lightheadedness in the case of severe blood loss.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially with significant acute blood loss.

Laboratory Tests

- Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
- TSH to rule out thyroid deficiencies
- If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging (MRI)
- Papanicolaou smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

Pathophysiology

Table 49–2 describes the pathophysiology of abnormal uterine bleeding and specific conditions resulting in abnormal uterine bleeding.

Treatment

▶ *Desired Outcomes*

LO 4 Goals of therapy include reducing menstrual blood flow, preventing or correcting iron-deficiency anemia, improving quality of life, and deferring the need for surgical intervention. Treatment recommendations are outlined in Table 49–1 and Figure 49–4.

▶ *Nonpharmacologic Therapy*

LO 3 Surgical interventions may be considered, and are based on the clinical stability of the patient, severity of bleeding, contraindications to medical management, and patient response to medical management. Options include dilation and curettage, endometrial ablation, uterine artery embolization, and hysterectomy and choice is often guided based on the patient's desire to maintain fertility.[19]

▶ *Pharmacologic Therapy*

LO 3 NSAIDs are first-line treatment for abnormal uterine bleeding associated with ovulatory cycles in women who do not desire

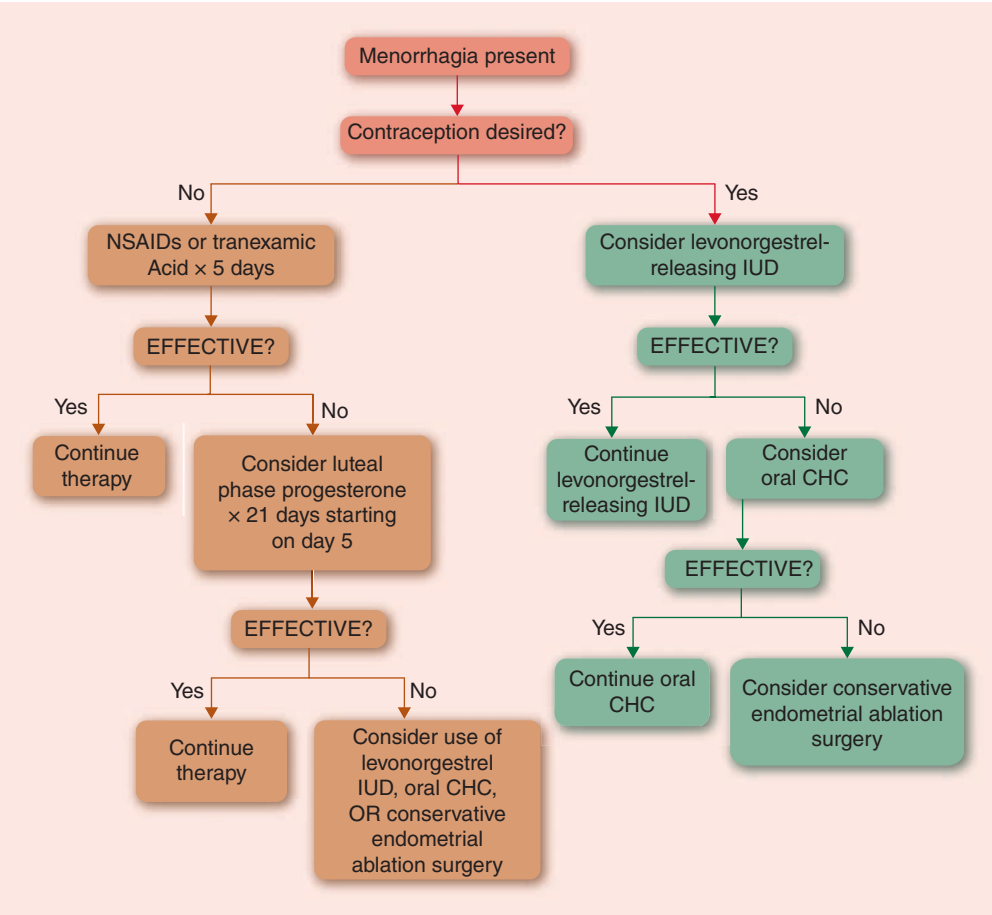

FIGURE 49–4. Treatment algorithm for abnormal uterine bleeding. (CHC, combination hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal anti-inflammatory drug.) (Data from Umland EM, Klootwyk J. Menstruation-related disorders. In: Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014, with permission.)

contraception or hormonal therapy.[21] They can be taken only during menses, and result in up to a 40% reduction in blood loss.[31] KEY CONCEPT This reduction is directly proportional to the amount of pretreatment blood loss.[32] NSAIDs are also beneficial if the patient is experiencing dysmenorrhea with the abnormal uterine bleeding.

Patient Encounter 3

A 15-year-old adolescent girl presents reporting moderate pelvic pain and cramping during menses. She notes her periods are "heavy" and require a change in super-size tampon every 2–3 hours. She reports issues with flow containment, and associated embarrassment. She has noticed over the last few months, she feels tired and her hair has thinned. Her last menstrual cycle was 10 days ago, and she entered menarche at age 10. She is not sexually active and she does not take any medications. She plays basketball for the high school team, and runs during the off season.

What diagnostic tests should be considered for the patient?

What nonpharmacologic and pharmacologic therapies are recommended for this patient?

What monitoring parameters are recommended to assess efficacy and safety of the therapeutic options?

Combination Hormonal Contraceptives CHCs are beneficial to women with abnormal uterine bleeding who do not desire pregnancy, and considered first-line for patients with known or suspected bleeding disorders.[19] Blood loss can be reduced by up to 40% to 50% with use of cyclic CHCs.[8] Continuous and extended cycle options may also reduce the number of menstrual cycles, and may achieve amenorrhea in some women.[8] KEY CONCEPT As with NSAIDs, the reduction in blood loss is proportional to pretreatment blood loss.

Progestins Abnormal uterine bleeding may also be treated with progestin-only contraceptives. The levonorgestrel IUD reduces menstrual flow by up to 86% after 3 months, and up to 97% after 12 months of use. Additionally, 20% to 80% of women experience amenorrhea by month 12.[8,21,32,33] In a small open-label study, the levonorgestrel IUD resulted in a greater blood loss reduction and number of days missed at work or school when compared to oral CHCs.[34] When compared to endometrial ablation, the levonorgestrel IUD causes similar reductions in menstrual blood loss and improved quality of life after 6, 12, and 24 months.[8] Its use may also help postpone or cancel the need for endometrial ablation or hysterectomy.

Cyclic progestin therapy, either during the luteal phase or for 21 days of the menstrual cycle, leads to regulation of the menstrual cycle in 50% of women.[31] A comparison of oral norethindrone and the levonorgestrel IUD concluded that IUD therapy is more effective, and had higher patient satisfaction rates.[8] Oral progestin use has also not been shown to be superior to NSAIDs.

Table 49–3

Expected Outcome Measures for Selected Menstrual Bleeding Disorders[10,12,19,25,28]

Menstrual Disorder	Expected Outcome Measures
Dysmenorrhea	*Efficacy:* Reduction in menses-related pelvic pain; reduction in time lost from work/school; improved quality of life. *Time to relief/effect:* Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as oral CHCs may be observed after a full 1–3 cycles of use.
Amenorrhea	*Efficacy:* Normal breast development (especially primary amenorrhea in adolescents); BMD preservation/improvement; return of menses. *Time to relief/effect:* Menses should occur within 1–2 months of therapy.
Anovulatory bleeding	*Efficacy:* Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of PCOS (eg, diabetes and cardiovascular disease); improved quality of life. *Time to relief/effect:* The acute treatment of heavy bleeding should reduce bleeding within 10 days of therapy onset; return of ovulation may require several months of therapy; when oral CHCs are used, abnormal bleeding control can be expected within 1–2 treatment cycles.
Abnormal uterine bleeding	*Efficacy:* Decline in amount of blood loss with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); increase in hemoglobin/hematocrit if anemia was present as because of abnormal uterine bleeding. *Time to relief/effect:* A decline in menstrual blood loss should be realized within 1–2 cycles of therapy initiation.

BMD, bone mineral density; CHCs, combination hormonal contraceptives; NSAID, nonsteroidal anti-inflammatory drug; PCOS, polycystic ovary syndrome.

Progestin-related side effects are typically greater in women using the levonorgestrel-releasing IUD when compared with oral progestin, and often include intermenstrual bleeding and breast tenderness.[8]

Tranexamic Acid Tranexamic acid works by preventing fibrin degradation, and is effective for patients with chronic abnormal uterine bleeding.[19] Evidence has shown that its use reduces bleeding in patients with chronic issues by 30% to 55%.[19] While an immediate-release product has been available for a long time, a modified-release product has recently become available. It has better gastrointestinal tolerability and gives women another nonhormonal option to manage abnormal uterine bleeding.[35,36] Additionally, it can be recommended for women with von Willebrand disease.

Abnormal Uterine Bleeding in Adolescents

An estimated 50% of adolescents with abnormal uterine bleeding have a bleeding disorder, most commonly von Willebrand disease or platelet dysfunction.[25] The incidence of von Willebrand disease is 1% to 2% in the general population; however, an estimated 5% to 36% of adolescents presenting with heavy menses have von Willebrand disease.[12,25] In addition, 74% to 92% of women with von Willebrand disease have abnormal uterine bleeding.[37] Platelet function disorders exist in 2% to 44% of adolescents with abnormal uterine bleeding.[25]

OUTCOME EVALUATION

Treatment success for menstruation-related disorders is measured by how well the treatment (a) relieves or reverses symptoms, (b) prevents or alleviates complications (eg, osteoporosis, anemia, and infertility), and (c) causes minimal adverse effects. A regular menstrual cycle should resume, with minimal premenstrual or dysmenorrhea symptoms. Depending on the desire for conception and related therapy, these cycles may be ovulatory or anovulatory.

LO 5

Assess treatment effectiveness in restoring normal menstrual cycles with minimal adverse effects after an appropriate treatment interval (1–2 months). Assess improvement in well-being and quality-of-life (eg, physical, psychological, and social functioning). Evaluate the patient for adverse drug reactions (see Table 49–1), drug allergies, and drug interactions. Table 49–3 lists the expected outcome measures for each discussed menstruation-related disorder.

Patient Care Process

Collect Information:

- Review medical history and physical assessment findings, and complete physical examination and review of systems, including gynecological history (eg, start of menarche, presence of galactorrhea, symptoms of androgen excess, review of typical menstrual cycle including frequency, duration, and associated symptoms, sexual history, and history of gynecological infections). Additional workup may be necessary depending on patient's presenting problem(s) (eg, amenorrhea, abnormal uterine bleeding, AUB, or PCOS), including a pregnancy test or pelvic examination.
- Perform medication history for use of prescription, nonprescription, and dietary supplements. Determine if any treatments have previously helped with chief complaint(s). Identify allergies to medications or other substances.
- Review current and future desire for children and contraception beliefs and preferences with the patient.

(*Continued*)

Patient Care Process *(Continued)*

Assess the Information:

- Based on medical history and presenting symptoms, determine which menstruation-related disorder the patient currently has.
- Review available diagnostic data to determine hormonal, reproductive, and pregnancy status.
- Document presenting symptoms and medical history, including pertinent family medical history.
- Based on physical examination, review of symptoms, and patient history, determine if patient is experiencing signs or symptoms of complications from menstruation-related disorder, such as symptoms of anemia in women presenting with abnormal uterine bleeding, or difficulty conceiving in women with amenorrhea or anovulatory bleeding.
- Assess the appropriateness, efficacy, safety, and adherence of current therapy.

Develop a Care Plan:

- Educate patient on lifestyle modifications and nonpharmacological therapy that will improve symptoms and prevent complications.
- Select pharmacotherapy, if indicated, that is safe and effective.
- Determine whether long-term maintenance treatment is necessary.
- Discuss the importance of adherence to medication management and lifestyle modifications.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential adverse effects, and how to manage and report adverse effects that occur.
- Address any patient concerns about their menstruation-related disorder and its management.
- Address any secondary concerns the patient may be experiencing (eg, infertility, anemia, decline in quality of life).
- Determine whether the patient has insurance coverage or whether recommended agents are included on the patient's insurance formulary.

Follow-up: Monitor and Evaluate:

LOS

- Follow up in 3–6 month intervals, or more frequently if needed, to assess efficacy and safety of therapy until goals are met, or symptoms resolve.
- Assess improvement in quality of life.
- Review medical history, physical examination findings, and laboratory and diagnostic tests to assess changes in clinical status and continued need for pharmacological therapy.
- Evaluate for adverse drug reactions, drug allergies, and drug interactions.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Jacqueline M. Klootwyk and Dr. Elena M. Umland, co-authors of this chapter in the first, second, third, and fourth editions of this book.

Abbreviations Introduced in This Chapter

50 Hormone Therapy in Menopause

Nicole S. Culhane and Regine Beliard

LEARNING OBJECTIVES

LO

Upon completion of the chapter, the reader will be able to:

1. Explain the physiologic changes associated with menopause.
2. Identify the signs and symptoms associated with menopause.
3. Determine the desired therapeutic outcomes for a patient taking hormone therapy (HT).
4. Explain how to evaluate a patient for the appropriate use of HT.
5. Recommend nonpharmacologic therapy for menopausal symptoms.
6. Explain the risks, benefits, and contraindications associated with HT.
7. Describe the circumstances by which nonhormonal therapies should be recommended.
8. Describe the monitoring parameters for a patient taking HT.

INTRODUCTION

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. The clinical diagnosis of menopause is made after a woman experiences amenorrhea for 12 consecutive months. The loss of ovarian follicular activity leads to an increase in follicle-stimulating hormone (FSH), which on laboratory examination may confirm the diagnosis.

The role of hormone therapy (HT) has changed dramatically. HT has long been prescribed for relief of menopausal symptoms and, until recently, has been purported to protect women from coronary heart disease (CHD). Recommending HT in postmenopausal women revolved around a simple theory: hormones lost during menopause could be replaced through drug therapy and protect women from both menopausal symptoms and sequelae of menopause. Recent studies have disproved this theory.

In 1996, the United States Preventive Services Task Force published its recommendations that not all postmenopausal women should be prescribed HT, but that therapy should be individualized based on risk factors. This recommendation was supported with publication of the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998, which demonstrated that women with established CHD were at an increased risk of experiencing a myocardial infarction within the first year of HT use compared with similar women without CHD risk factors. As a result, the authors concluded that HT should not be recommended for secondary prevention of CHD.[1] In 2002, the Women's Health Initiative (WHI) study was published. This trial demonstrated that HT was not protective against CHD but rather could increase the risk in women with underlying CHD risk factors. The risk of breast cancer was also increased after a woman was on combination estrogen and progestogen for approximately 3 years. Notably, this was not the case with estrogen alone. As a result of this study, the US Food and Drug Administration (FDA) issued a statement that HT, in general, should not be initiated or continued for primary prevention of CHD.[2,3]

This trial led to changes in how HT is prescribed and greater understanding of the associated risks. Systemic HT should be used primarily to reduce the frequency and severity of moderate to severe **vasomotor symptoms** (VMS) associated with menopause in women without risk factors for CHD or breast cancer.

EPIDEMIOLOGY AND ETIOLOGY

Menopause is a period of time marked by loss of ovarian follicular activity, inadequate estradiol production, and the subsequent cessation of menses. The median age for women to experience menopause is 52 years. However, women who have undergone a **total abdominal hysterectomy with bilateral salpingo-oophorectomy** experience menopause earlier compared with women who experience natural menopause. Other factors associated with early menopause include low body weight, increased menstrual cycle length, **nulliparity**, and smoking. Smokers generally experience menopause approximately 2 years earlier than nonsmokers.[4]

Perimenopause, known as the climacteric, is the transitional period prior to menopause when hormonal and biologic changes begin. These changes may begin 2 to 8 years prior to menopause and eventually lead to irregular menstrual cycles, an increase in cycle interval, and a decrease in cycle length. During this time, women also may experience physical symptoms similar to menopausal symptoms, which may require treatment depending on symptom severity.[4]

Because the perimenopausal and postmenopausal periods are marked by many biologic changes, women should inform their health care provider when they experience any signs and symptoms in order to discuss the most appropriate therapy.

PHYSIOLOGY

Reproductive physiology is regulated primarily by the hypothalamic–pituitary–ovarian axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the

Clinical Presentation and Diagnosis of Menopause

Menopausal Symptoms

- Vasomotor symptoms
- Sleep disturbances
- Mood swings
- Vaginal dryness, dyspareunia
- Depression

Less Common Symptoms

- Fatigue
- Irritability
- Migraine
- Arthralgia
- Myalgia
- Decreased libido

Diagnosis

- Amenorrhea for 1 year
- FSH greater than 40 mIU/mL (IU/L)
- Fivefold increase in LH

anterior pituitary to secrete FSH and luteinizing hormone (LH). FSH and LH regulate ovarian function and stimulate the ovary to produce sex steroids. These hormones are influenced by a negative-feedback system and increase or decrease based on the levels of estradiol and progesterone.

LO 1 The physiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and eventual loss of ovarian follicular activity. As women age, the number of ovarian follicles decreases. The remaining follicles require higher levels of FSH for maturation and ovulation. During perimenopause, **anovulatory cycles** are more likely. The lack of progesterone production leads to irregular and unpredictable menses. During menopause, FSH concentrations increase 10- to 15-fold, LH concentrations increase fivefold, and levels of circulating estradiol decrease more than 90%.[5]

Patient Encounter Part 1

A 53-year-old woman with a history of hypertension and hypothyroidism presents to the clinic complaining of hot flashes, vaginal dryness, dyspareunia, and insomnia. She states that she experiences approximately three hot flashes per day and is awakened from sleep at least two times a week requiring her to change her bed clothes. Her symptoms began about 3 months ago, and over that time, they have worsened to the point where they have become very bothersome. Upon questioning, she states she had a hysterectomy 1 year ago.

Which of the patient's symptoms and past medical history are consistent with menopause?

What additional information do you need to know in order to make an appropriate therapeutic plan for this patient?

LO 2 KEY CONCEPT Common symptoms of menopause include VMS and genitourinary syndrome of menopause (GSM), which includes **vulvovaginal atrophy**, vaginal dryness, and **dyspareunia**. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, urinary frequency, and decreased **libido**. Menopausal symptoms tend to be more severe in women who undergo surgical menopause compared with natural menopause because of the more rapid decline in estrogen concentrations.[3] Women who seek medical treatment should undergo laboratory evaluation to rule out other conditions that may present with similar symptoms, such as abnormal thyroid function or pituitary adenoma, before HT may be considered.

TREATMENT

Desired Outcomes

KEY CONCEPT HT remains the most effective treatment for VMS and vulvovaginal atrophy and should be considered, especially for women experiencing moderate to severe symptoms. The goals of LO 3 treatment are to alleviate or reduce menopausal symptoms and to improve the patient's quality of life (QOL) while minimizing adverse effects of therapy. Appropriate dose, duration, regimen, and route of administration should be patient specific, and aim to utilize the lowest effective dose of HT.

General Approach to Treatment

There are a number of national and international guidelines and consensus statements available on the management of menopause.[5-10] The most current guidelines should be consulted before making pharmacotherapeutic recommendations for women. Women with VMS should attempt lifestyle or behavioral modifications before seeking medical treatment. Women who seek medical treatment usually have symptoms that diminish their QOL, such as multiple **hot flashes** per day or week, sleep disturbances, vaginal dryness, or mood swings. HT should be considered for these women but is not the most appropriate choice for all women. LO 4 KEY CONCEPT Women should receive a thorough history and physical examination, including assessing for CHD and breast cancer risk factors and contraindications, before HT is considered. They should be informed of the risks and benefits of HT and encouraged to be involved in the decision-making process. If a woman does not have any contraindications to HT, HT could be an appropriate therapy option (**Figure 50–1**). Nonhormonal and alternative treatment options are available for women who are not candidates for HT or are unwilling to take HT, but they have limited effectiveness and may also have adverse effects.

Nonpharmacologic Therapy

Nonpharmacologic therapies for menopause-related symptoms have not been studied in large randomized controlled trials (RCTs), and evidence of benefit is limited. Nonpharmacologic interventions with the most evidence for improving VMS include cognitive-behavioral therapy and clinical hypnosis.[5,13] Group- and individual-based cognitive behavioral therapies are effective in reducing VMS symptoms. Evidence supporting clinical hypnosis is limited; however, two RCTs demonstrated significantly reduced hot flashes. Mindfulness-based stress reduction and weight loss may also be recommended. Due to the minimal adverse effects LO 5 of these interventions, patients should try lifestyle or behavioral modifications before and in addition to pharmacologic therapy. The following nonpharmacologic interventions are not routinely

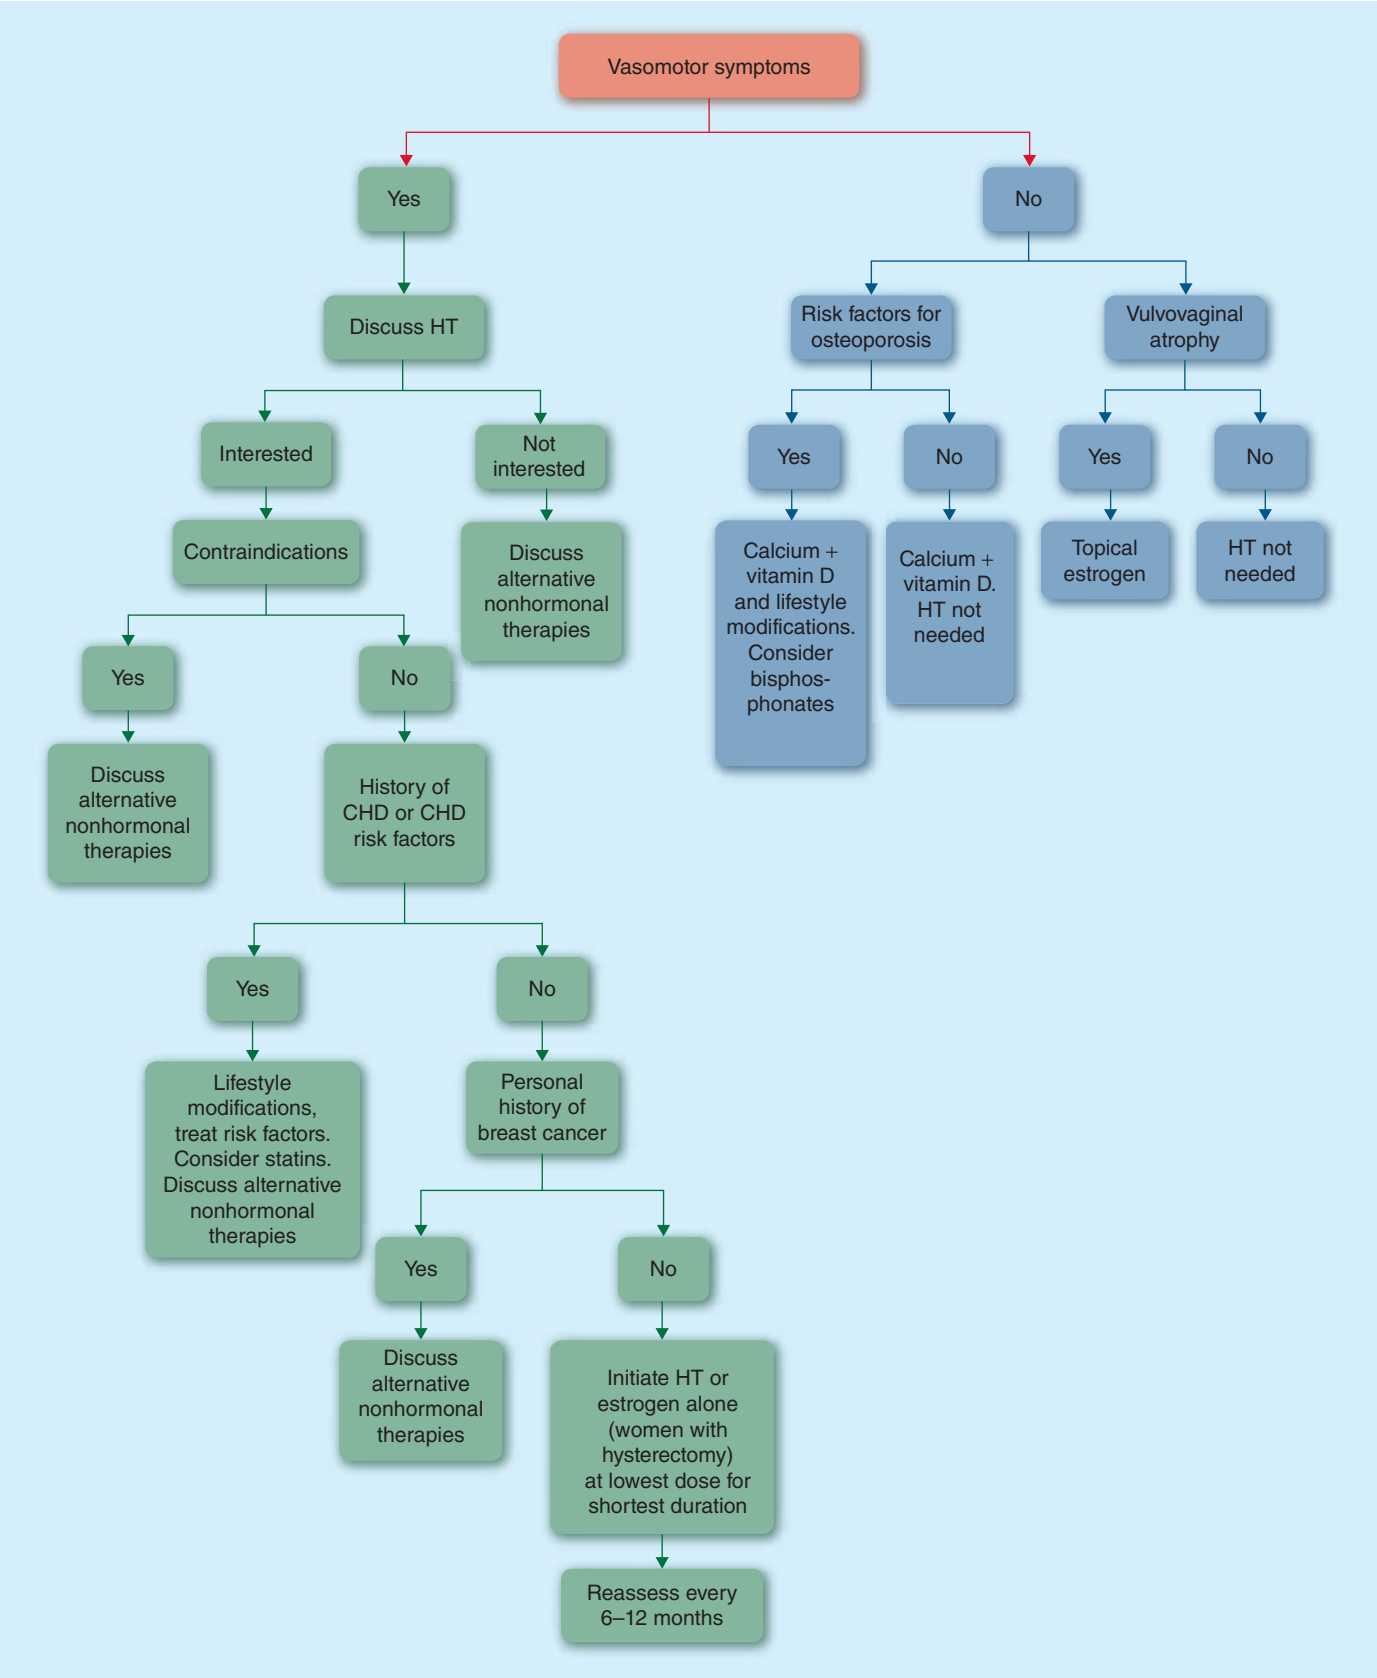

FIGURE 50–1. Treatment algorithm for postmenopausal women.[2,5,12,13] (CHD, coronary heart disease; HT, hormone therapy.)

recommended for relief of VMS, as there are negative, insufficient or inconclusive data supporting their use:

- Cooling techniques
- Avoidance of triggers
- Exercise
- Yoga
- Paced respiration
- Relaxation

Dyspareunia may result from vaginal dryness. Water-based lubricants may provide relief for several hours after application. Vaginal moisturizers may provide relief for a longer period of time and potentially can prevent infections by maintaining the acidic environment in the vagina. Both these treatments require frequent application.

A decline in estrogen concentrations may be associated with urinary stress incontinence. Kegel exercises are a first-line intervention for stress incontinence, followed by pharmacotherapy if needed. Kegel exercises strengthen the pelvic floor muscles and help to keep the urethral sphincter from relaxing at inappropriate times, such as when lifting heavy objects, coughing, or sneezing. These exercises have no adverse effects, take little time, and may be done inconspicuously.

Pharmacotherapy: Hormonal Therapy

▶ *Estrogens*

Estrogen is indicated for the treatment of moderate to severe VMS and vulvovaginal atrophy associated with menopause. It is also indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that nonestrogen medications be used long-term. KEY CONCEPT Appropriate dose, duration, regimen and route of administration should be patient specific, and aim to utilize the lowest effective dose of HT to provide relief of VMS. Topical vaginal products in the form of creams, tablets, or rings should be prescribed for women experiencing GSM without VMS.

Many systemically administered estrogen products are available in the United States. Transdermal estrogen preparations are also available and usually are prescribed for patients who experience adverse effects, elevated triglycerides (TG), or liver function abnormalities while taking an oral product. Multiple observational studies suggest that transdermal preparations have a lower incidence of venous thromboembolism (VTE) than oral preparations.[5,10,14]

▶ *Progestogens*

KEY CONCEPT Women who have an intact uterus should be prescribed a progestogen in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.[4] Progestogens should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously. Even low doses of oral estrogen therapy, as well as high dose vaginal preparations, require daily or intermittent administration of a progestogen in order to provide endometrial protection. Table 50–1 lists estrogen and progestogen preparations and dosages.

▶ *Adverse Effects*

Therapy with estrogen with or without a progestogen should be initiated at the lowest dose in order to minimize adverse effects. Because the adverse effects of these preparations can be similar, it may be difficult to assess whether the estrogen or the progestogen is the cause. Changing preparations, particularly the progestogen,

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

The workup reveals the following additional information:

PMH: Hypertension since age 45, currently controlled; hypothyroidism since age 25; hysterectomy 1 year ago.

FH: Father: Alive with HTN and CHD (MI at age 60). Mother: Alive with hypothyroidism, HTN, and GERD. Siblings: Two sisters alive and well, menopausal with hx of hot flashes.

SH: Occupation: physician assistant; nonsmoker; drinks one glass of red wine with dinner on the weekends; denies illicit drug use.

Meds: Lisinopril 20 mg once daily; levothyroxine 0.1 mg by mouth once daily; multivitamin with iron by mouth once daily (discontinued 2 months ago)—takes all medications 30 minutes before breakfast.

ROS: (+) hot flashes, night sweats, (+) dyspareunia; vaginal dryness and itching; (+) insomnia, (–) bowel changes, 5-lb (2.3 kg) weight loss since last visit 6 months ago.

PE:

VS: BP 120/70, P 72, RR 16, T 37.0°C (98.6°F), Wt 74.4 kg (164 lbs)

HEENT: WNL

Neck: Supple; no bruits, no adenopathy, no thyromegaly

Breasts: Supple; no masses

CV: RRR, normal S_1 and S_2; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; (+) BS, no masses

Genitourinary: Pelvic examination normal except (+) mucosal atrophy; (+) hysterectomy

Labs:

FSH: 125 mIU/mL (IU/L)

TSH: 0.27 μIU/mL (mIU/L)

Chem-7: Na 135 mEq/L (mmol/L), K 4.5 mEq/L (mmol/L), Cl 109 mEq/L (mmol/L), CO_2 25 mEq/L (mmol/L), BUN 9 mg/dL (3.2 mmol/L), SCr 0.9 mg/dL (80 μmol/L), Glucose 98 mg/dL (5.4 mmol/L)

CBC: Hgb 13 g/dL (130 g/L or 8.07 mmol/L), Hct 39% (0.39 volume fraction), WBC 5.5 × 10^3/mm^3 (5.5 × 10^9/L), platelets 234 × 10^3/mm^3(234 × 10^9/L)

Fasting lipid levels: Total cholesterol (TC) 180 mg/dL (4.65 mmol/L), low-density lipoprotein (LDL) 110 mg/dL (2.84 mmol/L), high-density lipoprotein (HDL) 50 mg/dL (1.29 mmol/L), triglycerides (TG) 115 mg/dL (1.30 mmol/L)

Assess the patient's condition based on this additional information.

What are the goals of treatment for this patient?

Assess the patient's risk factors for heart disease and breast cancer.

Recommend nonpharmacologic and pharmacologic treatment for this patient. Justify your recommendations.

Table 50–1

Hormone Formulations and Dosages[11,15,16]

Product	Available Strengths	Common Dosages
Oral estrogens		
Conjugated estrogens (Premarin)	0.3–1.25 mg	0.3–0.625 mg/day
Esterified estrogens (Menest)	0.3–1.25 mg	0.3–1.25 mg/day
Estradiol (Estrace[a])	0.5–2 mg	1–2 mg/day
Estropipate[a]	0.75–3 mg	0.75–6 mg/day
Transdermal estrogens		
Estradiol patch (Alora, Minivelle, Vivelle Dot)	0.025–0.1 mg/24 hour	0.025–0.1 mg, changed twice weekly
(Climara, Menostar[b])	0.025–0.1mg/24 hour	0.025–0.1 mg, changed weekly
Topical estrogens		
Vaginal creams		
Conjugated estrogens (Premarin)	0.625 mg/g	0.5–2 g/day
Estradiol (Estrace)	0.01%	1 g one to three times/week
Gel		
Estradiol gel		
(Elestrin)	0.06%	1–2 actuations of pump once daily
(EstroGel)	0.06%	1 actuation of pump once daily
(Divigel)	0.1%	0.25 gram/day packet once daily
Spray		
Estradiol spray (Evamist)	1.53 mg/actuation	1–3 sprays daily
Vaginal inserts		
Vaginal ring		
Estradiol (Estring)	2 mg	1 ring every 3 months
Estradiol acetate (Femring)	0.05–0.1mg/24 hour	1 ring every 3 months
Vaginal tablet		
Estradiol (Vagifem)	10 mcg estradiol	One tablet twice weekly
Progestogens[c,d]		
Medroxyprogesterone acetate (Provera)	2.5–10 mg	
Micronized progesterone (Prometrium®)	100–200 mg	
Norethindrone acetate (Aygestin®)	5 mg	
Combination products		
Oral		
Conjugated estrogens + medroxyprogesterone (Prempro; Premphase)	0.3/1.5 mg–0.625/5 mg	One tablet daily
Conjugated estrogens + bazedoxifene (Duavee)	0.45 mg/20 mg	One tablet daily
Estradiol + norethindrone (Activella; Amabelz)	0.5/0.1 mg–1/0.5 mg	One tablet daily
Estradiol + drospirenone (Angeliq)	0.25/0.5 mg–0.5/1 mg	One tablet daily
Ethinyl estradiol + norethindrone acetate (Femhrt low dose, others)	2.5 mcg/0.5 mg–5 mcg/1 mg	One tablet daily
Estradiol + norgestimate (Prefest)	1/0.09 mg	One tablet daily
(Covaryx)	1.25/2.5 mg	One tablet daily
(Covaryx HS)	0.625/1.25 mg	One to two tablets daily
Transdermal		
Estradiol + norethindrone acetate (Combipatch)	0.05/0.14–0.05/0.25 mg/24 hour	Apply one patch twice weekly
Estradiol + levonorgestrel (Climara Pro)	0.045/0.015 mg/24 hour	Apply one patch once weekly

[a]FDA-approved commercially available bioidentical product.

[b]Indicated for the prevention of postmenopausal osteoporosis only; available in 14 mcg patch.

[c]May be administered cyclically or continuously.

[d]Dose varies based on daily or cyclic administration.

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate.

LO 6 or changing the method of administration may help to alleviate adverse effects. Table 50–2 lists the adverse effects that may be associated with estrogen and progestogen preparations.

► *Contraindications*

LO 6 HT should not be prescribed to women with a history of or active thromboembolic disease, CHD, breast cancer, or estrogen-dependent neoplasm, pregnancy, liver disease, or undiagnosed vaginal bleeding. It also should not be used for the prevention or treatment of cardiovascular disease, cerebrovascular disease, or dementia.[5]

► *Methods of Administration*

Continuous Estrogen and Cyclic Progestogen Estrogen is administered daily, and progestogen is administered for 12 to 14 days of the month. The disadvantage of this method of administration is the return of monthly menses in approximately 90% of women 1 to 2 days following the last progestogen dose.

Table 50–2

Adverse Effects of Estrogens and Progestogens[5,11,15,16]

Estrogens
Common adverse effects
- Nausea
- Headache
- Bloating
- Breast tenderness
- Breakthrough uterine bleeding

Serious adverse effects
- Coronary heart disease
- Stroke
- Venous thromboembolism
- Breast cancer
- Gallbladder disease

Progestogens
Common adverse effects
- Nausea
- Headache
- Weight gain
- Bleeding
- Irritability
- Depression

Serious adverse effects
- Venous thromboembolism
- Breast cancer (in combination with estrogen)
- Decreased bone mineral density (effect of injectable medroxyprogesterone acetate)

Women may view this scheduled bleeding as an advantage to this method of administration as it limits spotting or soiling of undergarments.

Continuous Combined Estrogen and Progestogen Estrogen and progestogen are administered daily and result in endometrial atrophy. Therefore, women do not experience a withdrawal bleed but may experience unanticipated breakthrough bleeding or spotting during the month. Although this may sound more appealing than a withdrawal bleed, women may view the unpredictable bleeding or spotting as a disadvantage to this type of administration. If bleeding persists beyond 6 to 12 months, women should seek medical attention to rule out endometrial hyperplasia or carcinoma.

▶ *Low-Dose HT*

There is an increasing body of evidence proving the effectiveness of low-dose HT regimens in the management of menopausal symptoms. Several trials demonstrated that lower doses of conjugated equine estrogens (CEE) ± medroxyprogesterone acetate (MPA) (CEE 0.45 mg or 0.3 mg ± MPA 2.5 mg or 1.5 mg) decreased hot flashes comparable with standard HT, improved vulvovaginal atrophy, increased bone mineral density (BMD) at the spine and hip, and provided sufficient endometrial protection.[17-20] Currently, no data are available on the effects of low-dose HT on the incidence of VTE, breast cancer, or CHD. Although many women have switched to low-dose HT, time will tell if lower doses translate into lower risks.

▶ *Bioidentical HT*

Bioidentical hormones are exogenous hormones that are identical to those produced in a woman's body (eg, estradiol, estrone, estriol, and progesterone). They are either commercially manufactured or custom-compounded in pharmacies into formulations such as topical creams, gels, and suppositories. The commercially manufactured prescription products are subject to regulation by the FDA and have been tested for potency, purity, efficacy, and safety (see Table 50–1). Conversely, custom-compounded formulations are not subject to the same regulations and therefore, the efficacy and safety may be questionable. Often women view bioidentical hormones, particularly the custom-compounded formulations, as "natural" and assume these formulations are safer than currently marketed prescription hormone products. Women may feel more comfortable using custom-compounded products that are formulated based on individual hormone levels; however, due to a lack of regulation, these products may potentially cause more harm than benefit. In addition, custom-compounded formulations can result in higher costs, because they are generally not covered by third-party payers. There is little evidence comparing the safety and efficacy of conventional HT to prescription bioidentical HT, and thus the same risks and benefits should be assumed.[5,21]

▶ *Benefits of HT*

LO 6

Vasomotor Symptoms HT remains the most effective treatment for VMS, and systemic HT should be considered only in women experiencing these symptoms. Benefits must outweigh risks, and decisions should be made only after careful consideration by the woman and her health care provider. If it is decided to use HT, pharmacotherapy should be individualized for route, dose, and duration. Women should be reassessed every 6–12 months, and discontinuation of therapy should be considered. Extended treatment duration may be warranted for relief of persistent VMS and GSM and prevention of bone loss and fracture when unable to tolerate therapy primarily indicated for osteoporosis.[5]

LO 6

Vulvovaginal Atrophy Vulvovaginal atrophy is associated with vaginal dryness and dyspareunia and also may be associated with recurrent urinary tract infections, urethritis, and urinary urgency and frequency. Topical vaginal preparations should be prescribed as first-line therapy unless the patient is also experiencing VMS. Local vaginal estrogen has demonstrated increased efficacy over systemic estrogen and generally does not require supplementation with a progestogen in women with an intact uterus using low or ultralow doses.[4] Women using high doses of topical estrogen products may require intermittent treatment with a progestogen. Estradiol in the form of a vaginal tablet or ring is not significantly absorbed systemically, with the exception of Femring which is the only vaginal ring indicated for VMS. Other vaginal rings may be used safely in women with contraindications to estrogen therapy and symptoms of vulvovaginal atrophy.[5]

LO 6

Osteoporosis Prevention Postmenopausal osteoporosis is a condition that affects millions of women. Fractures, particularly hip fractures, are associated with a high incidence of morbidity and mortality and decreased QOL. Before the WHI study, only observational data were available regarding the association of HT and the reduction of fractures. The WHI was the first RCT that demonstrated a reduction in total fractures, including the hip, spine, and wrist.[2,22]

KEY CONCEPT Extended treatment duration with HT may be warranted in women with VMS for prevention of bone loss and fracture when unable to tolerate therapy primarily indicated for osteoporosis. Because of the associated risks, HT should not be prescribed solely for the prevention of osteoporosis.

▶ *Risks of HT*

Cardiovascular Disease CHD is the leading cause of death among women in the United States. The WHI was the first RCT conducted

in women without established CHD. Women with an intact uterus received HT daily. The WHI demonstrated an increased risk of CHD and stroke with HT compared with placebo.[23,24]

The estrogen-alone arm of the WHI did not demonstrate an increased risk of CHD compared with placebo. However, there was an increased risk of stroke with estrogen-alone compared with placebo.[3] Women who initiate HT 10 or more years after menopause have an increased cardiovascular risk.[5,25,26] A recent long-term analysis of the WHI study demonstrates that among postmenopausal women, use of oral estrogen plus progesterone for 5.5 years or oral estrogen alone for 7 years did not increase the risk of all-cause mortality.[27]

LO 6 HT should not be prescribed for the prevention of CHD or in patients with preexisting CHD.

Breast Cancer Breast cancer is the most common cancer in women in the United States. Observational data indicated an association between HT and breast cancer risk. The WHI was the first RCT to demonstrate an increased risk of invasive breast cancer among women taking HT.[2,28] The increase in risk did correlate with increased age of the women, and the risk appears to be greater in those who initiate therapy within 5 years of menopause. There were also more deaths from breast cancer and deaths overall with combination therapy than with placebo.[29] It should be noted that any increase in risk for breast cancer appears to dissipate over 2 to 3 years after HT is discontinued.[5,30] Whether HT is associated with an increased risk for breast cancer recurrence is still questionable.

Breast cancer was not increased in the estrogen-alone arm of the WHI.[3] These data point to a possible link of progestogen with breast cancer risk. Whether or not the risk differs between type of progestogen or continuous and sequential use of progestogens is controversial. Some evidence suggests that sequential use may be safer than taking progestogen each day.[5,31]

LO 6 Women with a personal history of breast cancer and possibly even a strong family history of breast cancer should avoid the use of HT and should consider nonhormonal therapies for the treatment of VMS.

Venous Thromboembolism The WHI demonstrated an increased risk for VTE with HT compared with placebo.[2] The risk for deep vein thrombosis was also increased in the estrogen-alone arm of the WHI, but pulmonary embolism was not increased significantly.[3] The risk of thromboembolism may be dose-related, and the oral route of administration is associated with a higher risk compared with the transdermal route.[14]

LO 6 KEY CONCEPT In summary, combined estrogen plus progestogen or estrogen alone should not be used for the prevention of chronic diseases.

▶ *Other Effects of HT*

QOL and Cognition Women consider QOL measures when deciding whether to use HT; however, the effects of HT on overall QOL have been inconsistent. HT did not demonstrate a clinically meaningful effect on QOL but women taking HT did have a small improvement in sleep disturbances, physical functioning, and bodily pain after 1 year of therapy.[32] Results from the HERS demonstrated that HT did improve emotional measures such as depressive symptoms, but only if women suffered from flushing at trial entry.[33]

Observational studies suggested a potential benefit of HT on cognitive functioning and dementia. However, the Women's Health Initiative Memory Study (WHIMS), conducted in postmenopausal women aged 65 years or older, failed to demonstrate an improvement in cognitive function and demonstrated a small increase in dementia rate, including Alzheimer disease.[34,35] The estrogen-alone arm of the WHIMS also demonstrated similar results.[36,37]

LO 6 KEY CONCEPT HT improves overall well-being and mood in women with VMS, but it has not demonstrated an improvement in QOL in women without VMS.

▶ *Discontinuation of HT*

KEY CONCEPT When treating moderate to severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best when HT is started close to the time of menopause. Consider tapering therapy before discontinuation to limit the potential recurrence of hot flashes. Although VMS in most women will subside within 4 years, approximately 10% of women continue to experience symptoms that interfere with their QOL. Literature suggests that one of every four women needs to be reinitiated on HT due to persistent and bothersome symptoms. There is no evidence to suggest that tapering is beneficial; however, it may be prudent to avoid bothersome recurrent symptoms.[5,38]

Limited evidence is available to guide health care providers regarding the least disruptive way to taper HT. Slowly discontinuing HT over 3 to 6 months may be associated with less risk of symptom return. Tapering HT may be done by a dose taper or day taper. The dose taper involves decreasing the dose of estrogen over several weeks to months and monitoring closely for symptom return. The day taper involves decreasing the number of days of the week that a woman takes the HT dose. If symptoms recur, the next reduction in dose or days should not occur until symptoms resolve or stabilize. These tapering regimens have not been studied in clinical trials and may not prove to be beneficial in individual women.[38]

Hormone Modulating Therapy

▶ *Selective Estrogen Receptor Modulators (SERMs)*

Although estrogen +/– progestogen remains first-line therapy for the relief of moderate to severe VMS and vulvovaginal atrophy, additional hormone options utilizing SERMs are available.

Ospemifene (Osphena) is approved for the treatment of moderate to severe dyspareunia associated with vulvovaginal atrophy. This drug acts as an estrogen agonist in some tissues (vaginal and endometrial) and antagonist in other tissues. Data suggests there is an increase in hot flashes and that there may be an increased risk of endometrial cancer in women with an intact uterus. This drug may be considered in women with symptoms of vulvovaginal atrophy. However, the risks and benefits should be discussed with women also presenting with VMS and an intact uterus.[5]

CEE 0.45 mg/bazedoxifene (BZA) 20 mg (Duavee), the first tissue selective estrogen complex, is approved for the treatment of postmenopausal osteoporosis and moderate to severe VMS in women with an intact uterus. This drug acts as an agonist in bone tissue and an antagonist in breast and uterine tissue. Clinical trials have demonstrated efficacy with no stimulation of breast or uterine tissue. Thus, progestogens are not needed. Adverse effects with CEE/BZA are minimal with musculoskeletal symptoms reported most commonly. When considering the place in therapy for CEE/BZA, efficacy appears to be similar to CEE/MPA with potentially less occurrence of estrogen-like adverse effects with CEE/BZA. In addition, an advantage of the formulation may be for women intolerant to progestogen adverse effects or when progestogen is contraindicated. However, because no long-term

Table 50–3

Nonhormonal Therapies for Menopause[13,39,40,42]

Drug	Brand Name	Initial Dose	Usual Dose Range	Potential Adverse Effects
Venlafaxine[a,b]	Effexor, Effexor XR	37.5 mg	37.5–150 mg/day	Nausea, HA, somnolence, dizziness, insomnia, hypertension, xerostomia constipation, diaphoresis, weakness
Desvenlafaxine[a,b]	Pristiq	25–50 mg/day	100–150 mg/day	Nausea, xerostomia, constipation, vomiting, anorexia, dizziness, drowsiness, and insomnia
Paroxetine mesylate[c]	Brisdelle	7.5	7.5 mg/day	Nausea, somnolence, insomnia, HA, dizziness, xerostomia, constipation, diarrhea, weakness, diaphoresis
Paroxetine CR	Paxil CR	12.5 mg CR	12.5 mg–25 mg CR/day	
Paroxetine HCl	Paxil	10–20 mg	10–20 mg/day	
Citalopram	Celexa	10 mg/day	10–20 mg/day	Xerostomia, nausea, drowsiness, and insomnia
Escitalopram	Lexapro	10 mg/day	10–20 mg/day	Nausea, insomnia, drowsiness, and headache
Clonidine	Catapres, Catapres TTS	0.1 mg/day	0.1–0.4 mg/day	Drowsiness, dizziness, hypotension, dry mouth
Gabapentin[a]	Neurontin	300 mg at bedtime	900 mg/day, divided in three daily doses (up to 2400 mg/day)	Somnolence and dizziness (can decrease with gradual increase in dosing)
Pregabalin[a]	Lyrica	75 mg twice daily	150–300 mg/day	Peripheral edema, dizziness, drowsiness, ataxia, headache, fatigue, weight gain, infection, diplopia, and tremor

[a]Dosage adjustments recommended in patients with renal impairment.

[b]Dosage adjustment recommended in patients with hepatic impairment.

[c]FDA approved for the treatment of moderate to severe hot flashes associated with menopause.

HA, headache.

data are available, the same precautions and contraindications as estrogen products should be assumed.[5]

Nonhormonal and Alternative Treatments

KEY CONCEPT Since publication of the WHI study, there has been an increase in the use of alternative and nonhormonal therapies for the management of menopausal symptoms, particularly for women with CHD and/or breast cancer risk factors. A wide range of therapies, both prescription and herbal, have been studied with limited success.

LO 7

Nonhormonal and alternative therapies (Table 50–3) have been studied for symptomatic management of VMS.[13] The limited and often conflicting evidence demonstrates that these agents are only modestly effective and also have associated adverse effects.

SSRIs and SNRIs reduce the frequency of hot flashes by increasing serotonin in the central nervous system. Of the SSRIs, paroxetine mesylate has the most published data demonstrating a reduction in hot flashes and is the only SSRI approved to treat moderate to severe VMS, while treating other symptomatic complaints such as depression and anxiety.[13,39] Other SSRIs such as escitalopram, citalopram, fluoxetine, and sertraline may also be effective. These antidepressant medications offer a reasonable option for women who are unwilling to or cannot take hormonal therapies, particularly those who suffer from depression or anxiety.[13]

Gabapentin, pregabalin, and clonidine have also been studied for the management of menopausal symptoms. In RCTs, gabapentin at doses of 900 mg/day demonstrated significant reductions in severity and frequency of hot flashes compared with placebo. In an RCT, pregabalin was studied at a dose of 75 mg twice daily and 150 mg twice daily. Both doses were effective in decreasing hot flash scores but adverse effects were more common with higher doses.[40] Clonidine has been studied in several small RCTs

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's hot flashes, vaginal dryness, dyspareunia, and insomnia. The plan should include:

(a) A statement identifying the problem and its severity

(b) Goals of therapy

(c) A therapeutic plan based on individual patient-specific factors

(d) Subjective and objective monitoring parameters

(e) A follow-up evaluation to assess for adverse effects and adherence and to determine whether the goals of therapy have been achieved

Patient Encounter Part 4

The patient has been in good health for the past 3 years. She reports adherence with her medications, a healthy diet and exercise routine, and her medical conditions are controlled. However, 2 months ago, she was diagnosed with a VTE secondary to being sedentary on a long airplane flight (14 hours). She is concerned that her hormone therapy may have caused the VTE.

Educate the patient regarding the risk of VTE and hormone therapy.

at doses of 0.1 to 0.4 mg/day and has demonstrated reductions in hot flashes but to a lesser extent than gabapentin.[39]

Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. Soy protein is a common source of phytoestrogens. There are differences among classes of phytoestrogens and biologic potencies vary, making it difficult to recommend specific dosing. The most commonly studied phytoestrogen is the isoflavone class. Because the effect of phytoestrogens on breast cancer and other female-related cancers is unknown, these products should not be considered in women with a history of estrogen-dependent cancers. After reviewing hundreds of studies, the North American Menopause Society (NAMS) determined that soy-based isoflavones are modestly effective in relieving menopausal symptoms.[13,41] The efficacy of soy isoflavones on bone, cognitive improvement, and cardiovascular health has not been proven.

Black cohosh has been one of the most studied alternative therapies for VMS. The mechanism of action, safety profile, drug–drug interactions, and adverse effects of black cohosh remain unknown. However, there have been case reports of hepatotoxicity with its use. In RCTs conducted for 6 months or less, there was no difference in black cohosh and placebo in reducing VMS.[13,39,42] Caution should be exercised if considering the use of this product, and it is not recommended for more than a 6-month period of time. Other alternative treatments that have been utilized include (but not limited to) dong quai, red clover leaf, kava, and evening primrose oil. These have not been shown to be effective in the treatment of menopausal symptoms and may have significant adverse effects.[13]

LO 7

Overall, alternative and nonhormonal therapies are less effective in treating VMS than HT, but do offer another option for women experiencing menopausal symptoms who cannot or are unwilling to take HT. SSRIs, SNRIs, and gabapentin have the best evidence for efficacy. Women should weigh the benefits and risks of all therapies, and discuss these options with their health care providers.[13]

OUTCOME EVALUATION

Evaluating the outcomes of any therapy for menopausal symptoms focuses primarily on the woman's report of symptom resolution. Ask women to report the resolution or reduction of hot flashes, night sweats, and vaginal dryness and any improvement or change in sleep patterns. Also ask women taking hormonal therapies to report any breakthrough bleeding or spotting. If abnormal or heavy bleeding occurs, refer the woman to her primary care provider. Monitor subjective parameters such as adverse effects and adherence to the therapy regimen. In addition, monitor objective parameters, including blood pressure, at every outpatient visit; encourage yearly clinical breast examinations, mammograms, lipid panel, and thyroid-stimulating

Patient Encounter Part 5

It has been 6 months since this patient discontinued taking hormone therapy secondary to her VTE. She presents to her PCP for follow-up with a chief complaint of recurrent hot flashes. She also complains of recurrent vaginal dryness and dyspareunia.

Recommend the most appropriate therapy for her recurrent hot flashes and vulvovaginal atrophy.

Patient Care Process

Collect Information:

- Obtain the chief complaint and history of present illness regarding symptomatology of VMS.
- Obtain patient health and functional goals for the treatment of VMS.
- Obtain a medical history that includes past medical history, social history, family history, surgical history, allergies, and information from a hot flash diary if the patient keeps one.
- Obtain a thorough medication history, including the use of over-the-counter and herbal products.

Assess the Information:

- Evaluate for the presence of VMS.
- Rule out other medical conditions that could be contributing to symptoms and manage those conditions prior to initiating therapy for symptoms.
- If the patient is experiencing bothersome VMS, consider the use of HT only after assessing for risk factors for heart disease and breast cancer.
- If VMS are tolerable and/or the patient has risk factors for heart disease and/or breast cancer, consider alternative, nonhormonal treatments for VMS.
- Consider appropriate nonpharmacologic interventions.

Develop a Care Plan:

- Create a patient-centered pharmacologic plan in conjunction with the health care provider.
- Create a patient-centered nonpharmacologic plan.

Implement the Care Plan:

- Recommend the appropriate dose of a pharmacologic agent and duration, regimen, and route of administration that are patient-specific, and aim to utilize the lowest effective dose of HT.
- Document findings and recommendations.
- Discuss the importance of adhering to the medication regimen.
- Discuss methods of administration, potential adverse effects, and expectations of therapy.
- Discuss lifestyle or behavioral interventions that may help to alleviate VMS.

Follow-up: Monitor and Evaluate:

- Efficacy: monitor for reduction in VMS and improvement in vulvovaginal atrophy, sleep, and QOL.
- Safety: monitor for breakthrough bleeding and spotting, adverse effects of HT, blood pressure at every outpatient visit, yearly mammograms, yearly TSH, and endometrial studies in women with undiagnosed vaginal bleeding.
- Assess symptoms every 6 to 12 months, and consider tapering the HT dose and discontinuing treatment after 5 years. If VMS return, determine whether a longer tapering schedule is warranted or if long-term treatment is necessary. If treatment beyond 5 years is necessary, consider switching to a nonhormonal product.

hormone (TSH) determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test as indicated. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Last, evaluate the patient's overall QOL. Because the management of menopause is largely symptomatic, it is important to document symptoms at the beginning of therapy and monitor symptom improvement and potential adverse effects at each visit. Frequent follow-up, proper monitoring, and education will help to ensure that the woman achieves optimal results from any therapy chosen to treat menopausal symptoms.

LO 8

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
CEE	Conjugated equine estrogens
CHD	Coronary heart disease
FDA	US Food and Drug Administration
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
GSM	Genitourinary syndrome of menopause
HDL	High-density lipoprotein
HERS	Heart and Estrogen/Progestin Replacement Study
HT	Hormone therapy
LDL	Low-density lipoprotein
LH	Luteinizing hormone
MPA	Medroxyprogesterone acetate
NAMS	North American Menopause Society
QOL	Quality of life
PCP	Primary care provider
RCT	Randomized controlled trial
SERMs	Selective estrogen receptor modulators
SSRI	Selective serotonin reuptake inhibitor
TG	Triglycerides
TSH	Thyroid-stimulating hormone
VMS	Vasomotor symptoms
VTE	Venous thromboembolism
WHI	Women's Health Initiative
WHIMS	Women's Health Initiative Memory Study

51 Erectile Dysfunction

Cara Liday

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

LO

1. Explain the pathophysiology of erectile dysfunction (ED).
2. Recognize risk factors and medications associated with the development of ED.
3. Identify the goals of therapy when treating ED.
4. Describe current nonpharmacologic and pharmacologic options for treating ED, and determine an appropriate first- and second-line therapy for a specific patient.
5. Identify patients with significant cardiovascular risk and recommend an appropriate treatment approach for their ED.
6. Compare and contrast the benefits and risks for the current phosphodiesterase type 5 (PDE5) inhibitors.
7. Assess reasons for PDE5 failure and determine an optimal approach to improve treatment efficacy.

INTRODUCTION

Erectile dysfunction (ED) is defined as the persistent inability to achieve or maintain an erection sufficient for sexual intercourse. ED is the most prominent sexual problem in men, and it can lead to lower quality of life and self-esteem.[1] Patients may also develop libido or ejaculatory disorders, but these are not considered ED.

EPIDEMIOLOGY AND ETIOLOGY

ED increases with age. Few men report erection problems before age 40, but ED increases to 61% in men aged 40 to 69 years and 77% in men older than 70 years.[2] The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis.

In the flaccid state, a balance exists between blood flow into and out of the corpora cavernosa. With sexual stimulation, nerve impulses from the brain travel down the spinal cord triggering a reduction in sympathetic tone and an increase in parasympathetic activity. This leads to an increased production of nitric oxide (NO), which enhances the activity of guanylate cyclase. This results in increased production of cyclic guanosine monophosphate (cGMP). The enzyme phosphodiesterase type 5 (PDE5) is responsible for the catabolism of cGMP within the cavernosal tissue. Vasoactive peptide and prostaglandins E_1 and E_2 stimulate increased production of cyclic adenosine monophosphate (cAMP). Both cAMP and cGMP reduce calcium concentrations within smooth muscle cells of the penile arteries and the sinusoidal spaces, leading to smooth muscle relaxation and increased blood flow. As the spaces become engorged, pressure increases, subtunical venules are compressed by the tunica albuginea, and the penis becomes rigid and elongated (Figure 51–1).

Detumescence, or return of the penis to a flaccid state, occurs with sympathetic discharge after ejaculation. Norepinephrine contracts smooth muscle leading to a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. In addition to stabilization of intracavernosal levels of NO synthase, the enzyme responsible for triggering the NO cascade, testosterone is responsible for much of a man's libido. In general, there is not a strong association between normal or low serum testosterone levels and erectile function.[4]

Normal penile erections are complex events that require the full function of the vascular, neurologic, hormonal, and psychogenic systems. Anything that affects the function of these systems may lead to ED. KEY CONCEPT ED can be classified as organic, psychogenic, or a mixture of these. Organic dysfunction includes abnormalities in the vascular, hormonal, or neurologic systems or may be medication-induced (Tables 51–1 and 51–2). It is estimated that 10% to 25% of ED cases are due to medications. Note that many of the risk factors for ED are the same as those for cardiovascular (CV) disease, including hypertension, diabetes, dyslipidemia, smoking, obesity, metabolic syndrome, and sedentary behavior. In many patients, ED is the first indication of the endothelial dysfunction associated with CV, with a time between onset of ED and a CV event of 2 to 5 years.[6] The presence of ED risk factors leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result of vascular disease and

LO 1

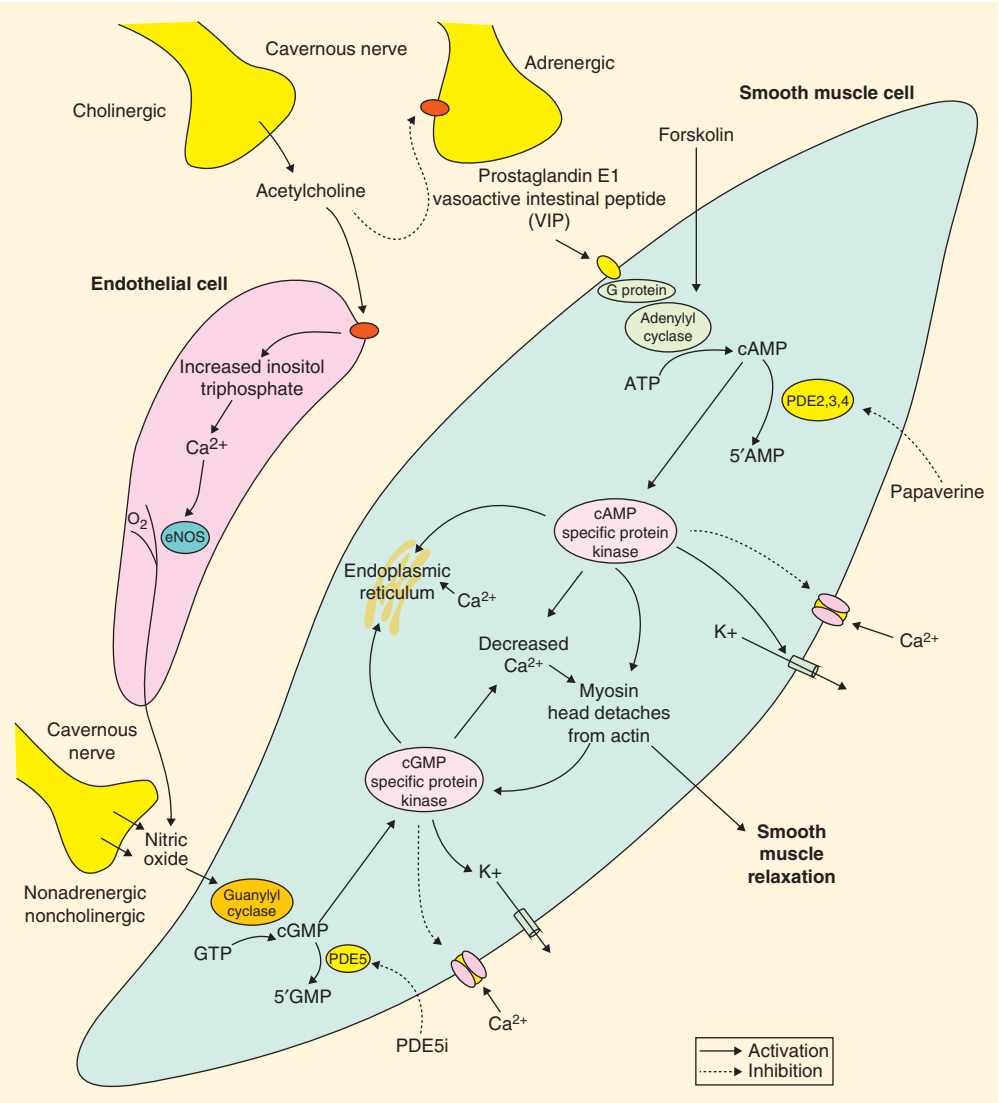

FIGURE 51–1. Molecular mechanism of penile smooth muscle relaxation. Cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), activate their specific protein kinases, which leads to sequestration of intracellular calcium by the endoplasmic reticulum. The resultant decrease in intracellular calcium leads to smooth muscle relaxation. Sildenafil inhibits the action of phosphodiesterase (PDE) type 5 and increases the intracellular concentration of cGMP. Papaverine is a nonspecific (PDE) inhibitor. (ATP, adenosine triphosphate; eNOS, endothelial nitric oxide synthase; GTP, guanosine triphosphate.) (Reproduced, with permission, from Lue T. Physiology of penile erection and pathophysiology of erectile dysfunction. In: Wein AJ, Kavoussi LR, Partin AW, et al, eds. Campbell-Walsh Urology, 11th ed. Philadelphia: Elsevier; 2016:630.)

neuropathy. Additionally, a relationship has been found between low testosterone levels and an increased incidence of metabolic syndrome and type 2 diabetes.[7]

Psychogenic dysfunction occurs if a patient does not respond to psychological arousal. Common causes include performance anxiety, strained relationships, lack of sexual arousability, and overt psychiatric disorders such as depression and schizophrenia. KEY CONCEPT Many patients may initially have organic dysfunction, but develop a psychogenic component as they try to cope with their inability to achieve an erection.[1]

CLINICAL PRESENTATION AND DIAGNOSIS OF ED

The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction.

TREATMENT

Desired Outcomes

ED is not a life-threatening condition, but if left untreated, it can be associated with depression, loss of self-esteem, poor self-image, and marital discord.[9] The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient and partner quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.

LO 3

General Approach to Treatment

KEY CONCEPT Before initiating treatment for ED, a physical examination and thorough medical, social, and medication

Table 51–1

Factors Associated with ED[1,5]

Chronic Medical Conditions
Hypertension
Diabetes mellitus
Benign prostatic hyperplasia
Coronary and peripheral vascular disease
Neurologic disorders (eg, Parkinson disease and multiple sclerosis)
Endocrine disorders (hypogonadism, pituitary, adrenal, and thyroid disorders)
Psychiatric disorders
Dyslipidemia
Renal failure
Liver disease
Penile disease (Peyronie disease or anatomic abnormalities)
Surgical Procedures
Perineal or vascular surgeries
Radical prostatectomy
Lifestyle
Smoking
Excessive alcohol consumption
Obesity
Poor overall health and reduced physical activity
Trauma
Pelvic fractures or surgeries
Spinal cord or brain injuries

LO 2

Table 51–2

Medication Classes Associated with ED[3,5]

Antihypertensives
β-Blockers (excluding nebivolol)
Thiazide diuretics
Centrally acting agents (clonidine, methyldopa, and reserpine)
Spironolactone
α-Blockers
CNS Depressants
Opioid analgesics
Benzodiazepines
Hypnotics
Lipid Medications
Gemfibrozil
HMG-CoA reductase inhibitors
Antidepressants/Antipsychotics
Tricyclic antidepressants
Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors/serotonin-norepinephrine reuptake inhibitors
Lithium
Anticonvulsants
Carbamazepine
Phenytoin
Gastrointestinal Agents
Histamine 2-receptor antagonists
Proton pump inhibitors
Antiandrogens and Hormones
5α-Reductase inhibitors
Progesterone and estrogen
Corticosteroids
Recreational Drugs
Ethanol
Cocaine
Marijuana
Opiates

Clinical Presentation and Diagnosis

Possible Signs and Symptoms

- Marital difficulties
- Low self-confidence or morale; depression
- Full or partial inability to achieve erections
- Erections sufficient for intercourse, but early detumescence
- The problem may have a slow or acute onset, or may wax and wane.

Diagnosis

- ED may be the presenting symptom of other chronic disease states.
- The following should be performed to determine areas that can cause or exacerbate ED and to assess the patient's ability to safely perform intercourse:
  - Medical history with emphasis on cardiovascular and psychiatric disorders, diabetes, trauma, and surgical procedures
  - Social history including nutrition and history of smoking, recreational drug use, exercise, and alcohol consumption
  - Medication history including prescription, nonprescription, and herbal or dietary supplements

Physical Examination

- Review for hypogonadism (gynecomastia, testicular atrophy, reduced body hair, increase in body fat)
- Digital rectal examination to determine whether prostate is enlarged
- Vital signs
- Abnormalities of the penis; impaired vasculature or nerve function to the penis

Labs

- Fasting glucose or HbA_{1c}
- Serum testosterone if signs of hypogonadism
- Fasting lipid panel
- Further cardiac testing if warranted

Determine Severity

- Use an abridged, five-item version of the International Index of Erectile Function (IIEF-5) as a diagnostic tool.[8]
- How do you rate your confidence that you could get and keep an erection?
- When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
- During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
- During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?
- When you attempted sexual intercourse, how often was it satisfactory for you?
- Questions scored 1 to 5, very low to very high, respectively. Score of 21 or less indicates ED likely.

Table 51–3

The Princeton III Consensus Recommendations for Cardiovascular Risk Assessment and the Management of Erectile Dysfunction[6,10]

Risk	Risk Description	Treatment Recommendation
Low	Able to perform exercise of moderate activity without symptoms Successful revascularization (CABG, stent, angioplasty) Asymptomatic, well-controlled hypertension Mild valvular heart disease Left ventricular dysfunction/heart failure (NYHA classes I and II) Uncomplicated previous MI	May initiate or resume sexual activity and begin ED treatment without further evaluation
Intermediate	Has three or more risk factors for CV disease Mild or moderate, stable angina Had a recent MI within the past 2–8 weeks Moderate heart failure (NYHA Class III) Noncardiac sequelae of atherosclerotic disease (PAD, stroke, TIA)	Further evaluation using exercise stress testing is required before resuming sexual activity. After completion, will be reassigned to low or high risk category
High	Moderately or severely symptomatic Unstable or refractory angina, despite treatment Uncontrolled hypertension Severe heart failure (NYHA Class IV) Recent MI without intervention (< 2 weeks) High-risk cardiac arrhythmia Obstructive hypertrophic cardiomyopathy with severe symptoms Moderate or severe valvular heart disease	Sexual activity should be deferred until cardiac condition stabilized

CABG, coronary artery bypass grafting; CV, cardiovascular; NYHA, New York Heart Association; PAD, peripheral arterial disease; PDE, phosphodiesterase; TIA, transient ischemic attack; MI, myocardial infarction.

histories with emphasis on cardiac disease must be taken to assess for ability to safely perform sexual activity and to assess for possible drug interactions. The Princeton Consensus was developed to estimate risk associated with sexual activity and determine the safety of ED treatment.[6,10] In patients with intermediate or high CV risk, additional testing should occur to determine whether sexual activity is safe (Table 51–3).

LO 5

KEY CONCEPT Treatment options for ED include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately. Additionally, combining different treatment modalities, that is, devices and pharmacologic options, may increase efficacy.

KEY CONCEPT When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. KEY CONCEPT The choice of treatment is primarily left up to the couple, but oral PDE5 inhibitors are considered first-line with vacuum erection devices (VEDs) as another noninvasive option. Ultimately, the choice of therapy should be individualized, taking into account patient and partner preferences, concomitant disease states, response, administration route, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in Table 51–4.

▶ *Nonpharmacologic Therapy*

Lifestyle Modifications Control of risk factors and general lifestyle modifications should always be addressed first in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher IIEF scores and an improvement in erectile function.[11] The clinician should also recommend smoking cessation, reduction in excessive alcohol intake, and discontinuation of illicit drug use.

Psychotherapy Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. Counseling may include simple sex education and improved partner communication in addition to cognitive and behavioral therapy. Psychotherapy may help relieve anxiety and eliminate unrealistic expectations while enhancing pharmacologic efficacy.[9,12]

Vacuum Erection Devices VEDs induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (Figure 51–2). VEDs may be used as often as desired, but it is recommended that the constriction band not be left in place longer than 30 minutes at a time.

Patient Encounter 1, Part 1

A 68-year-old man with type 2 diabetes, hypertension, and obesity comes into your clinic for routine follow-up. When reviewing his history, he describes problems with his erections. After further questioning, you determine that his erectile dysfunction has progressively gotten worse over the last year. He is quite emotional and states that the problem is distressing and has caused significant marital discord.

Based on the available information, how would you classify his ED?

What additional information do you need before establishing an appropriate treatment regimen and determining his ability to safely perform intercourse?

Table 51–4

Common Drug Treatment Regimens for ED

Route of Administration	Generic Name	Brand Name	Typical Dosing Range[a]	Maximum Dosing Frequency
Oral	Sildenafil	Viagra	25–100 mg 1 hour prior to intercourse	Once daily
	Tadalafil	Cialis	5–20 mg 30 minutes prior to intercourse or daily dose of 2.5–5 mg	Once daily
	Vardenafil	Levitra, Staxyn	5–20 mg 1 hour prior to intercourse	Once daily
	Avanafil	Stendra	100–200 mg 15 minutes prior to intercourse	Once daily
Intracavernosal	Alprostadil	Caverject, Caverject Impulse, Edex	1.25–60 mcg 5–20 minutes prior to intercourse[b]	3 times weekly, 24 hours between injections
Intraurethral	Alprostadil	MUSE	125–1000 mcg 5–10 minutes prior to intercourse[b]	2 times daily
Intramuscular	Testosterone cypionate	Depo-Testosterone	50–400 mg every 2–4 weeks	Once weekly
	Testosterone enanthate	Delatestryl	50–400 mg every 2–4 weeks	Once weekly
	Testosterone undecanoate	Aveed	750 mg on day 1 and week 4; then every 10 weeks	After titration once every 10 weeks
Topical	Testosterone patch	Androderm	2–6 mg/day applied at night to back, abdomen, upper arms, or thighs	Once daily
	Testosterone gel	AndroGel 1%, Testim, Vogelxo	5–10 g gel per day (50–100 mg testosterone) in morning to shoulders, upper arms, abdomen (AndroGel 1% only)	Once daily
		AndroGel 1.62%	40.5–81 mg/day in morning to shoulders or upper arms	Once daily
		Natesto	11 mg intranasally 3 times daily; 6–8 hours apart (2 pump actuations, 1 per nostril)	3 times daily
		Fortesta	10–70 mg/day in morning to thigh (1–7 pumps)	Once daily
	Testosterone solution	Axiron	30–120 mg/day in morning to axilla (1–4 pumps)	Once daily
Buccal	Testosterone	Striant	30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose	2 times daily
Subcutaneous implantable pellet	Testosterone	Testopel	150–450 mg (150 mg for every 25 mg testosterone propionate required weekly)	Every 3–6 months

[a]Use the lowest effective dose to limit adverse effects.

[b]Initial dose, to achieve erection lasting 1 hour, must be titrated in physician's office.

MUSE, medicated urethral system for erection.

Onset of action is slow, which limits spontaneity. In addition, patients and partners may complain of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or inability to ejaculate are additional adverse effects. VEDs are relatively contraindicated in persons with sickle cell disease and should be used with caution in those on oral anticoagulants or who have bleeding disorders.

VEDs are highly effective treatment modalities for ED and are considered a first- or second-line therapy. They are generally more acceptable to older patients in stable relationships and with infrequent sexual encounters. Efficacy rates are as high as 90% in obtaining an erection sufficient for intercourse, and although satisfaction rates are as high as 94%, the discontinuation rate after 2 years is close to 50%.[13] A double pumping technique in which the vacuum is applied for 1 to 2 minutes, removed, then reapplied for another 3 to 4 minutes may improve comfort levels and rigidity. Higher efficacy rates can also be achieved by combining VEDs with other therapies.

Prostheses Penile prostheses are semirigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa (see Figure 51–3). The malleable rods are rigid at all times, but may be bent into position by the patient when desired. The inflatable prostheses are preferred due to a more "natural" erection as they remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

Patient satisfaction rates can be as high as 100%, with partner satisfaction rates slightly lower, but prostheses are the most invasive treatment available so are considered last-line therapy.[13]

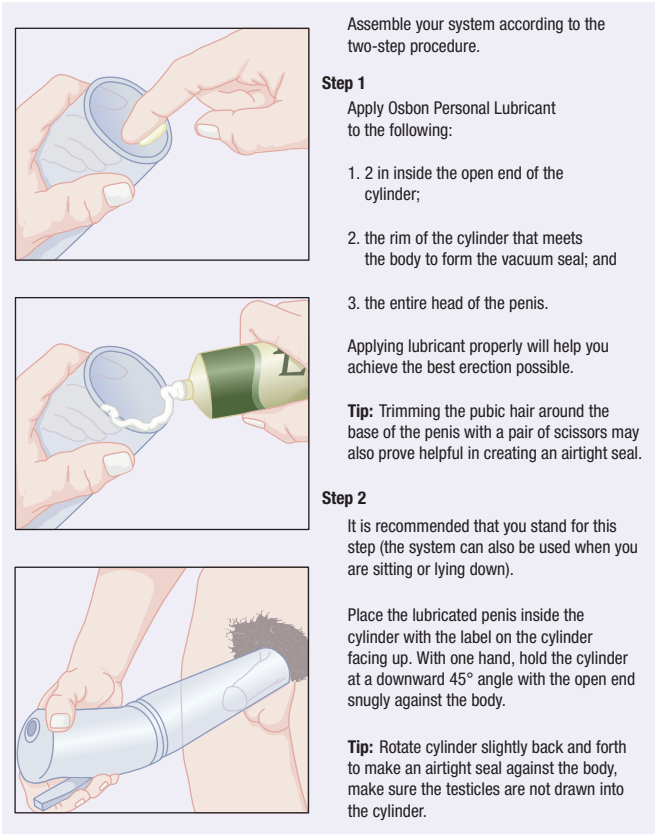

FIGURE 51–2. Technique for using a vacuum erection device. (From Lee M, Roohollah S. Erectile dysfunction. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York: McGraw-Hill; 2017:1319.)

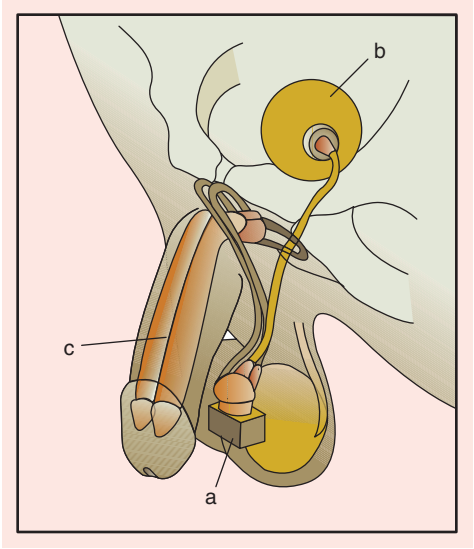

FIGURE 51–3. Example of a surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) (From Lee M, Roohollah S. Erectile dysfunction. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York: McGraw-Hill; 2017:1331.)

Complications include mechanical failure and infection. Failure rates are less than 5% while infection occurs in 2% to 3% with primary implantation.[13]

▶ *Pharmacologic Therapy*

Phosphodiesterase Type 5 Inhibitors Avanafil, sildenafil, tadalafil, and vardenafil act by selectively inhibiting PDE5, which is responsible for degradation of cGMP. With prolonged cGMP activity, smooth muscle relaxation is induced, leading to an erection (see Figure 51–1). However, the PDE5 inhibitors are only effective in the presence of sexual stimulation to drive the NO/cGMP system, making them facilitators of an erection, not initiators.

LO 6 KEY CONCEPT Effectiveness of the four available PDE5 inhibitors is essentially comparable, but differences exist in onset, duration of action, absorption with a fatty meal, and, to a small degree, incidence of side effects and drug interactions (Table 51–5). Review of available data for each individual agent shows a 60% to 75% response rate depending on the dose of agent used and the etiology of dysfunction.[1,5] Although efficacy rates appear to be similar between agents, there are some data to suggest that continuation rates are higher and patient preference greater with tadalafil due to its longer duration of efficacy.[14] The PDE5 inhibitors are considered first-line therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

The most dramatic difference among the four agents is tadalafil's extended duration of action (18 hours), earning it the nickname "the weekend pill." All are approved for as-needed dosing. Tadalafil has also been approved for use as a daily medication at a lower dose (2.5–5 mg) than the as-needed dose with similar efficacy. It also has an indication for treatment of lower urinary tract symptoms associated with benign prostatic hyperplasia with a daily dose.

The most common side effects experienced with PDE5 inhibitors include headache, facial flushing, nasal congestion, dyspepsia, myalgia, back pain, and, rarely, priapism. Vardenafil and sildenafil may also cause blurred vision, difficulty in discriminating blue from green, bluish tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE type 6 in the retina. Labeling for all PDE5 inhibitors includes a warning about rare nonarteritic ischemic optic neuropathy in which blood flow is blocked to the optic nerve. If patients experience sudden or decreased vision loss, they should call a health care provider immediately. PDE5 inhibitors have also been associated with acute hearing impairment although a causal relationship has not been established.[1]

In addition to the inherent risk of renewing sexual activity, PDE5 inhibitors can lead to significant hypotension. Patients taking organic nitrates are at highest risk, as these drugs potentiate the drop in blood pressure. All four PDE5 inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or sublingual for acute situations. Additionally, caution should be used when combining a PDE5 inhibitor with α-blockers. Vardenafil contains a precautionary statement about the possibility of QT prolongation. Drug interactions and cautions vary slightly between agents and are described in Table 51–5.

LO 7 Up to a third of patients will not respond to therapy with PDE5 inhibitors. To achieve the greatest effect, patients must be fully informed of the onset and duration of effect, impact of high-fat meals, the need for sexual stimulation, and explanation

LO 6

Table 51–5

Comparison of PDE Inhibitors

	Sildenafil (Viagra)	Tadalafil (Cialis)	Vardenafil (Levitra, Staxyn)	Avanafil (Stendra)
Available strengths	25-, 50-, 100-mg tabs	2.5-, 5-, 10-, 20-mg tabs	2.5-, 5-, 10-, 20-mg tabs	50, 100, 200 mg
Initial dosage in healthy adults	50 mg up to once daily taken 1 hour prior to sexual activity	10 mg up to once daily taken 30 minutes prior to sexual activity or 2.5 mg daily at the same time each day	10 mg up to once daily taken 1 hour prior to sexual activity	100 mg up to once daily taken 15 minutes prior to sexual activity
Dosing range for healthy adults	25–100 mg	5–20 mg	5–20 mg	50–200 mg
Dosage in the elderly	25 mg	10–20 mg	5 mg	50–200 mg
Dosage in renal impairment	50 mg (moderate[a]) 25 mg (severe[b])	5–10 mg (moderate[a]) 5 mg (severe[b])	5–20 mg	50–200 mg[c]
Dosage in hepatic impairment	25 mg	10 mg[c]	5 mg[c]	50–200 mg[c]
Time to onset	60 minutes	30–60 minutes	60 minutes	15 minutes
Onset delayed by high-fat meal?	Yes	No	Yes	No
Duration of effect	Up to 4 hours	Up to 36 hours	Up to 4 hours	Up to 4 hours
Half-life	3–4 hours	18 hours	4–6 hours	5 hours
Metabolism	CYP3A4 (major) CYP2C9 (minor)	CYP3A4	CYP3A4 (major) CYP3A5 (minor) CYP2C (minor)	CYP3A4 (major) CYP2C9 (minor)
Clinically relevant drug interactions	Nitrates, α_1-blockers,[d] protease inhibitors, azole antifungals, erythromycin, grapefruit	Nitrates, α_1-blockers,[d] protease inhibitors, azole antifungals, erythromycin	Nitrates, α_1-blockers,[d] antiarrhythmic agents,[e] grapefruit, erythromycin	Nitrates, α_1-blockers,[d] protease inhibitors, azole antifungals, erythromycin, grapefruit

[a]Moderate renal impairment = creatinine clearance (CrCl) 31 to 50 mL/min (0.51–0.83 mL/s).

[b]Severe renal impairment = CrCl less than 30 mL/min (0.50 mL/s).

[c]Mild to moderate only—contraindicated in severe disease.

[d]Selective α_1-blockers (such as alfuzosin, silodosin, and tamsulosin) are appropriate in combination. If nonselective, initiate with lowest dose possible.

[e]Vardenafil can cause QT-interval prolongation; this effect in combination with certain antiarrhythmic agents can lead to life-threatening arrhythmias.

CYP, cytochrome P-450 isoenzyme.

that a single trial is not adequate. It is estimated that six to eight attempts with a medication and specific dose may be needed before successful intercourse.[5]

Alprostadil Alprostadil is a prostaglandin E_1 analog that induces an erection by stimulating adenyl cyclase, leading to increased cAMP, smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity (see Figure 51–1). Alprostadil is available as an intracavernosal injection (Caverject or Edex) or an intraurethral suppository (MUSE, medicated urethral system for erection), with the injectable dose showing greater efficacy.[5,13] Both forms of alprostadil are considered more invasive than oral medications or VEDs and are therefore second-line therapies.

MUSE consists of a urethral pellet of alprostadil with an applicator (Figure 51–4). Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Initial dose titration should occur in a physician's office to ensure correct dose and prevent adverse events. Success rates are between 30% and 66%, with higher doses showing the most consistent response.[13] Aching in the penis, testicles, legs, and perineum; warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism; and light-headedness are all possible adverse effects. In addition, partners may experience burning or itching, and use is contraindicated with a pregnant partner unless using a condom.

Intracavernous alprostadil injection is the more effective route and is the only Food and Drug Administration (FDA)-approved injection for ED. The onset of action is similar to intraurethral alprostadil, but duration varies with dose and must be titrated in a physician's office to achieve an erection lasting no more than 1 hour. Papaverine and phentolamine are nonapproved intracavernosal agents which are only used in combination. Injections should be performed into one side directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug to both corpora (Figure 51–5). Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. Intracavernosal injections are effective in 60% to 80% of patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use as first-line therapy, and therefore this therapy is most appropriate for patients in long-term stable relationships.[1,5] Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have bleeding disorders, due to an increased risk of priapism and bleeding.

Testosterone Supplementation KEY CONCEPT Androgens are important for general sexual function and libido, but testosterone supplementation is only indicated in patients with documented low serum testosterone levels. In patients with hypogonadism, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. However, testosterone is contraindicated in patients with prostate cancer, erythrocytosis, uncontrolled heart failure, or sleep apnea.

Testosterone supplementation may improve ED symptoms, but is not universally effective. Initial supplementation should occur for 3 months with reevaluation and the addition of another ED therapy if needed at that time. Dosage forms include intramuscular, an implanted pellet, topical patches or gel, nasal spray, and a buccal tablet.

Injectable testosterone cypionate and enanthate offer the most inexpensive replacement option. There are several drawbacks associated with parenteral testosterone, including the need to administer deep intramuscular injections every 2 to 4 weeks. Testosterone undecanoate offers the benefit of an extended dosing interval of 10 weeks, but is a more expensive injectable option. Concentrations of hormone are well above physiologic values within the first few days, and then decline and eventually dip below physiologic levels prior to the next dose. These changes in concentration may lead to mood swings and a reduced sense of well-being.[15] Implantable subcutaneous testosterone pellets are a longer-acting and convenient alternative which are placed every 3 to 6 months.

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than the injections. Testosterone patches and gels are administered daily and result in serum levels within the physiologic range during the 24-hour dosing period.[16] Care must be taken with the use of the gel to prevent transfer of testosterone to children and females by washing hands thoroughly, allowing the site to dry, and covering immediately. Newer formulations for the axilla and thigh may reduce this risk. It is recommended to avoid swimming or showering for 2 to 3 hours after patch or gel application. The most common side effects of topical testosterone are dermatologic reactions.

Oral testosterone products are also available for supplementation. Unfortunately, testosterone has poor oral

Patient Encounter 1, Part 2

PMH: Type 2 diabetes for 15 years, not controlled and is unmotivated to improve. Hypertension for 8 years, currently controlled. Dyslipidemia for 15 years, uncontrolled.

SH: Works in an office 40 hours/week; 3–4 alcoholic drinks daily; has a 25-pack per year smoking history with occasional marijuana use. No regular exercise and eats fast food regularly.

Meds: Metformin 1000 mg orally twice daily; insulin glargine 60 units subcutaneously once daily; lisinopril/HCTZ 20/25 mg orally once daily; simvastatin 20 mg orally once daily; has tried herbal products as well as "online" medications for ED with inconsistent success.

ROS: (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, urgency, incomplete bladder emptying, dribbling; (–) symptoms of prostatitis; (–) chest pain or anginal symptoms; (+) significant life stressors; (+) mild pain in feet

PE:

VS: BP 135/78, P 85, RR 18, Wt 249 lb (113 kg), Ht 70 in (178 cm)

CV: Normal examination

Labs: Lipid pofile: total cholesterol, 240 mg/dL (6.21 mmol/L), HDL 38 mg/dL (0.98 mmol/L), LDL163 (4.22 mmol/L), triglycerides 246 mg/dL (2.78 mmol/L); fasting glucose 189 mg/dL (10.5 mm/L); HbA_{1c} 9% (0.09; 74 mmol/mol Hgb), total testosterone 300 ng/dL (24 nmol/L); SCr 0.9 mg/dL (80 µmol/L)

Given this additional information, what are his risk factors for ED?

Identify treatment goals for this patient.

Perform a cardiovascular risk assessment to determine risk.

What pharmacologic and nonpharmacologic alternatives are available for this patient?

Patient was referred to his cardiologist and it was determined that he may safely resume sexual activity at this time. Based on the information available, which of the available options will be your treatments of choice based on concomitant disease states and medications, degree of invasiveness, side effects, ease of use, and side-effect profile?

What are the safety and efficacy monitoring parameters for the chosen treatment?

Describe the education that should be given to the patient regarding his use of herbal and possibly counterfeit treatment for ED.

bioavailability and undergoes extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated, but this modification makes them considerably more hepatotoxic and therefore undesirable.

An alternative to the oral route is the buccal mucoadhesive system. This system adheres to the inside of the mouth and testosterone is absorbed through the oral mucosa and delivered to the systemic circulation with no first-pass effect. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of heart failure also occur due to sodium retention. The undecanoate formulation also carries a risk of serious pulmonary oil microembolism reactions and anaphylaxis after any dose; therefore, patients must be monitored for 30 minutes after the injection. Before initiating testosterone, the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer. Routine follow-up includes yearly prostate-specific antigen, digital rectal examination, hemoglobin and liver function, in addition to assessment of response.

Patient Encounter 2

A 62-year-old man presents with a history of hypertension, dyslipidemia, coronary artery disease, and recently diagnosed ED. When in the office for a routine follow-up, he asks about treatment options for his ED.

Meds: Losartan/hydrochlorothiazide 50/25 mg orally once daily, metoprolol XL 100 mg orally once daily, amlodipine 5 mg orally once daily, atorvastatin 40 mg orally once daily, aspirin 81 mg orally once daily.

ROS: (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, or urgency; (–) chest pain

PE:

VS: BP 173/96 mm Hg, P 69, Wt 214 lb (97 kg), Ht 69 in (175 cm)

Labs: Lipid panel, complete metabolic panel, testosterone within normal limits

Based on the information provided, what is your assessment of the patient's ED?

What should be recommended as the next step in treatment of his ED?

OUTCOME EVALUATION

Successful therapy for ED results in an increase in erections suitable for intercourse and, most importantly, in an improvement in the patient's quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical examination are not necessary for evaluation of effectiveness but may be necessary for adverse event monitoring.

Evaluate satisfaction and effectiveness after a 4-week trial. Some therapies will require multiple visits over the long term to determine the correct dose and to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine whether the initial assessment of comorbid disease states, type of dysfunction, and patient goals were appropriate. After providing further education and determination of realistic goals, providers may then increase the dose of medication, switch to another therapy, or add a therapy if indicated.

Patient Care Process

Collect Information:

- Assess the patient's specific symptoms to determine the type of dysfunction.
- Ask specific questions related to onset and frequency of dysfunction, and status of sexual relationships. Assess severity with the IIEF-5 questionnaire.
- Perform complete full histories, physical examination, and laboratory tests (see Clinical Presentation and Diagnosis, Tables 51–1 and 51–2).
- Assess cardiovascular risk (see Table 51–3).

Assess the Information:

- Evaluate medications, concomitant disease states, and lifestyle factors which could exacerbate ED or indicate a need to defer sexual activity.
- Based on histories, determine whether the patient has either compelling indications for or contraindications to specific therapies.
- Review relevant laboratory and cardiac tests (eg, testosterone, A1c, complete metabolic panel, treadmill).
- Assess the efficacy, safety, and adverse effects of current treatment.

Develop a Care Plan:

- Treat underlying diseases, discontinue medications, and eliminate risk factors which can exacerbate ED.
- PDE5 inhibitors are first-line treatment unless contraindicated, not tolerated, or ineffective, but treatment should be individualized.
- Give supplementation if patient has low testosterone.

Implement the Care Plan:

- Initiate PDE5 inhibitor or patient treatment of choice and provide education regarding:
  - ED
  - Lifestyle
  - Treatment of associated disease states
  - Drug therapy—mechanisms of action and adverse effects
  - Device technique

Follow-up: Monitor and Evaluate:

- Follow-up in 4 to 6 weeks or more frequently to assess effectiveness and safety of therapy including specific warning signs (eg, vision changes, fibrosis, pain, priapism, or hypotension).
- Reeducate on lifestyle, associated disease states, expectations, and methods for increasing efficacy with therapy.
- Increase dosage, switch to alternate therapy, or add alternate therapy if needed.

Abbreviations Introduced in This Chapter

cAMP	cyclic adenosine monophosphate
FDA	Food and Drug Administration
cGMP	Cyclic guanosine monophosphate
IIEF	International Index of Erectile Function
MUSE	Medicated urethral system for erection
NO	Nitric oxide
PDE5	Phosphodiesterase type 5
VED	Vacuum erection device

52 Benign Prostatic Hypertrophy

Mary Lee and Roohollah Sharifi

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of benign prostatic hypertrophy (BPH).
2. Recognize the symptoms and signs of BPH.
3. List the desired treatment outcomes for BPH.
4. Identify factors that guide selection of a particular α_1-adrenergic antagonist for an individual patient.
5. Compare and contrast α_1-adrenergic antagonists versus 5α-reductase inhibitors in terms of mechanism of action, treatment outcomes, adverse effects, and interactions.
6. Describe the indications, advantages, and disadvantages of various combination drug regimens that include an α_1-adrenergic antagonist, 5α-reductase inhibitor, anticholinergic agent, tadalafil, or mirabegron.
7. Describe the indications for surgical intervention.
8. Apply the patient care process to develop an individualized treatment plan.

INTRODUCTION

The prostate is an organ, which is of the shape and size of a horse chestnut, that encircles the portion of the proximal posterior urethra that is located at the base of the urinary bladder. The prostate produces secretions, which are part of the ejaculate.

Benign prostatic hypertrophy (BPH) is the most common benign neoplasm in men who are at least 40 years of age. BPH can produce lower urinary tract symptoms (LUTS), a collection of obstructive and irritative voiding symptoms that are consistent with impaired emptying of urine from and defective storage of urine in the bladder, respectively. Medications are a common mode of treatment to reduce symptoms and/or delay complications of BPH.

EPIDEMIOLOGY AND ETIOLOGY

BPH first presents as benign prostatic hyperplasia, a histologic disease in many elderly men which increases in prevalence with advancing patient age. Benign prostatic hyperplasia may progress to BPH, which is clinically evident, and then to benign prostatic obstruction, which produces LUTS. Of patients with histologic disease, only about 50% of patients develop an enlarged prostate on digital palpation and 25% of patients exhibit clinical voiding symptoms.[1,2] It is estimated that 8% of men 40 years of age, increasing to 35% of men 60 to 69 years of age, have voiding symptoms consistent with BPH, and 20% to 30% of all male patients who live to the age of 80 years will require a **prostatectomy** for severe voiding symptoms of BPH.[2]

Two chief etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

- Prior to 40 years of age, the prostate in the adult male is approximately 15 to 20 g. However, in men who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as the men advance in age. BPH can result in clinically symptomatic LUTS.
- The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly Type II 5α-reductase converts testosterone to dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis that promote glandular tissue growth of the prostate. Thus 5α-reductase inhibitors (eg, finasteride and dutasteride) directly interfere with one of the major etiologic factors of BPH.
- The prostate is composed of two types of tissue: (a) glandular or epithelial tissue, which produces prostatic secretions, including prostate-specific antigen (PSA), and (b) muscle or stromal tissue, which can contract around the urethra and bladder outlet when stimulated. Whereas androgens stimulate glandular tissue growth, they have no direct effect on stromal tissue. Stromal tissue growth may be stimulated by estrogen. Because testosterone is converted to estrogen in peripheral tissues in males, testosterone may be associated indirectly with stromal hyperplasia. Stromal tissue is innervated by α_{1A}-adrenergic receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

PATHOPHYSIOLOGY

LO 1

KEY CONCEPT LUTS and signs of BPH are due to static, dynamic, and/or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate

occludes the urethral lumen. The dynamic factor refers to excessive stimulation of α_{1A}-adrenergic receptors in the smooth muscle of the prostate, urethra, and bladder neck, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen and causes obstructive voiding symptoms. The detrusor factor refers to bladder detrusor muscle hypertrophy in response to prolonged bladder outlet obstruction. To further explain, detrusor muscle fibers undergo hypertrophy so that the bladder can generate higher pressure to overcome bladder outlet obstruction. The hypertrophic detrusor muscle becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. This causes storage voiding symptoms (urinary frequency, nocturia, urgency, or urinary incontinence). If obstruction is not treated, the bladder muscle will decompensate and be unable to empty completely; postvoid residual urine volume (PVR) will increase.

In an enlarged gland, the epithelial/stromal tissue ratio is 1:5.[3] Androgens stimulate epithelial, but not stromal tissue hyperplasia. Hence, androgen antagonism does not induce a complete reduction in prostate size to normal. This explains one of the limitations of 5α-reductase inhibitors.

Stromal tissue is the primary locus of α_1-adrenergic receptors in the prostate. An estimated 98% of the α-adrenergic receptors in the prostate are found in prostatic stromal tissue. Of the α_1-receptors found in the prostate, 70% of them are of the α_{1A}-subtype and the remainder are of the α_{1B} and α_{1D} subtypes.[4] In some patients, excessive α_1-adrenergic stimulation of stromal tissue may cause significant LUTS even though the prostate is only slightly enlarged. This explains why α_1-adrenergic antagonists are effective for managing symptoms of BPH independent of prostate size.[5]

More recently, atherosclerosis of the pelvic vascular supply to the prostate and bladder has been linked to BPH. Specifically, atherosclerosis leads to hypoxia, which stimulates prostate stromal tissue to increase release of growth factors.[6] Also, in experimental rat models, chronic inflammation may also stimulate prostate gland growth.[7]

The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5-year period.[8] It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. On the other hand, a significant portion of patients with mild symptoms will likely experience disease progression. Patients with moderate to severe symptoms can experience decreased quality of life as daily activities are reduced because of LUTS. Also, such patients may develop complications of BPH. Predictors of disease progression include an enlarged prostate of at least 30 g (1.05 oz) or PSA of 1.4 ng/mL (1.4 mcg/L) or greater.[9] Finally, erectile dysfunction commonly develops in patients with BPH. Effective treatment of BPH symptoms often improves sexual function without initiating specific treatment for erectile dysfunction.[10]

Patient Encounter 1

A 65-year-old man with a BPH and an AUA Symptom Score of 22, urinary hesitancy, a slow urinary stream, urinary frequency, and nocturia presents to the clinic. He wakes up two times every night to void. A DRE reveals a prostate of 40 g (1.40 oz). His PSA is 1.8 ng/mL (1.8 mcg/L). A urinary flow rate is 7 mL/s and PVR is 100 mL.
